was not observed in animals that received HAMC gels alone. Our initial degradation of BDNF-loaded PLGA particles studies suggest that the microparticles can lasts for up to 28 days *in vitro*. We are currently optimizing *in vitro* and *in vivo* growth factor release profiles using this hydrogel microparticle composites. If appropriate release rates are observed, we will perform longer-term local delivery of BDNF for spinal learning after SCI. Our data indicate that an injectable HAMC hydrogel provides a flexible platform for loading bioactive molecules for sustained, localized delivery. Composite systems like these can be used for sustained and localized delivery of therapeutics to the brain and spinal cord.

Title: The feasibility of using human induced pluripotent stem cells derived oligodendrocyte progenitors in treatment of spinal cord injury

Authors: *P. MOHAMMAD GHARIBANI[1], A. ALL[1], C. KERR[2]
[1]Johns Hopkins Sch. of Med., Baltimore, MD; [2]Univ. of Maryland, Baltimore, MD

Abstract: Pluripotent stem cells can expand indefinitely and differentiate into any other cell type such as neurons and glial cells. Induced pluripotent stem (iPS) cells, a type of pluripotent stem cell that can be generated directly from adult cells, are highly similar to natural pluripotent stem cells and since iPS can be derived directly from adult tissues they can be made in a patient-matched manner for autologous transplants without the risk of immune rejection. In this study, three different reprogramming strategies were used to generate Oligodendrocyte Progenitor cells

(OPs) from three different iPS cell lines (BC1, A1-4 and MR3). These cells were also used in transplants for moderate spinal cord injury (SCI) during the acute stage. Interestingly, in our *in vitro* studies, iPS derived OPs (iPS-OPs) from all three cell lines yielded 40-60% of total cells. Moreover, all three cell lines generated a similar number of early neural and glial progenitors. BC1-iPS derived OPs (using episomal, non-integrating plasmid approach) expressed more mature OP markers than early OP markers. Our *in vivo* studies showed that engrafted OPs survived for several months and almost 70% of them differentiated into mature oligodendrocytes. Notably, not only transplanted OPs yielded a significant increase in the number of myelinated axons, but also led to almost 5 fold reduction of cavity size and glial scarring in the contusion site. In addition, no tumor formation or any abnormal growth was seen in the site of injection. In conclusion, our results demonstrated that iPS derived OPs can be a candidate for replacing oligodendrocyte populations and axon remyelination following spinal cord injury.

Title: Intracranial xenograft model as a validation system to assess tumorigenicity of NS/PCs for transplantation therapy

Authors: *K. HORI[1,2], J. KOHYAMA[2], K. MATSUBAYASHI[1,2], A. IWANAMI[1], H. OKANO[2], Y. TOYAMA[1], M. NAKAMURA[1]
[1]Dept. of Orthopaedic Surgery, Keio University, Sch. of Med., Tokyo, Japan; [2]Dept. of Physiology, Keio University, Sch. of Med., Tokyo, Japan

Abstract: [Purpose] Transplantation of neural stem/progenitor cells (NS/PCs) is now considered to be a promising treatment for various central nervous system disorders including spinal cord injury, Alzheimer's disease, Parkinson's disease, and brain infarction. In countries where fetal NS/PCs are not allowed to use due to ethical issues, iPS cells are especially a potential cell source of NS/PCs for cell therapy. To apply these cells to clinic, the risk of tumorigenicity must be eliminated. The purpose of this study is to establish an *in vivo*-validation system to assess tumorigenicity of transplanted NS/PCs efficiently. [Method] Human NS/PCs induced from adult

dermal fibroblast-derived hiPS cells were labeled with Lenti-ffLuc (Venus fused to firefly luciferase) vector. Two kinds of xenograft models were examined in this study: intracranial and spinal xenograft models. For intracranial xenograft models, 1x10^6 cells were injected into each side of the striatum of NOG mice or NOD/SCID mice without injury. For spinal xenograft models, 5x10^5 cells were transplanted into the spinal cord of NOD/SCID mice 9 days after contusion injury. Survival of transplanted cells was evaluated using bioluminescence-imaging system in both models. For histological analysis, mice were intracardially perfused 6~30 weeks after transplantation. [Result] The transplanted cells could be detected by bioluminescence-imaging throughout this study, both in intracranial and spinal xenograft model. Histological examinations revealed that the transplanted NS/PCs proliferated at the injected site, differentiated into neurons predominantly, and extended neuronal process to broad areas. In some cases of brain xenograft model, extramedullary proliferation of transplanted cells was found. [Conclusion] The transplanted cells survived and proliferated in both models. Compared with spinal xenograft model, intracranial xenograft model would be better to detect tumorigenicity of NS/PCs for transplantation therapy, since it allows us to evaluate a larger number of cells in each animal by the reproducible procedure. Further study exploring the character of transplanted cells around injection site is needed.

Title: Gabapentin management of autonomic dysreflexia: Effects on systemic inflammation

Authors: *A. G. RABCHEVSKY[1], K. C. ELDAHAN[1], J. L. VANROOYEN[1], C. Y. WANG[2], T. L. SMITH[2], D. H. COX[2], S. P. PATEL[1]
[1]Spinal Cord & Brain Injury Res. Ctr. (SCoBIRC) & Dept. of Physiol., [2]Spinal Cord & Brain Injury Res. Ctr. (SCoBIRC), Univ. of Kentucky, Lexington, KY

Abstract: Autonomic dysreflexia (AD) is an abnormal hypertensive syndrome often triggered by unperceived pain that affects individuals with a spinal cord injury (SCI) above the sixth thoracic (T6) level; the vast majority of cases. We are currently investigating whether treatment with a widely-used drug for chronic neuropathic pain, gabapentin (GBP, Neurontin), after complete T4 SCI in rats abrogates the inflammatory responses in dorsal root ganglia (DRG) that contribute to maladaptive intraspinal plasticity underlying the temporal development of AD. DRG sprouting responses to injury invariably involve macrophage activation, 'inflammatory' cytokine production and upregulation of 'sprouting' transcription factors. Critically, administration of GBP significantly attenuates both noxious colorectal distension (CRD)-induced AD and induced tail spasticity weeks after complete T4 SCI, and daily GBP administration reduces spontaneous AD events detected using an algorithm based on blood pressure telemetry data. The current studies, therefore, were designed to test the hypothesis that prolonged, repeated CRD is correlated with increased 'inflammatory cytokine' and 'sprouting factor" gene expression in the L6/S1 and T13/L1 DRGs, their corresponding spinal cord segments, and the colon, bladder and visceral organs they innervate. We further hypothesized that since GBP treatment effectively reduces the severity of AD, then this will be correlated with blunted injury-induced gene expression in central and peripheral tissues. One week after abdominal aorta probe implantation, adult female Wistar rats underwent complete T4 SCI and 21 days later were subjected to prolonged, intermittent CRD for 1.5 hr (30 sec on, 60 sec off) before all sampled tissues were processed by qRT-PCR for mRNA expression of stress-induced transcription factors (e.g. ATF-3) and inflammatory cytokines (e.g. IL-1b, CCL2), with or without accompanying GBP. In addition, ELISA was used to examine IL-1b protein expression in innervated pelvic visceral tissues, with or without GBP treatment. Preliminary results show that chronic T4 SCI alone increased the expression of ATF-3 and inflammatory cytokines in neural tissues. Moreover, CRD further elevated IL-1b protein expression in peripheral tissues that was also reversed by GBP. Since AD has recently been reported to result in chronic immunosuppression, these studies are critical to establish whether GBP has immunomodulatory effects that are associated with its alleviation of AD. Such an effect may allow individuals with SCI to be weaned off other drugs that they are also taking for AD, spasticity and/or immunotherapy (e.g. polypharmacy).

Title: Using transcription factors to promote the survival of transplanted cells for spinal cord injury repair

Authors: *K. A. SCORPIO, J. L. BROWN, B. T. DAVID, R. R. RATAN, C. E. HILL
Burke-Cornell Med. Res. Inst., White Plains, NY

Abstract: Cellular transplants offer a multifaceted approach for spinal cord injury (SCI) repair. Despite significant progress in understanding their clinical utility, a common feature of all cell transplants, which may have detrimental effects on the use of transplants clinically, is the early death of transplanted cells.The precise cause of transplanted cell death remains elusive and strategies that significantly enhance transplant survival have not yet been developed. To date, strategies to prevent transplanted cell death have focused on either blocking induction of cell death or blocking cell death signaling once started. Although there has been some success with these strategies, the presence of multiple cell death inducers and complex cross-talk between cell death pathways once activated have meant that the effects of the aforementioned strategies are modest. An alternative strategy is to counteract acute cell death signaling via direct activation of pro-survival pathways. One method to elevate pro-survival pathways in cells is to activate transcription factors involved in endogenous adaptive responses to stress. Among the transcription factors implicated in adaptive cellular responses to stress are the hypoxia inducible factors (HIFs). In the current study we examine the effect of enhancing HIF activity in Schwann cells following transplantation into the injured spinal cord of rats. We demonstrate that transplanted cells normally have low levels of HIF transcriptional activity and that enhancing HIF activity through either over-expression or pharmacological manipulation results in improved survival of transplanted cells. This suggests that transcription factor activation may be a beneficial strategy for promoting the survival of transplanted cells.

Title: Chronic L1 overexpression causes widespread changes in expression of molecules engaged in neuronal plasticity Adcy1, GAP-43 and synaptophysin, but not in ADAM10 - L1 shedding metalloprotease in rats with complete spinal cord transection

Authors: *R. K. PLATEK[1], A. WIECKOWSKA[1], K. GRYCZ[1], J. CZARKOWSKA-BAUCH[1], S. KÜGLER[2], M. SKUP[1]
[1]Neurophysiol., Nencki Inst. of Exptl. Biology, PAS, Warsaw, Poland; [2]Univ. of Göttingen, Göttingen, Germany

Abstract: Recovery from spinal cord injury (SCI) requires neuronal remodeling which is regulated by cell adhesion molecules (CAMs) and inhibited by chondroitin sulfate proteoglycans (CSPGs). Among approaches targeting restoration of function after SCI a promising one is to use L1 cell adhesion molecule (L1-CAM), found to promote axon growth, guidance, fasciculation and myelination during development and after injury of the nervous system. Our aim was to evaluate the effectiveness of L1 in (1) promoting regeneration of the corticospinal tract (CST) and (2) altering markers of synaptic plasticity [synaptophysin (Syn), adenylate cyclase1 (Adcy1), growth-associated protein 43 (GAP43)] and CSPG phosphacan expression in the chronic phase after complete spinal cord transection in an adult rat. To overexpress L1, adeno-associated viral vector serotype 5 encoding L1 (AAV5-L1) was injected into the first lumbar spinal segment after complete spinal cord transection at Th10/Th11. Two groups of spinal AAV5-L1 and AAV5-EGFP rats were used (for histology 4 rats/group; for biochemistry 7 AAV5-L1, 5 AAV5-EGFP rats). Five weeks after transection AAV5-L1 rats showed reduced retraction/increased outgrowth of DiI-labeled CST axons in 2 mm segment rostrally to the lesion border, as compared to the rats receiving AAV5-EGFP ($p<0.05$). AAV5-L1 rats showed increased levels of Syn, Adcy1 and GAP43 transcripts below the transection (BT) and of Adcy1 above (AT), as compared to AAV5-EGFP rats, which showed widespread decrease of Syn and Adcy1 after transection. On the contrary, significantly elevated phosphacan immunostaining BT in AAV5-EGFP rats was reduced (2-fold, $p<0.05$) in AAV5-L1 rats. AAV5-L1 transduced neurons and astrocytes in segments below transection. It lead to 80-and 60-fold increase of L1 mRNA level at thoracic segments BT (Th<L; $p<0.05$) and in L1-2 segments ($p<0.05$), respectively, as compared to intact control. While AAV5-L1 caused an increase of endogenous L1 protein AT, transgenic L1 was found only BT. This raised a question whether overexpression of L1 molecule BT may stimulate the production of soluble L1 forms, which might reach segments AT and interact with transected

CST. To examine it, an expression of metalloprotease ADAM10 responsible for L1 membrane shedding was evaluated. AAV5-L1 rats upregulated ADAM10 mRNA at Th<L and L1-L2, where overexpression of L1 occured but was not followed by increased ADAM10 protein. We conclude that both increased endogenous L1 above and transgenic L1 below transection contribute to structural remodeling of spinal network by decreasing phosphacan expression and upregulating molecules indispensible for axonal growth.

Title: Neural progenitor cells overcome extrinsic inhibitors and extend axons in chronically injured spinal cord

Authors: *K. KADOYA[1], K. NGUYEN[1], M. TUSZYNSKI[1,2]
[1]Neurosciences, UCSD, LA JOLLA, CA; [2]VAMC, La Jolla, CA

Abstract: Environment of chronic stage of spinal cord injury (SCI) is more refractory to adult axonal growth, at least due to additional obstacles, including myelin debris and developed scar formation at lesion sites consisting of reactive astrocytes and chondroitin sulfate glycosaminoglycans (CSPGs). At the previous SFN meeting, we reported a great axonal extension from 6 months delayed NPC grafts (chronic) placed in T3 complete transection sites. But, there was a significant reduction in their number of axons, compared to 2 weeks delayed NPC grafts (subacute) placed in the same lesion. Because size of graft/lesion, presence of fibrous tissue separating the graft, and the extent of atrophy of host spinal cord were different, the

undiluted effect of chronically injured spinal cord on axonal growth from NPCs remains to be clarified. To ask this question, in the present study, GFP expressing NPCs were grafted into sites of rat C4 dorsal column injury at a time point 2 weeks (subacute) or 6 months (chronic) after the initial injury. Six weeks later, lesion sites were filled with mature neurons and glia without fibrous tissue, and there was no difference of graft/lesion size in both groups. GFP-labeled, graft-derived axons emerged from the lesion site in high numbers and extended over long distances of up to 2cm. Of note, there was no significant difference in the number of emerging GFP axons in host white matter when quantified 3mm caudal and rostral to grafts. In both grafted groups, GFAP and CSPG expression around the lesion site was attenuated compared to control lesioned, non-grafted groups. In another group of subjects, we examined whether degenerating white matter in chronic SCI inhibits NPC-derived axon outgrowth. Lesions were placed in the C5 dorsal columns, and GFP expressing NPCs were micro-grafted subacutely or chronically into dorsal column sensory tract at the C4 level, where axons were undergoing Wallerian degeneration after injury. While numerous myelin debris were present from 1 week to 6 weeks after injury, clearance of much debris had occurred by 6 months. Extending axons from NPCs in this degenerating tract were in equal numbers in both groups at a point 3 mm rostral to grafts, when examined 6 weeks later, indicating that NPCs can extend axons robustly in degenerating white matter at the both of chronic and subacute stage of SCI. Collectively, these findings indicate that NPCs exhibit a remarkable ability to extend axons over chronic scar formation around injury site and through degenerating white matter.

Title: Histology and mechanisms underpinning dose response injections of a PTPRS modulator following spinal cord injury

Authors: ***A. TRAN**[1], B. T. LANG[1], J. M. CREGG[1], M. A. DEPAUL[1], Y. SHEN[2], J. SILVER[1]
[1]Neurosciences, Case Western Reserve Univ., Cleveland, OH; [2]Ctr. for Brain and Spinal Cord Repair, Dept. of Neurosci., The Ohio State Univ., Columbus, OH

Abstract: A lack of restorative medical treatments has prompted a greater drive towards understanding molecular mechanisms following spinal cord injury (SCI) in order to develop new therapies that promote regeneration and restore function. Following SCI-induced gliosis, upregulation of inhibitory components of the extracellular matrix such as chondroitin-sulphate proteoglycans (CSPGs) result in signaling by membrane-bound receptor Protein Tyrosine Phosphatase Sigma (PTPRS). Our lab has designed a small peptide modulator of PTPRS (Intracellular Sigma Peptide, ISP), which we have previously shown to restore coordinated walking and micturition following a T8 contusive injury. This peptide is capable of pulling down rat and mouse PTPRS from brain and spinal cord lysates, in addition to binding to recombinant human intracellular PTPRS. No interaction was seen between ISP and either LAR or NOGO-Receptor. Here, we also tested whether locomotor and urinary behaviors could be further restored by increasing the daily subcutaneous dose of ISP following moderate to severe spinal cord injury (T8 Infinite Horizon Contusion at 250kDyne). Interestingly, locomotor recovery, as measured by the BBB scale and gridwalk test was not ISP dose-dependent, as each treatment group showed a similar number of responding animals. However, improvements in micturition, as measured by void frequency at 12 weeks post SCI, was remarkably ISP dose-dependent. Indeed, all animals became responders showing the greatest average improvement at the 4x (44ug/day) dose. We monitored anatomical plasticity by bi-lateral injections of the retrograde label Fast-Blue caudal to the lesion. Behavioral improvements correlated with an increased number of Fast-Blue positive neurons in various regions rostral to the lesion in ISP-treated rats compared to controls. The activation of PTPRS elicits a cascade of intracellular pathways that may cause axonal growth cones to become dystrophic resulting in a failure of neuronal regeneration; however, the exact mechanisms underlying regeneration is still unknown. Using *in vitro* dorsal root ganglion (DRG) cultures, we are beginning to elucidate how ISP induces such remarkable behavioral outcomes. In this way, we are beginning to show how PTPRS signaling is implicated in SCI.

Title: Breathing easier: The benefits of neural progenitor transplantation after cervical spinal cord injury

Authors: ***V. SPRUANCE**[1], K. M. NEGRON[1], D. SANCHEZ[2], T. BEZDUDNAYA[1], B. OSTEEN[2], P. REIER[2], M. A. LANE[1], T. J. WHELAN[1]
[1]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Neurosci., Univ. of Florida college of medicine, Gainesville, FL

Abstract: Breathing deficits and related complications remain the leading causes of mortality following cervical spinal cord injury (SCI). Considering over half of all SCIs occur at the cervical level, therapeutic approaches to improve respiratory function are desperately needed. Enhancing endogenous spinal plasticity will likely yield the greatest improvements in long-term respiratory recovery, rather than relying on long distance regeneration of respiratory circuits. The goal of the present study is to promote repair of the injured spinal cord using a cell transplantation strategy, and harness ongoing respiratory neuroplasticity, to improve phrenic motor function and recovery of diaphragm activity. Recent studies have revealed that a population of pre-phrenic interneurons may play an integral role in plasticity related to recovery of diaphragm function, the major muscle of inspiration. Therefore, we hypothesized that transplantation of interneuronal rich progenitor cells derived from fetal spinal cord tissue may provide an anatomical substrate for the formation of new, relay pathways that will improve diaphragm function. Adult, female Sprague-Dawley rats received lateralized C3/C4 contusion injuries using the Infinite Horizons Impactor Device (intended impact force: 200 kilodynes). One week following injury, FSC tissue suspension obtained from E13.5 day rats was transplanted into the injury cavity. Animals were allowed to recover for one month before receiving injections of pseudorabies virus (a retrograde, transynaptic tracer, PRV) to the diaphragm or transplant, and were sacrificed 72 hours later. Respiratory function was assessed using terminal diaphragm EMG recordings or phrenic nerve recordings. To assess temporal change in function, a subset of animals was implanted with telemetric diaphragm electrodes and underwent weekly plethysmograph and EMG recordings. Electrophysiological recordings were made under normoxic and hypoxic (10% oxygen) conditions to assess function during eupneic and challenged breathing. Immunohistochemical analysis of PRV demonstrated anatomical connectivity between host and transplanted tissue, while EMG and plethysmograph studies reveal improved breathing abilities during both normal conditions as well as respiratory challenge. Ongoing experiments will combine transplantation with optogenetic and rehabilitative

techniques to further enhance synaptic integration between host and transplant, endogenous respiratory plasticity and optimize long-term recovery of breathing.

Title: Cell-type specific analysis of antipsychotic drug action in D1 and D2 neurons of the striatum

Authors: ***R. C. SCHWARCZ**[1], S. CHENG[2], P. GREENGARD[2], A. C. NAIRN[3]
[1]Cell Biol., Yale Univ., New Haven, CT; [2]Lab. of Mol. and Cell. Neurosci., Rockefeller Univ., New York, NY; [3]Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT

Abstract: Antipsychotic drugs (APDs) have been the primary treatment for the positive symptoms of Schizophrenia for over fifty years. APDs are classified as either typical or atypical drugs. Although both drug classes were found to block dopamine D2 receptors to some extent, the downstream mechanisms of therapeutic action remain unclear. Furthermore, APDs usually produce potentially irreversible side effects (including movement and metabolic disorders), indicating the need for a more targeted approach. In this study, we will examine cell-type specific effects of APDs on downstream signaling elements in the two primary cell types of the striatum: D1 and D2-type neurons. We hypothesize that phosphorylation at residue Serine-97 (S97) of the striatal enriched protein DARPP-32, a mediator of dopamine action, will be decreased by APD exposure. Dephosphorylation of the S97 residue results in the nuclear retention of DARPP-32, which can promote changes in histone modifications and potentially result in long term gene expression changes. We are employing a line of BAC transgenic mice with differentially tagged flag and myc-tag DARPP-32, expressed under the control of the D1 or D2 receptor promoter, respectively. We have treated these animals (n=10) with both typical and atypical antipsychotics, differentially immunoprecipitated flag/myc-DARPP-32 (D1/D2), and used immunoblotting to assess S97 phosphorylation in total, D1, and D2 extracts. We have also

used immunohistochemistry to correlate our results with DARPP-32 cellular localization. Our results indicate that APDs can induce significant cell-type specific alterations, which are sometimes masked in overall striatal extracts. This may help provide insight into potential common mechanisms of APD-induced signaling regulation, and possible targets for future therapeutics.

Title: Molecular changes in odorant signaling in olfactory neuroepithelial cells from patients with schizophrenia

Authors: *K. BORGMANN-WINTER[1,2], H.-Y. WANG[3], R. RAY[4], B. WILLIS[1], B. TURETSKY[1], C.-G. HAHN[1]
[1]Dept Psychiatry, Univ. Pennsylvania, PHILADELPHIA, PA; [2]Children's Hosp. of Philadelphia at Perelman Sch. of Med. at the Univ. of Pennsylvania, Philadelphia, PA; [3]City Univ. of New York Med. Sch., New York, NY; [4]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Schizophrenia is associated with pervasive deficits in olfactory function, including odor detection and discrimination. Little is known, however about the molecular underpinnings of pathophysiologic deficits in olfactory function in schizophrenia. Turetsky and colleagues have demonstrated that patients with schizophrenia exhibit increased electrolfactogram (EOG) measures induced by odorants while they show decreased olfactory evoked potentials. In this study we examined human olfactory neuroepithelial (ON) cells derived from 18 patients with schizophrenia and their matched controls for odorant and neurotransmitter mediated G protein coupling. .To assess ligand induced G protein activation, we examined membrane fractions from ON cells, incubated with odorants and S35-GTPgS. Incorporation of S35-GTPgS into G proteins

were assessed by immunoprecipitation of membrane fractions for specific subclasses of G proteins and measurement of S35 incorporation. In ON cells of patients and controls, we found a significant decrease in the activation of Gs/olf (students t test; t = 2.264, df=32 and p = 0.03) and of Go in the SCZ group (two tailed students t test; t=3.348 df=32 and p = 0.002). A subgroup of the same matched pairs were also examined for G protein activation in response to odorant Mix B. We observed similar decreases in Gs/Golf as well as Go. To test whether these changes were mediated by the expression of key molecules of G protein coupling, we examined mRNA and protein expression of ACIII, PKCgamma, Gs and Golf in a subset of 7 subjects and their matched controls. No between group differences were seen at the mRNA level, but ACIII protein expression was decreased in patients with schizophrenia (students paired t test; t = 3.077, df=7 and p = 0.02). Together, these suggest that increased odorant signaling found in EOG studies may not be the direct result of decreased G protein coupling but rather reflect increased function of G protein activation or ACIII. Alterations in G protein coupling could be either a reflection of pervasive deficits across various receptors or specific to receptors. We examined G protein activation in response to dopamine (DA) or 5HT in OE cells of SCZ patients and controls. We found significant increases in activation of Gs/olf and Gq/11 mediated by dopamine (DA) or 5HT in OE cells of SCZ patients. Divergent changes in G protein activation between odorant- and DA/5HT- stimulation may suggest altered G protein coupling in a receptor specific manner in schizophrenia. Future studies should test if increased DA induced G protein coupling could be a molecular substrate for increased activation of D2R signaling as implicated for schizophrenia.

Title: Dissociation kinetics of [14C]F17464 binding at human dopamine D2S and D3 receptor subtypes

Authors: *J.-C. MARTEL, N. DANTY, A.-M. ORMIERE, G. PULOU, P. SOKOLOFF
Neurologie & Psychiatrie, Inst. Recherche Pierre Fabre, Castres, France

Abstract: Receptor-ligand dissociation rate seems to be a more critical parameter for the kinetics of brain receptor occupancy by antipsychotic drugs than changes in blood concentration. For instance, perospirone, which displays a high affinity (Ki = 0.58 nM) at dopamine hD2 receptor, has a short plasma half-life (1.9 h), but a long-lasting hD2 receptor occupancy with an occupation half-life of approximately 24 h. While development of D3-selective antipsychotics is still being actively investigated, the available clinical reports suggest that optimal hD3 receptor occupation has not yet been achieved in clinical studies, thus highlighting the importance of a better control over this parameter in future clinical studies. F17464 is a D3-selective antipsychotic candidate, having 46-71 fold higher affinity at hD3 versus the hD2 receptor subtype isoforms, suggesting that it should dissociate much faster from hD2 than from hD3. In order to verify this property of F17464 and better predict its brain dopamine receptor occupancy kinetics, the dissociation kinetics of [^{14}C]F17464 was evaluated at 37°C on hD2S and hD3 receptor subtypes. Binding assays on dopamine hD2S and hD3 receptors were performed on membranes from Chinese hamster ovary cells expressing these receptors at high levels (hD2S: 24 pmol/mg proteins and hD3: 4.1 pmol/mg proteins). [^{14}C]F17464 (final concentration of 32 nM (hD2S) or 6 nM (hD3) in 2 mL final volume) was incubated with 1600 µL of the appropriate membrane preparation which was added to start the kinetics. Incubations were performed for times ranging from 2 to 360 minutes, and nemonapride (10 µM) was added after an initial 1 hr incubation to initiate dissociation. At the end of the set incubation time, each tube was rapidly filtered under vacuum through GF/B filters. While [^{14}C]F17464 dissociated rapidly from hD2S (K_{OFF} : 0.51 min^{-1}; $t_{1/2}$: 1.4 min), a dissociation constant close to that of clozapine at hD2, it dissociated much more slowly from hD3 (K_{OFF} : 0.0064 min^{-1}; $t_{1/2}$: 110 min). This study demonstrates that [^{14}C]F17464 binds relatively tightly to hD3 receptors, while having a much looser attachment to hD2S receptors, in agreement with its hD3 receptor selectivity. Such tight attachment of F17464 to hD3 predicts a long-lasting hD3 occupancy *in vivo*.

Title: Chronic treatment with the D2 receptor partial agonist 2-bromoterguride does not induce changes in body weight and body fat composition in rats

Authors: *R. T. FRANKE[1], H. H. PERTZ[2], H. FINK[3], J. BROSDA[3]
[1]Free Univ. Berlin, Berlin, Germany; [2]Dept. of Biology, Chemistry, and Pharmacy, FU Berlin, Inst. of Pharm., Berlin, Germany; [3]Sch. of Vet. Medicine, FU Berlin, Inst. of Pharmacol. and Toxicology, Berlin, Germany

Abstract: Introduction: Schizophrenia is a chronic mental illness. Current pharmacological therapy has limited efficacy and is related with severe side effects, e.g. motor adverse effects, weight gain and changes in body fat composition. Partial agonism at dopamine D2 receptors represents a sophisticated option for effective antipsychotic treatment with diminished risk for side effects. Our previous *in vitro* and *in vivo* data revealed that 2-bromoterguride (2-BT) is a dopamine D2 partial agonist that shows promising antipsychotic characteristics in acute treatment [1]. Methods: We examined chronic effects of 2-BT with the same doses as used before (0.1 and 0.3 mg/kg; 21 days; twice daily) [1] on food and water intake, body weight and fat tissues in female Sprague Dawley rats. In addition, we investigated the influence of chronic 2-BT on spontaneous behavior in the open field box and cataleptic behavior in the bar and grid test. The atypical antipsychotic olanzapine (2 mg/kg) was used as a positive control. Results: In contrast to olanzapine, chronic 2-BT administration did not induce changes in food and water intake, body weight and body fat composition. Similar to acute conditions, 2-BT induced no cataleptic behavior but decreased spontaneous locomotion. Conclusions: Apparently, chronic 2-BT treatment does not result in accelerated weight gain or altered body fat composition. Both doses of 2-BT seem to be slightly sedative without inducing motor adverse effects. The present study confirms our previous observations [1] that the D2 receptor partial agonist 2 BT could be a promising candidate for the treatment of schizophrenia with minor side effects. Title: Modulation of dopaminergic signalling in the striatum by phosphodiesterase 10A (PDE10A) inhibitors

Authors: J. NIELSEN[1], P. H. LARSEN[1], *B. STEINIGER BRACH[2]
[1]Synaptic Transmission, [2]Neuropharm., H Lundbeck A/S, Valby, Denmark

Abstract: Phosphodiesterase 10A (PDE10A) is a dominant phosphodiesterase in striatal medium spiny neurons (MSN) that hydrolyse the second messengers cAMP and cGMP. Inhibition of PDE10A leads to increased cyclic nucleotide levels in the striatum and is expected to negatively modulate dopamine D2 receptor signalling in the indirect pathway MSN and positive modulate dopamine D1 receptor signalling in the direct pathway MSN. Preclinical *in vivo* evidence suggests antipsychotic as well as pro-cognitive activity for PDE10A inhibitors. We present comparative behavioural data for structurally unrelated PDE10A inhibitors along with PDE10A occupancy assessed by *in vivo* binding. In agreement with previously published studies, PDE10A inhibitors exhibited a profile very similar to D2 antagonists in assays such as phencyclidine-induced hyperactivity and conditioned-avoidance response suggesting a predominant effect on indirect pathway MSNs. However, in models where dopamine is elevated, such as amphetamine-induced hyperactivity, D2 antagonist-like effects only dominated at low PDE10A occupancy, while prominent D1 agonist-like effects became apparent at higher occupancy. The mechanism underlying those observations was further investigated by examining induction of cFOS expression in D1 and D2 expressing MSNs at different levels of PDE10A inhibition as a measure of activation of those neurons. These studies supported predominant activation of D2-expressing MSNs at low occupancy and activation of all MSNs at high PDE10A occupancy.

Title: Inhibition of 5alpha-reductase enzyme restores gating deficits elicited by D1 and D3, but not D2 activation in rats

Authors: R. FRAU[1], L. MOSHER[2], V. BINI[1], A. PARDU[1], R. PES[1], S. FANNI[1], M. BORTOLATO[2], *P. DEVOTO[1]
[1]Neurosci. and Clin. Pharmacol. Section, Dept. of Biomed. Sci., Monserrato, Italy; [2]Univ. of Kansas, Lawrence, KS

Abstract: Although multiple lines of evidence support a role for neurosteroids in the modulation of dopamine (DA) neurotransmission, the neurobiological underpinnings of this link remain poorly understood. Accordingly, we previously found that inhibition of 5alpha-reductase (5AR), a key neurosteroidogenic enzyme, normalized the behavioral outcomes elicited by non-selective DA receptor agonists in rats, including stereotyped behaviors and sensorimotor gating deficits, as measured by the prepulse inhibition (PPI) of the acoustic startle reflex. Furthermore, we recently showed that in C57BL/6 mice the 5AR blockade attenuated the behavioral responses ensuing D1-, but not D2-like receptor activations. Notably, all these antidopaminergic effects were not associated to extrapyramidal manifestations. Here, to further delineate the specific influences of the 5AR in the DAergic regulation of PPI, we tested the impact of the 5AR inhibitor finasteride (FIN) on the PPI-disruptive effects of D1, D2 and D3 DA agonists in Sprague-Dawley (SD) and Long-Evans (LE) rats. We found that the mixed D1/D2 agonist apomorphine (0.5 mg/kg, SC) elicited PPI disruptions in both strain, and these deficits were efficiently reversed by FIN (100 mg/kg, IP) in SD, but not in LE rats. On the other hand, the D1 receptor agonists SKF-38,393 (10 mg/kg, SC), SKF-82,958 (1 mg/kg, SC) and SKF-83,959 (1 mg/kg, SC) had no effects on

PPI in SD rats. Nevertheless, the full D1 agonist SKF-82,958 (1 mg/kg, SC) was able to reduce PPI parameters on LE rats, and these impairments were normalized by FIN (100 mg/kg, IP). The D2/D3 agonists quinpirole (O.6 mg/kg, SC) and the selective D2 agonist sumanirole (3 mg/kg, SC) disrupted PPI in both strain, but FIN did not revert these effects. Of note, the pretreatment with FIN (100 mg/kg, IP) significantly restored the PPI deficits induced by the selective D3 agonist PD 128907 (0.1 mg/kg, SC) in SD rats, whereas this latter compound failed to disrupt PPI in LE rats. Finally, to ascertain whether FIN may regulate D3 receptors by pre- or -post synaptic mechanisms, microdialysis studies performed in the nucleus accumbens of SD rats revealed that the pretreatment with FIN fully counteracted the reductions of DA release produced by PD injections. These results indicate that 5AR plays a crucial role in the dopaminergic regulation of gating through multiple mechanisms, based on pre- and post- synaptic actions via D3 and D1 receptors, respectively. Furthermore, these findings strengthen our previous evidence supporting 5AR in the therapy of neuropsychiatric disorders and emphasize D3 receptors as a novel intriguing molecular target underlying FIN mechanisms.

Title: Chronic treatment with antipsychotic drugs disrupt histone H3 homeostasis in forebrain of rats

Authors: *I. PODDAR, C. M. HERNANDEZ, A. V. TERRY, Jr.
Pharmacol. and Toxicology, Georgia Regents Univ., Augusta, GA

Abstract: Cognitive dysfunction is considered one of the most debilitating symptoms of schizophrenia, however, our current understanding of how the primary treatments of this disease, first and second generation antipsychotics (FGAs and SGAs, respectively) affect cognition remains inadequate. This lack of knowledge extends to how antipsychotics (AP) affect the neurobiological substrates of cognition as well as responses to drugs that have been developed to improve cognition in schizophrenia. Our previous work in animals has established that both representative FGAs and SGAs can negatively affect attention, spatial learning, and memory if

administered chronically, however, the mechanism for these adverse effects have not been clearly elucidated. Here we tested the hypothesis that AP-related epigenetic modifications were the basis for the cognitive impairments. Male Wistar rats were treated with FGAs chlorpromazine (10.0 mg/kg/day), haloperidol (2.0 mg/kg/day) or SGAs risperidone (2.5 mg/kg/day), olanzapine (10.0 mg/kg mg/kg/day) in drinking water for 90 days and then sacrificed. Oral antipsychotic dosing was based on: 1) previous rodent studies in our laboratory in which time dependent behavioral and neurochemical effects were detected; 2) plasma drug levels were achieved that approximated those often associated with AP effects in humans 3) the doses selected were expected to achieve comparable and therapeutically relevant dopamine D2 receptor occupancy values *in vivo*. We evaluated the expression of post-translational histone H3 modifications with known associations to changes in gene expression that are a prerequisite for memory consolidation, specifically histone H3 lysine acetylation (K14) and methylation (K9) by western blot using epitope-specific antibodies. Our results indicate that both FGAs and SGAs were associated with significant changes in histone H3 homeostasis in regions important for learning and memory. Such epigenetic alterations may provide an explanation for AP-related cognitive impairments previously observed in animals as well as recent clinical failures of pro-cognitive agents in patients chronically treated with antipsychotics.

Inst., Univ. of Niigata, Niigata, Japan

Abstract: (Background) The administration of antipsychotics which attenuates mainly dopamine systems have been believed to be crucial. The both systems of dopamine and glutamate are also considered to be related to the pathophysiology of schizophrenia(SCZ). Since dopamine- and cAMP-regulated phosphoprotein of molecular weight 32 kDa (DARPP-32) and Calcineurin (CaN) are the regulatory molecules of these two systems, it has been strongly suggested that these molecules might play the central roles in the etiology of SCZ. Thus in this study, we analyzed the associations of the expression of DARPP-32 and CaN with dopamine D2 receptor gene (DRD2) polymorphism, -141C Ins/Del in the postmortem striatum from patient with SCZ. (Materials and methods) We used immunoblotting techniques to examine the expression levels of two major DARPP-32 isoforms, full-length (FL-DARPP) and truncated (t-DARPP), and of CaN in the striatum of postmortem tissue samples from patients with SCZ and from normal control individuals. We also determined the -141C Ins/Del polymorphism in the DRD2 of brain samples by polymerase chain reaction and assessed whether there was any significant correlation between the expression levels of either protein and the -141C Ins/Del polymorphism in the DRD2. 12 postmortem brain samples from patients with SCZ were obtained from the Fukushima Brain Bank at the Department of Neuropsychiatry, Fukushima Medical University and 12 normal control postmortem brain samples were obtained from autopsy cases at the Brain Research Institute, University of Niigata. This study was approved by the Ethics Committee of Fukushima Medical University and complied with the Declaration of Helsinki. (Results) We found that the expression of t-DARPP in the SCZ with Del allele was significantly decreased compared to that with Ins/Ins genotype in Putamen ($p=0.042$) and the expression of CaN in the SCZ with Del allele was marginally significantly decreased compared to that with Ins/Ins in the Caudate ($p=0.0504$). Also, in the control subjects the expression of FL-DARPP and t-DARPP in the Caudate was significantly associated with -141C Ins/Del polymorphism in the DRD2 ($p=0.040$, 0.001, respectively). (Discussion) In this study we found that the striatal expression of DARPP and CaN was decreased in Del allele carriers. One previous study indicates that SCZ with Del allele noncarriers might be better responders of antipsychotics for the anxiety and the depression than that with Del allele carriers. Therefore, these results may reflect potential molecular mechanisms based on the antipsychotics resistant to anxiety and depression in SCZ.

Title: Cacna1c haploinsufficiency leads to altered mesolimbic dopamine system function

Authors: ***C. TERRILLION**, M. ARAD, D. T. DAO, R. CACHOPE, J. F. CHEER, T. D. GOULD
Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: CACNA1C codes for the L-type calcium channel Cav1.2, and has been associated with clinical diagnoses of bipolar disorder, schizophrenia, and depression. L-type calcium channels are associated with normal function of the mesolimbic dopamine (ML-DA) system, dysregulation of which is linked to these disorders. We hypothesized that decreased levels of Cav1.2 leads to decreased ML-DA system function, resulting in attenuation of a subset of DA mediated behaviors. Cacna1c heterozygous (HET) and wild-type (WT) mice were tested in several behaviors following stimulant challenge, including acute locomotor response, sensitization, conditioned place preference (CPP), and stereotypic behavior. Using fast-scan cyclic voltammetry (FSCV), subsecond DA release and reuptake in the nucleus accumbens of HET and WT mice was measured following stimulation of the ventral tegmental area. Recordings were taken at a series of stimulation amplitudes and after GBR12909 administration. Western blot was used to determine levels of dopamine transporter (DAT) protein. HET mice manifested significantly reduced hyperlocomotion following acute administration of psychostimulants specific to DAT (amphetamine, cocaine, and GBR12909) but not to glutamate (MK-801), as well as delayed sensitization. There was no effect of genotype on stereotypic behavior or CPP. FSCV revealed that HET mice had significantly more rapid DA reuptake following GBR12909 administration compared to WT mice. There was no effect of genotype on

DAT protein levels. Cacna1c haploinsufficiency was associated with attenuation of selective DA dependent behaviors. FSCV revealed that Cav1.2 has a role in presynaptic ML-DA system function, including a likely role in regulating DAT function. However, this is not due to total levels of DAT protein suggesting that DAT activity is regulated through an alternative mechanism. Current experiments include using conditional Cacna1c knockout and transgenic lines to examine the specific role of Cav1.2 in the nucleus accumbens and ventral tegmental area.

Title: Effects of chronic treatment with typical and atypical antipsychotics on mouse brain volume in genetic deletion models of D2-like dopamine receptors

Authors: *E. GUMA[1], J. ROCCHETTI[1], B. COURCOT[2], A. MATHIEU[2], G. DAL BO[1], P. PATEL[1], B. GIROS[1]
[1]Douglas Res. Ctr. - McGill Univ., Montreal, QC, Canada; [2]Douglas Mental Hlth. Univ. Institute's Brain Imaging Ctr., Montreal, QC, Canada

Abstract: Longitudinal MRI studies have consistently shown that schizophrenic exhibit brain volume reductions over the course of the illness. However, these patients are often treated with antipsychotic (AP) medication. Thus, it is difficult to determine whether the changes are related to the disorder, to the effects of the medication or both. The use of animal models allows for a more ethical assessment of the effect of AP treatment on brain volume, without interference of the pathology. Naïve C57BL/6J mice received daily intraperitoneal (i.p.) injections of saline or haloperidol (HAL) (0.5mg/kg/day) for 9 weeks. Animals were scanned using a Bruker 7T small MRI scanner before starting treatment, then at 3, 6 and 9 weeks to assess volumetric changes in the whole brain and predefined subregions, such as the prefrontal cortex, hippocampus, and

striatum. In accordance with previous studies done in rats, this treatment lead to a decrease in pre-frontal cortex volume. With access to D2 and D3 dopamine (DA) receptor knockout transgenic mice, we aimed to assess the role that D2-like DA receptors may play in the brain volume changes associated with AP use. Thus, D3-KO, D2-KO mice and their wild-type littermates were treated with daily i.p. injections of saline, HAL (typical AP) (1mg/kg/day), or clozapine (atypical AP) (5 mg/kg/day) for 9 weeks. Again, animals were scanned before starting the treatment, and then at 3, 6, and 9 weeks to track brain volume changes. Furthermore, to understand the cellular basis of volume changes, stereological analysis of NeuN+ neuronal populations, Iba1+ microglia, and GFAP+ astrocytes was performed in the prefrontal cortex. Studying the effect of a typical and atypical AP medication on the brain volume in D2KO and D3KO mice will allow us to better explain if the decrease in volume of the prefrontal cortex observed in wild-type animals after HAL medication is primarily due to the activity of D2-like receptors, highly targeted by typical AP medication, or whether these changes involve alternate - dopaminergic or non dopaminergic - pathways. In conclusion, this study helps to elucidate the region-specific structural effects of antipsychotics on mouse brain and the pathways implicated in these changes, which could allow for improvements in the design of treatments for psychotic disorders.

Title: Exploration of the role of dopamine D4 receptor in methamphetamine-induced psychosis

Authors: *I.-M. LIAO[1], J.-C. CHEN[2]
[2]Dept. of Physiol. and Pharmacol., [1]Grad. Inst. of Biomed. Sciences, Chang Gung Univ., Taoyuan County, Taiwan

Abstract: Chronic methamphetamine (METH) use not only leads to addiction, but also gives rise to the development of psychotic symptoms, including delusion, hallucination, and

disorganized speech, in humans. Preclinical and clinical studies have addressed the significance of dopamine system in METH-induced psychosis; however, most studies were dopamine D2 receptor-oriented due to its putative role as the main drug target of typical antipsychotics. In spite of the fact that many studies attempt to address the potential of dopamine D4 receptor (D4R) as a novel molecular target of psychosis treatment, it remains unclear whether D4R signalling is critically participated in psychosis due to inconsistent results. Therefore, the purpose of this study is to investigate and delineate the role of D4R in METH psychosis development. To this aim, we used pharmacological manipulations and behavioral assessments to evaluate if D4R is involved in the development of METH psychosis. Male mice from six to eight weeks were used in this study. Selective D4R antagonist (also an atypical antipsychotic) clozapine (1, 2.5, 5 mg/kg, i.p.) was pre-treated before daily METH (2 mg/kg, i.p.) administration for 7 consecutive days. Horizontal locomotor activity and stereotypy were evaluated on the first and last day for 1 hour after METH treatment. Results showed that clozapine (1, 2.5, 5 mg/kg/day, i.p.) pre-treatment dose-dependently inhibited METH-induced behavioral sensitization (by 25%, 50%, 80%, respectively), suggesting that D4R may be critically involved during the sensitization process. The molecular mechanism underlying D4R-mediated METH sensitization antagonism is currently under investigation to elucidate the action of D4R, as well as D4R-associated protein(s), in METH-induced psychosis.

Title: Forebrain Specific Ankyrin G knockout Mouse displays mania like behavior, rescued by anti-psychiatric drugs and shows deficit in GABAergic synapse formation and ion channel activity

Authors: *S. ZHU[1], J. KIM[2], X. WANG[1], V. BENNETT[5], M. PLETNIKOV[1], S. BROWN[2], C. ROSS[1,2,3,4]
[1]Psychiatry and Behavior Sci., The Johns Hopkins Univ., Baltimore, MD; [2]Neurosci.,

[3]Pharmacol. and Mol. Sci., [4]Neurol. and Neurosurg., the Johns Hopkins Univ., Baltimore, MD; [5]Cell Biology, Biochemistry, and Neurobio., Duke Univ., Durham, NC

Abstract: The ANK3 (Ankyrin G) locus is a risk factor for schizophrenia and bipolar disorder. In the CNS, Ankyrin G localizes to the axon initial segment (AIS) and Node of Ranvier, and tethers sodium and potassium channels. In local cortical circuits, chandelier cells are fast spiking interneurons that send axon-axonic inhibitory synapses to the pyramidal cell AIS, forming GAT-1 and GAD67 positive cartridge-like structures wrapping around the AIS. We established a forebrain-specific Ankyrin G conditional knockout (KO) mouse model, in which knockout is restricted to adulthood, characterized its behavior, examined the effects of psychiatric medications and explored the molecular mechanisms using double label immunofluorescence and electrophysiology. The forebrain conditional Ankyrin G knockout model displays increased motor activity, increased exploratory activity, and less anxiety-like behavior, reminiscent of affective disorder. Interestingly, c-fos (a marker of neuronal activity) expression is significantly increased in Ankyrin G KO mice. Application of several anti-mania agents such as Clozapine, Lithium and Valproic Acid ameliorated the hyperactivity. Voltage gated sodium channel and potassium are missing from AIS and Node of Ranvier. Intriguingly, neurons that lost Ankyrin G expression have altered excitability. Chandelier interneuron cartridge structures were diminished in the Ankyrin G KO mice. This forebrain-specific Ankyrin G conditional knockout mouse model may be useful as potential model of mania, and for development of tools to explore the mechanisms of psychiatric drugs, and to develop new therapeutic strategies for bipolar and schizophrenia.

Abstract: P-glycoprotein is a 130-kDa adenosine triphosphate (ATP) dependent drug transport protein that is abundantly distributed in the apical side of brain capillary endothelial cells forming the tight junctions of the blood-brain barrier (BBB). P-glycoprotein has been demonstrated to influence the absorption, distribution, and elimination of many commonly used drugs. It has, furthermore, been shown that P-glycoprotein influences the distribution of drugs across the BBB. The location of P-glycoprotein at the BBB is of importance for the delivery of antipsychotic medications. The antipsychotic drugs such as aripiprazole and risperidone are the substrates for P-glycoprotein. On the other hand, Clozapine is a therapeutic drug of treatment-resistant schizophrenia, but is not the substrate of P-glycoprotein. There may be association between treatment of treatment-resistant schizophrenia and P-glycoprotein. But we do not know how the P-glycoprotein function after the chronic treatment with atypical antipsychotic drugs in the brain. Then we investigated which chronic treatment with the atypical antipsychotic drugs as the substrates for P-glycoprotein was changed the function of P-glycoprotein in the brain. We examined that the expression of RNA P-glycoprotein after chronic treatment with the antipsychotic drugs and compared with before treatment. C57BL/6N mice (weighing 20-25 g) were orally administrated of 10mg/kg/day atypical antipsychotic drugs once daily for six weeks. To quantify the amount of mRNA in mice brain, we performed real-time PCR (StepOne Real-Time PCR System)by using TaqMan Fast Universal PCR Master Mix (life technologies). A PCR reaction mixture of 10µl containing 5µl of TaqMan Fast Universal PCR Master Mix, 4.5µl of cDNA and 0.5µl TaqMan Gene Expression Assays.

Title: Nicotine effect on a model of hyperactivation of the dopaminergic system using a temporal bisection task

Authors: *I. GONZALEZ RIVERA[1], D. B. PAZ-TREJO[2,3], O. ZAMORA-AREVALO[1], O. GALICIA[4], H. SANCHEZ-CASTILLO[2,3]

Nacional Autonoma de Mexico, Psychology School., Mexico DF, Mexico; [3]Sociedad Iberoamericana de Neurociencia Aplicada, Mexico DF, Mexico; [4]Neurociencias, Univ. Iberoamericana, Mexico DF, Mexico

Abstract: Schizophrenia is a disorder that involves many biochemical abnormalities. Patients with schizophrenia have a high prevalence of smoking. Nicotine is theoretically able to reduce some of the symptoms of schizophrenia. However, there is controversy regarding the role of nicotine in the disorder. The main goal of this investigation was to examine the effect of nicotine administration on a model of hyperactivation of the dopaminergic system, using a temporal bisection task. We use 8 male Wistar rats tested in a temporal bisection task discriminating durations of 2 or 8 seconds and intermediate duration (2.5, 3.17, 4, 5 and 6.4 s) with repeated administration of methylphenidate (3.0 mg/kg) for seven days and thereafter they were tested with repeated administration of methylphenidate (3.0 mg/kg) and nicotine (1.5 mg/kg) administered simultaneously for 7 days. We obtain the percentage of responses for the long stimulus and compare the responses on the control condition against the responses with each drug condition. Also, we compare psychometric measures for bisection task: bisection point, limen and Weber fraction. There were not statically significant differences in bisection point, Limen or Weber fraction. However, we observed a displacement of the sigmoidal curve and a decrement of the responses with the administration of methylphenidate (3.0 mg/kg). We also observed that the sigmoidal curve of repeated administration of nicotine and methylphenidate together is very similar to the curve of the control condition. The results support the fact that the cognitive effects of nicotine dependent on a variety of factors, including the underlying neural systems used for tasks and interaction with other drugs and systems. It is proposed that the evaluation of the processing of temporal information can serve as a tool in the understanding and assessment of the cognitive deficits of schizophrenia.

Title: Redox and methylation effects of D4 dopamine receptor expression and activation

Authors: *R. C. DETH[1], N. HODGSON[1], Y. LI[1], M. WALY[2]
[1]Dept Pharmceut Sci., Northeastern Univ., BOSTON, MA; [2]Food Sci. and Nutr., Sultan Qaabos Univ., Muscat, Oman

Abstract: We previously described the ability of the D4 dopamine receptor (D4R) to promote methylation of the phospholipid phosphatidylethanolamine, using methyl groups provided by the folate and vitamin B12-dependent enzyme methionine synthase (MS). Genetic variants of the D4R, resulting in proline-rich repeats in the third cytoplasmic loop, have been linked to different personality traits, drug abuse liability and to longevity. Using stably transfected CHO cells expressing D4Rs with 2, 4 or 7 repeats, we compared the ability of dopamine (DA; 10 μM) to induce phospholipid methylation (PLM), activate MS, affect the levels of redox and methylation pathway metabolites and alter global DNA methylation. The D4.7R was <50% as effective as D4.2R or D4.7R in supporting DA-stimulated PLM. Lower activity of the D4.7R may relate to its linkage to ADHD. Expression of each D4R was associated with a similar 90% decrease in basal MS activity. DA treatment increased MS by 90, 140 and 180% for D4.2R, D4.4R and D4.7R, respectively, while the D4R antagonist L-745870 decreased basal activity by ~65% for all three D4Rs. This indicates that D4Rs compete for MS activity and this competition is sensitive to receptor conformation. Expression of each D4R decreased basal GSH levels, but addition of DA increased levels by 49, 45 and 37% for D4.2, D4.4 and D4.7 receptors. Thus D4R expression endows cells with redox responsiveness to DA. DA increased the methylation index (SAM to SAH ratio) by 5.1, 8.6 and 4.6-fold for D4.2, D4.4 and D4.7 receptors, while global DNA methylation was increased 2.3, 2.0 and 2.0-fold, respectively. All responses were blocked by L-745870. These results demonstrate that D4R expression also confers DA responsiveness to methylation pathways, including DNA methylation. Since epigenetic mechanisms are linked to memory formation, D4Rs may provide a mechanism by which attended information can be remembered.

Title: Homer transcripts topography is modulated in cortex and striatum by minocyline or memantine when added to haloperidol: Implication for treatment resistant psychosis

Authors: E. F. BUONAGURO[1], C. TOMASETTI[1], F. MARMO[1], C. SARAPPA[1], A. ERAMO[2], F. IASEVOLI[1], *A. DE BARTOLOMEIS[1]

Abstract: Compounds targeting the N-methyl-D-aspartate (NMDA) receptor, such as memantine and minocycline, have been proposed as add-on therapies in treatment-resistant schizophrenia. NMDA receptors are the core of the post-synaptic density (PSD), a protein mesh deputed to glutamatergic signaling and implicated in dopamine-glutamate interplay. PSD genes (e.g. Homer1a and Homer1b genes of the Homer1 family) are induced by dopaminergic compounds including antipsychotics. PSD genes modulation could be a marker of glutamate/dopamine neurotransmission. Herein, we evaluated the expression of Homer1a and Homer1b genes as a marker of dopamine-glutamate interplay in different translational models utilizing both dopaminergic and glutamatergic compounds, either alone or in combination. Expression of Homer1a and Homer1b genes was assessed in cortical and striatal regions by means of *in situ* hybridization. The relative ratio of Homer1a/Homer1b expression was calculated in all paradigms. Data were processed by ANOVA and Tukey's post-hoc test. Acute NMDA receptor modulation paradigm. Sprague-Dawley rats were treated by vehicle; ketamine (25mg/kg and 50mg/kg); memantine 5mg/kg. Homer1a expression was significantly induced and Homer1b expression decreased by ketamine (25mg/kg) in cortical regions. Memantine shifted the Homer1a/Homer1b ratio toward Homer1b in the same brain regions. Chronic haloperidol/acute memantine add-on paradigm. Rats were chronically treated by haloperidol (0.8mg/kg) and then acutely treated by memantine 5mg/kg or vehicle before sacrifice. Acute memantine administration significantly increased Homer1a mRNA expression compared to acute vehicle in the cortex. No significant differences where found in Homer1a and Homer1b gene expression in both acute vehicle and memantine administered-rats. Minocycline add-on paradigm. Minocycline (45mg/kg) alone or in combination with haloperidol (0.8mg/kg) was administered to rats exposed or not to ketamine (30mg/kg). Minocycline per se did not affect gene expression. In the ketamine treated rats, Homer1a expression was significantly reduced by haloperidol+minocycline compared with vehicle in the cortex and, albeit less extensively, in the striatum. These results suggest that memantine and minocycline may have low propensity to affect glutamatergic genes when administered alone. However, they modify the effects of

haloperidol on these genes when administered in add-on, contributing to provide a rationale for the clinical efficacy of these compounds.

Title: Homodimerization and phosphorylation of n-terminal serines control the subcellular localization of PDE11A4

Authors: ***G. PATHAK**[1], S. HEGDE[2], S. P. WILSON[2], J. L. FISHER[2], M. P. KELLY[2]
[2]Pharmacology, Physiology, and Neurosci., [1]Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: Phosphodiesterases (PDEs) are the only known enzymes to degrade cAMP and cGMP; therefore, PDEs are also crucial for a number of physiological processes including brain function. PDE11A, the most recently identified PDE family, has 4 isoforms. We study PDE11A4, as it is the only PDE11A isoform expressed in brain and it is the only PDE in brain with expression restricted to the hippocampus, a brain region affected in many neuropsychiatric illnesses. Recently, we identified disease-relevant genetic and environmental manipulations that change expression of PDE11A4 within select subcellular compartments of hippocampal tissues. Therefore, we sought to identify the intramolecular signals that control PDE11A4 subcellular compartmentalization. The regulatory N-terminal of PDE11A4 contains 2 confirmed phosphorylation sites and 2 full GAF domains: GAF-A and GAF-B. The GAF-A domain binds cGMP and the GAF-B domain is a protein-protein binding domain that mediates homodimerization. Currently, nothing is known about what signals control the subcellular localization of PDE11A4; however, phosphorylation and protein-protein binding are known to

control compartmentalization of other PDE families. As such, we determined if phosphorylation of N-terminal residues or homodimerization at the GAF-B domain could control the compartmentalization of PDE11A4 in COS1 and HEK293T cells. In both cell types, microscopy showed wild-type PDE11A4 was localized throughout the cytosol and in punctate aggregates. Phosphomimic mutations of serines 117 and 124 drove PDE11A4 from the cytosol towards the punctate structures; whereas, the phosphomimic mutation of serine 162 shifted PDE11A4 away from the punctate structures towards the cytosol. Introduction of an isolated GAF-B domain designed to disrupt PDE11A4 homodimerization also shifted wild-type PDE11A4 from the puncta toward the cytosol and reversed the effects of phosphomimic mutations at serines 117 and 124. Importantly, this effect of the isolated GAF-B domain did not require phosphorylation of serine 162. Biochemical fractionation studies yield similar results, with phosphomimic mutations of serines 117 and 124 driving PDE11A4 from the cytosol toward the membrane and phosphomimic mutation of serine 162 and addition of the isolated GA-B domain driving PDE11A4 from the membrane toward the cytosol. These results suggest that phosphorylation of serine 162 prevents homodimerization at the GAF-B domain, whereas phosphorylation of serines 117 and 124 promotes homodimerization at the GAF-B domain, thereby controlling subcellular localization of PDE11A4.

Title: Global profiling of phospoproteome using mass spectroscopy to identify phosphorylation changes upon M1 activation in striatum

Authors: *M. POPIOLEK, J. HARMS, S. XI, S. GRIMWOOD
Neurosci. Res. Unit, Pfizer, Cambridge, MA

Abstract: Preclinical and clinical studies suggest that muscarinic receptor activation may be therapeutically beneficial in treatment of schizophrenia and Alzheimer's disease. The M1 receptor is a Gαq-coupled member of the muscarinic acetylcholine receptor family which is thought to mediate some of those beneficial effects. TBPB [1-(1'-2-methylbenzyl)-1,4'-

bipiperidin-4-yl)-1H-benzo[d]imidazole-2(3H)-one], a highly selective M1 receptor activator, has been reported to potentiate NMDA receptor currents in hippocampal pyramidal cells, increase cFos expression in prefrontal cortex and striatum, and reverse amphetamine-induced hyperlocomotion in rats. We aimed to profile biochemical effects mediated by M1 *in vivo*. With this M1-selective and brain penetrant tool we explored striatal phospho-proteome in mice through mass spectrometry. By utilizing mass spectrometry and label-free quantification, we detected 1930 phospho-peptides from 747 proteins. Out of these, 182 sites on 116 proteins showed phosphorylation changes (p value < 0.1). Expected outcomes such as increased pERK levels have been observed due to TBPB treatment. We will discuss novel phosphoprotein changes associated with M1 activation. Results obtained with the mass spectrometry were confirmed with Western blots showing wide effect of M1 activation on regulation of striatal phosphorylation.

Title: Haloperidol-environment interaction modulates expression of c-Fos proteins within the regions of the basal ganglia in rats

Authors: *L. N. SCHIMMEL[1], E. HAWKEN[1], E. DUMONT[1], T. BANASIKOWSKI[2], R. BENINGER[1]

Abstract: Repeated treatment with dopamine (DA) receptor antagonists reduces the incentive value of environmental stimuli and gradually produces motivational impairments observed as a loss of motor engagement with the environment. The neural mechanisms of context-dependent catalepsy sensitization in rats were examined with an immunohistochemical assay for c-Fos, a marker of recent neuronal activity. During the training phase (15 daily sessions), the paired group received haloperidol (0.25 mg/kg; n=9), a DAD2 receptor-preferring antagonist, 1 h prior

to a catalepsy test carried out in a specific environment by placing the rats with their forepaws resting on a horizontal bar. The unpaired group (n=9) was treated with saline before catalepsy test and then injected with haloperidol 1 h later; a third group (n=9) was treated with saline before and 1 h after catalepsy test. On the test day all animals were treated with haloperidol prior to the catalepsy test. Behavioral results showed that animals in the paired group spent significantly more time with both paws on the bar compared to the unpaired and saline controls. Our results confirm previous findings that acquisition and expression of catalepsy sensitization to haloperidol is conditional on the interaction between the drug and test environment. Rats were sacrificed immediately following this test. Immunohistochemical results paralleled our behavioral findings;we found that paired animals had significantly fewer neurons expressing c-Fos compared to unpaired and saline controls following haloperidol challenge on test day. Specifically we observed a significant impairment in c-Fos expression in the nucleus accumbens shell and ventral pallidum, regions that link motivation to actions and process incentive learning. Results implicate basal ganglia circuitry in the neuronal mechanisms modulating catalepsy sensitization.

Title: Burst firing in the mediodorsal thalamus and related cognitive circuits is modulated by metabotropic glutamate receptors

Authors: *C. S. COPELAND[1], S. A. NEALE[2], T. E. SALT[1]
[1]Univ. Col. London, London, United Kingdom; [2]Neurexpert Ltd., London, United Kingdom

Abstract: Cognitive deficits in schizophrenia remain largely unaffected by current antipsychotic therapies. Thalamo-cortical synchronization between the prefrontal cortex (PFC) and mediodorsal thalamus (MD) is thought to play an important role in cognition: disturbed synchrony in this and other thalamo-cortical circuits may therefore account for cognitive deficits

associated with schizophrenia. As Group II metabotropic glutamate receptor (mGlu2/3) compounds have efficacy in animal models of schizophrenia, with two compounds reaching phase 2 clinical trials, we sought to investigate the action of the Group II agonist LY354740 and the mGlu2 positive allosteric modulator (PAM) LY487379 on the firing pattern of MD and somatosensory ventrobasal thalamus (VB) neurons. Extracellular single neuron recordings were made *in vivo* with multibarrel electrodes in the MD or VB of urethane-anaesthetized Wistar rats. Drugs were applied locally by iontophoresis. For MD recordings, the PFC was electrically stimulated to activate the MD, whilst for VB recordings neurons were activated by vibrissa stimulation. The Group II agonist disinhibited responses to vibrissa stimulation in the VB; a disinhibition that was potentiated upon co-application of the mGlu2 PAM (Copeland et al., 2012; J Physiol 590:937-51). Furthermore, the Group II agonist significantly reduced burst firing in the VB, an effect that was also potentiated by the mGlu2 PAM (control: 66±7% spikes in bursts; LY354740 alone: 51±9% spikes in bursts; LY354740 plus LY487379 38±9% spikes in bursts). Whilst focal application of the Group II agonist also significantly disinhibited responses to PFC stimulation in the MD (156±10% of control) and significantly reduced burst firing (control: 76±5% spikes in bursts; LY354740: 57±2% spikes in bursts), neither of these effects were potentiated upon co-application of the mGlu2 PAM. The significance of these results is two-fold. Firstly, they demonstrate that Group II mGlu receptor function across thalamic nuclei is not uniform. Secondly, compounds active exclusively at the mGlu2 receptor are unlikely to perturb cognitive deficits arising from MD malfunction, with activity at mGlu3 receptors likely more appropriate. Interestingly, genetic studies have detected polymorphisms in the mGlu3 receptor gene GRM3, but not the mGlu2 receptor gene, in schizophrenia patients (Harrison et al., 2008; J Psychopharmacol 22:308-22).

Abstract: Schizophrenia is a complex, pervasive, and heterogeneous neuropsychiatric disorder characterized by positive, negative, and cognitive symptoms. First-generation antipsychotics (FGAs) typically alleviate only positive symptoms, have undesirable extrapyramidal side-effects (EPS), and act primarily through antagonism of the dopamine (DA) D2 receptor (D2R). Second generation antipsychotic drugs (SGAs) are successful also in controlling positive symptoms and some drugs show improvement in negative symptoms with few EPS. While all SGAs act through D2Rs, they exert actions also through multiple serotonin (5-HT) receptor subtypes. Thus, while modulation of D2R-mediated signaling is important, targeting it directly is not sufficient to alleviate all symptoms of schizophrenia. Since activation of 5-HT_{2C} receptors in the ventral tegmental area decreases DA release in mesolimbic areas, 5-HT_{2C}-selective agonists may reduce mesolimbic DA activity without affecting the nigrostriatal system; thereby diminishing psychotic symptoms without inducing EPS. Interestingly, 5-HT_{2C} receptors are found also in cortical and other non-dopaminergic limbic forebrain regions implicated in schizophrenia. In our studies several novel 5-HT_{2C} agonists were tested in mouse models of schizophrenia. Since Compounds 2 and 3 were similar in structure, they were not examined in the same behavioral tests. In C57BL/6 mice, compound 3 reduced amphetamine-stimulated hyperlocomotion in the open field, it restored phencyclidine-disrupted prepulse inhibition, and decreased conditioned avoidance responding. It also had very low cataleptic activity compared to haloperidol. We used NR1-knockdown (NR1-KD) mice for assessments of social and cognitive behaviors. Compared to the wild-type controls, untreated NR1-KD mice were severely deficient in social affiliation and in episodic memory. Compound 2 rescued the NR1-KD deficits in social affiliation in the sociability test and in episodic memory at 24 hr in the novel object recognition memory test. These preclinical results provide support for the 5-HT_{2C} receptor as a potential therapeutic target in the treatment of schizophrenia.

Institute/AIIM Fac., Innovation Campus, University of Wollongong, Australia; [4]Sch. of Psychology, Fac. of Social Sci., University of Wollongong, Australia

Abstract: Background and Aims: Dysfunctional myelination is one of the strongest hypotheses implicated in schizophrenia pathophysiology. Interestingly, myelination peaks during late adolescence, coinciding with the onset of schizophrenia. Lingo-1, a transmembrane signal-transducing molecule expressed on oligodendrocytes and neurons, is a potent negative regulator of oligodendrocyte differentiation, axonal growth and myelination. Since myelination and neuronal outgrowth disturbances lead to cognitive dysfunction, and considering the involvement of Lingo-1 in these processes, we have investigated the effects of pharmacological inhibition of Lingo-1 as a novel treatment for schizophrenia. Methods: Adolescent male Sprague Dawley rats (4 weeks) were injected subcutaneously with either saline vehicle or PCP (10 mg/kg, Sigma) for a total of 8 days. On the third day, rats (n=12/group) were concurrently treated for 5 days with either saline, olanzapine (Olz) (oral administration by cookie dough 1 mg/kg/day, 3 times/day) or anti-Lingo-1 functional antibody ab23631 (Abcam, UK), (intraventricular injection, with surgery for intracranial cannula implantation performed one week prior). Relative protein expression levels of Lingo-1, and myelination marker myelin basic protein (MBP) were examined within the prefrontal cortex of the treated rats. Results: Lingo-1 levels were significantly increased in PCP treated rats ($p=0.015$) and MBP was significantly reduced in PCP treated rats ($p=0.002$); both were restored to near control levels in anti-Lingo-1/Olz treated rats ($p=0.032$). Restoration of MBP levels was most likely to have been caused by the anti-Lingo-1 treatment, as rats treated with PCP/Olz had similar MBP levels as PCP/Vehicle treated rats in the prefrontal cortex. Conclusions: This is the first study to have shown that Lingo-1 and myelination levels are altered

following PCP treatment and that these levels are restored following treatment with a Lingo-1 antagonist. We suggest that Lingo-1 may be a suitable target for the development of new future therapeutic treatments for schizophrenia.

Title: D-serine treatment enhances cortical parvalbumin GABAergic neuronal development through synaptic NMDA receptors

Authors: H. LIN[1], F.-C. HSU[1], A. JACOBI[1], B. H. BAUMANN[1], D. A. COULTER[2,1], S. A. ANDERSON[2,1], *D. R. LYNCH[2,1]
[1]The Children's Hosp. of Philadelphia, Philadelphia, PA; [2]CHOP, Hosp Univ. Pennsylvania, PHILADELPHIA, PA

Abstract: D-serine, synthesized by the enzyme serine racemase (SR) through the conversion of L-serine to D-serine, is an endogenous coagonist which preferentially gates synaptic rather than extrasynaptic NMDA receptors(NMDARs). NMDAR hypofunction due to specific loss of D-serine has been implicated in the pathophysiology of schizophrenia and other neuropsychiatric disorders. Our previous studies have demonstrated that deletion of α7 nicotinic acetylcholine receptor (nAChR) gene in mice leads to specific loss of synaptic NMDARs and their coagonist D-serine, as well as cortical parvalbumin (PV) GABAergic deficits reminiscent of schizophrenia. Here we report that D-serine treatment enhances cortical PV GABAergic neuronal development through synaptic NMDARs in neuronal cultures and organotypic slice cultures from wild-type

(WT) and α7 nAChR knockout (α7-KO) mice. D-serine (50μM) treatment promotes GABAergic marker expression in WT and α7-KO cortical cultures, including Glutamic Acid Decarboxylase 65/67 (GAD65/67), the α1 subunit of GABAA receptors (GABAAα1), and gepherin. D-serine treatment not only increases PV levels in cortical PV GABAergic interneurons in WT neuronal and organotypic slice cultures, but also rescues cortical PV GABAergic deficits, demonstrated by increase of PV levels and perisomatic synapse formation in α7-KO in neuronal cultures and organotypic slice cultures. Moreover, D-serine treatment increases pCREB levels in cortical cultures, which can be blocked by NMDAR antagonist MK-801. Taken together, our findings suggest that D-serine treatment enhances cortical PV GABAergic development through synaptic NMDARs, thereby providing important insights into designing better treatment for schizophrenia and other interneuron-related neuropsychiatric diseases.

Title: NR_{2b} antagonist CP101,606 abolishes pitch-mediated deviance detection in awake rats

Authors: *S. V. DIGAVALLI, P. CHEN, Y. YANG, Y.-W. LI, R. PIESCHL, M. K. AHLIJANIAN
Neurosci Drug Discovery, Bristol Myers Squibb Co., WALLINGFORD, CT

Abstract: Schizophrenia patients exhibit a decreased ability to detect change in their auditory environment as measured by auditory event related potentials such as mismatch negativity. This deficit has been linked to abnormal NMDA neurotransmission since, among other observations, non-selective channel blockers of NMDA reliably diminish deviance detection in human subjects as well as in animal models. Recent molecular and functional evidence link the NR_{2b} receptor subtype to aberrant NMDA transmission in schizophrenia. However, it is unknown if NR_{2b} receptors participate in pre-attentive deviance detection. We recorded event related potentials from the vertex of freely behaving rats in response to frequency mismatch protocols. We saw a robust increase in N1 response to deviants compared to standard as well as control stimuli indicating true deviance detection. Moreover, the increased negativity was highly sensitive to

odd-ball probability. Next, we tested the effect of a non-selective NMDA channel blocker (ketamine, 30 mg/kg) and a highly selective NR_{2b} antagonist, CP-101,606 (10 or 30 mg/kg) on deviance detection. Ketamine attenuated deviance mainly by increasing the amplitude of the standard N1. Amplitude and/or latency of several other ERP components were also markedly affected. In contrast, CP-101,606 robustly and dose-dependently inhibited the deviant's N1 amplitude and as a consequence, completely abolished deviance detection. No other ERP or components were affected. Thus, we report first evidence that NR_{2b} receptors robustly participate in processes of automatic deviance detection in a rodent model. Lastly, our model demonstrates a path forward to test specific pharmacological hypotheses using translational endpoints relevant to aberrant sensory processing in schizophrenia.

Title: Neuregulin-1 treatment prevents PCP-induced parvalbumin and GAD67 changes in frontal cortex neurons

Authors: *M. ENGEL[1,2], L. OOI[1], X.-F. HUANG[1,2], E. FRANK[1,2]
[1]Fac. of Science, Med. and Hlth., Illawarra Hlth. and Med. Res. Inst., Wollongong, Australia; [2]Schizophrenia Res. Inst., Sydney, Australia

Abstract: Evidence from genetic and post-mortem studies strongly suggest that altered Neuregulin 1 (NRG1) signaling through ErbB4 is associated with the pathophysiology of schizophrenia. ErbB4 receptors are primarily located on GABAergic interneurons in schizophrenia-relevant brain areas, including the prefrontal cortex. Application of phencyclidine (PCP) is commonly used to identify compounds with antipsychotic potential. In our previous studies, we showed that NRG1 application reduces PCP-induced behavior impairments and GABA level changes in the PFC and hippocampus. In the present study we explored the ability of NRG1 to counterbalance PCP-induced alterations of the GABA-producing enzymes GAD65 and GAD67 and the calcium binding protein parvalbumin (PV) in primary frontal cortex cultures. Dissociated frontal cortex cultures from C57BL6 mice (post natal day 1-2) were

maintained for seven days before being treated with NRG1, PCP or both for 24h. Expression of GAD65, GAD67, PV, DISC1, NMDA-NR1 and synaptophysin mRNA levels were quantified via qPCR. GAD67 and PV levels were significantly increased and GAD65 decreased following PCP application in the frontal cortex cultures. Combined treatment with NRG1 dose-dependently prevented the PCP-induced changes. NRG1 at the lowest concentration reduced GAD65 and 67 levels, with no further effect on other targets or at higher concentrations. Together with our previous behavioral and microdialysis findings, these results demonstrate a critical role of NRG1 in neurotransmission relevant to schizophrenia. With NRG1 application proven safe in phase II trials for heart disease, our results suggest that NRG1 treatment has a promising treatment potential for patients with schizophrenia.

Title: Potential implication of the kynurenine pathway in a juvenile two-hit animal model of schizophrenia: Reversal of PPI deficits by the inhibition of indoleamine 2,3-dioxygenase

Authors: *J. DESLAURIERS[1], P. SARRET[1], S. GRIGNON[1,2]
[1]Physiol. and Biophysics, [2]Psychiatry, Univ. de Sherbrooke, Sherbrooke, QC, Canada

Abstract: The levels of kynurenic acid, a metabolite of kynurenine pathway of tryptophan degradation, have shown to be increased in the CSF and in postmortem prefrontal cortex (PFC) of schizophrenia patients. Also, chronic treatment with antipsychotics normalized the same levels in patients, supporting the hypothesis of the implication of kynurenine pathway in schizophrenia. We have previously developed a two-hit animal model, based on prenatal immune challenge (PIC) followed by juvenile restraint stress (RS), showing that PIC combined to RS induced a potentiated disruption of prepulse inhibition of acoustic startle (PPI) in mice. These findings led us to assess whether an inhibitor of indoleamine 2,3-dioxygenase (IDO), the enzyme that catalyzes the degradation of L-tryptophan to N-formylkynurenine, could prevent PPI deficits in this juvenile *in vivo* model of schizophrenia. Gestational mice were injected with polyIC (20 mg/kg; IP) or with saline at gestational day 12. Mice pups were then submitted or not to RS for 2 hours, for three consecutive days, from postnatal days 33 to 35. Three hours before each period

of RS, pups were treated with either 1-methyl-D-tryptophan (1-MT) (50 mg/kg; IP), an inhibitor of IDO, or vehicle. PPI was assessed 24 hours after the last period of RS. According to previous findings, we found that PIC combined with RS resulted in a significant decrease in PPI (-39%; $P < 0.001$, compared to control group). Importantly, the inhibition of IDO, through the administration of 1-MT, prevented the development of PPI deficit (+26%; $P < 0.05$, compared to vehicle) in mice submitted to both insults. Also, the combination of PIC and RS lead to increased cortical and striatal mRNA IDO levels (+61%; $P < 0.01$ and +41%; $P < 0.05$, respectively, as compared to saline without RS). The treatment with 1-MT reduced cortical and striatal mRNA IDO levels (-43%; $P < 0.01$ and -44%; $P < 0.01$, respectively, as compared to vehicle) in mice submitted to both insults. Also, as previously demonstrated, PIC followed by RS reduced GAD67 mRNA levels in the PFC (-29%; $P < 0.05$) and the striatum (-35%; $P < 0.05$) of polyIC-treated dams' offspring submitted to juvenile RS. Importantly, treatment with 1-MT prevented GABAergic abnormalities by increasing cortical and striatal GAD67 mRNA expression (+44%; $P < 0.05$ and +51%; $P < 0.05$, respectively, as compared with vehicle) in mice submitted to both insults. These results support the hypothesis that the kynurenine pathway plays an important role in the development of PPI deficits, a well-known behavior associated with schizophrenia, and in GABAergic abnormalities, recognized as a core feature of schizophrenia and found to be disturbed in our two-hits model.

Title: Muscarinic M_4 receptor regulation of psychosis-like behaviors induced by a dopamine D_1 receptor-selective agonist in mice

Authors: *A.-Y. CHEN, A. CHRISTOPOULOS, M. CANALS, D. T. MALONE
Drug Discovery Biol., Monash Inst. of Pharmaceut. Sci., Parkville, Australia

Abstract: Muscarinic M_4 receptors are found most abundantly in the striatum and are thought to modulate striatal dopaminergic activity. Specifically, in the striatum, M_4 receptors are co-localized with dopamine D_1 receptors on GABAergic output neurons and have been shown to functionally antagonize D_1 receptor-mediated activities in M_4 receptor knockout studies. However, the specific interaction between these two receptors has yet to be explored *in vivo* due to the lack of receptor subtype selectivity of M_4 receptor orthosteric agonists. In order to study the ability of M_4 receptors to regulate D_1 receptor-induced behaviors in C57BL/6J mice, a M_4 receptor positive allosteric modulator (LY2033298), an acetylcholinesterase inhibitor (donepezil), and a D_1 receptor-selective agonist (R(+)-6-Br-APB) were used. Allosteric modulators bind to the site of the receptor that is topographically distinct from that of the endogenous ligand and have the potential to possess increased receptor subtype selectivity. R(+)-6-Br-APB disrupted prepulse inhibition and increased locomotor activity in C57BL/6J mice, which are models of aspects of psychosis-like behavior that involve the striatum. LY2033298, when treated in combination with a sub-effective dose of donepezil, which increases endogenous acetylcholine levels, was able to significantly reverse R(+)-6-Br-APB-induced disruption of prepulse inhibition and increase of locomotor activity. These results demonstrate that selective M_4 receptor activation can indeed regulate D_1 receptor-mediated behaviors, as well as add to the increasing evidence of M_4 receptors as a novel target for the treatment of psychosis.

Title: The role of ERK and AKT kinases in the antipsychotic efficacy of Clozapine

Authors: *M. SCARSELLI[1], S. ARINGHIERI[2], S. KOLACHALAM[2], C. GERACE[2], V. VERDESCA[2], M. CAPANNOLO[3], R. MAGGIO[3]

Abstract: Clozapine is the most effective antipsychotic to date, thus considered the “gold standard” for the treatment of schizophrenia. Among atypical antipsychotic drugs, clozapine is the most efficacious in treating positive, negative, and cognitive symptoms in schizophrenia, particularly in patients resistant to other antipsychotics. However, its benefits are counterbalanced by relevant side effects such as the risk of severe hematological effects. The mechanism of action of Clozapine is still unclear, multifactorial and probably based on its affinities for different receptors and different targets. Relevant to this, the new concept of “biased agonism” has made drug actions even more complicated, whereas some ligands can behave as agonists or antagonists on the same receptor depending from the pathway examined. Indeed, for example, clozapine can act as an agonist or antagonist on 5HT2a serotonin receptor depending from the target taken in consideration. In our study, we decided to investigate the action of clozapine and other antipsychotics as agonists on kinases activity such as ERKs (Extracellular signal-regulated kinases) and AKT (Protein kinase B). These kinases have a prominent role in synaptogenesis, neurogenesis and neuronal survival, and they might be important for antipsychotic efficacy particular for negative and cognitive symptoms in schizophrenia. In our experiments, we found that clozapine has a unique profile in ERK and AKT activation. This evidence might be relevant to explain why Clozapine is the “gold standard” for the treatment of schizophrenia.

Title: Analysis of effects by repetitive Transcranial Magnetic Stimulation (rTMS) on neurosychatricand neurodegenerative disorder

Authors: ***T. IKEDA**[1], N. NUKINA[2]
[1]Kyoto Prefecture Univ. of Med., Kyoto, Japan; [2]Juntendo Univ., Tokyo, Japan

Abstract: rTMS is a noninvasive technique to induce electric current in the brain and is supposed to be beneficial for the treatment of patients with depression, schizophrenia and neurodegenerative disorders. We reported previously that rTMS modulates monoamine tranporter. However, the mechanisms underlying the effects of rTMS are still unclear. We analyzed the changes in mRNA expression in mouse brain that occurred after rTMS with an Affymetrix GeneChip. Following 20days of rTMS, many genes were differentially expressed in the mouse brain. Down-regulation of Period 2, 3 and hypocretin mRNA expression levels and a subsequent decrease in food and water intake were observed. HSP70 mRNA expression levels were up-regulated after transient and chronic rTMS. In N2A 150Q cells, an up-regulation of HSP70 mRNA and protein levels and subsequent cell-protective effects were observed after chronic rTMS. In addition, dopamine receptor 2 mRNA expression levels were down-regulated, and a subsequent decrease in the binding of [3H]raclopride was observed. A decrease in the Bmax and no change in the KD of [3H]raclopride binding was observed in the binding assay.These results indicated that the modulation of several genes may be involved in the therapeutic mechanisms of acute and chronic rTMS for patients with neuropsychiatric disorders.

Title: modified DRL task in ad libitum fed rats: Effects of Sigma 1 receptor blockade

Authors: *P. COTTONE[1], A. BLASIO[1], K. C. RICE[2], M. R. IYER[2], V. SABINO[1]
[1]Departments of Pharmacol. and Psychiatry, Boston Univ. Sch. of Med., Boston, MA; [2]NIH, Bethesda, MD

Abstract: BACKGROUND: Impulsivity can be defined as a predisposition toward rapid, unplanned reactions to internal or external stimuli, and a diminished regard to the negative

consequences of such reactions. Existing animal models of impulsivity frequently use food restriction/deprivation to increase subjects' motivation. Food restriction/deprivation represents an energy-homeostasis limitation, which may confound the interpretation of results and limit the applicability of these models. The first aim of this study was to validate face and convergent validities of a modified differential reinforcement of low rates (DRL) task, which assesses impulsive action in ad libitum fed rats. The second aim of this study was to evaluate the effects of Sigma receptor (SigR) ligands on the modified DRL task. METHODS: Ad libitum fed male Wistar rats were trained in a DRL-15 task during which a press on the active lever resulted in the delivery of a supersaccharin solution, consisting of 1.5% w/v glucose and 0.4% w/v saccharin. Delivery only occurred if at least 15 s had elapsed since the previous lever press. If rats made a premature lever press, the 15 s time period would reset; thus, rats were only reinforced if they withheld a response for longer than 15 s. Responses on the inactive lever were recorded. To pharmacologically validate the task, we tested the effects of the non-competitive NMDA receptor antagonist MK-801 and the partial dopamine receptor agonist Aripiprazole, which have been demonstrated to respectively increase and decrease impulsive action. We also tested the effects of the SigR ligands BD1063 and DTG on impulsive action using the modified DRL task. RESULTS: Rats quickly learned the DRL task, and impulsivity was a very stable and consistent trait. MK-801 dose-dependently increased premature responding in this modified DRL task. Conversely, Aripiprazole dose-dependently decreased premature responding. The Sig1R agonist BD1063 decreased premature responding only in high-impulsive rats. The SigR agonist DTG on the other hand had no effect on impulsive responding. No effects on inactive lever responding were observed following treatment with any of the drugs tested. CONCLUSIONS: Here we have validated a rodent task of impulsive action, which eliminates typical energy-homeostasis limitations and, therefore, opens new avenues in the study of impulsivity in preclinical feeding and obesity research. In addition, we show that Sig1R represents a novel pharmacological target for the modulation of impulsive action.

Title: Neuromodulation induced by focused ultrasound-induced blood-brain barrier opening combined with intravenous GABA agonists

Authors: *H.-Y. LAI[1,2], P.-C. CHU[3], Y.-T. CHANG[2], T.-Y. CHEN[1], H.-L. LIU[3], Y.-C. PEI[1,2]
[1]Dept. of Physical Med. and Rehabil., Chang Gung Mem. Hosp. At Linkou, Taoyuan County, Taiwan; [2]Sch. of Med., [3]Dept. of Electrical Engin., Chang Gung Univ., Taoyuan County, Taiwan

Abstract: Focused ultrasound (FUS) administered in the presence of microbubbles can temporarily disrupting the blood-brain barrier (BBB). FUS-induced BBB opening has been applied in the drug deliver for the treatment of brain tumor as it could elicit a dramatic increase of drug penetration at the target brain area. Furthermore, our previous studies demonstrated that FUS-induced BBB opening was accompanied with neuromodulation as evidenced by the changes in somatosensory evoked potentials (SSEPs) and blood-oxygen-level dependent (BOLD) signals. In theory, FUS-induced BBB opening combined the drug delivery could elicit facilitation, inhibition, or other effects. In the present study, we proposed that FUS-induced BBB opening combined with the intravenous administration of neuronal suppressant, such as GABA agonists, could induce suppression of local neuronal activities. To induce BBB disruption of SD rats, we presented 0.35 MPa FUS to the left primary somatosensory cortex forelimb region (S1FL,1 mm posterior and 4 mm lateral to the bregma) for 90 s with concurrent injection of intravenous microbubbles (SonoVue® SF6-coated, 2-5 μm mean diameter, 10 μl/kg). We also injected intravenously gabapentin (10 or 120 mg/kg) or muscimol (0.2 or 0.4 mg/kg) that were intended to be flow through the BBB disruption to induced neuromodulation. SSEPs elicited by electrical forepaw stimulation and recorded by epidural electrodes implanted on the scalp were evaluated before and after FUS (every 10 min in the first hour, and 1-day post-FUS). Compare to the control group, both the 0.2 and 0.4 mg/kg muscimol group showed significant suppression of SSEP amplitude (time window 10-20 ms after stimulus onset) in the first hour ($p<0.05$), and SSEPs recovered at 1-day follow-up. The effect was more robust in the 0.4 mg/kg muscimol group. Similar to the results for SSEP amplitude, the FUS prolonged SSEP latency in the 0.2 and 0.4 mg/kg muscimol groups. On the contrary, both gabapentin groups showed no changes in SSEP amplitude or latency after FUS. These results indicate that muscimol of 0.2 mg/kg can induce measurable neuromodulation in the local brain. This present study proposed a novel non-invasive, reversible and local neuromodulation method that is suitable for neurophysiological experiments and clinical applications.

Labs., west Point, PA; [6]Merck Res. Labs., west point, PA; [7]Merck Resarch Labs., West Point, PA; [8]Merck research Labs., West point, PA

Abstract: One novel approach to improving cognitive function and reducing negative symptoms of schizophrenic patients is enhancing NMDA-R function by acting on the glycine modulatory site (GMS). The inhibition of the alanine serine cysteine transporter-1 (Asc-1) was proposed as a novel therapeutic strategy targeting this mechanism. The rationale is that inhibition of Asc-1 transporter potentiates NMDA-R activity via an increase in synaptic levels of the GMS ligand, D-serine, by blocking its re-uptake. However, although this target is mechanistically attractive, it also presents some target validation challenges including the lack of tool compounds and viable adult knockout mice. We therefore used siRNA and inducible knock-down (iKD) mice to evaluate the effects of Asc-1 knock-down on NMDA-R function both *in vitro* and *in vivo*. In rat neuronal cultures, siRNA-induced Asc-1 knock-down resulted in a decrease in D-serine uptake that was associated with an enhanced NMDA-R activity measured by the phosphorylation levels of NMDA-R subunit 1 (pNR1). Intracerebral injection of Asc-1 siRNA produced an increase in basal synaptic levels of D-serine measured by microdialaysis that was also associated with elevated pNR1 levels. Asc-1 iKD mice showed a reversal of the hyperlocomotion induced by the NMDA partial agonist (L-687,414) and increased levels of pNR1 in both the cortex and hippocampus. Finally, the electrophysiological recording in hippocampal slices showed larger

NMDA-mediated field response in slices from Asc-1 iKD mice compared to wild type mice, suggesting an enhanced NMDA-R synaptic transmission associated with Asc-1 knock-down. Taken together, these results provide evidence for the role of Asc-1 in enhancing NMDA-R function and neurotransmission, and validate Asc-1 inhibition as a potential novel strategy for the treatment of schizophrenia.

Title: M4 muscarinic acetylcholine receptor-specific modulation of immediate early gene expression in mouse brain

Authors: ***X. WANG**, M. PEARSON, R. GENTZEL, J. USLANER, F. THOMSON
Merck Res. Labs., West Point, PA

Abstract: Deficits in the muscarinic cholinergic system have been implicated in the pathophysiology of many neurologic and psychiatric disorders, including Alzheimer's disease (AD) and schizophrenia. Specifically, evidence suggests that activating M4 muscarinic acetylcholine receptor (mAChR) may alleviate psychosis and behavioral disturbances associated with these diseases. To investigate the brain regions activated by selective potentiation of M4 mAChR, we measured immediate early gene (IEG) expression, including arc, c-fos and zif268, in the brain of wildtype and M4 knockout mice. We examined several M4 potentiating compounds, such as M1/M4 preferred mAChR agonist (Xanomeline), an M4 specific agonist

(Sumitomo) and the M4 positive allosteric modulator (PAM) (VU0152100). The expression levels of IEGs were determined by qPCR and *in situ* hybridization in various brain regions, including striatum, cortex and hippocampus. Consistent with the hypothesis that activating M4 receptors in the striatum attenuates dopaminergic and glutamatergic neurotransmission, IEG expression was reduced in wildtype mice administered the M4 activators, but not in M4 knockout mice. The magnitude of IEG reduction was more robust in striatum as compared to cortex and hippocampus likely due to the higher expression levels of M4 receptors in striatal neurons. Thus, these data demonstrate that M4 mAChR plays a pivotal role in regulating neuronal activity in multiple brain regions.

Biol. & Drug Discovery, Div. of Chem. Biol. & Med., Eshelman Sch. of Pharmacy, Univ. of North Carolina, Chapel Hill, NC

Abstract: Schizophrenia is a devastating neuropsychiatric disorder characterized by positive, negative, and cognitive symptoms. Currently available FDA-approved antipsychotic drugs are effective in treating positive symptoms, but have limited efficacy on negative or cognitive

symptoms. The current drugs have a common feature in that they all target primarily the dopamine D2 receptor (D2R) for action. Over the past 10 years, it has become evident that D2Rs can also signal through a β-arrestin (βarr*)* mediated-pathway independently from the Gi pathway. There is some evidence that stimulation of D2Rs can result in the recruitment of βarr2 with changes in Akt and GSK-3. Interestingly, alterations in these two signaling molecules have been reported in brains from schizophrenic patients. A recent study has shown that many antipsychotic drugs can perturb both the Gi and βarr pathways. We have developed ligands that are devoid of activity at D2R-mediated Gi protein signaling, but are simultaneously high affinity partial agonists for D2R/βarr2 interactions. The purpose of these studies was to test the effectiveness on one of these ligands, UNC9975, on schizophrenia-like behaviors in mice. UNC9975 was observed to depress the hyperlocomotion of NR1-knockdown (NR1-KD) and dopamine transporter knockout (KO) mice in the open field. The compound rescued prepulse inhibition (PPI) in NR1-KD mice. It also rescued phencyclidine-disrupted PPI in βarr2 wild-type mice at a lower dose than in βarr2-KO mice, supporting the idea that UNC9975 acts primarily through the βarr pathway. In a test for social behavior, UNC9975 increased social affiliation in NR1-KD mice and it reduced immobility of the vesicular monoamine 2 heterozygotes in the tail suspension test. Moreover, it decreased conditioned avoidance responses without impairing associative memory from fear conditioning, indicating its effective antipsychotic property. UNC9975 was found also to produce much less catalepsy than haloperidol in the horizontal bar test. Together these findings suggest that the new βarr-biased compound is efficacious in reducing positive- and negative-like symptoms of schizophrenia without having untoward extrapyramidal side-effects in mice.

Title: Nitric oxide signaling system as an augmentative therapeutic target in schizophrenia: experience from a trial with l-lysine

Authors: *M. FAROKHNIA[1], P. MAZAHERI[1], H. YEKEHTAZ[1], N. BEHBAHANI-NEJAD[2], S. AKHONDZADEH[1]
[1]Tehran Univ. of Med. Schools, Tehran, Iran, Islamic Republic of; [2]Dept. of Mol. and Integrative Physiol., Univ. of Michigan, Ann Arbor, MI

Abstract: Background: Many schizophrenic patients do not respond optimally to the antipsychotics monotherapy and augmentation with novel agents is a promising strategy to address this issue. L-lysine reduces nitric oxide (NO) synthesis in the brain as it competes with l-arginine for the common cationic amino acid transporter. Considering the evidenced contribution of NO signaling system in the pathophysiology of schizophrenia, we aimed to evaluate the efficacy and safety of l-lysine as an add-on to risperidone in patients suffering from chronic schizophrenia. Methods: In a double-blind, placebo-controlled, parallel-group, randomized clinical trial, 72 patients with chronic schizophrenia (DSM-IV criteria, disease duration ≥ 2 years) and a total score of ≥ 60 on the positive and negative syndrome scale (PANSS) were randomized to receive risperidone (up to 6 mg/day) plus either l-lysine capsules (6 mg/day) or placebo for 8 weeks. The efficacy assessment measure of this study was PANSS and its different subscales by which patients were evaluated every other week after the baseline visit (weeks 0, 2, 4, 6, and 8). Probable adverse events were closely monitored as well. Results: By the study endpoint, l-lysine-treated patients experienced greater improvement than the placebo group as shown by significant effect of time × treatment interaction for the PANSS total [$F(1.96, 137.21)=12.16$, $P<0.001$], negative [$F(2.01, 140.73)=14.46$, $P<0.001$], and general psychopathology [$F(1.86, 130.39)=9.20$, $P<0.001$] scores, but not for the positive symptoms [$F(2.56, 179.27)=0.56$, $P=0.61$]. No significant difference was detected between two groups in the frequency of adverse events. Conclusions: Inhibiting the NO overproduction seems to be an effective way to attenuate some of the schizophrenic symptoms. In the present study, l-lysine was an efficacious and tolerable add-on therapy for improving negative and general psychopathology symptoms in chronic schizophrenia. Further well-designed clinical trials with larger sample sizes and longer follow-up durations are warranted.

Title: Differential effects of antipsychotics on serotonin transporter, 5-HT2A and 5-HT2C receptor binding density in the brain of male and female juvenile rats

Authors: *C. DENG, J. LIAN
Sch. of Medicine, Illawarra Hlth. and Med. Res. Inst., Univ. of Wollongong, Wollongong, Australia

Abstract: Introduction: Antipsychotic drugs (APDs) were developed to treat schizophrenia in adults, however, they have been widely and increasingly prescribed (mostly "off label") for short-term control of various mental disorders in children and adolescents, without understanding the underlying mechanisms. Therefore this study investigated the effects of aripiprazole, olanzapine and risperidone (the three most widely-used APDs in children and adolescents) on the binding sites of serotonergic 5-HT2A, 5-HT2C receptors (5-HT2AR, 5-HT2CR) and 5-HT transporters (5-HTT) in various brain regions of juvenile rats. Methods: Male and female Sprague Dawley rats were treated orally with aripiprazole (1mg/kg, t.i.d.), olanzapine (1mg/kg, t.i.d.), risperidone (0.3mg/kg, t.i.d.) or vehicle (control; n = 6/group) starting from postnatal day (PD) 23 (±1 day) for 20 days (a period corresponding to the childhood-adolescent period in humans). Quantitative autoradiography was applied to detect the density of [^{3}H]ketanserin, [^{3}H]mesulergine and [^{3}H]paroxetine binding sites to 5-HT2AR, 5-HT2CR and 5-HTT. Results: Olanzapine significantly decreased 5-HT2AR binding in the nucleus accumbens (NAc), and 5-HT2AR and 5-HT2CR binding in the prefrontal cortex (PFC) and cingulate cortex (Cg) of both male and female rats. There were also some gender differences; male rats have higher 5-HT2CR binding density in the NAc than female rats. Olanzapine decreased 5-HT2CR binding in the NAc of only male rats. Risperidone decreased 5-HT2AR/5-HT2CR binding in the PFC of female rats. However, aripiprazole had no effects on 5-HT2AR and 5-HT2CR binding compared with controls. None of the three APDs had any effect on 5-HTT binding. Conclusion: These results suggested that early treatment with these antipsychotics had different effects on the 5-HT2AR and 5-HT2CR binding, and some of these changes were gender-dependent. It illustrates the importance of investigating how individual antipsychotic drugs act in the developing brain of both genders.

Title: MT-3014, a novel PDE10A inhibitor I. pharmacological characterization of MT-3014

Authors: M. TAKAKUWA, Y. WATANABE, M. MURATA, J. ANABUKI, M. KATSU, K. TAKASHINA, *H. YASUMATSU
Pharmacol Lab., Mitsubishi Tanabe Pharma Corp, Kanagawa, Japan

Abstract: Phosphodiesterase 10A (PDE10A), a dual hydrolase of cAMP and cGMP, is highly expressed in striatal medium spiny neurons. Inhibition of PDE10A is expected to be a novel therapeutic approach for schizophrenia. In this study, we evaluated the pharmacological profile of a novel PDE10A inhibitor MT-3014. First, *in vitro* profile of MT-3014 was evaluated. MT-3014 inhibited PDE10A with an IC50 value of 0.37 nmol/L. Its selectivity against other PDE families or other 52 targets (enzymes, ion channels, receptors and transporters) was more than 300-fold. Second, MT-3014 was evaluated in rat models to assess antipsychotic potential. MT-3014 inhibited the MK-801-induced hyperactivity and suppressed the conditioned avoidance responses. The ED50 value in each test was less than 1 mg/kg, p.o., which was equivalent to that of risperidone. Third, MT-3014 was evaluated in rat models of cognitive impairment. MT-3014 attenuated the MK-801-induced prepulse inhibition (PPI) deficits and reversed MK-801-induced novel object recognition (NOR) deficits at the same dose ranges as those which demonstrated the antipsychotic potential above. On the other hand, risperidone required much higher dose to attenuate MK-801-induced PPI deficits and failed to reverse MK-801-induced NOR deficits. Finally, side effects-liability of MT-3014 was evaluated. Although MT-3014 induced catalepsy, its magnitude was less than that of risperidone. MT-3014 did not increase plasma prolactin concentration, though risperidone increased it. Also, repeated administration of MT-3014 (once daily for 21days) did not increase the body weight compared to the vehicle-treated group. The above results indicate MT-3014 possesses not only antipsychotic activity but also procognitive potential. Additionally, MT-3014 has less potential to exhibit side-effects seen with present antipsychotics. Therefore, MT-3014 could be a new generation of therapeutic agent for schizophrenia.

Title: MT-3014, a novel PDE10A inhibitor II.The relationship between the inhibitory effect of MT-3014 on conditioned avoidance response and the brain PDE10A occupancy in rats

Authors: Y. WATANABE[1], T. SAIJO[2], K. KOJIMA[2], S. SATO[3], M. TAKAKUWA[1], K. TAKASHINA[1], *K. TESHIMA[4,1], H. YASUMATSU[1]

Abstract: MT-3014, a potent and selective PDE10A inhibitor, suppresses the rat conditioned avoidance response (CAR) which is used as a test with high predictive validity for antipsychotic activity. In this study, we evaluated the relationship between the inhibitory effect of MT-3014 on CAR and the brain PDE10A occupancy in rats. The inhibitory effect on CAR peaked at 1 h after oral administration (ED50=0.52 mg/kg) and was decreased in a time-dependent manner. The plasma concentration correlated with its inhibitory effect on CAR and was 50.07 ± 11.56 ng/mL (mean±S.E.M, n=3) at the dose of 0.5 mg/kg. To evaluate the brain PDE10A occupancy of MT-3014, the rat PET imaging study was conducted using a PDE10A PET tracer, ^{11}C-IMA107. Specific binding of ^{11}C-IMA107 was localized to the striatum and it was dose-dependently decreased by pre-treatment of MT-3014. To determine the relationship between the PDE10A occupancy of MT-3014 and its plasma concentration, blood samples were collected during the PET scan. The plasma concentration required to achieve a 50% PDE10A occupancy (EC50) was estimated to be 58.00 ± 5.80 ng/mL (mean±S.E.M., n=16 from 8 rats) using Emax model. Above results indicate that the ED50 in CAR and the EC50 in the PET imaging are achieved almost same plasma concentration.

Title: Modulation of dopamine release in the nucleus accumbens core by lithium treatment

Authors: *A. CAN[1], R. CACHOPE[4], D. O. FROST[2], J. F. CHEER[3], T. D. GOULD[1]
[1]Psychiatry, [2]Pharmacol., [3]Anat. and Neurobio., Univ. of Maryland, Sch. of Med., Baltimore, MD; [4]CHDI Fndn., Los Angeles, CA

Abstract: Lithium (Li+) is a prototypical mood stabilizer with efficacy in the treatment of bipolar disorder and reduction of suicidal behavior. Chronic Li+ treatment lowers extracellular dopamine (DA) concentrations in NAc, as assessed by microdialysis. However, it is unclear whether this finding reflects alterations of basal extracellular DA levels or changes in the magnitude or duration of phasic DA transients. To address this issue, we used fast-scanning cyclic voltammetry (FSCV) to analyze changes in extracellular DA concentrations in the NAc core evoked by electrical stimulation of the ventral tegmental area (VTA) with sub-second temporal resolution. We tested the effects of chronic and acute Li+ treatments on DA release in mice. In the chronic Li+ treatment experiment, mice were fed LiCl containing chow or control chow for at least three weeks prior to FSCV. For acute treatment experiment, 300 mg/kg LiCl or vehicle was injected i.p. five hours prior to FSCV recordings. A bipolar stimulating electrode was placed in the VTA and a carbon fiber electrode was placed in the NAc core. DA transients were evoked by trains of increasing amplitude, 60 rectangular, biphasic pulses that were applied to the VTA. In depletion experiments, control or chronically lithium treated mice were given repeated stimulus trains of either 20Hz-20 pulses or 60 Hz-60 pulses. Mice treated chronically with Li+ manifested significantly decreased peak amplitudes of stimulation-evoked DA transients in the NAc core. Chronic Li+ treatment did not significantly alter the rise time or decay time of the DA transients. Repeated stimulation experiments revealed that while DA release in the lithium group was attenuated early on, but this difference disappeared in further stimulations and both groups had similar depletion curves in the 60Hz-60 pulses run. Acute Li+ treatment did not significantly alter the peak amplitude or decay constant of stimulus-evoked DA transients. These results demonstrate that chronic but not acute Li+ treatment attenuates phasic DA release in the NAc core evoked by electrical stimulation of the VTA without altering the kinetics of DA release or reuptake. We also showed that this difference was not due to the availability of DA. DAergic neurotransmission in the NAc has been associated with both mania-like and depression-like behaviors in animal models. The amplitude and timing of DA transients in the NAc are critical in reward prediction, motivational and cognitive control of behavior, and impulsivity. Because impulsivity is strongly associated with suicide, our findings suggest that reduced DA release in the NAc may be part of the mechanism of lithium's anti-suicidal effects.

Title: Ketamine acts on 5-HT1B receptors in the nucleus accumbens and ventral pallidum: a possible role for its antidepressant action

Authors: H. YAMANAKA[1], C. YOKOYAMA[1], H. MIZUMA[1], H. DOI[1], S. J. FINNEMA[3], C. HALLDIN[3], *H. ONOE[2]
[1]Bio-Function Imaging Team, [2]Functional Probe Rese Lab., RIKEN CLST, Kobe, Japan; [3]Karolinska Inst., Stockholm, Sweden

Abstract: Ketamine is a unique anesthetic reagent known to produce various psychotic symptoms, such as hallucinations and dissociative state. Interestingly, ketamine has been reported to elicit fast-acting and long-lasting antidepressant effect in patients with major depression. Since existing antidepressants take several weeks to achieve their full therapeutic effect, ketamine seems to be an attractive antidepressant with some unique actions. Although recent studies provide insight into the molecular mechanisms of the effects of ketamine, its antidepressant mechanism has not been fully elucidated. To understand the involvement of the brain serotonergic system in the actions of ketamine, we performed a positron emission tomography (PET) study on non-human primates. Four rhesus monkeys underwent PET studies with two serotonin (5-HT)-related PET radioligands, [^{11}C]AZ10419369 and [^{11}C]DASB, which are highly selective for the 5-HT1B receptor and serotonin transporter (SERT), respectively. Preclinical evidence suggests that the 5-HT1B receptor plays an important role in the pathophysiology of depression, and SERT is a target protein for some existing antidepressants, such as 5-HT selective reuptake inhibitors and tricyclic antidepressants. Voxel-based analysis with the standardized brain MRI revealed that ketamine administration significantly increased 5-HT1B receptor binding in two brain regions: the nucleus accumbens and ventral pallidum, both of which are key neural substrates in motivation and reward systems, while it significantly reduced SERT binding in these brain regions. Pretreatment with NBQX, a potent antagonist of

the glutamate AMPA receptor, blocked the action of ketamine on 5-HT1B receptor but not SERT binding. This indicates the involvement of AMPA receptor activation in ketamine-induced alterations of 5-HT1B receptor binding. Because NBQX is known to block the antidepressant effect of ketamine in rodents, alterations in the serotonergic neurotransmission, particularly upregulation of postsynaptic 5-HT1B receptors in the nucleus accumbens and ventral pallidum may be critically involved in the antidepressant action of ketamine. A recent clinical PET study has also shown that 5-HT1B receptor binding within the identical brain regions is significantly low in patients with major depressive disorder compared with that in healthy subjects. Therefore, PET imaging studies for 5-HT1B receptor binding might be useful for a diagnosis of major depression as well as for the development of novel antidepressants.

Title: Deconstructing auditory verbal hallucinations: a phenomenological approach

Authors: *C. ROSEN[1], K. A. CHASE[2], H. GIN[2], R. P. SHARMA[2]
[2]Psychiatry, [1]Univ. of Illinois At Chicago, Chicago, IL

Abstract: Background: Auditory Verbal Hallucinations (AVHs) are an important transdiagnostic phenomenon occurring in schizophrenia, bipolar disorder, major depression and existing along a continuum within the general population (van Os, 2000; Badcock and Hugdahl, 2014). AVHs are sensory experiences that occur in the absence of external stimuli with a sufficient similarity to the real percept that they are attributed to an external source, outside of the individuals control. AVHs are frightening experiences, leading to high levels of distress, social isolation, and functional disability (Hayward, 2013). The heterogeneity of AVHs is substantial, and may be experienced as either ego-syntonic or ego-dystonic, and can involve one or multiple voices with distinct personalities that give commands, insult or affirm the patient (McCarthy-Jones, 2013). Lastly, AVHs have similar characteristics and attributes of real individuals, thus are experienced

as an integrated individual coherent relationship (Paulik, 2012). Methods: The Maastricht Interview was administered to participants who endorsed current auditory hallucinations (Romme & Escher, 2000). The interview consists of a comprehensive evaluation of AVH regarding the following aspects of the experience, characteristics, history, triggers, content, impact, relationship with AVH, and coping strategies. The phenomenological interview was recorded using reflection, clarification, requests for examples and descriptions, listening techniques to establish the context and construction of the experience, and reflection on meaning. Open coding of the qualitative interview was followed by selective identification of emergent themes. Results: The phenomenology of AVHs was examined in subjects who have experienced AVHs for more than 20 years. We identified three primary categories and themes in our analysis specific to participants': 1.) Conceptual understanding of AVHs, 2.) Characteristics of AVHs, and 3.) Ability to influence AVHs. Discussion: AVHs are a complex and fascinating phenomenon that patients may attribute to a Higher Power, spirits, ghosts, guardian angels, and, more recently, messages generated by radio or computers. AVHs are extremely heterogeneous in terms of frequency, duration, location, content, personification, acoustic quality, linguistic complexity, and ongoing commentary or voices conversing. The phenomenological approach in deconstructing AVH elucidates common themes, thereby decreasing the overall heterogeneity for ultimate uses in better treatment outcomes and constructs of possible neurobiological mechanisms of action.

Title: Transgenerational effects of female adolescent morphine exposure on offspring morphine self-administration, reinstatement, and gene expression

Authors: *F. M. VASSOLER, E. M. BYRNES
Dept. of Biomed. Sci., Tufts Univ. Cummings Sch. of Vet. Med., North Grafton, MA

Abstract: The prescription of opiates has escalated dramatically over the past decade, resulting in increased access and misuse of these highly addictive medications. The use in adolescent populations, and in particular adolescent female populations, is particularly concerning because opioids play a significant role in neuroendocrine function and development. Thus, exposure to opioids during this critical developmental period could have significant consequences for the female, as well as her future offspring. Here we utilize a rat model established in the laboratory to examine the influence of adolescent morphine exposure, followed by prolonged abstinence on the behavior of the progeny. Female Sprague dawley rats were administered daily subcutaneous (s.c.) injections of morphine sulphate for 10 days using an increasing dosing regimen and beginning at postnatal day 30 (P30). The dose started at 5 mg/kg and increased every other day by 5 mg/kg. Therefore, on P30 and P31 the animals received 5 mg/kg, on P32 and P33 10 mg/kg and so forth until P40 when they received 25 mg/kg. Age-matched control animals received saline injections. A minimum of 20 days later (on or after P60) the females were mated with naïve males. Morphine self-administration, extinction and reinstatement in the offspring were examined during adulthood (P60). The acquisition of morphine self-administration was examined at two doses: 0.25 or 0.75 mg/kg/infusion. At the low dose, a main effect of maternal treatment was observed demonstrating that MorF1 animals self-administered significantly more morphine than the SalF1 animals. This effect appeared to be driven by the MorF1 males, who took significantly more morphine than the SalF1 males ($p<0.05$). In contrast, at the higher dose, there was no difference in the acquisition between the male animals but the MorF1 females took significantly less morphine than the SalF1 females ($p<0.05$). Following extinction, reinstatement was induced with a 1 mg/kg intraperitoneal (i.p.) priming injection. We found significant attenuation of reinstatement in both male and female MorF1 animals (following high dose self-administration). This suggests that female adolescent exposure to opioids, even following prolonged abstinence, affects the offspring's response to morphine. Experiments examining the transcriptome of the nucleus accumbens at baseline and in response to a morphine injection using RNA deep sequencing are ongoing.

Title: Augmentation of heroin seeking following chronic food restriction in the rat: A role for mesolimbic and nigrostriatal dopamine?

Authors: *T. M. D'CUNHA, E. DAOUD, A. BISHOP, L. HAMEL, F. SEDKI, U. SHALEV
Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: In human drug addicts chronic food restriction or dieting augments drug taking and increases the risk for relapse during abstinence. We recently reported that chronic food restriction during a period of prolonged withdrawal augments heroin seeking in rats with a history of heroin self-administration. Previous research on chronically food restricted (FDR) rats has found alterations in the mesolimbic dopamine (DA) system, a critical component of the reward system. Moreover, it has been suggested that the nigrostriatal DA system is also a critical component in reward and addiction. Here we assessed levels of extracellular DA in various terminal regions of the mesolimbic and nigrostriatal DA pathways, including the nucleus accumbens (NAc) shell and core, the basolateral amygdala (BLA), and the dorsolateral striatum (DLS). Rats were trained to self-administer heroin for 10 days. Next, rats were moved to the animal colony for 14 days of withdrawal. During the withdrawal period rats were given unrestricted access to food or subjected to a mild chronic food restriction that decreased their body weight to approximately 90% of their original body weight. On the 14th day of food restriction rats were returned to the operant chambers for a drug seeking test conducted under extinction conditions. Extracellular DA was assessed using *in vivo* microdialysis and HPLC during baseline conditions in the animal facility and then during the 3 hour drug seeking test. Food restriction significantly augmented heroin seeking compared to sated control rats. In the NAc shell there was a significant increase in DA only in the FDR group upon re-exposure to the drug context and throughout the drug seeking test. Conversely, DA in the NAc core increased during re-exposure to the drug context but returned to baseline during the drug seeking test regardless of food condition. Similarly, in the DLS DA increased at initiation of the drug seeking test in both groups. No changes in DA were found in the BLA during the drug seeking test, or between FDR and sated rats. Taken together, these results suggest that food restriction results in changes in DA release in only the NAc shell during the augmentation of heroin seeking. Future studies will investigate if DA antagonists can block the augmentation of heroin seeking induced by chronic food restriction.

Title: A classically conditioned opioid cue acquires greater control over motivated behavior and induces greater Fos protein expression in rats prone to attribute incentive salience to a food cue

Authors: *L. M. YAGER[1], K. K. PITCHERS[1], S. B. FLAGEL[2,3], T. E. ROBINSON[1]
[1]Psychology, [2]Mol. and Behavioral Neurosci. Inst., [3]Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: Cues associated with natural or drug rewards can acquire such powerful motivational control over behavior that individuals sometimes have difficulty resisting them. There is, however, considerable individual variation in the ability of reward cues to gain such control over behavior, which is due, at least in part, to intrinsic individual variation in the extent to which reward cues are attributed with incentive salience. For example, if a spatially discrete stimulus (the conditioned stimulus, CS) is repeatedly paired with delivery of a food reward (the unconditioned stimulus, US), in some rats (sign-trackers, STs), the food cue itself becomes attractive, eliciting approach and engagement with it, and desired, in that rats will work to obtain it. In other rats (goal-trackers, GTs) the food cue itself is less attractive, presentation of the CS instead elicits approach to the location where food will be delivered, and GTs do not work as avidly to gain access to the cue. Importantly, the propensity to attribute incentive salience to a food cue predicts the extent to which a discrete cocaine cue acquires motivational properties. Although we have shown that a cocaine cue acquires greater control over motivated behavior in STs relative to GTs, we do not know if this generalizes to other drug classes. Thus, the first aim of the experiments reported here was to determine whether the propensity of an individual to attribute incentive salience to a food cue predicts the extent to which a cue associated with administration of an opioid drug (remifentanil) acquires incentive motivational properties. The second aim was to begin to explore whether the neurobiological correlates underlying individual variation in the attribution of incentive salience to food and opioid cues are similar. To do this we measured Fos protein expression elicited by presentation of either a food or opioid cue in STs and GTs. Consistent with previous studies using cocaine, we found that relative to GTs, STs

were more attracted to a classically conditioned opioid cue (they approached it) and they found the opioid cue more desired (they worked for it). We also found that in order for either a food or an opioid cue to engage cortico-striatal-thalamic circuitry it must be imbued with incentive salience, as indicated by the fact that such cues induced Fos protein expression preferentially in STs.

Title: Sex, drugs, and food: The role of sex hormones in chronic food restricted-induced augmentation of heroin seeking in female rats under withdrawal

Authors: *F. SEDKI, J. GREGORY GARDNER, A. LUMINARE, I. AKHTAR, T. D'CUNHA, J. DUCHESNEAU
CSBN, Concordia Univ., Montreal, QC, Canada

Abstract: Food restriction enhances drug seeking following prolonged withdrawal from drug taking. Recently, we reported augmented heroin seeking in chronically food restricted male rats under withdrawal, an effect that has yet to be examined in female rats. Women and female rats possess an increased vulnerability to drugs of abuse, which may be mediated by fluctuations in ovarian hormones. As such, it is hypothesized that progesterone and estradiol play opposing roles in drug seeking. Estradiol may enhance drug seeking, while progesterone may attenuate drug seeking. Previous studies have predominantly investigated the effects sex hormones on cocaine-trained rats, and there are relatively few reports on the effects in heroin-trained rats. Thus, we investigated the role of estradiol and progesterone in the augmentation of heroin seeking in chronically food restricted female rats, under withdrawal. Methods: Female Long-Evans rats were trained to self-administer heroin for 10-12 days in operant conditioning chambers. Next, rats were moved to the animal colony and maintained on free access to food (sated group) or subjected to 14 days of mild chronic food restriction (FDR group), which sustained their body weight at 90% of their baseline body weight. On day 14, rats underwent a 3 h heroin seeking test under extinction conditions, in the operant conditioning chambers. Exp. 1:

Rats underwent bilateral ovariectomy (OVX) or sham surgery, as well as estradiol (low maintenance dose of approximately 35 pg/ml E2 in plasma) or cholesterol (CH) silastic capsule implantation (s.c.) prior to the food restriction phase. Exp. 2: Rats underwent bilateral OVX and were repeatedly administered with a high dose of E2 (0.5 mg/kg; s.c.) for 8 days prior to testing. Exp. 3: Progesterone injections (0.0, 2.0 mg/kg) were administered 24 h and 2 h prior to testing. Results: In all experiments, food restriction resulted in augmented heroin seeking, compared to the sated controls. Specifically, in Exp. 1 food restriction resulted in increased heroin seeking in the OVX-CH and sham-CH groups, compared to their respective sated controls. In contrast, E2 replacement attenuated the food restriction effect. Preliminary data from Exp. 2 suggests a similar pattern as in Exp. 1. Injections of progesterone in Exp. 3 had no effect on heroin seeking in both the sated and FDR groups. Conclusions: Overall, the effect of food restriction on heroin seeking in female rats under withdrawal is as robust as in males. Interestingly, low-dose E2 replacement attenuated the food restriction effect in the OVX rats, possibly due to its anorexic properties. However, progesterone does not modulate heroin seeking in female rats.

Title: Role of projections from ventral subiculum to nucleus accumbens shell in context-induced reinstatement of heroin seeking

Authors: *J. M. BOSSERT[1], R. M. ST. LAURENT[1], N. J. MARCHANT[1,3], H. WANG[2], M. MORALES[2], Y. SHAHAM[1]

Abstract: Background: In humans, exposure to contexts previously associated with heroin use can provoke relapse. In rats, exposure to heroin-paired contexts after extinction of drug-

reinforced responding in different contexts reinstates heroin seeking. We previously demonstrated a causal role for projections from ventral medial prefrontal cortex to accumbens shell in this reinstatement. Here, we examine the contribution of glutamate projections from ventral subiculum to accumbens shell. We combined Fos with the retrograde tracer Fluoro-Gold to assess activation of this pathway during context-induced reinstatement. We then employed an anatomical disconnection procedure to examine the interaction between glutamatergic projections from ventral subiculum to accumbens shell and local dopamine D1 postsynaptic receptors in this reinstatement. Methods: We trained rats to self-administer heroin for 12 days; drug infusions were paired with a discrete tone-light cue. Lever pressing was subsequently extinguished in a non-drug-associated context in the presence of the discrete cue. We then tested the rats in the heroin- or extinction-associated contexts under extinction conditions. Results: Exposure to the heroin but not extinction context reinstated lever pressing. Context-induced reinstatement was associated with increased Fos expression in ventral subiculum neurons, including those projecting to accumbens shell. We also found that inactivation of ventral subiculum in one hemisphere combined with dopamine D1 receptor blockade into contralateral or ipsilateral accumbens shell decreased this reinstatement. Conclusions: Results suggest that the glutamatergic projections from ventral subiculum to accumbens shell are part of a circuit in which activation provokes context-induced relapse to heroin seeking.

Abstract: Addiction to opiates is a major public health problem and non-medical use of prescription opiates has risen substantially. Although chronic use of opiates can induce physical and psychological dependence, molecular mechanisms that contribute to the opioid dependence are not well understood. Using chronic intravenous morphine self-administration (MSA), brain imaging (18FDG-PET and CT) and RNA sequencing, we investigated the effects of withdrawal from chronic MSA on *in vivo* regional glucose utilization and transcriptome expression levels in rats. Male Sprague Dawley rats self-administered morphine (0.5 mg/kg/infusion) or saline for 3 weeks (4 hours/day, 5 days per week), and glucose uptake and transcriptome expression levels were measured during spontaneous withdrawal. The animals reliably self-administered intravenous morphine with average daily intake of 7 mg/kg for three weeks. Glucose uptake was decreased in the brainstem in 2-day withdrawal from MSA. Morphine challenge dramatically increased glucose uptake in multiple brain regions including the nucleus accumbens, hypothalamus, amygdala and brainstem. The animals also exhibited behavioral sensitization to morphine challenge. RNA sequencing analysis with the nucleus accumbens tissue (1-week withdrawal) identified a substantial number of genes (FDR-adjusted q-value < 0.05) that are associated with biological functions such as synapse, neuron development, ion channels and neurotransmitter receptors. Spontaneous withdrawal from chronic MSA induced robust changes in *in vivo* glucose utilization and gene expression in the brain. By combining a clinically relevant animal model, a non-invasive brain imaging and a high-throughput transcriptome sequencing, we demonstrated the utility of investigating the biological basis of opioid addiction.

Title: Environmental enrichment protects against self-administration of the short-acting opioid remifentanil

Authors: *R. S. HOFFORD, M. T. BARDO
Dept. of Psychology, Univ. of Kentucky, Lexington, KY

Abstract: Rearing environment affects many behavioral outcomes, including self-administration of drugs of abuse. In particular, several studies have shown that rats raised in an isolated condition (IC) self-administer more amphetamine, methylphenidate, and cocaine than rats raised in an enriched condition (EC) at low unit doses. The data on the effects of rearing environment on opioid self-administration are less clear. This study examined the acquisition of self-administration of the short-acting opioid remifentanil (1 μg/kg) in IC, EC, and pair-housed controls (social condition, SC). Additionally, after acquisition, these rats were allowed to administer several different doses of remifentanil (0, 0.1, 0.3, 1, 3, and 10 μg/kg) in semi-random order to generate a dose-response curve for each group. Given IC rats' propensity to self-administer more stimulants at low unit doses, it was hypothesized that IC rats would acquire self-administration more rapidly and would take more remifentanil at low doses compared to EC rats. As hypothesized, IC rats acquired self-administration more quickly than EC and SC rats. In addition, at stable responding, IC rats self-administered more remifentanil than EC rats; the increased responding was evident at both low doses and higher doses of remifentanil. IC and SC rats did not differ in their intake of remifentanil during the maintenance and dose-response phases of the experiment. These findings support previous literature suggesting that environmental enrichment can protect against self-administration of drugs of abuse. However, the exact mechanism underlying this protection may be different for opioids and stimulants.

Title: Sex differences in conditioned morphine reward

Authors: D. G. WEIDEMANN, A. K. DENOBREGA, H. HANIF, S. A. M. BOBZEAN, *L. I. PERROTTI
Psychology, UT Arlington, ARLINGTON, TX

Abstract: Compared to males, women and female rodents are more responsive to cues associated with drug reward. Recent studies suggest that these sex differences are due, in part, to activational effects of rising and falling levels of ovarian hormones throughout the reproductive cycle of females. However, to date, most of the research examining sex differences in drug reward has been conducted using psychostimulants. Thus, the aim of the present study was to investigate sex differences in morphine conditioned place preference. To this end, adult female and male Long Evans rats were conditioned to associate one of two visually and tactically distinct environments with one of four doses of morphine sulfate (0, 1.25, 2.5, or 5mg/kg) or saline over three 60 minute alternating (morning and afternoon) conditioning sessions. Conditioned place preference (CPP) was defined as a significant increase in the amount of time spent in the morphine-paired environment during the 30 minute post-conditioning test compared to the amount of time spent in this same compartment during the 30 minute pre-conditioning test. Preliminary data analyses determined that female rats expressed CPP to the higher conditioning dose of morphine (5mg/kg; $p<0.01$), while male rats expressed CPP only at the lower conditioning doses of the drug (1.25, 2.5mg/kg; $p<0.05$). These findings demonstrate that sex significantly influences the expression of morphine CPP. Experiments are currently underway to examine a wider range of morphine doses as well as the influence of the estrous cycle on morphine CPP.

Title: Exposure to HIV-1 Tat protein potentiates the rewarding effects of morphine, and reinstates extinguished conditioned place preference

Authors: *J. P. MCLAUGHLIN[1], M. L. GANNO[2], Y. ZHANG[3], M. J. KREEK[3], J. J. PARIS[2]
[1]Torrey Pines Inst. For Mol. Studies, Port Saint Lucie, FL; [2]Pharmacol. and Neurosci., Torrey Pines Inst. for Mol. Studies, Port St. Lucie, FL; [3]The Lab. of the Biol. of Addictive Dis., The Rockefeller Univ., New York, NY

Abstract: Aims: While exposure to the HIV-1-accessory protein Tat is known to increase striatal dopamine levels, the functional consequences of Tat protein on the behavioral response to abused drugs are little known. Accordingly, we hypothesized that HIV-1 Tat expression in brain would modulate the rewarding effects of morphine. Methods: Using the GT-tg bigenic mouse model, where brain-selective Tat expression is controlled by activation of a doxycycline (Dox) promotor, we tested the effects of Tat protein on morphine-conditioned place preference (CPP) and consumption in a two bottle choice (TBC) assay. Microdialysis was performed with additional mice expressing Tat protein and repeatedly administered opioid treatment. Results: Western blot analysis confirmed the expression of Tat protein in GT-tg bigenic mice correlated with dose and duration of Dox treatment. In initial behavioral testing, although GT-tg bigenic mice expressing Tat demonstrated saline-conditioned place preferences similar to uninduced littermates and saline- or Dox-treated C57BL/6J mice, Tat expression for 7 days significantly doubled morphine-CPP. Subsequent characterization found the potentiation of CPP for morphine to be dependent on the magnitude of exposure to Tat protein. Consistent with this observation, exposure to Tat protein increased the levels of dopamine released in response to heroin in GT-tg mice. Of interest, among GT-tg bigenic mice demonstrating extinction of morphine-CPP, subsequent expression of Tat protein for 7 days resulted in the reinstatement of the extinguished place preference response in previously uninduced mice. Conclusions: Overall, these data suggest that expression of HIV-1 Tat protein in mouse brain potentiated heroin-induced dopamine release and the rewarding effects of morphine in a dose- and duration-dependent matter. These results suggest that exposure to Tat protein is sufficient to increase the rewarding effects of abused substances. Moreover, the Tat-induced reinstatement of an extinguished place preference for morphine suggests a biological means by which HIV infection may increase the vulnerability to substance abuse and relapse in abstinent subjects.

Title: Tracking sleep in a rodent model of heroin addiction

Authors: *A. A. COFFEY, Z. GUAN, P. S. GRIGSON, J. FANG
Penn State Col. of Med., Hershey, PA

Abstract: Addiction is a chronic disease characterized by multiple relapses. In the United States, heroin abuse is increasing dramatically. Drug abuse and sleep disturbances interact to form a vicious cycle where drug abuse disrupts sleep and sleep deficits, in turn, spur on drug abuse. With opioid abuse, the most commonly cited sleep deficit is a decrease in rapid eye movement (REM) sleep during withdrawal. Here, we sought to characterize the effects of drug on sleep patterns throughout the entire cycle of heroin addiction, including acquisition, abstinence, and a drug-induced reinstatement. To our knowledge, ours is the first study to examine the impact of acquisition of drug-taking, abstinence, and extinction/reinstatement on patterns of sleep. This comprehensive analysis allows us to relate sleep deficits to differences in drug taking behavior, including the amount of drug taken, the motivation to take drug, and the propensity to relapse. We used electroencephalography (EEG) and electromyography (EMG) to measure sleep patterns in male Sprague-Dawley rats over 20 days of acquisition, 14 days of abstinence, and a single day of extinction and reinstatement, a rodent model of relapse. Compared to saline controls, acquisition of heroin self-administration was associated with a poor quality of sleep as indicated by more rapid transitions between sleep and wake states. Ultimately, characterization of the drug-induced dysregulation of sleep may reveal new avenues for treatment.

Title: Mouse models of the OPRM1 (A118G) polymorphism: Differential heroin self-administration behavior compared to wild type mice

Authors: *Y. ZHANG[1], R. PICETTI[2], E. R. BUTELMAN[3], A. HO[3], J. BLENDY[4], M. KREEK[3]
[1]Rockefeller Univ., NEW YORK, NY; [2]The Lab. of the Biol. of Addictive Dis., [3]The Rockefeller Univ., New York, NY; [4]Perelman Sch. of Medicine; Univ. of Pennsylvania, Philadelphia, PA

Abstract: Rationale: Mu opioid receptors (MOPRs) are the target of opioids, which are currently responsible for massive addiction morbidity in the U.S. The gene coding for the human MOPR (OPRM1) has an important functional single nucleotide polymorphism (SNP), A118G, in which an adenine-to-guanine substitution exchanges an asparagine for an aspartic acid at a putative N-glycosylation site. The OPRM1 A118G genotype results in substantially increased risk of heroin addiction; however the neurobiological mechanism for this increased risk is not fully understood. Objectives: The current study examined heroin self-administration (SA) behavior in A112G (G/G) mice in extended SA sessions. Methods: Adult male G/G and wild type litter mate (A/A) mice were allowed to SA heroin (0.25 mg/kg/unit dose, FR1 with a nose poke response) for 4 hours/day for 10 consecutive days. Half of the mice then continued in a heroin dose-response study, while extinction from heroin SA was studied in the other half. Results: Male G/G mice responded for heroin significantly more often than A/A mice in the initial 10 days of heroin SA and in the subsequent dose-response study. The number of responses at the active hole escalated over the 10 consecutive daily SA sessions regardless of genotypes. There were no significant differences in extinction of SA between the A/A and G/G mice. Conclusion: male G/G mice self-administered more heroin than did A/A mice over a 10-day period. These are the first studies to examine the acquisition of heroin SA in this mouse model of the clinically relevant A118G OPRM1 SNP and may lead to a better understanding of the neurobiological and behavioral mechanisms that underlie greater risk of heroin addiction in carriers of the A118G SNP.

Title: Endomorphin analogs fully substitute for morphine without suppressing operant responses for food in a discrimination model: Potential role in opioid addiction pharmacotherapy

Authors: *M. R. NILGES[1], J. E. ZADINA[2,3]
[1]Grad. Neurosci. Program, [2]Neuroscience, Pharmacology, and Med., Tulane Univ. Sch. of Med., New Orleans, LA; [3]Neurosci., SE LA Veterans Hlth. Care Syst., New Orleans, LA

Abstract: Endomorphins (EM) have the highest selectivity of any endogenous peptide for the pain modulating mu-opioid receptor (MOR). We have synthesized several metabolically stable, blood-brain barrier permeable EM analogs that have equal or greater analgesic potency than morphine, the current gold standard MOR agonist. Morphine and other exogenously derived opioid analgesics produce detrimental side effects such as respiratory depression, tolerance, glial cell activation, and have a large potential for abuse. We have shown that EM analogs do not induce respiratory depression, produce substantially less tolerance than morphine, and do not induce markers of microglia or astrocyte activation. In abuse liability assays, intravenous (i.v.) morphine produced a robust and dose-dependent conditioned place preference (CPP) effect, but the analogs did not produce CPP or aversive effects. In self-administration models, rats with 12-hour per day access to an i.v. EM analog infusion lever pressed no more than controls with access to i.v. vehicle infusions, suggesting the analogs lack reinforcing qualities. Furthermore, EM analogs appear to penetrate the blood-brain barrier since i.c.v. naloxone-methiodide attenuated the antinociceptive responses of the analogs. In this study we trained rats to discriminate i.v. infusions of morphine from vehicle in a 2-lever food choice drug-discrimination (DD) task to assess the substitution potential of the analogs for morphine. Methadone suppresses motor/appetitive responses for food in the DD model at doses that substitute for morphine. A compound which lacks CPP and self-administration, but substitutes for morphine in the DD model without motor/appetitive impairment, has potential as a pharmacotherapy for opioid addiction. We found that analogs 2 and 4 fully substituted for morphine, but did not impair motor/appetitive responding. The analogs fully substituted for morphine after randomized bolus injections (0.3 - 5.6 mg/kg i.v.) and after cumulative injections made in escalating ¼ log doses. Data provided here suggest the analogs may provide better therapy for opioid addiction than methadone, since motor impairment is a major limitation of methadone maintenance therapy. These data indicate EM analogs lack reinforcement qualities, provide potent CNS mediated analgesia, substitute for morphine in the DD model, and are novel candidates for opioid addiction pharmacotherapy.

Title: Differential effect of selective 5-HT7 receptor antagonist on reversal learning and attentional set shifting in rats

Authors: *A. HRNJADOVIC[1], P. J. ALLEN[2], B. KOCSIS[2]
[2]Psychiatry/BIDMC, [1]Harvard Med. Sch., Boston, MA

Abstract: Previous work has demonstrated that serotonin 7 receptor (5-HT7) antagonism ameliorates impairments in selective cognitive domains in animal models of schizophrenia induced by NMDA receptor blockade, particularly in novel object recognition and attentional set shifting tests (ASST), but not in prepulse inhibition. Rodent ASST (Birrell and Brown, 2000) allows for the identification of several types of cognitive rigidity, such as failure on reversals (when the +/- cues are switched), and intradimensional (ID; when a new pair of cues of the same dimension is introduced) and extradimensional set-shifting (ED; when the rat has to switch between cue dimensions). Importantly, failure on the reversals versus on the ID/ED shift were shown to develop after lesioning, respectively, the medial (mPFC) and orbital (OFC) regions of the prefrontal cortex. Since 5-HT7 receptors show stronger OFC expression compared with mPFC, we hypothesized that it might differentially affect these types of cognitive rigidity. Six male Sprague-Dawley rats were tested in the ASST, several times each, after subcutaneous administration of saline, MK-801 (NMDAR antagonist, 0.2 mg/kg), SB-269970 (5-HT7R antagonist, 1 mg/kg), and co-administration of the two compounds. Due to behavioral impairments induced by MK-801, the rats did not take food for the first ~2 hrs after injection, even if food was scattered in the recording arena. Therefore, ASST started only when the rats were able to find the food, hold it, and eat. Accordingly, SB-269970 was administered following two protocols: 1) shortly before MK-801 or 2) shortly before MK-801 and ~2 hrs later (i.e. immediately before starting the ASST). We found that MK-801 impaired performance on all discrimination phases of ASST whereas administration of SB-269970 alone had no effect. When co-administered with MK-801 however, SB-269970 reversed the effect of NMDA receptor blockade selectively on the reversal phases of ASST. When an additional dose of the 5-HT7 antagonist was given ~2 hrs after MK-801 injection (i.e. at the start of ASST) it also restored performance on the ED shift. We conclude that 5-HT7 receptor mechanisms may provide a

specific contribution to the complex of cognitive deficits in schizophrenia and possibly other psychiatric diseases, e.g. anorexia nervosa, which also express different forms of cognitive inflexibility.

Title: Distinct circuits underlie the effects of 5-HT1B receptors on aggression and impulsivity

Authors: *K. M. NAUTIYAL[1,2], K. TANAKA[5], M. M. BARR[6], Y. LE DANTEC[7], L. TRITSCHLER[7], D. J. DAVID[7], A. M. GARDIER[7], C. BLANCO[1,3], S. AHMARI[8], R. HEN[1,4]
[1]Neurosci., Columbia Univ., NEW YORK, NY; [3]Clin. Psychiatry, [4]Integrative Neurosci., [2]N.Y.S.P.I., New York, NY; [5]Keio Univ., Neuropsychiatry, Japan; [6]Neurosci., Barnard Col., NEW YORK, NY; [7]Faculté de Pharmacie, Univ. Paris Sud, Châtenay-Malabry, France; [8]Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Impulsive and aggressive behaviors are both mediated by the serotonin 1B receptor (5-HT1BR), an inhibitory GPCR expressed on both serotonergic and non-serotonergic neurons. However the circuit(s) underlying these effects have not been delineated, nor has the developmental contribution been assessed. In order to address these questions, we developed a novel mouse model to control spatial and temporal expression of the 5-HT1BR. A transgenic line was created by replacing the endogenous htr1b coding region with a cassette containing a floxed tetracycline operator and htr1b cDNA (tetO1B). Crossing tetO1B mice to mouse lines expressing the tetracycline-dependent transcriptional silencer (tTS) or Cre transgenes under the control of various promoters, allowed for tissue specific knock-down of 5-HT1BR, the former of which

could be rescued by treatment with doxycyline. Mice were tested for increased aggression using a male-male territorial aggression assay. Impulsivity was measured in operant behavior paradigms which tested response inhibition including differential reinforcement of low-rate responding and Go/No-go tasks. Whole-life, whole-brain knockout (β-Actin -tTS/tetO1B mice) resulted in high levels of aggression and impulsivity. Interestingly, rescue of 5-HT1BR expression in adulthood reversed the impulsive, but not the aggressive phenotype. The aggressive phenotype was ameliorated following post-natal rescue of 5-HT1BR expression, with a sensitive period around P21-28. To localize the receptors involved in mediating these behaviors, we first knocked out 5-HT1B autoreceptors, which are expressed on serotonin neurons (Pet-1-Cre/tetO1B mice). These mice were neither aggressive nor impulsive, suggesting a lack of involvement of autoreceptors. Next, a subset of heteroreceptors located in the cortex, striatum and hippocampus were knocked out (CaMKII-tTS/tetO1B). These mice displayed increased aggressive, but not impulsive behavior. This suggests that receptors in cortex, striatum, and/or hippocampus modulate aggressive behavior, and a different subset of heteroreceptors mediate impulsive behavior. To begin to dissect the mechanisms underlying the 5-HT1BR effect on impulsivity, we measured *in vivo* extracellular levels of dopamine (DA) in the nucleus accumbens (NAc), a known modulator of response inhibition. Levels of DA were correlated with impulsive behavior - increased following a lack of 5-HT1BRs throughout life and reversed with adult rescue of the receptor. Overall, our data suggest that 5-HT1BRs modulate aggression and impulsivity through distinct mechanisms and that 5-HT1BR effects on DA may modulate impulsivity.

Abstract: The perception of time is essential for survival, is required for the precise organization of sequences of activity, and the anticipation of behavioral outcomes and future events. One form of temporal perception is interval timing which refers to the discrimination of durations typically in the seconds to minutes range. Schizophrenia is associated with timing deficits. It has been proposed that impaired temporal processing is a core deficit of schizophrenia, contributing to cognitive dysfunction, hallucinations, and inappropriate behavior. There is also evidence that the serotonergic system, which is believed to play a role in the neuropathology of schizophrenia, regulates temporal perception. Unfortunately, little is known about the neural substrates that are involved in serotonergic modulation of timing. We have developed a discrete trials interval timing task in mice that can be used to elucidate the neural and receptor mechanisms underlying the modulation of interval timing by both endogenous serotonin and hallucinogenic drugs. In the discrete trials task, a lamp is illuminated for a variable duration, and then two levers are presented. Responding on lever A is reinforced if the stimulus duration is < 6.5 s while responding on lever B is reinforced if the stimulus duration is > 6.5 s. C57BL/6J mice were trained to discriminate between short (2.5 and 5 s) and long (8 and 10.5 s) stimulus durations, and then challenged with a wider range of test stimuli. We examined whether task performance was affected by 5HT2A receptor ligands. We found that mice can learn to reliably discriminate between the short and long duration training stimuli (>80% accuracy for the two extreme stimulus durations). Challenge studies revealed that the proportion lever B responding increased with the stimulus duration. The 5HT2A/2C agonist and serotonergic hallucinogen 2,5-dimethoxy-4-iodoamphetamine (DOI; 0.25-1 mg/kg, IP) altered interval timing ($F(18,216)=2.42$, $p<0.002$) and reduced T50 (time corresponding to %B = 50). A reduction of T50 indicates a change in the period of the internal pacemaker. The selective 5HT2A antagonist M100907 (0.1 mg/kg IP) also altered interval timing and reduced T50. These findings suggest that 5HT2A receptors modulate temporal discrimination. Our goal is to use this behavioral paradigm to investigate the regulation of interval timing by the serotonergic system and determine the neural sites involved in this effect. It is possible that the disruption of temporal perception induced by hallucinogens could represent an animal model for schizophrenia research, potentially facilitating the development of novel agents with antipsychotic activity.

Title: Prenatal exposure to antenatal depression and antidepressants alters the ROCK2 expression

Authors: *J. D. OLIVIER, H. ÅKERUD, H. KAIHOLA, Å. EDVINSSON, A. SKALKIDOU, I. SUNDSTRÖM-POROMAA
Uppsala Univ., Uppsala, Sweden

Abstract: Depressive symptoms during pregnancy affect about 25% of the pregnant women. Several studies have shown that antenatal depression has an impact on both the mother and the fetus. The use of antidepressants during pregnancy to relief the mother's symptoms has significantly increased during the last decade. Although no gross teratogenic effects on the offspring have been reported the effects of antidepressant treatment during pregnancy remain largely unknown. To unravel the molecular mechanisms underlying antenatal depression and antidepressant treatment a microarray was performed on human fetal placentae. Results show that, among others, ROCK2 was down-regulated in both depressed and antidepressant cases. In contrast to the RNA expression, a small increase in ROCK2 protein levels was found in total tissue lysate in both depressed and antidepressant cases. Moreover, immunohistochemistry of the placenta revealed that ROCK2 expression was slightly increased in trophoblasts, stromal, and endothelial cells of depressed and antidepressant cases. As ROCK2 is part of the Rho-ROCK signaling pathway, which plays a role in cardiovascular diseases, a rat model for depression (heterozygous SERT ko-rat) was used to further unravel the role of ROCK2 in prenatal depression and antidepressant treatment. Pregnant rats were treated from gestational day (G)1 till G19 with either fluoxetine or placebo. On G20 rats were sacrificed and placenta, fetal heart and fetal brain were collected. Rat experiments to validate and extent the human data are now ongoing. Together, the results of this study will give us more insights into the role of ROCK2 in prenatal depression and antidepressant treatment and the effects on the offspring.

Title: Individual wheel running activity of laboratory rats using a radio frequency identification technology

Authors: *N. KUBOTA[1], S. YANAGITA[1], Y. TAKANO[2], K. TAKEDA[1]
[1]Res. Inst. for Sci. and Technol., [2]Dept. of Pharmaceut. Sci., Tokyo Univ. of Sci., Chiba, Japan

Abstract: Spontaneous wheel running is a common physical exercise model to enhance physiological and psychological health in rodents. The effects of exercise on physiological and psychological health are known to be often regulated by amount of physical exercise. Thus, previous experimental data for wheel running have been collected in individual housing in order to measure the amount of individual physical activity. Recently, numerous studies have suggested that individual housing influences hypothalamic pituitary adrenal axis activity to stress while social housing can buffer the influence of stress responsiveness. Therefore, we cannot rule out a possibility of negative influences of living alone on beneficial effects of exercise. However, it is difficult to indentify individual animals in social housing. In this study, we tried to monitor individual wheel running activity in individual or social housing using radio frequency identification (RFID) technology in laboratory rats. We also assessed brain monoamine levels, which are crucial for health benefits on brain, using high-performance liquid chromatography. Male Wistar rats were implanted with subcutaneous microchips, i.e., electronic identification devices, providing each animal with a unique identification number. Animals were randomly assigned to either individual or social living conditions, and were housed in plastic cages with an attached running wheel for 4 weeks. Each cage was equipped to monitor an individual animal's access to running wheel using microchip-scale system. Daily wheel revolutions were recorded digitally, and running distance was calculated by multiplying wheel circumference by the number of revolutions. Four weeks of spontaneous wheel running made differences in both daily running distance and brain monoamine levels between individual and social living conditions. These results suggest a possibility that this RFID monitoring system facilitates the collection of individual wheel running data of rats in social housing.

Title: A highly efficient approach for specific targeting of postnatal brain serotonin synthesis

Authors: *M. S. WHITNEY, E. DENERIS
Neurosciences, Case Western Reserve Univ., Cleveland, OH

Abstract: Deficient serotonin (5-HT) signaling in the brain has been implicated in the pathogenesis of many devastating and highly prevalent psychiatric disorders. However, the importance of postnatal 5-HT for the maintenance of 5-HT neuron function and normal behavior is still poorly understood. This is partly due to the lack of specificity and efficiency of traditional techniques used to alter the 5-HT system in animal models. For example, many studies have employed genetic approaches to target transcription factors required for fetal 5-HT neuron development and function, which result in substantial decreases in the expression of *tryptophan hydroxylase 2* (*Tph2*), the rate-limiting enzyme in brain 5-HT synthesis, and deficiencies in 5-HT levels. However, those approaches also affect many other serotonergic genes not directly related to 5-HT synthesis, bringing into question the specific cause of the behavioral deficits seen in those models. Importantly, mouse models with germline targeting of *Tph2,* in which brain 5-HT synthesis is never initiated, have confirmed that 5-HT deficiencies beginning in early fetal life are sufficient to cause behavioral abnormalities in adulthood. Still, it remains to be determined if maintenance of postnatal 5-HT levels is critical for the functional integrity of 5-HT neurons and normal behavior. To address these fundamental questions, we have developed an efficient approach to decrease brain 5-HT synthesis, specifically, at different postnatal time points. *Tph2* expression is targeted by stereotaxic injection of a viral vector expressing Cre recombinase, AAV-Cre, into the dorsal raphe nucleus (DRN) of adult *Tph2fl/*Δ mice. This technique results in highly reproducible and severe losses of postnatal Tph2 and 5-HT. Representative targeting in the adult DRN resulted in a 91.8% (±0.9) decrease in *Tph2* mRNA, a 99.5% (±0.3) reduction in Tph2+ neurons, and a 93.9% (±1.9) decrease in forebrain 5-HT levels. Expression of aromatic L-amino acid decarboxylase, the other enzyme involved in 5-HT synthesis, was unchanged in AAV-Cre-targeted 5-HT neurons marked with Rosa-YFP, demonstrating that 5-HT neurons remain in normal numbers and loss of Tph2 and 5-HT are not due to 5-HT neuronal death. Preliminary data suggests the development of gene expression changes following chronic loss of 5-HT. Current studies are focused on investigating the impact of postnatal 5-HT deficiency on gene expression, anxiety-like behaviors, fear conditioning, behavioral inhibition, and the response to chronic stress.

Title: Stimulation of serotonin 5-ht3 receptors cause vomiting via the activation of ca/camkii-dependent erk1/2 signaling in the least shrew (cryptotis parva)

Authors: W. ZHONG, T. HUTCHINSON, S. CHEBOLU, *N. A. DARMANI
Coll Osteo. Med. Pacific, Western Univ. Hlth. Sci., POMONA, CA

Abstract: Activation of Ca^{2+}-permeable 5-HT_3 receptors (5-HT_3Rs) by the selective 5-HT_3 receptor agonist 2-methyl serotonin (2-Me-5-HT) can induce vomiting. We have previously demonstrated that L-type Ca^{2+} channel blockers, nifedipine and amlodipine or the selective 5-HT_3R antagonist palonosetron, suppress the induced vomiting in the least shrew. To clarify the contribution of Ca^{2+}-linked intracellular cascades in brainstem, we have examined the involvement of interaction of 5-HT_3R with calmodulin, Ca^{2+}/calmodulin-dependent protein kinase IIα (CaMKIIα) and extracellular signal-regulated kinase 1/2 (ERK1/2) signals in 2-Me-5-HT-induced emesis. Administration of 2-Me-5-HT (5 mg/kg, i.p.) significantly: i) enhanced the 5-HT_3R-calmodulin interaction in the brainstem as revealed by both immunoprecipitation, and colocalization in the area postrema by immunohistochemistry; and ii) activated CaMKIIα in brainstem as shown by Western blot and immunohistochemistry. These effects were suppressed by palonosetron pretreatment. Amlodipine also suppressed the 5-HT_3R-calmodulin interaction and CaMKIIα phosphorylation in the brainstem caused by 2-Me-5-HT. Furthermore, 2-Me-5-HT-induced emesis and CaMKIIα activation in the brainstem were blocked by dantrolene, an inhibitor of Ca^{2+}-release through ryanodine receptor channels in ER, but not by 2-APB, an inhibitor of ER inositol-1, 4, 5-triphosphate receptor. Inhibitors of CaMKII (KN93) and ERK1/2 (PD98059) dose-dependently suppressed emesis caused by 2-Me-5-HT. Moreover, 2-Me-5-HT activated ERK1/2 in the brainstem, which was abrogated by palonosetron, KN93, PD98059, amlodipine, and dantrolene. This study demonstrates that Ca^{2+} mobilization via extracellular Ca^{2+} influx through 5-HT_3Rs/L-type Ca^{2+} channels and intracellular Ca^{2+} release via RyRs on ER, initiate Ca^{2+}-dependent sequential activation of CaMKIIα and ERK1/2, which contribute to the 5-HT_3R-mediated, 2-Me-5-HT-evoked emesis.

Title: Anxiogenic-like effect of acute administration of two selective serotonin reuptake inhibitors - Repeated measurements of freezing behavior during presentation of brief acoustic stimuli

Authors: *S. M. HAGSÄTER, J. THORÉN, R. PETTERSSON, E. ERIKSSON
Inst. of Neurosci., Gothenburg, Sweden

Abstract: Objectives: Acute administration of selective serotonin reuptake inhibitors (SSRIs) may exacerbate anxiety. In a previous study we found an increase of "anxiety" after SSRI administration in a paradigm exploiting presentation of brief acoustic stimuli as an augmenter of freezing behavior. Hence, this paradigm appears to be feasible for investigations of agents with anxiogenic effects. In the current study we wanted to explore the repeatability of the animal response in this paradigm, and to what extent the baseline "anxiety" of the animals is of importance to the drug response. Animal response to two different SSRIs, escitalopram and paroxetine, was assessed. **Methods**: A total of 72 male Sprague Dawley rats were tested in two separate experiments. In both experiments repeated testing sessions consisting of 20 acoustic stimuli (0.2 s, 90 dB white noise bursts) with an interstimulus interval of 30 seconds were used. Experiment I: Rats (n=24) were tested on two separate days (day 1 and 18) in two identical sessions (no injections were given prior to testing). Experiment II: Rats (n=48) were first tested in one session (day 1) without injections similar to in experiment I. On day 5 and 18 half of the rats received a single injection of escitalopram (escitalopram oxalate, 10 mg/kg) one hour before testing. On day 12 (the same) half of the rats received a single injection of paroxetine (paroxetine hydrochloride, 10 mg/kg) one hour before testing. The remaining rats received 1 ml of 0.9% saline on day 5, 12 and 18. Effects of drug injections were analyzed separately for rats trichotomized in groups based on freezing response on day 1. **Results**: Experiment I: A strong

correlation was found for repeated testing in this paradigm ($r_{d1\text{-}d18} = .87$, $p_{d1\text{-}d18} < .0001$). Experiment II: For low anxiety rats (n=16) drug treated animals displayed increased freezing on all days versus control ($p_{d5} < .001$, $p_{d12} < .001$,$p_{d18} < .01$). Medium anxiety rats (n=16) displayed increased freezing on day 12 and day 18 ($p_5 = .42$, $p_{12} < .05$, $p_{18} < .01$). No significant effect of drugs was found for rats displaying high anxiety at baseline ($p_{d5} = .94$, $p_{d12} = .84$, $p_{d18} = .69$). **Conclusion**: As demonstrated by correlation analysis, freezing behavior measured during presentation of brief acoustic stimuli displays very high inter-test stability and repeatability for individual subjects. Acute administration of SSRI resulted in a pronounced increase in freezing for rats displaying low anxiety at baseline. Notably, there was no significant effect on freezing for animals displaying high anxiety at baseline.

Title: Increased impulsivity in the stop-signal reaction time task in a mouse model of Prader-Willi syndrome: Role of 5-HT2C receptors

Authors: J. R. DAVIES[1], T. HUMBY[3], L. S. WILKINSON[3], *A. R. ISLES[2]
[1]MRC Ctr. for Neuropsychiatric Genet. and Genomics, [2]Psychological Med., Neurosci. and Mental Hlth. Res. Inst., Cardiff, United Kingdom; [3]Sch. of Psychology, Cardiff Univ., Cardiff, United Kingdom

Abstract: Prader-Willi syndrome (PWS), is a neurodevelopmental disorder caused by deletion or inactivation of paternally expressed imprinted genes on human chromosome 15q11-q13, leads to an array of disabilities including compulsive hyperphagia and deficits in social behaviour, such as social withdrawal, temper tantrums, perseverative speech and behaviour, mental rigidity, stereotyped behaviour and impulsiveness. The PWS genetic interval contains several brain-expressed small nucleolar (sno)RNA species that are subject to genomic imprinting. One of these, *snord115*, negatively regulates editing and alternative splicing of the 5-HT_{2C} receptor

(*5htr2c*) pre-RNA which is thought to play an important role in regulation of behavioural inhibition and impulsivity[1,2]. In this study we have used the imprinting centre (IC) deletion mouse model for PWS (PWS-IC(+/-)), which results in a loss of all paternal gene expression for the PWS interval[3], including *snord115*, which leads to an increase in abundance of the less functional isoforms of *5htr2c*. Our previous results showed no effect of IC deletion on premature responding in the five-choice serial reaction time task (5-CSRTT)[4], however, an enhanced increase in impulsivity was seen relative to controls when the behaviour was probed with 5-HT_{2C} selective drugs. More recent studies have identified the contribution of 5-HT_{2C} receptors to inhibitory control, in tasks assessing impulsive action, such as the stop-signal reaction time task (SSRTT)[2]. In the SSRTT, control of responding was manipulated by altering the onset of an auditory 'stop-signal' during the go response. All mice showed the anticipated increases in impulsive responding as the stop-signal was moved closer to the end of the go response, but PWS-IC(+/-) mice showed increased impulsivity relative to wild-type controls at all stop-signal positions. Studies are on-going to investigate the effects of manipulating this behaviour with selective agonists and antagonists of the 5-HT_{2C} receptor. These data, in comparison with our previous work[3], suggest specific facets of inhibitory behaviour may be impaired in PWS-IC(+/-) mice and that *snord115* via its actions on the 5-HT_{2C} receptor gene may mediate this dissociation. **References** 1. Title: The roles of 5-Hydroxytryptamine 2A and 2C receptors in maternal behaviors in rats

Authors: *J. GAO, M. LI
Dept. of Psychology, Univ. of Nebraska-Lincoln, Lincoln, NE

Abstract: Maternal behavior in rats is a highly motivated and well-organized social behavior. Recently, we found a disruptive effect of 5-HT2C receptor agonism (but not 5-HT2A receptor antagonism) on maternal behavior in rats. In the present study, we explored how activation of 5-HT2A alone or both 5-HT2A and 5-HT2C receptors may influence the expression of maternal behavior. In addition, we examined the neuroanatomical basis of the central action of 5-HT2C receptor blockade on maternal behaviors. In Experiment 1, using a within-subject design, we examined the roles of 5-HT2A agonist and 5-HT2C antagonist on maternal behaviors (n=8 for each drug). On postpartum Days (PND) 4, 6, 8, and 10, Sprague-Dawley mother rats were injected with the 5-HT2A agonist TCB-2 (0, 1.0, 2.5 or 5.0 mg/kg, sc), or the 5-HT2C antagonist SB242084 (0, 0.2, 0.6 or 1.0 mg/kg, sc). Maternal behavior was tested for 10 min at 30 min before and 30 min, 120 min, 24 h after injection. TCB-2 (not SB242084) dose-dependently disrupted pup retrieval, pup licking, pup nursing, and nest building. In Experiment 2, using a between-subject design, we examined the roles of 5-HT2A agonism and the combined agonism on 5-HT2A and 5-HT2C. On PND 4, 6, 8, and 10, separate groups of mother rats were injected with saline, TCB-2 (2.5 mg/kg, sc), or the combined TCB-2 (2.5 mg/kg) and MK212 (5-HT2C agonist, 1.0 mg/kg), sc. Maternal behavior was tested at 30 min before and 30, 90, and 150 min after injection. Injection of TCB-2 or TCB-2+MK212 significantly disrupted various maternal behaviors. There appeared to be an additive effect in the TCB-2+MK212 condition. There was no apparent change in the magnitude of the disruptive effect of TCB-2 and TCB-2+MK212 across the test days (no sensitization or tolerance). In Experiment 3, 6 female rats were tested for their maternal behaviors at 10 min after central infusion of saline (on PND 3), or MK212 at 25, 75, or 250 ng/side (on PND 5, 7, and 9 respectively) into the nucleus accumbens shell (NAs). In Experiment 4, 12 rats were tested at 10 min and 60 min after infusion of saline, MK212 25, 250 ng/side, or 1.0, 2.0, 5.0 ug/side into medial prefrontal cortex (mPFC) on PND 4, 6, 8, and 10. Results show that intra-NAs or intra-mPFC MK212 infusion had no effect on various maternal behaviors. These findings suggest that activation of either 5-HT2A or 5-HT2C receptor has a detrimental effect on rat maternal behavior. The central action of 5-HT2C activation does not appear to occur in the NAs and mPFC. Future work will further investigate the neuroanatomical basis of 5-HT 2A/2C agonists and identify the antagonistic action between these two receptor systems.

Title: Monoamine precursor injections influence individual difference of spontaneous physical activity in rats

Authors: *S. YANAGITA[1], N. KUBOTA[1], Y. TAKANO[1], T. MATSUZAWA[1], T. ISHIWATA[2], K. TAKEDA[1]
[1]liberal arts, Tokyo Univ. of Sci., Chiba, Japan; [2]Rikkyo Univ., Saitama, Japan

Abstract: Daily amount of physical activity is an important factor to confer the physiological and psychological health benefits. Spontaneous wheel running is a common physical exercise model in order to enhance physiological and psychological health in rodents. It is well known that daily spontaneous wheel running distance gradually increases over several weeks from the starting day of running. We have investigated a novel methodological target to increase physical activity in these rat models. In the previous study, we showed that spontaneous activity in running wheel was implicated in the levels of brain serotonin (5-HT) and dopamine, and suggesting that the change of the balance of brain 5-HT and dopamien contents could regulate daily amount of physical activity. In this study, we examined the effects of 5-HT and dopamine precursor injections on daily spontaneous activity in physically active rats. Male Wistar rats were housed individually in cages with or without an attached running wheel and were randomly assigned to either physically active or sedentary conditions. Physically active rats were allowed voluntary access to their wheels for 4 weeks. After 3 weeks from the start of running, half the number of the rats in each group was injected 5-HT precursor, 5-Hydroxytryptophan (5-HTP), or dopamine precursor, levodopa (L-Dopa), every other day for a week (i.p. 60mg/g). We also assessed the levels of brain serotonin, dopamine, and its metabolite using HPLC. The results indicated that there is no significant difference between 5-HTP injected rats and vehicle control on the daily spontaneous wheel running distance in physically active conditions. The brain levels of 5-HT did not be influenced, although the levels of 5-HT metabolites and turn over tended to be increased by 5-HTP injections. Continuous L-Dopa injections influenced daily individual difference of running distance in physically active rats. Present results indicate that physically active state did not be regulated by only 5-HT contents, and lead to a hypothesis that the daily amount of physical activity could be regulated by the change of balance of brain 5-HT and dopamine contents.

Title: Mechanisms of 3,4-methylenedioxymethamphetamine(MDMA)-induced enhancement of prosocial behavior and sensitization in mice

Authors: *D. W. CURRY[1,4], A. BELKOFF[2,4], L. L. HOWELL[3,4]
[1]Neurosci. Grad. Program, [3]Psychiatry and Behavioral Sci., [2]Emory Univ., Atlanta, GA;
[4]Neuropharm. and Neurologic Dis., Yerkes Natl. Primate Res. Ctr., Atlanta, GA

Abstract: S,R(+/-)-3,4-methylenedioxymethamphetamine (MDMA) is an amphetamine derivative that became popular as a recreational drug (ecstasy) and therapeutic tool during the 1970's and early 1980's. Escalating use led to its prohibition but scientific interest in the drug has persisted due to its unique prosocial effects. Under clinical observation, volunteers report that MDMA increases feelings of closeness towards others, empathy, and gregariousness. In addition to these acute effects, there is evidence of enduring therapeutic effects such as improved interpersonal functioning and significant symptom reduction in PTSD patients. Ongoing studies are now investigating its potential for treating adults with autism. However, serious limitations remain to wider clinical use of MDMA, particularly its suspected neurotoxicity and history as an abused substance. Thus, there is significant impetus to determine the mechanisms that underlie MDMA's prosocial and therapeutic effects so that new medications can be developed that isolate and more safely harness these effects. We found that racemic MDMA (7.8 mg/kg) robustly increases social interaction in male mice and that subsequent treatments lead to a sensitization of this effect, indicating that neural adaptations are taking place. These adaptations may explain MDMA's long term therapeutic effects, but the mechanism remains unknown. Recent studies have suggested that 5-HT2A receptor activation may be necessary for sensitization to occur. We found that mice treated with the selective 5-HT2A antagonist M100907 (0.3 mg/kg) prior to MDMA during 3 conditioning sessions showed normal sensitization when test 48 hours later with a novel conspecific in a social interaction test. Only a high (1 mg/kg) dose disrupted sensitization to MDMA's prosocial effects, indicating that there may be important off-target effects that are responsible for blocking sensitization. When given as a pretreatment on test day,

neither dose decreased the acute prosocial effects of MDMA. *In vivo* microdialysis was used to determine the neurochemical sensitization to MDMA and the effect of M100907 pretreatment on dopamine and serotonin release. These results indicate that activation of 5-HT2A receptors is not necessary for the acute prosocial effects of MDMA and that their role in sensitization is unclear. Because MDMA is both a widely used drug of abuse and a potential therapeutic, there is great impetus to better understand its acute and long-term behavioral and neurobiological effects. Ongoing studies are investigating the importance of other receptors including 5-HT1A, 5-HT1B, and oxytocin receptors.

Title: 5-HT2A receptors expression in prelimbic cortex of rats selectively breed for high and low anxiety traits

Authors: *L. A. LEÓN[1], F. P. CÁRDENAS[2], S. ZARATE[2], V. C. GOMES[3], J. LANDEIRA-FERNANDEZ[4]
[1]Physics/Chemistry, Univ. of Sao Paulo, Ribeirao Preto, Brazil; [2]Univ. de los Andes, Bogotá, Colombia; [3]Univ. Federal de São João Del-Rei, São João Del-Rei, Brazil; [4]Pontificia Univ. Catolica de Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: Introduction: Genetic vulnerability to stress is considered to be a high risk factor in the development of psychopathologies, such anxiety disorders and depression. Several data have consistently showed the involvement of serotoninergic (5HT2A) neurotransmission of limbic structures in the genesis of such disorders. However, there are few studies exploring changes in the expression of 5HT2A receptors in the prelimbic cortex in the eclosion of anxiolytic-like or ansiogenic-like behavior. Importantly, the activity of 5HT2A receptors in this region is considered to be associated with structures responsible for the activation of defensive responses, like the amygdaloid complex. Methods: In the present study, we employed as subjects male rats selectively breed for High (n=12) and Low (n=12) conditioned freezing in response to contextual

cues previously associated with footshocks, animals that are known as the Carioca high-and low-conditioned freezing (CHF and CLF) rats. Recent reports have consistently showed that these lines present marked differences in both learned and innate fear responses and in several biological markers of anxiety. Also they had showed differences in the anxiolytic-like response when tested with the antagonist of 5HT2A receptors. In this sense, we evaluated the amount of 5HT2A receptors in the prelimbic cortex of both lines, after submitted them to the contextual fear conditioning protocol. Results: Our preliminary results indicate significant differences between the two lines, CHF and CLF rats, in the 5HT2A receptors expresion in the prelimbic cortex than CLF animals. This results support previous findings where the antagonist of 5HT2A receptor, ketanserin, showed differential effects for both lines of rats. These findings will help us in the understanding of neurobiological mechanisms that underlies vulnerability to stress.

Title: Mdma increases prosocial behavior and vocalizations in squirrel monkeys

Authors: *E. G. PITTS, M. T. LOGUN, L. L. HOWELL
Emory Univ., Atlanta, GA

Abstract: Several mental illnesses include disruption of social interactions, including autism, post-traumatic stress disorder (PTSD), and drug dependence. 3,4-methylenedioxy-N-methylamphetamine (MDMA) has been show to increase feelings of openness and trust, positive emotions, and sociability. Recently, MDMA has been examined as a therapeutic adjunct in the treatment of PTSD, with promising results. Yet, the mechanisms underlying the prosocial effects of MDMA are still not known. We are using a group housed non-human primate model to examine the prosocial effects of MDMA. Squirrel monkeys metabolize MDMA in a manner

similar to humans and provide a strongly translational model in which to examine the mechanisms underlying the prosocial effects of MDMA. We administered MDMA (racemic and its enantiomers) or saline intramuscularly to four group housed male squirrel monkeys. We then used a behavioral ethogram and vocalizations to examine the effects on behavior. We have found that racemic MDMA causes dose-dependent increases in affiliative behavior and vocalizations. The enantiomers of MDMA are known to have different neurotransmitter release and receptor binding profiles. We have also found that, although the enantiomers have different behavior profiles, they both increase prosocial behaviors. Using this established non-human primate model, we will be able to pharmacologically examine the mechanisms mediating the prosocial effects of MDMA.

Title: Role of 5-HT1A receptors located in the dorsal sub-region and lateral wings of the dorsal raphe nucleus in the modulation of inhibitory avoidance and escape behaviors

Authors: *R. L. POBBE, A. SPIACCI JR, H. ZANGROSSI JR
Univ. of São Paulo, Ribeirão Preto, Brazil

Abstract: A wealth of evidence indicates that the dorsal raphe nucleus (DR) is not a homogenous structure, but an aggregate of different subpopulations of serotonergic and non-serotonergic neurons that are morphologically and functionally distinct. This study was performed to assess the effects of the pharmacologic manipulation of 5-HT1A receptors placed within the dorsal sub-region (DRd) and the lateral wings (lwDR) of the DR on the expression of defensive responses generated by the elevated T-maze. This model allows the measurement, in the same rat, of two subtypes of anxiety-related responses, inhibitory avoidance and escape. Male Wistar rats were tested in the elevated T-maze ten minutes after intra-DRd or intra-lwDR administration of different doses of the 5-HT1A receptor antagonist WAY-100635, and of the 5-HT1A receptor agonist 8-OH-DPAT. The results showed that intra-DRd infusion of WAY-

100635 facilitated inhibitory avoidance acquisition, and impaired escape expression; interestingly, intra-lwDR administration of this same antagonist impaired escape performance and exerted no effect on inhibitory avoidance acquisition. In addition, intra-DRd injection of 8-OH-DPAT impaired inhibitory avoidance acquisition, and facilitated escape expression, while the infusion of this agonist into the lwDR facilitated escape response and did not alter the avoidance task. Overall, our results indicate that whereas 5-HT1A receptors in the DRd exert opposed control on inhibitory avoidance and escape behaviors, the pharmacologic manipulation of 5-HT1A receptors located in the lwDR preferentially alters the latter response.

Title: Wfs1-deficient mice display altered glycemic control and immobility behaviour in response to antidepressants treatment

Authors: *R. REIMETS, M. LOOMETS, M. PLAAS, S. RAUD, T. VISNAPUU, E. VASAR
Dept. of Physiol., Tartu, Estonia

Abstract: Mutations in the WFS1 gene predispose to type 2 diabetes and they also make humans more susceptible to mood disorders. On the other hand, there is a strong association between antidepressant treatment and the risk for diabetes. The aim of this study was to investigate the behavioral and metabolic effects of three classes of antidepressants in Wfs1-deficient mice. Namely, the tricyclic antidepressants (TCA) desipramine and amitriptyline, the selective serotonin reuptake inhibitor (SSRI) escitalopram and the atypical antidepressant bupropion were studied in terms of immobility behaviour in the tail suspension test (TST) and blood glucose levels in the glucose tolerance test (GTT). Results showed that the basal time spent immobile in the TST by Wfs1-deficient mice did not differ from that of their heterozygous or wild-type littermates. Moreover, the doses of desipramine, amitriptyline and escitalopram necessary to significantly reduce immobility time compared to drug-naive animals of the same genotype, were lower in homozygous and heterozygous mice than in their wild-type littermates. In the GTT, homozygous Wfs1-deficient mice exhibited impaired glucose tolerance. The hyperglycemic effect was aggrevated by both of the tested TCA-s, causing more severe and

long-lasting hyperglycemia and therefore indicating changes in monoamine signaling caused by Wfs1-deficiency which is not specific to the central nervous system. By contrast, the glucose tolerance of Wfs1-deficient mice was not affected by escitalopram. Together, results from this study indicate that, compared to other classes of antidepressants, SSRI-s might be more suitable for alleviation of depressive symptoms in patients with WFS1 mutations because they did not worsen deficits in glycemic control.

Title: Characterization of serotonin receptor subtype 2C (5-HT2C) in pain and depression using novel compounds derived from marine cyanobacteria

Authors: *N. C. LAX, C. M. IGNATZ, K. AHMED, K. J. TIDGEWELL, B. J. KOLBER
Duquesne Univ., Pittsburgh, PA

Abstract: Chronic pain and major depressive disorder are widespread conditions in the United States. Interestingly, these conditions often occur comorbidly, with each individual disease amplifying the symptoms of the other. Many medications available on the market today for treating pain or depression target G-protein coupled receptors (GPCRs), implying that this class of receptors may be involved in the development of the comorbidity of these conditions. Our lab has sought to characterize a poorly understood GPCR, the serotonin 2C (5-HT2C) receptor, and the role that it plays in comorbid pain and depression. Our approach for targeting this receptor uses compounds isolated from filamentous marine cyanobacteria collected off of the coast of Panama in the Pacific Ocean. Compounds from this cyanobacterial collection show strong affinity for the 5-HT2C receptor. These compounds were screened for *in vivo* activity using a series of pain and depression behavioral assays. Compounds were delivered in male C57Bl/6J

mice via intra-cerebroventricular (ICV) cannulas. Compounds were tested in naïve mice or in mice subjected to a model of comorbid pain and depression, the Spared Nerve Injury (SNI) surgery. SNI surgery involves ligating two of the three branches of the sciatic nerve, the tibial and common peroneal branches, while leaving the third branch, the sural branch, intact. SNI surgery induces mechanical hypersensitivity in the ipsilateral paw (modeling pain) and also induces depression-like behavior. We have found that ICV injections of the compound isolated from the marine cyanobacterium induce effects in several standard behavioral assays. Our results suggest that the 5-HT2C receptor may be a key target in the future development of compounds used to treat comorbid pain and depression.

Abstract: Neurological diseases are devastating to patients and their families and present significant research and diagnostic challenge. Biomarkers for diagnosis, disease onset, disease progression and therapeutic response are urgently needed to improve diagnostic and clinical outcomes of patients with neurodegenerative diseases such as Parkinson's and Huntington's disease. The mission of the NINDS Repository is to provide genetic support for scientists investigating the pathogenesis of the central and peripheral nervous systems, and accelerate discovery of causes and risks of neurological disease by sharing biomaterials and de-identified clinical data. The NINDS Repository is an integral component in the effort to identify and

validate biomarkers of neurological disorders by the virtue of being a centralized facility for storage, processing, and distribution of biofluids (cerebrospinal fluid, plasma, serum, whole-blood, urine) and nucleic acids (DNA and RNA). To harmonize sample collection across different clinical sites and minimize pre-analytical variables, the NINDS Repository: (i) ensures that samples collected for biomarker discovery are of premier quality by collaboratively establishing unified standards for sample collection; (ii) provides rapid feedback to clinical sites regarding sample appearance and quality; (iii) maintains secure, high quality sample storage conditions with real-time monitoring and recording systems and(iv) performs standardized laboratory processing and quality assurance using validated operating procedures. To further enhance the investigation and discovery of novel biomarkers the NINDS Repository is establishing large, long term longitudinal collections of biological samples obtained from affected and neurologically healthy individuals. Currently the NINDS Repository collects samples under multiple NINDS sponsored biomarker initiatives such as the Parkinson's Disease Biomarkers Program (PDBP), the Frontotemporal Degeneration (FTD) MAPT Carrier (FTD-MAPT) study, the Neurobiological Predictors of Huntington's Disease study (PREDICT-HD), as well as a jointly sponsored study (BioFIND) on Parkinson's Disease in collaboration with the Michael J. Fox Foundation. Thus, the NINDS Repository is a vital resource for research designed to discover and validate biomarkers of neurological disorders. Biomarker discovery samples are available upon request either directly from the NINDS Repository web catalog (http://ccr.coriell.org/NINDS), or via NIH-sponsored resources with links to the online catalog

Title: Oxidation of alternative energy substrates in response to reduced mitochondrial pyruvate transport is experimentally neuroprotective

Authors: A. S. DIVAKARUNI[1], A. Y. ANDREYEV[1], T. P. CIARALDI[2], C. R. GREEN[3], M. WALLACE[3], C. M. METALLO[3], *A. N. MURPHY[4]

Abstract: The persistent lack of effective therapies for chronic forms of neurodegenerative disease reinforces the need to explore novel approaches. To that end, a growing body of data provides a strong rationale for improvement of brain energy metabolism as a general approach. We find that neuronal energy metabolism can be improved through metabolic conditioning, and this conditioning can be achieved through mild inhibition of certain catabolic pathways. Specifically, pharmacologic inhibition of mitochondrial pyruvate uptake can acutely increase plasma membrane glucose uptake and enhance the oxidation of ketone bodies and branched chain amino acids. This alternative substrate oxidation can potentiate metabolic flexibility and resistance to excitotoxic injury of cortical neurons. Addition of beta-hydroxybutyrate +/- leucine to the culture medium provided roughly 25% protection from excitotoxic neuronal death, and inhibition of the pyruvate carrier further increased neuroprotection to about 50%. In experiments with cultured cells using metabolic flux analysis, chronic genetic and pharmacological inhibition of mitochondrial pyruvate uptake potentiates the rewiring of cellular metabolism, increasing glutamine and fatty acid oxidation to meet cellular energetic demands and increasing NAD(P)H production via malic enzyme. The data suggest that mild inhibition of substrate transport or oxidation is experimentally neuroprotective and may be a therapeutic target for the treatment neurodegenerative disease.

Abstract: Multiple Sclerosis (MS) is a chronic inflammatory demyelinating disease of the central nervous system (CNS). The majority of current therapies focus solely on modulating the immune system but do not address remyelination. The endogenous oligodendrocyte progenitor cells (OPC) within the brain are capable of spontaneous remyelination, but despite abundant numbers, eventually this regenerative mechanism also fails. The presence of the endogenous OPC population provides us an opportunity for therapeutic intervention in MS. Stimulation of OPC proliferation and differentiation could enhance long term recovery from MS injury. We have developed a high content screening method to test the capacity of small molecules to induce OPC differentiation using primary OPC cultures from transgenic animals expressing EGFP downstream of the PLP promoter. OPCs treated with T3 showed 2.8 fold increase in EGFP positive differentiated oligodendrocytes compared to DMSO. Densitometric analysis of western blots demonstrated a similar (2.3 fold) increase in PLP protein levels in OPCs treated with T3 when compared to DMSO controls. Furthermore, OPCs treated with T3 demonstrated increased phenotypic differentiation when immunolabled for PLP and MBP demonstrating robust oligodendrocyte differentiation. Together our data demonstrates that the expression of the PLP:EGFP transgene is a valid method to accurately represent the extent of differentiation in our OPC culture system to identify and evaluate new therapeutic molecules for MS.

Title: Targeting extracellular cyclophilin A-mediated neurovascular dysfunction

Authors: *R. D. BELL[1], G. SUIDAN[2], A. CAMERON[2], M. ILARDI[2], N. KABLAOUI[2], K. FONSECA[2]
[1]Neurosci. Res. Unit, Pfizer, Inc, Cambridge, MA; [2]Pfizer, Cambridge, MA

Abstract: The neurovascular unit (NVU) is composed of endothelium, pericytes, vascular smooth muscle cells, perivascular macrophages and glial cells. Cellular communication within the NVU controls blood-brain barrier (BBB) integrity, cerebral blood flow and the chemical composition of the CNS required for proper functioning of neuronal circuits. Importantly, NVU dysfunction has been implicated in many CNS disorders, including Alzheimer's disease, multiple sclerosis, stroke and schizophrenia. Cyclophilin A (CypA), a ubiquitously expressed and abundant cytosolic protein that plays an essential role in the immunosuppressant effect of cyclosporine A has been linked to vascular dysfunction and neurodegeneration. Preclinical data in APOE4 transgenic mice hows that elevated CypA causes significant NVU dysfunction and BBB damage, primarily due to NFκB-MMP9 mediated degradation of basement membrane and tight junction complexes as wellas direct neurovascular cell death. Loss of function of CypA via a conventional genetic knockout strategy or acute treatment with cyclosporine A (CsA) provides a significant degree of protection against APOE4-based neurovascular pathology. Recently, it has been demonstrated that increased extracellular CypA (eCypA) is found in the circulation of patients with vascular diseases, such as hypertension and diabetes, as well as in the cerebrospinal fluid of APOE4 carriers. Moreover, eCypA is actively secreted from vascular and white blood cells during various pathologic conditions and mediates pro-inflammatory signaling cascades. However, the respective contribution of extracellular versus intracellular CypA mediating neurovascular damage remains elusive. Here, we show eCypA is significantly elevated in the plasma and cerebral spinal fluid (CSF) of CD-1 mice following a lipopolysaccharide (LPS)-induced model of systemic inflammation and BBB damage. We then demonstrate that pharmacological inhibition of eCypA using a published cell impermeable CsA analog following LPS administration improves BBB integrity. More specifically, the CSF to plasma albumin quotient as well as fibrinogen extravasation into brain parenchyma are both significantly reduced following eCypA inhibition in LPS-treated mice. In summary, accumulating evidence suggests that inhibition of eCypA may be a novel strategy to improve the neurovascular dysfunction associated with CNS disorders.

Title: Transgenic mice that over-express NAAA in microglia: A tool to understand the role of NAAA in neuroinflammation

Authors: *A. RIBEIRO, S. PONTIS, A. GUIJARRO, D. PIOMELLI
Fondazione Inst. Italiano Di Tecnologia, Genova, Italy

Abstract: N-acylethanolamine acid amidase (NAAA) is a lipid amidase that preferentially hydrolyzes palmitoylethanolamide (PEA), an endogenous PPAR-alpha agonist with marked analgesic, anti-inflammatory and neuro-protective properties. Although the anti-inflammatory effects of PEA have been investigated, the role of NAAA in inflammatory diseases remains unclear. To fill this knowledge gap, we generated a knock-in (ki) mouse with conditional NAAA overexpression in macrophages and microglia. The coding sequence of NAAA isoform 1 was inserted within the Rosa26 locus, under the control of the ubiquitous CAGG promoter. A floxed (loxP flanked) transcriptional STOP cassette was incorporated between the transgene and the CAGG promoter. The resulting model is a NAAA conditional ki heterozygous mouse in which the expression of the transgene is dependent upon Cre recombinase. To achieve NAAA overexpression in microglia and macrophages, ki mice were crossed with CD11b-Cre transgenic mice [B6.Cg-Tg(ITGAM-cre)2781Gkl/Flmg; obtained from the Alexander Fleming Institute (Athens, GC) through the EMMA-European Mouse Mutants Archive]. Mice were genotyped using a downstream of the short homology arm and upstream of the NAAA-pA transgene sequence. For characterization of mice phenotype (n=5) we analyzed NAAA mRNA levels by qRT-PCR in the spinal cord, lungs, spleen, and liver of knock-in mice compared to wild-type (wt) littermates. Additionally, we analyzed NAAA protein expression in the spinal cord of ki by immunohistochemistry. The levels of NAAA mRNA were higher in ki mice than in wt littermates: 1.7-fold increase in the spinal cord, 1.9-fold increase in the lungs, 1.7-fold increase in the spleen, and 3.1-fold increase in the liver. Immunofluorescence analysis showed an increase in NAAA expression in Iba1-positive cells (microglia) in spinal cord of ki mice compared to wt littermates. Moreover, in ki mice it is possible to individualize two morphologically distinct types of Iba1-positive cells: (1) activated-like microglia expressing high levels of NAAA, which show large and ameboid shape; and (2) non-activated microglia expressing lower levels of NAAA with characteristic ramified form. Only the latter cell type is observed in wt littermates.

The generation of a mouse strain over-expressing NAAA in microglia opens new avenues to understand the role of this enzyme in inflammatory diseases of the central nervous system.

Title: Comparative evaluation of target engagement for monoacylglycerol lipase (MAGL) inhibitors and cyclooxygenase (COX) inhibitors: Impact of tandem mass spectrometry (LC-MS/MS) and automated behavioral analysis in mice

Authors: ***C. PORAZIK**[1,2], A. WITTING[2], B. FERGER[1]
[1]CNS Dis. Res., Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany; [2]Dept. of Neurol., Ulm Univ., Ulm, Germany

Abstract: Inhibition of the endocannabinoid metabolism of 2-arachidonoylglycerol (2-AG) by monoacylglycerol lipase (MAGL) has been studied in various animal models to elucidate the role of endocannobinoids (eCB) in disorders such as cancer, pain and neurodegenerative diseases. Newer findings suggest a prominent role for MAGL also in regulation of brain prostaglandin levels. Here, we investigate the effects of the commercially available MAGL inhibitors JZL184, KML29 and MJN110 on target engagement and behavior in comparison to the cyclooxygenase (COX) 1 selective inhibitor SC560, the COX2 selective inhibitors refecoxib and celecoxib and the non-selective COX1/2 inhibitor ibuprofen. We set up and validated a sensitive liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS) method to determine levels of 2-arachidonoylglycerol (2-AG) and anandamide (AEA) as well as arachidonic acid (AA) and prostaglandins (PGs) PGE_2, PGD_2, $PGF_{2\alpha}$ and TXB_2 out of different matrices. Male adult C57BL/6JRj mice were treated with MAGL and COX inhibitors (30 mg/kg) or vehicle. Brains and peripheral organs were removed 60 min after treatment and tissues were processed for LC-MS/MS analysis. Additionally, MAGL and COX inhibitors were analyzed in a separate study to investigate their effects on potential motor behavior impairment using an automated system to quantify rearing behavior and distance travelled in an open field by

interruptions of light beam arrays. The MAGL inhibitors significantly increased 2-AG levels and decreased AA and PGs in the brain and peripheral tissues. COX inhibition reduced PGs but had no effect on 2-AG and AA levels. Notably, SC560 was most effective in reducing PGs levels in the brain. Several compounds of this study showed a time-dependent hypomotility in the motor activity analysis. Interestingly, MJN110 which was very potent in increasing brain 2-AG did not show motor impairment in the behavioral observation test. In conclusion, we set up a reliable LC-MS/MS biomarker method to quantify changes in brain and peripheral tissue in the endocannabinoid and eicosanoid pathway induced by MAGL and COX inhibitors. These changes are indicative for target engagement and will help to elucidate the role of endocannabinoids in neurodegenerative diseases.

Title: CNS102 (trans-geranylgeranyl acetone) protects against kainic acid- induced neurotoxicity in rat through multiple signaling pathways

Authors: *Y. PAN[1], F. ERMINI[1], J. BRIDGEWATER[1], H. LISTER[1], W. G. HAAG[1,2], A. ARGADE[1], H. SERIZAWA[1]
[1]Coyote Pharmaceuticals, Menlo Park, CA; [2]Optim Sci. Corp., San Ramon, CA

Abstract: Mixture of trans- and cis- isomers of geranylgeranyl acetone (GGA), as an established drug product (teprenone) for treatment of ulcer, has been reported as neuroprotective in multiple disease models. Based on the prediction that the trans-isomer is a better conformational fit to the structure of GGA putative target geranylgeranyl transferase I (GGTase I), we purified the trans-GGA (named as CNS102). We then tested CNS102 efficacy in a kainic acid (KA) induced excitotoxicity model in rat. Sub-chronic oral administration of CNS102, at doses dramatically lower than reported for teprenone, significantly reduced CA3 neuronal death at 72 hours after KA challenge in CNS102- vs. vehicle-treated rats, indicating that CNS102 can protect against KA-induced hippocampal injury. We further measured induction of mRNA and protein for multiple heat shock proteins (HSPs) by CNS102 vs. vehicle in hippocampi following KA injury.

Consistent with reports that GGA is a known HSP inducer, we observed differential regulation of HSP family members with CNS102. Protection by CNS102 in our rat models may thus be mediated at least partially through HSP dependent neuroprotective mechanism. Consistently, our *in vitro* mechanistic studies in neuroblastoma 2A (N2A) cells revealed that CNS102 induces the expression of a luciferase reporter driven by i-HSP70 5'-UTR, and increases expression of selective HSPs. Interestingly, we also observed that CNS102 increases Rap1A prenylation and the level of active RhoA; both of these small GTPases have been implicated in modulating neuronal morphogenesis and function. This idea is further supported by our findings that CNS102 can promote the neurite outgrowth of N2A cells. Taken together, our results indicate that CNS102 targets pathways that underlie the etiology of multiple neurodegenerative diseases including Amyotrophic Lateral Sclerosis, and therefore may present itself as an effective drug candidate for therapeutic development.

Title: CNS102, a new drug in development for amyotrophic lateral sclerosis, improves survival and behavior in SOD1 mice

Authors: *F. ERMINI[1], Y. PAN[1], W. G. HAAG[1,2], A. ARGADE[1], H. SERIZAWA[1]
[1]Coyote Pharmaceuticals, Menlo Park, CA; [2]Optim Sci., San Ramon, CA

Abstract: The SOD1(G93A) transgenic mouse is a well-characterized model for familial amyotrophic lateral sclerosis (ALS). Here we evaluate the effects of CNS102, the purified all-trans isomer of geranylgeranyl acetone (GGA), on disease onset, motor behavior and survival in SOD1 mice. Mice were orally administered CNS102 (12 mg/kg), riluzole (8 mg/kg) or vehicle daily starting at P39 and assessed for motoric deficits, body weight and survival. Using a cat walk system for analysis of motor function, CNS102-treated SOD1 mice performed better, demonstrating improved gait, stride length and running speed. In addition, CNS102 significantly improved grip strength and hind leg extension by tail hang assay. Neuroscore analyses showed that the rate of increase was 33% greater in vehicle- vs. CNS102-treated SOD1mice, indicating that progression is delayed with CNS102. Physiologically, CNS102 delayed the loss of body weight vs. vehicle-treated animals, and the difference corresponds to a rate reduction of over 40%. Importantly, survival was prolonged in the CNS102-treated SOD1 mice as compared to those treated with riluzole or vehicle. It is important to note that CNS102 is efficacious at a much lower dose (12 mg/kg) compared to those reported for the mixed isomer GGA (teprenone) in other models of neurodegeneration (i.e. over 600 mg/kg), and chronic dosing (approximately 3 months) with CNS102 revealed no adverse effects in the SOD1 mice and wild type controls. These pre-clinical studies using a low dose CNS102 indicate its potential as a human therapeutic for ALS.

Title: The dimerization state of the human translocator protein (TSPO) is differentially affected by its ligands

Authors: *S. CHUA[1], A. MASEDUNSKA[2], S. BANISTER[3], Y. D. KE[1], P. GUNNING[2], M. KASSIOU[3], L. M. ITTNER*[1]
[1]Dementia Res. Unit (DRU), [2]Dept. of Anat., UNSW, Sydney, Australia; [3]Dept. of Chem., Univ. of Sydney, Sydney, Australia

Abstract: The translocator protein (TSPO) is a 5 transmembrane protein that resides in the outer mitochondrial membrane where it is involved in the regulation of cholesterol transport and neurosteroid synthesis. It has been found to be upregulated in activated microglia and astrocytes in both acute and chronic neuroinflammatory conditions. As such, recent work had focused intensely on developing TSPO as an *in vivo* brain imaging and drug treatment target. The functional form of the TSPO receptor is thought to be a dimer, however, the effects of pharmacological ligands on dimerization remains largely unknown. In this study, ligand effects on complex formation of TSPO and its missense variant, A147T, were studied using co-immunoprecipitation and confocal microscopy in 293T and HeLa cells respectively. Co-immunoprecipitation of co-transfected TSPO and A147T revealed the formation of spontaneous and stable dimers. However, various TSPO ligands had distinctly different effects on the formation of these dimers. It was shown that the diagnostic ligand PK11195, and significantly

more so DPA-714, but not Ro5-4864 disrupted TSPO dimer formation. Whilst the A147T polymorphism had no effect on dimer formation, it greatly enhanced the disruptive effect of PK11195. In addition to the effect of ligands, it was demonstrated that deletion of the cholesterol-recognition amino acid consensus sequence at the extreme carboxyl-terminus of TSPO affects homodimerisation. Hence, it can be concluded that the spontaneous and stable formation of TSPO homodimers is a ligand sensitive process and modulated by specific domains within the protein.

Title: NDC-1308, a gain of function estradiol analog for inducing remyelination in multiple sclerosis patients

Authors: *S. H. NYE, J. G. YARGER
Discovery, ENDECE Neural, LLC, Mequon, WI

Abstract: Several estrogens have advanced to clinical trials, yet they impact only the neuroprotective aspects of multiple sclerosis (MS), rather than the elusive remyelination activity needed to repair the damaged myelin sheath. We previously reported that NDC-1308, an estrogen receptor (ER) agonist, activates known intracellular pathways for oligodendrocyte progenitor cell (OPC) differentiation. Unlike E2, NDC-1308 induces mouse OPCs to differentiate into mature oligodendrocytes *in vitro*. Here, we determined the efficacy of NDC-1308 to repair the damaged myelin sheath in a validated animal model of demyelination. Intended outcomes also include: i) an initial benefit-risk assessment for NDC-1308, ii) determining the dosing parameters for non-clinical IND-enabling studies, and iii) design of the Phase 1 clinical study. NDC-1308 was formulated for injection using an SBE-beta-cyclodextrin and assessed for its ability to induce remyelination in the cuprizone mouse model of demyelination. Male mice were treated for 12-weeks with cuprizone and rapamycin to cause

demyelination of white and gray matter regions of the brain. The demyelinated mice were administered NDC-1308 by intraperitoneal (60 mg/Kg, i.p., q.d) or subcutaneous (15-60 mg/Kg, s.c., b.i.d.) injections for 3 or 6 weeks. Blood was collected at termination for clinical chemistry analysis, along with reproductive tracts for pathology, and brain regions for assessing the level of NDC-1308 remyelination. A 3-week NDC-1308 treatment in cuprizone demyelinated mice resulted in greater than 20% ($P<0.005$) and 16% ($P<0.05$) remyelination of cortical and hippocampal regions, respectively. At 6 weeks of NDC-1308 treatment, remyelination in hippocampal regions increased to 30% ($P<0.0001$). However, E2 did not induce remyelination. Thus, NDC-1308 has apparently retained several qualities of E2, while gaining the important ability to induce remyelination of axons *in vivo*. All animals tolerated the chronic NDC-1308 treatments well. Observed animal behavior and clinical chemistries were normal, and there was no evidence of aberrant mammary tissue. These results suggest there could be a significant benefit for treating MS patients with NDC-1308. Non-clinical IND-enabling studies and a first-in-human Phase 1 study are planned for 2015.

Title: The Nrf2 transcriptional target, OSGIN1, contributes to the cytoprotective properties of monomethyl fumarate

Authors: ***M. S. BRENNAN**[1], M. F. MATOS[2], C. SUN[2], S. SZAK[2], R. H. SCANNEVIN[2]
[1]Neurobio., Biogen Idec and Boston Univ., Cambridge, MA; [2]Neurobio., Biogen Idec, Cambridge, MA

Abstract: **Background**. Delayed-release dimethyl fumarate (DMF) is an oral therapeutic marketed for the treatment of multiple sclerosis (MS); however the detailed mechanisms that underlie the immunomodulatory and cytoprotective properties of DMF are not well understood. Previous data supports activation of the nuclear factor (erythroid-derived 2)-like 2 (Nrf2) pathway as a primary pharmacodynamic response to DMF or monomethyl fumarate (MMF, the primary metabolite of DMF) treatment and these responses may be differentially regulated in distinct cell types. In the central nervous system (CNS), we have identified the Nrf2 transcriptional target gene OSGIN1 to be significantly upregulated following DMF treatment *in vivo*; however, the contribution of this gene to the pharmacodynamic properties of DMF or MMF has not been previously described. **Objective**. To characterize the *in vitro* effects of MMF on OSGIN1 expression, and evaluate the necessity of OSGIN1 in mediating cytoprotective effects against toxic oxidative stress. **Methods.** Primary human astrocyte cultures were transfected with siRNA targeted against OSGIN1 or Nrf2 and treated with MMF, followed by toxic oxidative challenge with hydrogen peroxide. Cell viability was measured after treatment/insult and RT-PCR was conducted to determine transcriptional levels of OSGIN1, as well as the OSGIN1 associated genes PADI4 and p53. The potential involvement of PADI4 and p53 in MMF-mediated cytoprotection was also analyzed via siRNA knockdown. Furthermore, we analyzed the importance of OSGIN1 and its associated genes on cell proliferation since OSGIN1 has been previously identified as a regulator of the cell cycle. **Results.** siRNA knockdown of OSGIN1 significantly reduced the ability of MMF to protect human astrocytes against a toxic oxidative stress, and abrogated the MMF-induced increase in PADI4 expression levels. Additionally, the loss of PADI4 and p53 via siRNA knockdown also reduced the cytoprotective effects of MMF in human astrocytes against oxidative stress. **Conclusions**. These data support a role for the Nrf2 transcriptional target, OSGIN1, as an important mediator of cytoprotection in the CNS following DMF/MMF administration. Furthermore, these data identify a potential mechanism for DMF/MMF-mediated cytoprotection in human astrocytes that functions in an Nrf2-dependent manner.

Title: Preventing neurodegeneration by inhibiting the correct HDACs: Molecular and pharmacological strategies

Authors: *M. BOURASSA, R. R. RATAN
Burke-Cornell Med. Res. Inst., White Plains, NY

Abstract: Histone deacetylase inhibitors have demonstrated significant potential as therapeutics for a wide variety of neurological conditions, including stroke and Alzheimer's disease. By inhibiting HDACs, the deacetylation of histones is blocked, allowing acetylated regions of the genome to remain transcriptionally active. HDAC inhibitors have the significant advantage over other potential drugs in their ability to promote the transcription of a large cassette of neuroprotective genes. By studying them in detail, we can optimize their protective and restorative properties and reduce or eliminate their side effects. As HDAC inhibitors neuroprotective in an *in vitro* model of oxidative stress affect Class I HDACs (HDAC1, 2, 3 and 8), we have endeavored to identify which Class I HDAC(s) accounts for this neuroprotection. We have found that HDAC2 knock down is neuroprotective in the glutathione depletion model of oxidative stress. Thus we are testing the effects of HDAC2 knock down in neuroprotection in a mouse model ischemic stroke. By using the HDAC inhibitor Scriptaid, which inhibits several HDACs, including HDAC2 we also are investigating a genetic biomarker of neuroprotection to improve *in vivo* testing of HDAC inhibitors. As HDAC inhibitors alter the expression of a large number of genes, there are many potential biomarkers that could be used to identify the most neuroprotective dose. With the results from these experiments we hope to significantly expand our knowledge of how HDAC inhibitors protect neurons and how to optimize the most protective doses using biomarkers. In the future, this information will aid in the design of better HDAC inhibitors that could be used as even more effective drug treatments for a host of neurological conditions.

Title: UCB0255, a new and selective synaptic vesicle protein 2A (SV2A) ligand with promising efficacy for cognitive deficits

Authors: *E. R. DETRAIT, E. JNOFF, F. BROUTA, K. LECLERCQ, E. JIGOREL, M. WOOD, M. GILLARD, H. KLITGAARD, A. MATAGNE, Y. LAMBERTY, B. KENDA, L. PROVINS
UCB Biopharma, Braine-L' Alleud, Belgium

Abstract: SV2A is a family member of synaptic vesicle proteins, involved in the control of neurotransmitters exocytosis end endocytosis. SV2A knock down triggers spontaneous seizures and the antiepileptic SV2A ligand, levetiracetam, reduces neurotransmitters release, thereby acting as a positive SV2A modulator. We report here a new class of negative SV2A modulators that appear to constitute a promising new medication to improve cognitive deficits. Among these, UCB0255 was identified as a preclinical candidate for further drug development. UCB0255 displays high selectivity and affinity (p*K*i=7.9) for SV2A but is devoid of antiepileptic properties. In contrast, UCB0255 opposes seizure protection afforded by levetiracetam in the audiogenic mouse seizure model, differentiating it from anticonvulsant SV2A ligands. UCB0255 displayed pro-cognitive activity in a variety of tests and challenges that may be relevant to cognitive disorders observed in neuropsychiatric conditions. UCB0255 showed efficacy in mice against beta-amyloid$_{(25-35)}$-induced deficit in working memory, long-term contextual memory and spatial reference memory. Using the object recognition paradigm in rats, UCB0255 was able to alleviate 24h delay-dependent forgetting of a familiar object, following administration before or after the acquisition trial, and counteracted scopolamine and subchronic phencyclidine-induced recognition memory deficits. The activity brought performance back to control level in most tests and the active doses ranged from 0.03 to 3 mg/kg across all tests/models, which corresponds to SV2A occupancy ranging from 5 to 90%. UCB0255 displays drug-like properties with a promising PK profile including good oral bioavailability in rat, and a wide safety margin of multiples of pharmacologically active doses in 4-week rat and 2-week dog toxicity studies as well as a favorable preliminary developability assessment. UCB0255 is a selective and high affinity SV2A negative modulator. Its new mechanism associated with pro-cognitive properties holds promise for the treatment of cognitive deficits associated with neurological and neuropsychiatric disorders.

Title: Ameliorating the CNS Niemann-Pick type C phenotype by modulating Wnt signaling

Authors: *A. G. EFTHYMIOU[1], J. STEINER[2], M. S. RAO[2], N. MALIK[2]
[1]USUHS, Bethesda, MD; [2]NIH, Bethesda, MD

Abstract: Niemann-Pick type C (NPC) is a familial disorder that has devastating consequences on early development with multisystem effects. The disease involves neurodegeneration of the central nervous system that cannot be cured or modified through therapeutic treatment. Several drugs to treat this disorder have been identified in assays using rodent models and human fibroblasts from NPC patients, which are functionally different from the neural cells that express the neurodegenerative effects of NPC. In an effort to generate a more relevant cellular model for Niemann-Pick type C we generated an iPSC line from an NPC patient fibroblast sample and subsequently differentiated these cells to neural stem cells, neurons, and astrocytes. Few differences were seen at the neural stem cell stage by whole transcriptome array analysis, with no visible cholesterol accumulation or lysosomal abnormalities. Gene expression analysis indicated that Niemann-Pick type C iPSC-derived neurons displayed abnormal calcium signaling, suggesting that alterations in this pathway may underlie the phenotype. Candidate drugs including dantrolene and curcumin could rescue consistent specific loss of cortical neurons differentiated in culture from NPC neural stem cells. Further examination of the gene expression profiles of the cells revealed that Wnt signaling and ryanodine receptor expression were significantly altered. Our data suggest that altered Wnt signaling may be an important early event

in the etiology of the disease and that modulating Wnt or calcium signaling may be important even at early stages of Niemann-Pick type C.

Title: Systemic neonatal lipopolysaccharide-induced brain injury can be ameliorated by melatonin

Authors: ***L.-T. TIEN**[1], Y.-J. LEE[1], L.-W. FAN[2]
[1]Fu Jen Catholic Univ., Xingzhuang Dist., New Taipei City, Taiwan; [2]Dept. of Pediatrics, Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Our previous study showed that lipopolysaccharide (LPS)-induced brain injury in the neonatal rat is associated with nitrosative and oxidative stress. The present study was conducted to examine whether melatonin, an endogenous molecule with antioxidant properties, reduces systemic LPS-induced nitrosative and oxidative damage in the neonatal rat brain. Intraperitoneal (i.p.) injection of LPS (2 mg/kg) was administered to Sprague-Dawley rat pups on postnatal day 5 (P5), and i.p. administration of melatonin (20 mg/kg) or vehicle was performed 5 minutes after LPS injection. Sensorimotor behavioral tests were performed 24 h after LPS exposure, and brain injury was examined after these tests. The results show that systemic LPS exposure resulted in impaired sensorimotor behavioral performance, and acute brain injury, as indicated by the loss of oligodendrocyte immunoreactivity and a decrease in mitochondrial activity in the neonatal rat brain. Melatonin treatment significantly reduced LPS-induced neurobehavioral disturbances and brain damage in neonatal rats. The neuroprotective effect of melatonin was associated with attenuation of LPS-induced nitrosative and oxidative stress, as indicated by the decreased nitrotyrosine- and 4-hydroxynonenal-positive staining in the brain following melatonin and LPS exposure in neonatal rats. Further, melatonin significantly attenuated LPS-induced increases in

the number of activated microglia in the neonatal rat brain. The protection provided by melatonin was also associated with a reduced number of inducible nitric oxide synthase (iNOS)+ cells, which were double-labeled with ED1 (microglia). Our results show that melatonin prevents the brain injury and neurobehavioral disturbances induced by systemic LPS exposure in neonatal rats, and its neuroprotective effects are associated with its impact on nitrosative and oxidative stress.

Title: Investigations of the dose-dependent effects of the PDE10A inhibitor PF-2545920 on primate regional cerebral glucose metabolism in the resting state

Authors: *G. V. WILLIAMS[1,2], D. W. CAMPBELL[1,2], C. J. SCHMIDT[3], M. M. ZALESKA[3], C. M. SANDIEGO[1], R. E. CARSON[4], S. A. CASTNER[1,2]
[1]Psychiatry, Yale Univ. Sch. of Med., NEW HAVEN, CT; [2]VA Connecticut Healthcare Syst, West Haven, CT; [3]Neurosci Res. Unit, Pfizer Global Res. and Develop., Cambridge, MA; [4]Diagnos. Radiology, Yale Sch. of Med., New Haven, CT

Abstract: Phosphodiesterase (PDE) inhibitors alter neuronal function in particular brain regions by modulating cyclic nucleotide signaling. PDE10 is found almost exclusively in striatum and is linked to both cAMP and cGMP. While little is known of the role of PDE10 in cognition, there is interest in the use of PDE10 inhibitors as antipsychotics and cognitive enhancers for neurological disorders. Recently, we demonstrated that the dose-dependent effects of the AMPA potentiator PF-04958242 on [18F]fluorodeoxyglucose (FDG) uptake tested under normal conditions predicts its dose-dependent ability to prevent the disruption of cognition by ketamine. Here, we have investigated whether the dose-dependent effects of the PDE10A inhibitor PF-2545920 on glucose metabolism in the resting state might also reveal its potential to enhance frontostriatal function. A group of 8 animals were administered PF-2545920 (0.067 and 0.2 mg/kg, SC) or vehicle 2 hrs prior to FDG injection (~5 mCi, IV). FDG was administered when the animals were

sitting in the resting state where they remained for 20 - 25 min. They were then anesthetized with propofol and positioned in a microPET Focus 220 scanner where a 9 min transmission scan was acquired first, followed by a 20 min emission scan, commencing 60 - 75 min post-FDG injection. A nonlinear group template constructed from MRIs was used to spatially normalize the PET images prior to statistical parametric mapping (SPM). Univariate analysis revealed significant dose-dependent effects on metabolism, some of which survived multiple comparisons. In comparison to vehicle, PF-2545920 at 0.067 mg/kg induced elevations in metabolism in L. anterior cingulate (ACC) and lateral orbital cortices, as well as L. middle and superior temporal gyri. Conversely, this dose reduced metabolism in L. occipital gyrus as well as R. hippocampus/presubiculum, medial GPi, thalamus, motor cortex, and cerebellum. PF-2545920 at 0.2 mg/kg altered this pattern of influence, elevating activity in L. dorsal arcuate sulcus/dorsolateral prefrontal (dlPFC), infralimbic, and lateral orbital cortices, lateral amygdala n., ACC, hippocampus, cuneus and body of caudate n. as well as R. dlPFC and posterior cingulate cortex. This higher dose also suppressed activity in L. occipital gyrus, anterior ventromedial caudate n. and putamen, as well as R. thalamus, parietal cortex and cerebellum. These results were consistent with those derived from covariance with plasma exposure. These findings indicate that this PDE10A inhibitor not only influences corticostriatal and extrapyramidal circuitry but also modulates activity in a wider circuitry involved in cognition.

Title: The protective role of vitamin C against Alzheimer's disease

Authors: *S. DIXIT[1], F. E. HARRISON[2]
[1]Neuroscince, [2]Dept. of Med., Vanderbilt Univ., Nashville, TN

Abstract: Neurodegenerative diseases, such as Alzheimer's disease, involve high levels of oxidative stress. Vitamin C (VC) is a vital antioxidant molecule hypothesized to protect against the oxidative damage associated with Alzheimer's disease pathology. In fact, the highest concentrations of VC in the body are found in the brain, suggesting an important role of VC in neuronal health. VC is transported into the brain via the high-affinity Sodium-dependent Vitamin C Transporter-2 (SVCT2), which causes accumulation of VC in neurons against the concentration gradient. We hypothesize that an increased concentration of VC in neurons, via over expression of SVCT2, will provide greater protection against Alzheimer's disease. Primary cortical neuron cultures were established from wild-type mouse embryos and embryos transgenically modified to overexpress SVCT2 (SVCT2-Tg). Cell viability was measured using MTT assays following challenge with increasing concentrations of hydrogen peroxide to mimic increasing oxidative stress in these cultures. SVCT2-Tg cultures showed significantly greater viability across all doses when compared to wild-type cultures. Similarly, a trend toward greater viability of SVCT2-Tg cultures compared to wild-type cultures was detected when challenged with amyloid beta (1-42), the protein responsible for plaque formation characteristic of Alzheimer's disease. Taken together, these data suggest that VC has a protective function against oxidative stress associated with Alzheimer's disease.

Title: Effect of the nicotinic α4β2-receptor partial agonist varenicline on non-invasive brain stimulation-induced neuroplasticity in the human motor cortex

Authors: *M. A. NITSCHE[1], M.-F. KUO[1], W. PAULUS[2], J. GRUNDEY[2], G. BATSIKADZE[2]
[1]Georg-august-University, Goettingen, Germany; [2]Georg-August-University, Goettingen, Germany

Abstract: Nicotine alters cognitive functions in animals and humans most likely by modification of brain plasticity. In the human brain, it alters plasticity induced by transcranial direct current stimulation (tDCS) and paired associative stimulation (PAS), probably by interference with calcium-dependent modulation of the glutamatergic system. We aimed to test this hypothesis further by exploring the impact of the α4β2-nicotinic receptor partial agonist varenicline on focal and non-focal plasticity, induced by PAS and tDCS, respectively. We administered low (0.1mg), medium (0.3mg) and high (1.0mg) single doses of varenicline or placebo medication before PAS or tDCS on the left motor cortex of 25 healthy non-smokers. Corticospinal excitability was monitored by single-pulse transcranial magnetic stimulation (TMS)-induced motor evoked potential (MEP) amplitudes up to 36 hours after plasticity induction. Whereas low-dose varenicline had no impact on stimulation-induced neuroplasticity, medium-dose abolished tDCS-induced facilitatory after-effects, favoring focal excitatory plasticity. High-dose application preserved cathodal tDCS-induced excitability diminution and focal excitatory PAS-induced facilitatory plasticity, but abolished anodal tDCS- and inhibitory PAS-induced excitability alterations. These results are comparable to the impact of nicotine receptor activation and might help to further explain the involvement of specific receptor subtypes in the nicotinic impact on neuroplasticity and cognitive functions in healthy subjects and patients with neuropsychiatric diseases.

Title: Lithium reduced hippocampal progenitor cell death, inflammation, central hypothyroidism and cognitive dysfunction after irradiation to the young rat brain

Authors: *C. ZHU[1], K. ZHOU[2], C. XIE[2], Y. ZHANG[3], T. LI[3], Y. SUN[2], Y. XU[4], K. BLOMGREN[5]
[1]Ctr. For Brain Repair & Rehabilitation, Univ. of Gothenburg, Goteborg, Sweden; [2]Ctr. for Brain Repair & Rehabilitation, Univ. of Gothenburg, Goteborg, Sweden; [3]Zhengzhou Children's Hosp., Zhengzhou, China; [4]Zhengzhou Univ., Zhengzhou, China; [5]Karolinska Inst., Stockholm, Sweden

Abstract: Background: There is growing evidence that lithium (Li) is protective in a variety of brain injury paradigms. Cranial radiotherapy in children usually results in cognitive as well as pituitary dysfunction. Objective: Our aim was to evaluate the short- and long-term effects of Li in the immature brain after irradiation (IR). Design/Methods: Male Wistar rats were injected with 2 mmol/kg LiCl i.p. on postnatal day 7 (P7) and additional lithium injections, 1 mmol/kg, were administered at 24 h intervals for up to 14 days (until P20). On P11 the whole brain received a single IR dose of 6 Gy. Blood samples were collected from the tail vein 1, 3, and 5 weeks after IR. Results: Body weight gain was identical in all groups from P7 until P25. After P25 growth rate increased, but irradiated rats now followed a lower growth trajectory. Li did not affect growth rate, neither in controls, nor in irradiated rats. Serum creatinine was not different in Li-treated rats at any age. IR-induced progenitor cell death in the subgranular zone of the hippocampus was reduced by Li treatment. IR-induced inflammation, as judged by the levels of CCL2 (MCP-1), IL-1α, IL-1β, and GRO/KC in the hippocampus 6 h after IR, was reduced by Li. Neurogenesis was reduced by IR, but increased by Li, both in control rats and after IR. Astrogenesis was also reduced by IR, but rescued by Li treatment. Thyroid-Stimulating Hormone (TSH) tripled when the growth rate increased. The normal, growth-related TSH increase was abolished in irradiated rats, but Li treatment restored TSH levels and thereby prevented the central hypothyroidism that otherwise would have developed. Novel object recognition was used to test memory and learning. Recognition index at P60 was reduced 50% by IR, but normalized by Li treatment. In an open field test at P60, the distance moved was decreased and time spent in the open zone was increased after IR, but again normalized by Li treatment. Conclusion: Together, these results demonstrate that Li can be safely administered to young rats during the

second and third weeks of life and prevent both short- and long-term damage to the brain caused by ionizing radiation.

Title: Treatment with Nymphaea lotus lowers blood pressure, anxiety and improves erectile function in L-Name rats

Authors: ***M. P. KAMENI**, D. D. P. DZEUFIET, P. KAMTCHOUING, T. DIMO
Animal Biol. and Physiol., Univ. of Yaounde 1, Yaounde, Cameroon

Abstract: Background: Erectile dysfunction (ED) is a common, multifactorial disorder that is associated with aging and a range of organic and psychogenic conditions, including hypertension, hypercholesterolemia, diabetes mellitus, cardiovascular disease, and depression and/or anxiety. Aim: To clarify the relation between erectile dysfunction hypertension and anxiety; we evaluated the effects of a chronic oral treatment with L-NAME separately or concomitantly with Losartan or aqueous extract of Nymphaea lotus flowers, on blood pressure and cardiac frequency levels, on anxiety with an elevated alley (Suok test) and on standard patterning of sexual behaviour of male rats. Methods and results: L-NAME (10 mg/kg) only and Losartan (10 mg/kg) were used as negative and positive control respectively. Thirty days lasting treatment with L-NAME increased anxiety and distressed sexual behaviour parameters of sexually experimented adult male rats. Moreover the ejaculatory rate was hit harder by L-NAME than motivation and copulatory patterning. After 30 days withdrawal of L-NAME treatment, the sexual response and anxiety-elevated factors, were recovered. The extract of N. lotus at the doses of 75 and 200 mg/kg were able to reverse partially or totally the inhibitory effects of L-NAME, suggesting that the chronic oral treatment with L-NAME induces erectile and ejaculatory dysfunctions by peripheral mechanisms. Conclusion: Its earlier investigated anti-stress properties is considered to supplement the stimulation of sexual activity as stimulants/anti-depressants have associated effects such as improving libido, erection, ejaculation time and orgasm. The results obtained also suggest that chronic oral treatment with NO synthase inhibitor is a relevant and

powerful model to evaluate the effects of drugs on male sexual disorders in male rats. Keywords: Nymphaea lotus, sexual disorders, anxiety, blood pressure, L-NAME.

Abstract: Abstract: Background The number of patients suffering from diabetes mellitus (DM) is increasing and cerebral infarct is often associated with DM. Recent studies revealed that glucagon-like peptide-1 (GLP-1) exerted neuroprotective effects. In this study, we investigated whether liraglutide, a GLP-1 analogue, exerts therapeutic effects on cerebral infarct models of rats. Methods Transient middle cerebral artery occlusion was performed for Wistar rats. At 1 hour after reperfusion, liraglutide or saline was intraperitoneally administered. Behavioral test was performed at 1 and 24 hours. Rats were subsequently euthanized for histological evaluation. Peripheral blood was taken for measurement of blood glucose level and evaluation of oxidative stress. Brain tissues were collected to measure the level of vascular endothelial growth factor (VEGF). Results Liraglutide-treated rats significantly preserved motor functions, compared with control rats. Infarct volumes of liraglutide-treated rats decreased, compared with those of control rats. The level of derivatives of reactive oxygen metabolite reduced in liraglutide-treated rats. VEGF level of liraglutide-treated rats in the cerebral cortex was significantly upregulated, compared to that of control rats. Conclusions Liraglutide exerted neuroprotective effects on cerebral infarct model of rats through anti-oxidative effects and VEGF upregulation. Keywords: cerebral infarct; diabetes mellitus; liraglutide; oxidative stress; VEGF

Title: Gentamicin improves survival and outcome after experimental subarachnoid hemorrhage

Authors: R. LISEK[1], V. FRIEDRICH[2], M. G. BAXTER[2], J. B. BEDERSON[1], *F. A. SEHBA[1]
[1]Neurosurg., [2]Neurosci., Mount Sinai Sch. of Med., NEW YORK, NY

Abstract: Aneurysmal subarachnoid hemorrhage (SAH) is a medical emergency that requires prompt diagnosis and therapeutic intervention. Almost 12% of patients die before receiving medical attention, 33% within the first 48 hours and up to 50% within the first 30 days. The mechanisms leading to early death after SAH are not understood; as a result no specific therapy or strategy to reduce early mortality currently exists. During our ongoing experimental studies on acute phase injury in rat after SAH, we found that gentamicin treatment improves survival after SAH. Since those studies examined a single dose we then studied gentamicin efficacy at varied doses, using 30 day survival and behavioral status. Animals received a single dose of gentamicin (8, 16 or 32 mg/Kg) or saline 3 hours after the surgery (n=11-14 per dose group). Dose assignment was randomized and the investigator was blinded to dose. Animal survival studied at 7 and 30 day after SAH by Kaplan-Meier curve and animal outcome was measured as changes in general behavior, cognition and neurological status compared to saline injected animal. Survival at 7 days was 36% in saline and 58%, 71% and 66 % in 8, 16 and 32 mg/kg gentamicin groups, respectively. Survival at 30 days post-SAH was 9% in saline, and 58, 26 and 48% in 8, 16 and 32 mg/Kg gentamicin group, respectively. Behavioral status in gentamicin treated groups was not significantly improved over the saline controls. These results show that gentamicin extends animal survival post SAH and this effect is not dose dependent over the range tested. The data suggest that, while gentamicin treatment may not improve behavioral status, but it does not worsen it. Gentamicin is currently not used to improve acute phase survival and neurological

outcome after SAH, nor is any other agent administered clinically for this purpose. This preclinical translational study explores the possibility of developing gentamicin treatment protocols to improve survival in the first days after SAH.

Title: Neural detection of signals in noise

Authors: *K. M. SCHRODE[1], M. A. BEE[2]
[1]Grad. Program in Neurosci, Univ. of Minnesota, St Paul, MN; [2]Dept of Ecology, Evolution, and Behavior, Univ. of Minnesota, Saint Paul, MN

Abstract: Acoustic communication in social groups in difficult because intense background noise levels dramatically reduce the signal to noise ratio. Often listeners perform better when the amplitude of the background noise fluctuates over time. It is typically thought that this improvement is due to catching “acoustic glimpses” during dips in the noise level. This exploitation of increased signal to noise ratio is known as dip listening. Recently, it was discovered that females of Cope’s gray treefrog (Hyla chrysoscelis), but not the green treefrog (H. cinerea), showed better detection of a conspecific communication signal (or call) in noise when there were temporal fluctuations imposed on the noise. While these results suggested that gray treefrogs may have been using a dip listening mechanism, we cannot rule out stochastic resonance from the temporal fluctuations in the noise as an alternative possible mechanism. To test which mechanism frogs were using, we performed neural recordings from the auditory midbrain while presenting conspecific calls in the presence of sinusoidally amplitude-modulated noise. We manipulated the timing of calls such that they were either centered in a dip or at a peak of the background noise and used signal detection theory to calculate thresholds for detection. Detection thresholds were compared under these manipulations and between species to identify

potential species-differences in the mechanisms underlying exploitation of temporal fluctuations in noise.

Title: Critical period hearing loss disrupts subsequent amplitude modulation detection

Authors: *M. L. CARAS, D. H. SANES
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Transient bouts of pediatric hearing loss increase the risk for disrupted speech and language processing. Though these deficits can persist for years after normal auditory input is restored, their neural and perceptual bases are poorly understood. We addressed this issue in an established model of human auditory processing, the Mongolian gerbil, by inducing moderate, reversible hearing loss in developing pups via bilateral earplug insertion. After restoration of normal auditory input via earplug removal, gerbils were trained and tested on an amplitude modulation (AM) detection task. AM cues are necessary and sufficient for speech comprehension, and AM detection capabilities display a prolonged maturational time course in both gerbils and humans. Here, we report that auditory deprivation from the age of ear canal opening (postnatal day (P)11) to P23 elevates AM detection thresholds compared to control littermates, whereas earplugging at a later time point (P23-35) produces no behavioral impairment. Chronic multi-unit recordings from auditory cortex of freely moving animals engaged in the AM detection task will reveal whether AM detection deficits can be explained by impaired sensory coding. Together, our findings suggest that there is a critical period of development during which the maturation of AM perception is vulnerable to hearing loss and may help to explain speech and language delays associated with temporary hearing loss in children.

Title: Effects of noise-induced tinnitus on frequency discrimination acuity in mice

Authors: L. MWILAMBWE-TSHILOBO, A. J. O. DAVIS, *M. N. GEFFEN
Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: The goal of the present study is to characterize the effects of noise-induced tinnitus on auditory processing. Tinnitus is a subjective phenomenon in which affected individuals perceive a phantom sound (e.g. ringing, buzzing) in the absence of any external acoustic stimulation. A variety of animal models have been developed over the years in order to elucidate the neural mechanisms which underlie this complex auditory disorder. While it has been shown that induction of tinnitus leads to a selective decrease in gap detection in the frequency bands of the ringing sound, whether auditory discrimination is affected in those bands is less understood. Here, we induced tinnitus in mice by prolonged exposure to loud band-pass limited noise, and assayed whether mice exhibited a change in frequency discrimination acuity. We used the acoustic-startle reflex model to assess frequency discrimination (Clause et al. 2011). Tinnitus was induced in mice during a 1 hour exposure to a 10 kHz 120 db SPL tone, and assessed using a gap detection paradigm (Turner et al., 2006). We measured the frequency discrimination threshold for a set of high and low frequency tones embedded within a 22 kHz and 12 kHz background tone respectively prior to noise exposure and at 1, 4, and 8 weeks post-exposure. Tone-exposed mice that demonstrated robust gap detection deficits exhibited an increase in high-tone frequency discrimination threshold. This increase was sustained at 8 week post-exposure. Interestingly, although the low frequency bands were less severely affected during gap detection, frequency discrimination threshold for low tones also increased. These findings reveal that the

induction of tinnitus in the higher frequency bands adversely effects overall frequency discrimination, and suggests that tinnitus adversely affects auditory processing.

Title: Aldosterone augments prepulse inhibition but not startle amplitude in middle-aged cba/caj mice

Authors: *J. D. HALONEN[1,2,3], A. HINTON[1,2], X. ZHU[4], A. LOWE[4], J. WALTON[2]
[1]CSD, Global Ctr. For Hearing and Speech Res., TAMPA, FL; [2]Communication Sci. & Disorders, Univ. of South Florida, Tampa, FL; [3]Psychology, Univ. of Tampa, Tampa, FL; [4]Chem. & Biomed. Engin., Univ. of South Florida, TAMPA, FL

Abstract: The mineralocorticoid aldosterone (ALD) is released from the adrenal cortex and regulates Na^+ and K^+ flow across cell membranes. Previous research has demonstrated in aged humans that ALD serum levels correlate significantly with pure-tone thresholds, with higher serum ALD levels associated with better hearing. Furthermore, ALD treatment has been shown to significantly improve cochlear function, as measured by the auditory brainstem response, in autoimmune deficient mice. This experiment was designed to investigate if ALD treatment improves behavioral measures of hearing using prepulse inhibition (PPI) of the acoustic startle response (ASR). Middle-aged (15-17 mon.) CBA/CaJ mice were randomly assigned to 2 groups, either placebo or treatment, 1.67 µg per day of D-aldosterone, administered via extended release pellets implanted subcutaneously. The ASR was measured using standard methods and stimuli were presented through speakers located 30 cm directly above the transducer platform. ASR input-output functions were collected by presenting the wideband startle elicitor at intensities ranging from 55-115 dB, in 10 dB increments. Approximately 30 minutes after startle testing, noise PPI testing occurred. Pre-pulse stimuli were presented at 20, 40, 55, and 75 dB SPL, which terminate 30 ms prior to the wideband startle elicitor. Baseline tests were followed by tests at 4, 6, 10, and 16 weeks post hormone pellet treatment. No significant differences were found in the

startle input-output functions at any testing point. However, significant differences at 4, 6, 10 and 16 weeks post treatment were found. ALD treated animals were found to have greater PPI as compared to the control group at 40 dB at 4 weeks and 20, 40, and 55 dB at every test after. The increase in PPI indicates increased salience for low level noise signals and supports the hypothesis that ALD improves hearing sensitivity. These results are the first we are aware of to demonstrate a behavioral effect on prepulse inhibition in CBA/CaJ mice treated with aldosterone. The importance of this behavioral assay ties together our previous *in vitro* work showing the upregulation of a key Na^+-K^+ pump, NKCC1, in the lateral wall of the cochlea following ALD treatment as a possible mechanism to prevent age-related hearing loss . Title: Aldosterone modulates both simple and complex auditory processing in the auditory midbrain of aging CBA mice

Authors: E. J. BRECHT[1,2], X. ZHU[1,2], R. D. FRISINA[1,2], *J. P. WALTON[1,2,3]
[1]Global Ctr. for Hearing & Speech Res., [2]Chem. & Biomed. Engin., [3]Communication Sci. & Disorders, Univ. South Florida, Tampa, FL

Abstract: Aldosterone (ALD) is a mineralocorticoid hormone secreted by the adrenal cortex which plays a primary role in controlling sodium (Na+) and potassium (K+) serum levels within the peripheral and central auditory system. It has been shown that serum ALD levels decline with age in humans and other mammals. Deficiencies or imbalances between Na+/K+-ATPase, K+ channels and Na-K-Cl cotransporter in the cochlea have also been observed to cause morphological and functional changes on cells downstream in the K+ recycling pathway, leading subsequently to hearing loss. A causative role for ALD in age-related hearing loss has yet to be demonstrated; however our group discovered a link between low serum ALD and severity of

presbycusis in elderly humans. While extensive work has been conducted exploring the effects of ALD within the peripheral auditory system, the effects of ALD treatment on the central auditory system have yet to be investigated. The goal of this study was to assess the long-term therapeutic effect of ALD treatment on neural processing of inferior colliculus (IC) auditory midbrain neurons in aged mice. We investigated the effects of ALD treatment (1.67 μg per day via a 120 day slow release, subcutaneous pellet) on the receptive fields (RFs) and the temporal processing abilities of IC neurons in age-paired control and treated mice. Multi-unit activity was assessed via analysis of the changes in RFs based on the minimum response threshold (MT) and width of tuning (Q10 & Q40), with the tonotopic axis divided into low, mid and high frequency regions. Temporal processing was measured using a gap-in-noise signal from which minimum gap thresholds were derived. Following ALD treatment, a significant positive effect for both RFs and temporal processing was observed, as well as a significant improvement in mean MTs of 11, 14 and 17 dB for the three frequency regions, respectively. Tuning was also affected by ALD treatment, evident by a broadening of RFs for Q10 for all regions and Q40 values for high BFs. There was no effect of treatment on the proportion of response types observed. These results suggest that ALD alters RF properties, with improvements in absolute sensitivity, and temporal processing abilities of IC neurons in aging CBA mice. Changes in MCR expression and function may be a contributing factor to central auditory processing deficits found in aged listeners. Furthermore, these results are the first to indicate a role of MCR in neural correlates of temporal processing. The results point to a potential target for future therapeutic interventions to prevent or slow down the progression of age-related hearing loss.

Title: The aftermath of hormone replacement therapy in CBA/CaJ middle age female mice

Authors: *T. WILLIAMSON[1], X. ZHU[2], J. P. WALTON[3], R. D. FRISINA[2]
[1]Global Ctr. For Hearing and Speech Res., Tampa, FL; [2]Chem. and Biomed. Engin., [3]Communication Sci. and Disorders, Univ. of South Florida, Tampa, FL

Abstract: Hormone replacement treatment (HRT- with estradiol (E) and progestin (P)) has been used extensively to reduce menopausal symptoms in aging women sometimes with serious side effects. Previous findings have suggested that estrogen plays a vital role in preserving the cochlea, including hair cell function (Al-Mana et al., Neurosci. 153: 881-900, 2008). Meanwhile, progesterone has been thought to be very detrimental to the ear and the central auditory system (Price et al., Hear. Res. 252: 29-36, 2009). These findings were obtained during the time HRT was administered. Therefore, the end-result that these hormones have on the auditory system, i.e. effects of a recovery period, remains unclear. So, a primary motivation for the following investigation was to examine the recovery period after HRT was performed to see if hearing improved, worsened, or remained the same. Ovariectomized middle-aged female CBA mice were placed into 4 groups based upon treatment: E, P, E+P and placebo (Pb) via slow-release subcutaneous hormone pellets. All of the mice underwent Auditory Brainstem Response (ABR) Gap-in-noise (GIN) testing, longitudinally, where peak 1 (P1) for the second noise burst (NB2) was assessed to measure temporal processing deficiencies during the 6 months of HRT and 2-month recovery period. The results showed that mice treated with E+P had P1 amplitude levels that decreased and P1 latency values that increased significantly after 3 months of HRT. These values never quite recuperated during the recovery period. Decreased P1 latency values displayed by the E group indicated improvements in temporal processing. Mice treated with P showed little to no change of their temporal processing abilities during or after HRT. Meanwhile, the Pb group displayed typical age-related hearing loss (ARHL) changes, which diminished peripheral function throughout the study. Overall, there was no improvement observed in the hearing levels for any of the hormone treated mice during the recovery period, and the HRT groups all experienced some kind of decline in temporal processing by 3 months. For some groups, the decline in auditory function was noteworthy enough to consider HRT as harmful (the E+P group). Work supported by NIH Nat. Inst. on Aging grant P01 AG009524.

Title: A mouse model of hormone replacement therapy reveals positive effects of estrogen on hearing

Authors: *A. S. HINTON[1,2], T. T. WILLIAMSON[2,3], X. ZHU[2,3], J. M. MANSOUR[2,3], R. D. FRISINA[1,2,3], J. P. WALTON[1,2,3]

Abstract: Gonadal hormones play an important role in auditory development and they have recently been implicated in modulating age-related hearing loss. Estrogen and progesterone are reproductive hormones and influence excitatory activity of auditory nerve fibers, as well as help regulate neurotransmitters in the CNS. It has also been shown that rats given hormone replacement therapy (HRT) perform better on hippocampal tasks, yet they perform worse on prefrontal tasks. However, it is unknown how HRT affects behavioral measures of audition. In order to test the effects of estrogen and progesterone on auditory processing, mice received HRT using different combinations of gonadal hormones. Our goal was to determine if these hormones improve behavioral measures of hearing using pre-pulse inhibition (PPI) of the acoustic startle reflex (ASR). Middle-aged (15-17 mon) CBA/CaJ mice were randomly assigned to 5 groups. Male mice were assigned to a no-pellet control group. Female mice were assigned to placebo, estradiol (0.0056 mg/day), progesterone (0.39 mg/day), or estradiol + progesterone, groups. Hormones were administered by extended release pellets implanted subcutaneously. The ASR was measured using standard methods and stimuli were presented through speakers located 30 cm directly above the transducer platform. ASR input-output functions were collected by presenting the wideband startle elicitor at intensities ranging from 55-115 dB, in 10 dB increments. Approximately 30 minutes after startle testing, noise PPI testing occurred. Pre-pulse stimuli were presented at 20, 40, 55, and 75 dB SPL, 30 ms prior to the wideband startle elicitor. Baseline tests were followed by tests at 1, 2, and 3 months post hormone pellet treatment. We found that estrogen results in greater PPI as compared to the placebo, control, and progesterone groups at 1 month, as well as, at the 2 month test; while the progesterone HRT resulted in a reduction in startle amplitude. The progesterone group also showed significantly lower PPI

testing 3 months post-treatment at 20, 40, and 55 dB compared to control. A decrease in startle amplitude and PPI with progesterone treatment suggests that treatment may negatively affect sensorimotor reflexes and decrease hearing sensitivity. Increased inhibition with estrogen treatment at sub-threshold pre-pulse levels indicates increased salience for low level noise signals and demonstrates improvement in hearing sensitivity. These results indicate that reflex modification using acoustic PPI can assess the effects of HRT on auditory processing in mouse models.

Title: Phase coherence of auditory steady-state response (ASSR) reflects internal brain activation level modulated by a modified N-back task: an MEG study

Authors: *Y. YOKOTA, Y. NARUSE
NICT, Kobe, Hyogo, Japan

Abstract: The auditory steady-state response (ASSR) is oscillatory brain activity induced by repetitive auditory stimuli. Previous studies reported that the power and inter-trial phase coherence (ITPC) of ASSR could be modulated by the degree of brain activation level. For example, Griskova et al. (2011) compared ASSR activation between low and high-arousal conditions in order to examine the relationship between brain activation level and ASSR, resulting stronger in the low-arousal condition. Moreover, Roth et al. (2013) used a Tetris game as a visuospatial attention task, and reported that the difficult version of Tetris task reduced 40Hz auditory cortical responses compared with the easy version. However, those studies used different physical stimuli for different difficulty tasks, and the effect of the internal brain activation level itself has not been clarified enough. In this study, we employed modified N-back task as a visual working memory task in order to regulate the degree of difficulty with an identical physical stimulus. The experiment involved four types of tasks: no-load (NL), 1back, 2back, and 3back task. Images of two numbers (‘1’ or ‘2’) with two colors (white or red) were used as visual stimuli. One of two images (50% for each) was randomly presented for 0.5 s with

randomly selected color (80% for white and 20% for red). The number of trials was 200 in each task, and a blank image with a fixation point was presented with 2.0s duration between trials. In the NL task, participants did not perform the N-back task, however, they reported the number by pressing one of two buttons when the color of the stimulus was red. In contrast, in 1, 2, and 3 back tasks, participants reported whether the current number is same with the N-th before number. The 40Hz auditory stimulus was click, and transmitted to the participant continuously via plastic tubes. Sixteen healthy subjects participated in the present study and MEG responses were recorded using a 148-channel magnetometer system. The continuous MEG data was processed by a digital bandpass filter (butterworth 1-50Hz), and then divided into 1s epochs (0 to 1s from the onset of the auditory stimulus) with artifact rejection. Fourier analysis was performed, and ITPC of 40 Hz responses was calculated. Grand averaged phase coherence activities of fifteen showed the 40 Hz ASSR reductions accompanying with increase in the task difficulty. The phase coherence activities in 1-3 back tasks were significantly lower than the in NL task, and those in high load task (3back) were significantly lower than those in low load task (1back). The result suggests that ASSR reflects the internal brain activation level and can be a useful indicator for it.

Title: Internal stochastic resonance within the human brain elicited by binaural noises

Authors: ***A. GUTIERREZ**[1], N. HUIDUBRO[2], R. KRISTEVA[3], E. MANJARREZ[2]
[1]Inst. De Fisiologia, Benemerita Univ. Au, Puebla, Mexico; [2]Inst. of Physiol., Benemerita Univ. Autonoma de Puebla, Puebla, Mexico; [3]Dept. of Neurol., Univ. of Freiburg, Freiburg, Germany

Abstract: The internal stochastic resonance is a phenomenon of non-linear systems in which the enhancement in the coherence, or synchrony, between two or more signals is produced by the

addition of a particular level of noise. Little is known about this phenomenon in the nervous system. The first experimental evidence of internal stochastic resonance in the central nervous system was reported by Manjarrez et al., (2002), who found that the coherence between spinal and cortical somatosensory neurons, in the cat, can be enhanced by the application of a particular level of tactile noise. Recently, we reported that the addition of an intermediate level of mechanical noise on the finger skin enhances the corticomuscular coherence during a visuomotor task (Trenado et al., 2014). However, in such studies only one source of external noise was applied, with the assumption that an internal noise source was also involved. The aim of the present study was to examine the electroencephalographic (EEG) coherence (between pairs of electrodes of the 10-20 system located over homologous auditory areas in the left and right cerebral hemispheres) during binaural hearing of two uncorrelated Gaussian noises. Experiments were performed in eight healthy subjects. The stimulation protocol was the following. One Gaussian noise of fixed intensity was delivered to the left ear, while a second Gaussian noise of variable intensity was delivered to the right ear. We found that all the subjects exhibited an enhancement in the beta and/or gamma band EEG coherence during this binaural noise protocol when an intermediate level of auditory noise was applied on the right ear. These results are the first demonstration that the internal stochastic resonance phenomenon can be evoked within the human brain by the interaction of two controlled noise sources.

Title: Differentiating phase-locked responses to the temporal envelopes of speech sentences

Authors: ***R. E. MILLMAN**, S. R. JOHNSON
York Neuroimaging Centre, Univ. of York, York, United Kingdom

Abstract: The temporal envelopes of sounds contain important cues for auditory perception. In the context of speech comprehension, the role of neural activity phase-locked to the speech temporal envelope is controversial: It remains unclear whether linguistic content can enhance neural temporal envelope tracking for intelligible speech sentences. Whole-head

magnetoencephalography (MEG) and novel beamformer-based analyses of time series data were used to test the hypothesis that phase-locking to the temporal envelope of speech sentences is enhanced by linguistic information. The novel beamforming analyses were an extension of the Source Stability Index [Hymers et al., (2010). "Source Stability Index: A novel beamforming based localisation metric. NeuroImage 49, 1385-1397] but here analyses focussed on identifying *differences* (i.e., the Difference Stability Index, DSI) in phase-locked responses elicited by listening to intelligible and unintelligible speech sentences. Perceptual "pop-out" was used to change the percept of physically identical tone-vocoded speech sentences from unintelligible to intelligible. The use of pop-out dissociates changes in phase-locking to the speech temporal envelope arising from acoustical differences between unintelligible and intelligible speech from changes in speech intelligibility itself. In a 2 x 2 factorial design the DSI was calculated for speech sentences with 1) identical or different temporal envelopes and 2) identical or different percepts (i.e. unintelligible or intelligible). Differences in phase-locked responses elicited by listening to speech sentences with different temporal envelopes and identical/different percepts localised to the temporal lobes bilaterally. There were no functionally significant differences between the phase-locked responses to speech sentences with identical temporal envelopes and identical/different percepts. These results add to the evidence against a top-down amplification of speech envelope tracking to intelligible speech stimuli.

Title: Differential oscillatory responses to aversive sounds in children with autism spectrum disorder showing auditory hypersensitivity

Authors: *K. SHIMONO[1], J. MATSUZAKI[2], H. SUGATA[3], I. HIRATA[4], R. HANAIE[2], F. NAGATANI[2], M. TACHIBANA[2], K. TOMINAGA[2], M. HIRATA[3], I. MOHRI[2], M. TANIIKE[2]

Abstract: Aim: Although auditory hypersensitivity is the most common sensory impairment in autism spectrum disorder (ASD), its neurophysiological mechanism has not been known. We reported that auditory hypersensitivity in ASD revealed increased M50 dipole moment to sinusoidal tones using magnetoencephalography (MEG; Matsuzaki et al, 2012). In real life, however, ASD subjects with hypersensitivity are not always hypersensitive to all environmental sounds, but to specific ones. In this study, we studied oscillatory responses to aversive sounds and analyzed its correlation with hypersensitivity. Method: Oscillatory responses for two sounds were measured by 160 channel whole head MEG system (PQ1160C, Yokogawa Electric Corporation) in 18 boys (age: 8-12 years) with ASD (IQ≧75), consisting of 12 with and 6 without auditory hypersensitivity, and 9 age-matched typically developed (TD) controls. In all subjects, auditory hypersensitivity was assessed by the sensory profile. A neutral sound and an aversive sound were selected as auditory stimuli. The duration time was 4 seconds, and number of stimulation were 30 times of each. To determine the differentiation of cerebral oscillatory changes in each group, adaptive beamforming and group analysis were used. Result: α band event-related synchronizations (ERS) appeared in auditory cortex around 200ms after neutral sounds, followed by β and low γ band event-related desynchronization (ERD) in TD. However, in addition to β band and low γ band ERD, ERS also appeared after aversion sounds in TD. On the other hand, in ASD with hypersensitivity, delayed, wide and prolonged α band ERS was recognized for neutral sounds. In addition, instead of β band and low γ band ERD, high γ ERD were appeared. Furthermore, specific β and γ band ERS were activated after 400-1000 ms of aversive sounds. Discussion: Increased responsiveness in primary auditory cortex was previously reported in ASD children with hypersensitivity. In this study, although oscillatory difference between neutral sounds and aversive sounds were recognized even in TD. γ oscillation was gererated in ASD with hypersensitivity especially to aversive sounds. γ band synchronization was reported to play a crucial role in cognitive functions including perceptual and emotional processes. Thereafter, our data may suggest the basic mechanisms of emotional response to auditory stimuli in ASD with hypersensitivity.

Title: A model of theta band oscillation entrainment to speech

Authors: ***D. HARRELL**[1], O. GHITZA[2], E. LARGE[1]
[1]Univ. of Connecticut, Storrs, CT; [2]Boston Univ., Boston, MA

Abstract: Entrainment of cortical theta rhythms to the syllabic rhythm of natural speech is thought to engage neurodynamic mechanisms of temporal anticipation to segregate incoming information and organize spike timing. These neurodynamic mechanisms may also be critical for intelligibility of spoken language. Previous studies have demonstrated that the insertion of silent gaps into speech can be deleterious to intelligibility in certain circumstances and remedial to intelligibility in others. For example, when speech is temporally compressed by a factor of three, insertion of silent gaps can restore some intelligibility. However, beyond a certain duration of silent gap, intelligibility begins to deteriorate. One oscillator based model of speech perception, proposed to account for these results, tracks the artificial rhythm created by the insertion of silent gaps. However, this model requires the introduction of oscillatory bands beyond theta to explain the loss of intelligibility once gap length reaches a critical duration. This loss of intelligibility can be explained using only theta band processes by considering speech with artificially inserted silent gaps to be a stimulus with two rhythms: the syllable rhythm and the gap rhythm. Here, we present a model using two coupled theta band oscillators in which one oscillator tracks the syllable rhythm and the other tracks the rhythm of the silent gaps. For silent gaps less than a critical duration, the rhythms remain distinct. However, beyond that duration, both oscillators entrain to the rhythm of the silent gaps. These oscillator dynamics can account for the results shown in rhythmically interrupted speech. Implications for the role of theta oscillations in speech perception are discussed.

Title: Influence of efferent innervation on lateral line sensing in larval zebrafish (Danio rerio)

Authors: *M. HAEHNEL[1], C. A. SMITH[2], J. C. LIAO[2]
[2]Whitney Lab., [1]Univ. of Florida, St Augustine, FL

Abstract: A swimming fish generates flow stimuli from its own motion, which it must distinguish from biologically relevant stimuli from the environment. It does this with the mechanosensory hair cells of the lateral line system, which receives direct efferent feedback from the octavolateral efferent nucleus (OEN) located in the hindbrain. In adult fishes, efferent feedback is thought to reduce or increase lateral line sensitivity. The mechanisms that regulate lateral line sensitivity likely already exist in larval fish as well, given that they are less likely to respond to a flow stimulus when swimming. To understand how lateral line sensitivity is regulated and coordinated during swimming in larval zebrafish we simultaneously recorded posterior lateral line sensory afferent and peripheral motor neuron activity during fictive swimming. We found that in about 30% of the cases spontaneous activity in sensory afferents decreased about five-fold, from 50 to 10 Hz during spontaneous swimming bursts (25-30 Hz). We hypothesize that efferent neurons provide inhibitory corollary discharge of the motor activity to lateral line hair cells. Our current work focuses on making direct recordings from the efferent neurons to test this hypothesis and to look at how efferent effects on afferent sensitivity may change with swimming speed. We also suspect a regional specialization of efferent feedback within the posterior lateral line system. There are two subpopulations of efferent neurons targeting the posterior lateral line, located rostral and caudal relative to each other. By carefully backfilling groups of efferent neurons with dye injection from their target neuromasts, we were able to identify a regional differentiation between the rostral efferent neuron (REN) which exclusively innervates the most rostral midline neuromast in the posterior lateral line and the caudal efferent neurons (CEN), of which one innervates all probed midline neuromasts, while the other innervates only the caudal portion of the midline neuromasts. We hypothesize that the functional significance of this subdivision might lie in providing regionally specific feedback, for example to offset self-stimulation induced by fin versus tail motion during swimming.

Title: Population coding for sound localization in the owl's midbrain

Authors: *F. CAZETTES[1], B. J. FISCHER[2], J. L. PENA[1]
[1]Albert Einstein Sch. of Med., Bronx, NY; [2]Seattle Univ., Seattle, WA

Abstract: A major challenge in sensory neuroscience is to understand how populations of neurons capture the uncertainty in sensory information. Extracting the signal from unreliable input is essential in sensory processing. However, to what extent this is the result of averaging out noise or selecting the invariant parameters in the environment is a matter of debate. We study this question in the sound localization system of the barn owl using physiological, behavioral and modeling approaches. The interaural time difference (ITD) is a primary cue used to localize sound. Due to the filtering effect of the head, ITD varies depending on frequency and the presence of background noise. This statistically complex relationship between direction and ITD poses a problem to reliably localize sounds. We found that at each direction there is a frequency range within which ITD is most invariant. We show that neurons' preferred frequencies match this range. We are now exploiting the tight relationship between frequency and ITD to stimulate separately the units tuned to the front or to the periphery. We combine model predictions and behavioral results to investigate whether the direction estimate relies on the entire population of neurons. We monitor head saccades in response to sound stimulation and assess the consistency of the behavioral output with population decoding schemes such as population vectors or maximum a posteriori.

Title: Temporal sequence processing & natural song time-scales in Zebra finch auditory cortex

Authors: *T. J. GARDNER[1], B. SHINN-CUNNINGHAM[2], Y. LIM[3,4]
[1]Biol., Boston Univ., BOSTON, MA; [2]Biomed. Engin., [3]Cognitive and Neural Systems, Boston Univ., Boston, MA; [4]Ctr. for Bionics, Biomed. Engin. Res. Inst., Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: A highly developed auditory cortical network supports auditory-vocal behavior in songbirds. The hallmark of this cortical network is the ubiquitous presence of fine temporal coding in response to natural song (*1-3*). In this study we take advantage of the precise spike timing in songbird auditory cortex to ask how temporally patterned stimuli are transformed in the transition from primary to secondary cortical zones. We first demonstrate that in the transition from primary (L2a) to secondary (L2b) auditory cortex, neural responses to song become less synchronous across neurons and more informative about the identity of specific syllables. To zero in on temporal aspects of this process, we examined the same circuit transformation in response to click sequences defined by the temporal ordering of intervals between clicks. The interval distribution between clicks was chosen to produce, in area L2a, population firing patterns similar to the responses to natural songs. In L2a, each individual click elicited a synchronous response in all recorded neurons, regardless of the temporal context of the click. In secondary auditory cortex (L2b), neurons responded asynchronously and selectively, in a manner dependent on the temporal context of the click. We next tested whether songbirds could discriminate different click sequence patterns in a "restart-go" operant paradigm. In this training procedure, 24 zebra finches rapidly learned to discriminate between the different click sequences. However, when the click stimulus set was slowed by a factor two (no longer driving L2a in a manner similar to song), the sequence selectivity in the secondary auditory area (L2b) was significantly reduced, and zero of 15 zebra finches were able to perform the operant task. This work suggests that the zebra finch auditory cortex is capable of transforming temporal patterns to sequence-selective population responses or "spatial codes." We suggest that this transformation is tuned to the time-scale of sub-syllabic acoustic transitions in conspecific songs.

Title: Compensatory gain control partially restores midbrain and cortical sound coding following profound peripheral nerve degeneration

Authors: *A. R. CHAMBERS[1,3], Y. YUAN[4], A. S. EDGE[2,3], M. C. LIBERMAN[2,3], D. B. POLLEY[2,3]
[2]Dept of Otolaryngology, [1]Harvard Med. Sch., Boston, MA; [3]Eaton-Peabody Laboratories, Massachusetts Eye and Ear Infirmary, Boston, MA; [4]Dept of Otolaryngology, Fu Dan Univ., Shanghai, China

Abstract: Peripheral deafferentation occurs routinely in the auditory system as a consequence of acoustic trauma, ototoxic insult, or aging. Central neurons corresponding to deafferented regions of the cochlea exhibit changes in sound-evoked tuning, wherein Hebbian mechanisms guide a shift in central responsiveness toward neighboring, intact regions of the periphery. In addition, central neurons maintain activity levels based on non-Hebbian homeostatic mechanisms involving synaptic or intrinsic changes to compensate for reduced sensory drive. The degree to which these processes are involved in recovery following hearing loss, as well as their consequences for perception, are unknown. We recorded from the inferior colliculus (IC) and primary auditory cortex (A1), in awake mice after 95% of Type-I auditory nerve fibers were eliminated unilaterally via administration of ouabain, a Na+/K+ ATPase pump inhibitor. Thresholds for auditory brainstem evoked potentials were substantially elevated. However, behavioral detection thresholds were near normal, indicating that neural activity at higher stations of the auditory pathway could support perception. We recorded central representations of tones and broadband pulse trains in order to address a three-fold hypothesis: First, we predicted that the rapid expansion of representations of the normal auditory nerve would occur in addition to a slower potentiation of the remaining inputs from the profoundly degenerated nerve, possibly by homeostatic mechanisms. Second, we predicted that the latter potentiation would occur to a greater extent in A1 than IC. Third, we predicted that this plasticity would increase the fidelity of a spike rate code, due to a preservation of firing rate magnitudes. We found that unit

thresholds were lower than those predicted from brainstem metrics, possibly indicating a central compensatory plasticity. A1 evoked firing rates with contralateral stimulation were preserved at near normal levels. Finally, using vector strength and classifier models to test the integrity of temporal encoding in IC and A1, the neurophysiological and behavioral categorization of rapidly modulated sounds was impaired while rate encoding mechanisms recovered to a greater extent over time. Ongoing studies compare single-unit responses to sound stimulation with optogenetic stimulation of the brainstem. These studies form a conceptual framework for understanding the contributions of competitive and non-competitive plasticity to recovery from hearing loss, as well as the limits of perceptual ability that can be preserved via the brain's intrinsic recovery mechanisms.

Title: Linear integration for perceptual behavior in mouse primary auditory and visual cortex

Authors: *M. H. HISTED, N. T. COMFORT, R. T. OHMAN, A. R. PERILLO, J. H. R. MAUNSELL
Neurobio., Harvard Med. Sch., Boston, MA

Abstract: Many mammalian species can treat sensory information similarly whether it is distributed over time or concentrated over a short interval. Such near-perfect linear integration means that behavioral ability to perceive a stimulus is predicted by the product of stimulus duration and amplitude, a phenomenon often called Bloch's Law. By directly stimulating mouse visual cortex, we have previously shown that this linear integration can arise from computations in the cerebral cortex (Histed and Maunsell, 2014). Linear behavior of cortical circuits might have been unexpected because cortical neurons' spiking is a non-linear function of their inputs. However, behavioral linearity can be explained by a decoder that applies a threshold rule to a population spike count. Because near-perfect sensory temporal integration is seen in many species and different sensory systems, it is likely to be a computation that circuits in many cortical regions can perform. To determine if auditory cortex as well as visual cortex can use

linear integration to guide behavioral decisions, we trained mice to perform an auditory task in which we measured their ability to detect pure tones of different durations and amplitudes embedded in noise. We find that mice show linear integration for audition, following Bloch's law: detection threshold is related to the product of duration and tone amplitude (duration: 2-100ms, N=2 mice). We previously found using direct stimulation of visual cortex that small changes in neuronal activity can be detected and reported by mice. These small changes mean that individual neurons do not carry enough information for animals to do the task. Instead, a population of neurons must be decoded to achieve the observed behavioral performance. We find that neurons in mouse primary auditory cortex are also modulated only weakly by stimuli near detection threshold (median change in firing rate over interval before behavioral response: 0.5 spk/s; 75th percentile 1.7 spk/s; N=13 single units and 47 multiunits, recorded extracellularly in awake mice). Thus, despite the widely different types of sensory input processed in primary visual and auditory cortex, both areas can support linear integration. Linear behavior is useful under many behavioral circumstances, as when it is desirable to weight inputs equally regardless of their arrival time. The cerebral cortex might have evolved to support linear integration as one important computational regime.

Title: Brain state dependency of rate and temporal coding in the primary auditory cortex

Authors: *J. BAMBER[1], S. SAKATA[2], J. HERRMANN[3]

Abstract: The mammalian brain is always active, with different patterns of spontaneous activity corresponding to different behavioural states. For example, deep sleep is associated with large, slow oscillations in EEG and LFP, as cortical neurons alternate between firing and silence in a locally collective manner (inactivated state). Wakefulness, however, is associated with a suppression of such oscillations and desynchronisation of cortical neural activity, with neurons spontaneously firing near independently. Such differences in brain state may be indicative of different modes of processing, but this is not well understood. Here, we analyse brain state dependency of auditory processing using spiking data from medial geniculate body (MGB) and multiple layers of primary auditory cortex (A1) of five urethane anaesthetised adult rats. To quantify stimulus information conveyed, decoding and information theoretic procedures were applied to both rate and temporal measures of single unit evoked responses to different stimuli in two distinct brain states: the inactivated state, natural under urethane anaesthesia; and the activated state, induced through electrical stimulation of the nucleus basalis in the basal forebrain. Provisional results indicate that the most informative cortical neurons convey increased stimulus information in the activated state, whereas thalamic neurons show no clear difference between brain states, suggesting that auditory cortical processing is affected by brain state.

Title: The contribution of sensory and cortical processing to perceptual decision-making

Authors: *M. INSANALLY[1], I. CARCEA[1], B. ALBANNA[2,3], R. FROEMKE[1]
[1]NYU Sch. of Medicine, Skirball Inst., New York, NY; [2]Dept. of Physics, [3]Redwood Ctr. for Theoretical Neurosci., Univ. of California, Berkeley, Berkeley, CA

Abstract: The process of perceptual decision-making requires the use of sensory information to guide action and consequently involves coordinated activity in multiple cortical regions. Little is known about the combined functional contributions of cortical sensory and frontal areas to perceptual decision-making in rodents. In this study, we investigated the role of auditory and frontal cortex in perceptual decision-making using electrophysiological recordings from animals performing an auditory cue-driven task. While traditionally it may be thought that auditory cortex acts as a feature detector for acoustic stimuli, there is growing evidence that it plays a role in perception and cognition as well. Activity in frontal cortical regions such as medial agranular cortex has been shown to reflect action selection, but it is unknown how activity in this region reflects other task related variables such as stimulus identity. We made 70 single-unit recordings from behaving rats trained to respond to 4 kHz tones and ignore tones of other frequencies (see Carcea et al. SfN abstracts 2014 for more details of the go/no-go task). The spike trains observed in this study are complex and highly variable from trial to trial. However, on a given trial, these responses are the only information available to downstream neurons. Accordingly, we used a novel analysis technique to assess how much information about task variables is encoded in the responses and the timing of the most informative responses during each trial. In this analysis, we first determined the probability of finding a given inter-spike interval (ISI) pattern conditioned on its occurrence during a particular task condition (e.g., go or no-go). Using this conditional probability, we inferred a task variable on a specific trial (e.g., is this a go or no-go trial?) by considering the responses on that trial as a sequence of ISI patterns and updating our certainty about the variable using Bayes' Rule as the trial progresses . Using this method, we find that (1) information about task variables is distributed throughout auditory and frontal cortex indicating that neurons in both regions have access to information regarding the stimulus (23/41 cells in AC and 18/29 cells in FC) and the future choice of the animal (23/41 cells in AC and 17/29 cells in FC), (2) responses related to the stimulus are most informative well after stimulus presentation has ended, and (3) accurate encoding of stimulus identity predicts improved behavioral performance. We are currently investigating how these representations vary across cortical regions and how robust these representations are across neurons and individual animals.

Title: Characterization of invariances to stimulus perception in auditory processing

Authors: *J. F. LIÉNARD[1], S. V. DAVID[2], A. G. DIMITROV[1]
[1]Mathematics, Washington State Univ., Vancouver, WA; [2]Oregon Hearing Res. Ctr., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Local probabilistic invariances, defined by the range of transformations that can be applied to a sensory stimulus without affecting the corresponding neural response, are largely unstudied in auditory cortex. We propose to assess these invariances at two stages of the auditory hierarchy using single neuron recordings from the primary auditory cortex (A1) and the secondary auditory cortex (PEG) of awake, passively listening ferrets. First, we hypothesize that neurons will show increasing degrees of local invariance at successively more central stages of the auditory hierarchy. To test this hypothesis, we considered two types of stimuli commonly known to evoke activity in the auditory system. The first set of stimuli was a sequence of isolated pure tones with randomly varying frequency, spanning 5-6 octaves and encompassing the best frequencies of the recorded neurons. The second was a sequence of bandpass noise bursts with varied durations, consisting of 20-30 bursts that logarithmically tile 5-7 octaves, thus achieving a bandwidth each of approximately 0.25 octave. Using these data sets, we have analyzed local invariance to frequency shifts by estimating the width of the tuning curve for the best responding neurons, and found that the corresponding 95% confidence interval was significantly larger in PEG than in A1. Similarly, preliminary analyses on invariance time shifts indicated that the invariance to time shift is higher in PEG than in A1. Second, we further hypothesize that parametric models having built-in invariance properties will provide a suitable basis to model spectro-temporal receptive fields (STRF). To confirm this hypothesis, we fitted low-parametric invariant kernels (9 parameters), in a boosting optimization setup using species-specific vocalization stimuli in A1. The performances of these models were then compared to similarly fitted non-parametric STRF (361 parameters). According to Akaike's Information Criterion, which corrects for model complexity, we found that the invariance-based models were significantly better models in A1. The generalization capability of the models, assessed with Pearson's correlation coefficient in a testing dataset, was also significantly better for the invariant kernels. We interpret this to mean that the constraints of invariant kernels capture well auditory neuronal dynamics. Overall, our result show that (a) stimulus invariance to frequency and time shifts are present at every stage and increase along the hierarchical auditory processing and (b) at least in the early stages, parametric models having invariance properties by design, are well-suited to describing biological functions.

Title: Neural encoding of noisy vocalizations in primary auditory cortex of the marmoset monkey

Authors: *R. NI[1], N. M. LEDBETTER[1], J. R. GAMBLE[1], D. A. BENDER[2], D. L. BARBOUR[1]

Abstract: The ability to extract behaviorally relevant sensory information from a cluttered environment is important for humans and animals to survive. Relatively little is known, however, about the single and population cortical neuron representation of noisy vocalizations in primates. To uncover how the neural code of behaviorally relevant signals is degraded when contaminated by noise, the neural representation of conspecific vocalizations embedded in noisy backgrounds was studied in marmoset monkey primary auditory cortex. Twenty different natural marmoset vocalizations were mixed with white noise to generate noisy vocalizations of different signal-to-noise (SNR) ratios (-15 dB to 20 dB SPL), and the corresponding responses of individual auditory cortical neurons were recorded in awake marmoset monkeys. Information theoretic analysis showed that the addition of white noise in vocalizations led to a monotonically decreasing relationship between total information content represented in neural code and SNR. This observation was consistent across different types of vocalizations. In addition, neural responses were quantified with an extraction index profile, which measures the similarity between neuron responses to distorted vocalizations (i.e., different SNRs) and responses to target vocalizations. About one-third of neurons displayed an extraction index profile with a critical SNR value around -5 dB SPL, below which the neural representation was more noise-like instead of vocalization-like. This trend agrees with studies in other species and supports the existence of noise-invariant neurons, while also revealing the overall variety in individual neuronal responses. Furthermore, by applying dimensionality reduction techniques to the pooled single neuron responses, we were able to visualize dynamic neural ensemble responses to noisy vocalizations as trajectories in low-dimensional space. The resulting trajectories showed a clear transition from pure vocalization to pure noise with a systematic change in trajectory shape,

demonstrating that the population of neurons encodes vocalizations more precisely than the individual neurons. The results of this study revealed the effect of white noise on the neural encoding of noisy vocalizations, a better understanding of which is critical for providing the link between cortical neural responses and auditory perception in primates in challenging acoustic environments.

Title: Contribution of transient neural responses to stimulus discriminability in auditory cortex

Authors: *W. SUN, N. M. LEDBETTER, D. L. BARBOUR
Dept. of Biomed. Engin., Washington Univ. in St. Louis, Saint Louis, MO

Abstract: In response to steady-state sound stimuli, neural responses are transiently spread across a large number of neurons following sound onset, then restricted to sustained firing in a small subset of neurons. To better understand the role of transient and sustained components in sensory coding, neural spiking responses to 500 ms tones were tested at six different frequencies across 1 to 32 kHz at 85 dB SPL for 99 neurons in the auditory cortex of awake marmoset monkeys. On average, the number of stimuli an individual neuron is responsive to is larger immediately following stimulus onset than during the later portion of the stimulus. This is consistent with previous observations of higher selectivity for sustained responses than onset responses. Then the ability to recover the stimulus frequency label from the responses of the neuron population was tested every 20 ms through the recording duration. Principal component analysis and linear discriminant analysis were used to construct a linear classifier for each time point. The frequency prediction accuracy quickly peaked to about 85% immediately following sound onset, and then gradually decreased to a plateau. Immediately following sound offset, prediction accuracy exhibited another, smaller second peak. Therefore, despite the low selectivity of onset responses of individual neurons, these responses when combined across a

neuron population are sufficient to achieve stimulus discriminability. To better understand the population response dynamics, firing rate response trajectories were examined next. The instantaneous firing rates of the neuron population were treated as a point in a high dimensional space, where each dimension is the response amplitude of one neuron. Connecting the firing rate points at different time points in temporal order produces a trajectory in the neural response space. Corresponding with the discriminability results, the population response trajectory quickly emerged from the locus of spontaneous firing after sound onset, finished a transient dynamical response process, and remained around a fixed point for the sustained portion of the stimuli before returning to the spontaneous locus after sound offset. This result reveals that in response to steady-state sound stimuli, the neural system begins responding with a dense code and quickly evolves to a stable state maintained with a sparser code. This response trajectory pattern and the distinct properties of onset and sustained responses resemble the behavior of the neurons in the olfactory system, potentially signifying a unified neuronal strategy for sensory coding.

Title: Neural mechanisms underlying long lasting contextual modulations in auditory cortex of awake marmoset studied by intracellular recording

Authors: *L. GAO[1], X. WANG[2]
[1]BME, The Johns Hopkins Univ., Baltimore, MD; [2]Dept. of Biomed. Engin., The Johns Hopkins Univ. Sch. of Med., baltimore, MD

Abstract: Extracellular recording studies have demonstrated long-lasting contextual modulations in spiking activity in auditory cortex of many species. For example, preceding sound stimuli with long duration could suppress or facilitate responses to succeeding sound stimuli for as long as a few seconds after the preceding stimulus ends in auditory cortex of awake marmosets (e.g. Bartlett and Wang 2005). Such long-lasting modulations are often specific to both preceding and following stimuli and likely form the basis for contextual processing in auditory cortex.

However, cellular mechanisms for the contextual modulations in auditory cortex are largely unknown. Using an intracellular recording technique developed in our laboratory for awake marmosets, we have studied neural mechanisms for contextual modulations in auditory cortex of the marmoset (callithrix jacchus), a highly vocal and social primate species. We found that there were long-lasting depolarization and hyperpolarization after sound termination in many cortical neurons. Furthermore, these long-lasting subthreshold events depended on parameters of sound stimuli, such as stimulus type, sound level and duration, carrier and modulation frequencies and so on. The duration of these subthreshold events after sound termination can last from hundreds of millisecond to more than one second, which is comparable to the duration of long-lasting contextual modulation observed in spiking activity. These findings suggest that long-lasting depolarization and hyperpolarization after the sound termination are possible neural correlates of long-lasting contextual modulations in auditory cortex under the awake condition.

Title: Frequency tagging and neural correlates of the cocktail party effect in the monkey inferior colliculus

Authors: *D. S. PAGES, V. C. CARUSO, S. TOKDAR, J. M. GROH
Cognitive Neurosci., Duke Univ., DURHAM, NC

Abstract: Humans and monkeys can perceive multiple simultaneous sounds in an auditory environment. Identifying the neural substrates supporting perception of each sound is challenging because it is difficult to determine from firing rates alone which of the multiple stimuli evokes a given spike. Here, we employ a frequency-tagging approach similar to that used in the EEG domain. Neurons in the inferior colliculus tend to phaselock their action potentials to the envelope of a sound. By evaluating phaselocking of spikes to each of two simultaneous sounds with different envelopes, we can infer which sound in the auditory environment triggered them. . We presented auditory environments containing two broadband sounds, each of which

originated from a different location and had a different AM envelope, to 2 monkeys who were passively listening. We found that most sites in our sample (N=17/27 recording sites) preferentially synchronized their spikes to the envelope of one of the two sounds (circular K test, $p<0.00001$, p value corrected for two conditions per site). Usually the more contralateral sound induced more phaselocking, regardless of carrier frequency (sign test, N=27, $p<0.001$). This was true even if the more contralateral sound evoked fewer spikes overall than the more ipsilateral sound (when each was presented separately). For example, even in cases where the ipsilateral sound was a better match to a neuron's frequency response area, neurons exhibited greater phaselocking to the contralateral sound. Furthermore, neurons reliably phaselocked to the ipsilateral sound when it was presented in isolation, so the preferences in phaselocking we observe are specific to the dual-sound condition. Together, these findings suggest the presence of a neural assembly "sorting" mechanism that is active when the animal is exposed to more than one sound at the same time, but weaker or absent when the animal is exposed to a single sound. . Our results implicate phaselocking as part of the mechanism contributing to maintaining information about multiple sound sources, and suggest that this mechanism exerts effects at the level of the inferior colliculus.

Title: Specialized auditory temporal processing in the theta and gamma bands revealed by priming

Authors: *X. TENG, D. POEPPEL
Dept. of Psychology, New York Univ., New York, NY

Abstract: Abstract The auditory system extracts acoustic information at different timescales to form a global percept, and cortical oscillations are argued to play an important role in chunking acoustic information. It has been proposed that acoustic dynamics at a longer timescale (~ 200 ms) are tracked by the theta oscillations (4-7 Hz) and at a shorter timescale (~30 ms) by low

gamma oscillations (here: 30-45 Hz). We test to what extent theta and gamma oscillations are specialized for processing information at the corresponding timescales and whether an intermediate timescale (~ 100 ms) is tracked by a corresponding oscillation band (alpha). Here we use a priming paradigm in the context of MEG recording to address this question. After being primed by sounds with modulation rates in the theta and gamma band ranges, we find that the power is maintained at the theta and gamma bands, but is decreased at other bands. Priming with sounds of different modulation rates does not cause corresponding power decreases. Interestingly, the sound with the modulation rate in the alpha band range does not induce such a priming effect. Furthermore, the priming effect is largely observed in the right hemisphere. These results suggest that the theta and gamma band oscillations are specifically driven by the sounds of corresponding modulation rates and that there are specialized processing modes for acoustic information at the long and short timescales (~200 and ~30 ms), but a different processing regime at an intermediate scale (~ 100 ms).

Title: Influence of aging on cortical auditory temporal processing of speech in noise

Authors: *A. PRESACCO[1], S. ANDERSON[2], J. SIMON[3]
[1]Hearing and Speech Sci., Univ. of Maryland, College Park, MD; [2]Hearing and Speech Sci., [3]Electrical and Computer Engin., Univ. of Maryland, College Park, MD

Abstract: Older adults frequently report that they can hear what they have been told, but cannot understand the meaning, particularly in a noisy environment. The use of hearing aids is beneficial in quiet, but less so in noise, suggesting that weakening of signal amplification is not the main problem. Earlier results have demonstrated that low frequency auditory cortical activity is so reliably synchronized to the slow temporal modulations of speech that it can be used to

reconstruct the speech envelope, even when the background noise is significantly stronger than the speech signal. This has been shown only in young adults, however. We hypothesize that the neural encoding of the speech envelope in background noise is degraded in older adults compared to younger adults, even when the older adults have “normal hearing” based on commonly used clinical assessments. Thus, in the presence of noise, accurate cortical temporal encoding would be a prerequisite for speech recognition and would affect the performance of listeners for speech-in-noise recognition. Magnetoencephalography (MEG) recordings were made from 8 younger (20 - 28 years) and 8 older adults (60 - 68 years old), all with normal hearing, while listening to two simultaneous speech streams but attending to only one stream. Participants’ sentence recognition in noise was behaviorally assessed using the Quick Speech-in-Noise test (QuickSIN). The MEG responses in the 1 - 8 Hz frequency band were used to reconstruct the envelope of the speech stimulus to which the participant was instructed to attend, with success measured by the linear correlation between the reconstructed and actual speech envelope. Results show that both younger and older adults’ neural responses can reconstruct the envelope of the target speech, even at 0 dB SNR. The two groups are differentiated, however, by the inability of older adults to efficiently suppress the competing speech, as demonstrated by their reduced contrast in decoding accuracy between the target and competing speech. Moreover, younger adults had significantly lower thresholds on the QuickSIN than older adults. Our findings suggest that aging may indeed cause deterioration of auditory temporal processes at the cortical level, a potential key explanation for why normal hearing older adults have problems understanding speech in noise.

Title: Nonlinearities of auditory neurons explained by predictive coding

Authors: *I. B. YILDIZ, S. DENEVE
Ecole Normale Superieure, Paris, France

Abstract: The response properties of neurons in the auditory system are usually characterized by the spectrotemporal receptive fields (STRF). Despite its descriptive power, the STRF performs poorly when used to predict auditory neuronal responses because of the nonlinearities in the responses that are functionally important. Moreover, response properties of auditory neurons are subject to significant variability depending on the context, percept, and task. Here, we propose that auditory neurons are predictors rather than filters of their input and we hypothesize that they have a "true selectivity" independent of stimulus context. We build a dynamic Bayesian inference model and train it on a large database of natural speech to reveal this invariant selectivity, i.e. predictive fields. We show that the model can account for nonlinear contextual effects such as two-tone and forward suppression. We also demonstrate that the model neurons can adapt their predictive fields to recent input statistics such as behaviorally relevant tones in an online fashion. Moreover, simulations reveal how the STRF of a neuron depends on the selectivity and dynamics of other neurons in the network and point out the importance of analyzing neuronal data collectively instead of describing each neuron's response separately. Furthermore, we employ the model to analyze neuronal responses to natural speech obtained from the primary auditory cortices of ferrets. Following the hypothesis that auditory neurons aim to reconstruct their stimuli, we compute the decoding filters of auditory neurons as an approximation to their predictive fields and then employ the model to quantitatively describe neuronal responses. As hypothesized by the model, the decoding filters of auditory neurons differ significantly from the encoding filters (STRFs) and they provide a basis for explaining nonlinear interactions between neurons which cannot be explained by classical receptive fields. This confirms the view that auditory responses are not only shaped by the stimulus itself but also by other neurons' responses and selectivities. In conclusion, the proposed model (i) provides mechanistic explanations to several nonlinear phenomena in auditory processing, (ii) introduces a state-of-the-art analysis tool for novel interpretations of neuronal data, (iii) produces testable hypotheses and measurable quantities to design and analyze future auditory experiments.

Title: Maximum noise entropy models reveal multidimensional auditory cortical receptive fields

Authors: *C. A. ATENCIO[1], T. O. SHARPEE[2], C. E. SCHREINER[1]
[1]Otolaryngology, UCSF, SAN FRANCISCO, CA; [2]Computat. Neurobio. Lab., The Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: The receptive fields of many auditory cortical neurons are multidimensional. However, standard methods that are often used to characterize multidimensional stimulus selectivity, such as spike-triggered covariance (STC) or maximally informative dimensions (MID), are either limited to Gaussian stimuli or are only able to recover a few stimulus features due to data limitations. To overcome these limitations, we applied an information theoretic extension of STC, the maximum noise entropy (MNE) model. The model assumes a logistic nonlinear input/output function and can be used with non-Gaussian stimulus distributions to find an arbitrary number of stimulus dimensions. For auditory cortical neurons, we often found more than two stimulus dimensions that influenced neuronal firing. Additionally, we employed two stimuli that differed only in their short-term correlation structure and found that cortical neurons were sensitive to these stimulus statistics. Our results suggest that the MNE approach is a principled method that can be used to recover the multidimensional receptive fields of auditory neurons.

Title: Combinatorial analysis of models for high-order neural representation of natural sounds

Authors: *I. L. THORSON[1], J. F. LIÉNARD[2], A. G. DIMITROV[2], S. V. DAVID[1]
[1]Oregon Hearing Res. Ctr., Oregon Hlth. & Sci. Univ., Portland, OR; [2]Mathematics Dept., Washington State Univ., Vancouver, WA

Abstract: Despite the central role of the auditory system in guiding behavior, neural computations underlying the transformation of raw auditory inputs into meaningful high-level representations remain poorly understood. Filter models derived from theories of signal processing, such as the Spectro-Temporal Receptive Field (STRF), provide powerful tools for studying representations of complex dynamic stimuli, including vocalizations and other behaviorally relevant sounds. We have recently developed multiple model architectures, extending the classic linear STRF with models that incorporate two nonlinear mechanisms widely observed in the brain: synaptic depression (DEP STRF) and co-tuned excitatory and inhibitory currents (EI STRF). The goal of this work is to assess the ability of these new plausible models to describe the representation of natural sounds at successive stages of the auditory processing hierarchy (primary and secondary cortical areas). The experimental data used to constrain the models consist of single-unit recordings collected during the presentation of natural stimuli from across the auditory hierarchy of awake ferrets. We first used boosting methods to fit each model to a training dataset. We then performed an exhaustive combinatorial analysis of models using the same dataset, employing a stacking model combination paradigm. Finally, we assessed the performance of individual and combined models on a reserved validation dataset. In our preliminary analysis of A1 recordings, the combined models performed significantly better in predicting the validation dataset than the best individual model for 76% of neurons, confirming the existence of unexplored degrees of freedom. We further report that models including both EI STRF and DEP STRF are selected significantly more frequently in model combination than all other models, even when their individual performance in training was not significantly different. This leads to the hypothesis that the specific interplays between EI and DEP STRFs allow for better characterization of neural dynamics than the classic linear STRF. Critically, our analysis also distinguished clusters of cells that were best fit by different single models, suggesting the presence of functionally different groups of neurons. Despite being widely employed in statistical and ecological sciences, model combination techniques have been barely explored in computational neuroscience, and their applications have been mostly limited to neuroimaging. Extensions of our work at other levels of the auditory hierarchy, will allow to further testing a very large number of hypotheses about auditory coding.

Title: Neural computations underlying temporal and rate coding in auditory cortex

Authors: *D. A. BENDOR
Psychology and Language Sci., UCL, London, United Kingdom

Abstract: When a brief sound is slowly repeated, the resulting percept is a stream of discrete events, referred to as acoustic flutter. If the sound's repetition rate increases above ~40-45 Hz, the percept changes from flutter to fusion; the sensation of discrete events is transformed into a fused percept, with a pitch equal to its repetition rate. Within auditory cortex, repetitive acoustic stimuli are encoded by two main types of responses, synchronized and non-synchronized. Synchronized neurons represent a repeated sound temporally by virtue of their ability to stimulus lock to the onset of each repeated sound for repetition rates within the perceptual range of flutter. Non-synchronized neurons form a complimentary neural code, increasing their firing rate monotonically with repetition rate over the perceptual range of fusion. To explore the underlying mechanisms that could generate these dichotomous neural coding regimes, I created a leaky integrate and fire (LIF) computational model of an auditory cortical neuron. Using this model, I find that strong, delayed inhibition (relative to excitation) leads to stimulus synchronization while non-synchronized responses can be generated by excitation occurring in close temporal proximity with weaker inhibition. To help validate this model, I recorded single unit activity in the auditory cortex of four awake marmosets, and tested several predictions made by this computational model, including the existence of additional neural coding regimes and the ability of some neurons to switch between synchronized and non-synchronized response modes. These results suggest that the underlying mechanism responsible for temporal and rate coding in auditory cortex can be parsimoniously explained as a byproduct of inhibition varying in strength and timing.

Title: Locally competitive networks mediated by inhibition as a basis for the development of cortical processing of natural auditory stimuli

Authors: *O. ROURKE, D. A. BUTTS
Univ. of Maryland, College Park, MD

Abstract: Connectivity to and within sensory cortices are guided by exposure to natural stimuli, but the underlying principles that might explain how cortical networks are shaped by their inputs is still not understood. We hypothesize that a fundamental property of such networks is inhibition-mediated competition between neurons, which can govern both how natural stimuli are represented by a given cortical area, as well as how the receptive field of each neuron develops. We consider cortical networks governed by excitatory- and inhibitory-specific learning rules based on spike timing, and model the development of selectivity in these layers in response to natural auditory stimuli. The inputs and outputs of the network are in population averaged firing rates, allowing networks to be stacked so that selectivity to more complex stimulus features may develop in higher layers. Furthermore, this network can be applied to visual stimuli as well, building on previous work studying sparse representation of natural visual stimuli. This work helps distill how the interacting excitatory and inhibitory networks allow for the collective processing of a variety of inputs, with implications to both experimental work and to machine learning.

Title: A neurodynamic model of pitch perception

Authors: *K. D. LERUD, J. C. KIM, E. W. LARGE, III
Psychology, Univ. of Connecticut, Storrs, CT

Abstract: All levels of the auditory system are known to respond to the amplitude envelope of complex sounds, and amplitude modulation is important for the perceived pitch of these sounds. However, the calculated envelopes of certain sounds can be identical while the sounds elicit different pitches. This can result, for example, from complex sounds consisting of multiple equally spaced frequency components when the absolute frequencies in the sounds differ. This is the case if one starts with multiple higher harmonics of a missing fundamental, and then shifts these harmonics linearly up or down. The perceived pitch then shifts in the same direction of the frequency shift, but to a lesser degree that is a function of harmonic number. The perceived low pitch of higher complexes such as these is called residue pitch, and this specific phenomenon is called “pitch shift of the residue”. Increasing amounts of this shift can result in ambiguity of pitch, in which the perceived frequency may vary depending on context. Since sounds with this relationship have identical amplitude envelopes, their temporal fine structure clearly plays a role in their perceived pitches. Here we develop an account and a model of these phenomena with canonical nonlinear oscillators. Organized in gradient-frequency neural networks, they model essential signal processing characteristics of the auditory system. The networks correctly predict the multistable pitch correlates of the stimuli. Dynamical analysis shows, as predicted, that the fine structure of these stimuli plays a crucial role in the development of regions of network resonance corresponding to the pitch perceptions. These results arise naturally in highly nonlinear systems, of which the auditory system is a prime example.

Title: Facilitated inhibition biases tritone comparison in a network model

Authors: *C. HUANG[1], B. ENGLITZ[3,4], S. SHAMMA[4], J. RINZEL[1,2]
[1]Courant Inst. of Mathematical Sci., [2]Ctr. for Neural Sci., New York Univ., New York, NY; [3]Auditory Behavior & Computat. Neurosci. Group, Equipe Audition, École normale supérieure, Paris, France; [4]Dept. of Electrical and Computer Engin., Univ. of Maryland, College Park, MD

Abstract: Perception can be strongly influenced by preceding context. Ambiguous stimuli are well suited to study the contextual effect. Shepard tones are comprised of octave-spaced pure tones, represented by their base pitches within one octave. A sequentially played pair of Shepard tones can be perceived as ascending or descending if the second tone, T2, is less than one-half octave above or below, respectively, the first tone, T1 [Shepard 1964]. The comparison task is ambiguous when two Shepard tones are separated by a half octave (tritone). However, a pre-test sequence of Shepard tones with pitch classes between the tritone pair can bias the perception toward ascending/descending for biasing tones above/below the first test tone [Chambers and Pressnitzer, 2011]. Results of the two-tone comparison with biasing implies a shorter perceived distance between T1 and T2 across the biasing region while a pitch-based decoding algorithm of extracellular recordings in A1 of awake ferrets indicates a larger distance [Englitz et al., 2013]. To investigate potential neural mechanisms of the Shepard tone comparison, we consider two tonotopically arranged direction-selective populations (UP and DOWN) that drive a common inhibitory array that provides recurrent feedback but with oppositely directed asymmetric footprints. Inhibitory synapses slowly facilitate in the biasing region. When the biasing tones are below T2, DOWN units tuned to T2, which receive inhibition from where facilitation has built up, are more suppressed than UP units. Hence, competition is favored toward UP units. Similarly, when biasing tones are above T2, DOWN units will win over UP units. The biasing effects gradually build up with the number of bias tones, reaching above 90% after 5 tones. Moreover, we found that pitch class of the most effective bias tone depends on the tuning width of the inhibitory population; tones near T2 have strongest effects if tuning is narrow, while tones at center between T1 and T2 is most effective if tuning is broad. Our model also accounts for the variation among subjects in the tritone comparison when non-uniform inhibitory synaptic strengths are incorporated. A simplified winner-take-all model is analyzed to explain the mechanisms of biased competition. Lastly, we compare alternative mechanisms for adaptation, such as feedforward depression and spike-frequency adaptation, with our model with the same architecture. In sum, our model is an idealized mean-field model, designed to account for trends

in behavior data. We utilize frequency shift detectors to account for the results of Shepard tones and predict that facilitation of inhibitory synapses underlies the context effects.

Title: Noise-robust automatic speech recognition by detecting syllables and phonetic features

Authors: ***P. SCHAFER**, D. Z. JIN
Pennsylvania State Univ., University Park, PA

Abstract: Despite decades of technological development, systems for automated speech recognition still underperform human listeners. This performance disparity is particularly large in noisy acoustic environments. Previously, we demonstrated that sparse spike representations modeled from those seen in auditory cortex can robustly represent the phonetic content of speech, and that sequences of spikes can be used to recognize isolated words in noise. However, in the case of continuous speech, where the word boundaries are not known, we find that noisy corruption of the spike code leads to insertion errors. Here we present a new, perceptually-motivated method for identifying syllable locations in continuous speech, which constrains the alignment of spike patterns to words and eliminates these errors. We train a population of spiking neural units to detect acoustic patterns corresponding to the nuclei of syllables, and integrate the activity of these neurons to generate candidate syllable locations and durations. Using the Aurora-2 noisy digits database, we show that the method performs well in varied noise conditions without fine-tuning parameters to any one condition. To identify words, we train a separate population of feature-detecting neurons to determine the phonetic content of the speech during short time windows within each syllable candidate. A dynamic programming search finds the best alignment of feature detector spikes to the syllable candidates, thereby robustly recognizing the speech.

Abstract: Understanding how information is processed in neuronal circuits is a central question in neuroscience. A neuron's function is fundamentally dependent on how it is connected within its network. Therefore, understanding the relationship between connectivity - circuit structure - and cellular function will help us understand how neurons and networks transform information to bring about perception and behavior. Recent advances in non-linear light and high-throughput electron microscopy (EM) allow detailed mapping of neuronal sensory physiology and network anatomy. To examine the sparsely connected pyramidal cell network, we used volumetric *in vivo* two-photon calcium imaging of a genetically-encoded calcium indicator to measure the time-resolved responses of a large population of identified neurons to a wide array of stimuli. We then used large-scale EM of serial sections to reconstruct the local neuronal network. In contrast to local connectivity of the inhibitory circuit, we find that the local connectivity between excitatory neurons exhibits functional specificity. First, we find that excitatory neurons with similar sensory physiology converge onto downstream neuronal targets. Interestingly, downstream, interlaminar targets have dissimilar selectivities. Finally, we observe topological organization of synaptic input onto dendrites from individual axons and from axons of presynaptic cells with similar tuning. This wiring specificity may act as a substrate for computations underlying cortical sensory processing.

Title: Resting state correlations in visual cortex reflect fluctuations of cortical arousal

Authors: ***B. MOORE**, M. A. COX, K. DOUGHERTY, M. S. YOUNG, A. MAIER
Vanderbilt Univ., Nashville, TN

Abstract: The spatial structure of spontaneously occurring neural correlations, termed functional connectivity, is highly organized and often reflects known anatomical connections at multiple scales. These spontaneously generated neural activity patterns are typically recorded with subjects resting idly rather than engaging in a task. Even in the absence of explicit stimulation, however, a subject's internal state is constantly changing. As resting state studies typically collapse data across several minutes of time, the influence of these internal dynamic variables on spontaneous neural activity is largely uncharacterized. In order to determine whether cortical functional connectivity during rest is constant or time-varying, we examined dynamic changes of spontaneous neural correlations across the laminae of primary visual cortex. Local field potentials (LFPs) were recorded from two linear multi-electrode arrays that were simultaneously placed in nearby (1-5mm) locations in V1 of two macaque monkeys that were at rest in a dark room. We first examined LFP coherence between all electrode positions across the cortical laminae and found that for all electrode pairs, interlaminar coherence varied greatly throughout our recording period. We then compared these dynamic changes in interlaminar functional

connectivity with a time-varying measure of cortical arousal. More specifically, we related the pair-wise measures of LFP coherence to fluctuations of an arousal-related index that was derived from the ratio between high frequency (60-100Hz) and low frequency (5-10Hz) LFP power. We found that interlaminar coherence correlated inversely with this index, suggesting that periods of low arousal are marked by periods of high coherence between laminae. Coherence between electrode locations within the same laminar compartment covaried less with the state of cortical arousal than coherence between electrode contacts spaced farther (>1mm) apart. These findings add to the body of evidence suggesting that resting state functional connectivity is not a static condition but rather a dynamic process that is linked to changes in cortical arousal.

Title: Orientation tuning of Gamma band measured in human MEG and across multiple scales of measurement in macaque V1 reveals network mechanisms

Authors: *M. J. ROBERTS[1,2], E. LOWET[1,2], A. HADJIPAPAS[3], A. PETER[4], P. DE WEERD[1,2]
[1]Dept. of Cognitive Neuroscience, Fac. of Psychology and Neurosci., Univ. of Maastricht, Maastricht, Netherlands; [2]Donders Institue for Brain, Cognition and Behavior, Radboud Univ. Nijmegen, Nijmegen, Netherlands; [3]Univ. of Nicosia Med. Sch., Nicosia, Cyprus; [4]Ernst Strungmann Inst. for Neurosci. in cooperation with Max Planck Society, Frankfurt, Germany

Abstract: Studying the properties of gamma band oscillations offers a route to understanding their generative mechanisms; however different measurement techniques may be sensitive to different generative mechanisms. Single unit spikes and network (gamma band) activity in primate visual cortex are sensitive to stimulus orientation. However, while the preferred

orientation of single units is variable between orientation columns, gamma band power and frequency have more uniform preferred orientations across the population. One possible explanation for this discrepancy may be that most measures of gamma band activity combine activity over large volumes of cortex typically encompassing many orientation columns. Orientation tuning of network gamma activity may therefore reflect the summation of activity over a volume of cortex in which there is an overrepresentation of specific orientation domains (summation hypothesis). Alternatively, the gamma band may reflect the temporal coordination of activity within a large synchronous network encompassing many orientation columns, orientation tuning may here reflect network properties in which all units have the same behavior (network hypothesis). To dissociate these hypotheses we measured gamma band orientation tuning using a range of measurement techniques sensitive to various spatial scales from single unit activity, Current Source Density, Local Field Potential and surface ECoG in Macaques to MEG in humans. In all experiments, gratings of varying orientation where presented parafoveally while the subject performed a color change detection task at fixation and ignored the grating. We reasoned that under the summation hypothesis orientation preference diversity and closeness to spike rate orientation preference would increase for the more local signals. However, in line with the network hypothesis, we found that even for the most local signals gamma band orientation tuning was homogonous over the population and was not associated with spike rates. We conclude that 1) gamma band activity and spike rate tuning do not reflect the same process. 2) Gamma band activity recorded over a range of measurement scales reflect largely the same process. This work highlights the major contribution of basic stimulus features in determining gamma power and frequency in addition to high level factors such as grouping or attention.

Abstract: While recordings of extracellular potentials are common in monitoring neural activity, the interpretation of the low frequency part, the local field potential (LFP), remains ambiguous. Several studies have shown that the LFP depends on the electrode position, tissue volume conduction, neuronal morphology, membrane properties, synaptic locations and -input correlations [1-4]. To gain insight into the relation of experimentally measured LFPs to the underlying spiking network activity, we have developed a hybrid modeling scheme. In this framework, spike trains generated by a network of single-compartment leaky integrate-and-fire neurons are used as synaptic input onto equivalent multi-compartment neurons with reconstructed morphologies, which in turn generate the LFP. Here, we apply this scheme to a multi-layered excitatory-inhibitory (E-I) point-neuron network model (implemented in NEST [5]) describing 1 mm^2 of cat primary visual cortex (modified from [6], Fig. 1a,b). For the LFP model (Fig. 1c,d), unconnected neurons of sixteen cell types with passive membranes (implemented with LFPy [7] / NEURON [8]) receive type- and layer-specific inputs derived from the network model and anatomical data [9]. In both models, a total of 78000 cells are distributed across layers 2/3 to 6. We show that both spontaneous and stimulus-evoked LFPs (ERPs) depend critically on the underlying network state (local recurrent dynamics). Further, we demonstrate that the effect of synaptic-input correlations on LFP power can only be accounted for in a full-scale model with realistic neuron density.

Title: Stimulus dependent spatial distribution of synaptic inhibition in simple cells of cat striate cortex

Authors: ***M. SEDIGH-SARVESTANI**, L. VIGELAND, L. A. PALMER, D. CONTRERAS
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Our goal is to understand visually evoked synaptic inputs to thalamorecipient simple cells in primary visual cortex. The push-pull model of simple cell receptive fields (RF) based on extracellular recordings (Palmer and Davis, 1981) suggests excitatory and inhibitory synaptic inputs with reciprocal spatial arrangement. In contrast, the lateral inhibition model suggests

broad inhibitory synaptic input covering all regions of the receptive field (Priebe and Ferster, 2008). Both models assume that the spatial distribution of synaptic excitation and inhibition is fixed and independent of the visual stimulus. We conduct measurements of excitatory and inhibitory synaptic input to simple cells in the cat striate cortex. Our preliminary data suggests that the spatial distribution of synaptic inhibition in simple cells depends on the spatiotemporal properties of the stimulus and is not a fixed property of the RF. We use sharp electrodes to obtain intracellular recordings of simple cells in layer 4 of the primary visual cortex of the anesthetized and paralyzed adult cat. We use two different stimulus sets: (i) individual bars of light of optimal orientation at 2 different contrasts (bright/dark) and 8 positions across the cell's RF and, (ii) the same 8 optimally oriented bars presented simultaneously, with bright or dark contrasts. We inject 5-7 levels of current into the cell during visual stimuli to estimate the excitatory and inhibitory synaptic conductance and combined reversal potential. Some pipettes include QX-314 solution in order to block action potential generation and allow for more accurate conductance estimates. We observe both push-pull and spatially broad inhibition in simple cells. Single bar stimuli usually result in spatially broad inhibition whereas multiple bar stimuli result in push-pull type inhibition. The spatial distribution of excitation is similar under both stimulus conditions. Thus our results indicate that the spatiotemporal properties of the stimulus modulate the spatial distribution of intracortical inhibition. Works Cited: Palmer LA, Davis TL. Title: Modeling optogenetic manipulation of neural circuits

Authors: ***M. AVERY**, J. H. REYNOLDS, J. J. NASSI
Salk Inst., San Diego, CA

Abstract: In recent years, a host of optogenetic tools have been developed, enabling experimentalists to manipulate neuronal activity with high temporal precision and cell-type specificity. This makes it possible to causally perturb the cortical circuit in ways that, when

linked with computational modeling techniques, enable the testing of specific hypotheses regarding how optogenetic activation of excitatory pools influences neurons embedded in a network. Using optogenetics in the alert macaque, we have found that activation of excitatory neurons results in a variety of different forms of facilitation and suppression of visually-evoked responses. These include additive, multiplicative, and more complex changes in the contrast response function, including suppression, even under conditions when the laser alone evokes an excitatory response. We showed that many of these changes can be accounted for by a normalization model in which optogenetic stimulation recruits both excitation and inhibition in the local cortical circuit. This model, however, is abstract, and does not adequately account for the dynamics of the network response. We have thus developed a neural network model that incorporates optogenetic stimulation as a light activated conductance expressed on excitatory neurons. We use this model to make testable predictions about how network dynamics will change under laser optogenetic stimulation conditions, including sustained laser activation and laser activation across a range of biologically relevant temporal frequencies.

Title: How SOM+ and PV+ inhibitory neurons could differentially modulate surround suppression of cortical neurons

Authors: ***M. JADI**, T. J. SEJNOWSKI
Salk Inst., La Jolla, CA

Abstract: Surround suppression in the cortex can be explained by normalization models in which the output is modulated by the summed local activity. In these models, the region of the sensory space that is pooled to produce suppression to a neuron is larger than that for summation. The neural implementation of normalization in the visual cortex is thought to involve inhibitory neurons that contribute the suppressive field by summing over a larger visual space compared to the local pyramidal neurons. There are two competing models for the action of inhibitory

neurons in the neural implementation of surround suppression: The lateral inhibition model proposes that local inhibitory neurons increase their activity in response to stimulation of a larger visual space. On the other hand, the inhibition-stabilized network model predicts the activity of inhibitory neurons to decrease in response to stimulation of a larger visual space (Tsodyks et al., 1997; Ozeki et al., 2009). Empirical evidence from the visual cortex suggests both an increase (Haider et al., 2010) and a decrease in inhibitory activity (Ozeki et al., 2009) in response to surround suppression. Activity of Somatostatin-expressing (SOM+) inhibitory neurons increases during surround suppression and their optogenetic silencing weakens the suppression, thus supporting the lateral inhibition model (Adesnik et al., 2012). However, the contribution and operating regime of other subclasses of inhibitory neurons, for example the Parvalbumin-expressing (PV+) inhibitory neurons, during surround suppression is not well understood. Since the exquisite sensitivity of the cortical circuit to the manipulation of PV+ inhibitory neurons offers significant experimental challenges, we explore the two competing proposals with a computational approach. We propose a model for the surround suppression circuitry consisting of both SOM+ and PV+ inhibitory neurons in which the differences in experimental observations are accounted for by differences in the inhibitory neuron subclasses in terms of their network connectivity and post-synaptic targets.

Title: Spatial summation induce layer-specific gamma oscillations in the local field potential in primate V1

Authors: ***M. A. GIESELMANN**, J. CLARKSON, A. THIELE
Inst. of Neurosci., Newcastle Univ., Newcastle upon Tyne, United Kingdom

Abstract: Neurons of primary visual cortex (V1) typically show a lower response to visual stimuli when the stimuli are covering the neurons' receptive field (RF) as well as areas of the visual field surrounding the RF (surround suppression). We have shown earlier (Gieselmann and

Thiele, 2008) that simultaneous to the decrease in firing rate, the local field potential (LFP) recorded from the same electrode shows an increase in oscillatory activity in the gamma range, as stimuli extend into the inhibitory surround. To identify to what extent these effects differ between cortical layers and to identify the networks involved in the generation of gamma oscillations we used multi-contact laminar recordings of the LFP and current-source density analysis (CSD). We recorded from 16-channel laminar electrodes inserted perpendicularly into the primary visual cortex. Electrode contacts we arranged vertically along the probe with a distance of 150 μm between them. We trained two awake monkeys on a passive fixation task during which they were presented with a series of square-wave gratings of different sizes. We analysed 23 experiments (17 in monkey, 5 in monkey 2). For all experiments recording channels were aligned in depth to the channel closest to the border between layer 4c and layer 5. We then calculated the LFP signal generated locally at each channel by estimating the CSD on a trial-by-trial basis. Large grating stimuli (>7° diameter) consistently induced strong sustained gamma oscillations in the LFP with a peak around 40 Hz in both monkeys. However, the amplitude of the gamma peak varied strongly across layers. In both monkeys the amplitude of the gamma-peak dropped below a z-score of 3 (normalized to spontaneous activity) in channels equivalent to the granular layers (monkey 1, 150 μm below layer 4c; monkey 2, 150 μm above layer 4c alignment). In supra-granular layers the strongest gamma-oscillations were found 600 μm (monkey1, z-score=9.4) and 750 μm (monkey2, z-score=27.1) above the layer 4c alignment, equivalent to cortical layer 2/3. Compared to small stimuli (<1°) this constitutes a 1.8 fold and 4 fold increase for monkey 1 and 2 respectively. In infra-granular layers the strongest gamma-oscillations were found 450 μm below the layer 4c alignment in both monkeys (monkey1, z-score=7.5; monkey2, z-score=20.3), which is equivalent to cortical layer 5/6. This corresponds to a 1.7 fold (monkey 1) and 3.8 fold (monkey 2) increase in gamma activity compared to small stimuli. Thus, spatial summation and surround suppression as measured by the gamma power CSD, does not manifest in granular layers of V1, but is prominent in supra and infragranular layers.

Title: Intra-cortical excitatory circuitry innervating layer 6 pyramidal neurons of the rat primary visual cortex

Authors: *F. COTEL[1], J. APERGIS-SCHOUTE[2,3], S. R. WILLIAMS[1,3]
[1]Queensland Brain Inst., Brisbane, Australia; [2]Dept. of Pharmacol., [3]Lab. of Mol. Biol., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Layer 6 (L6) is a key output layer of the visual cortex. L6 pyramidal neurons receive direct thalamo-cortical input, which is integrated together with intra-cortical circuit activity to form unique visual receptive fields (RFs). However, the source(s) of the intra-cortical excitatory circuitry that drive L6 pyramidal neurons are poorly determined. Functionally, L6 pyramidal neurons can be divided into two classes: L6-corticothalamic neurons (L6-ct), which possess end-stopped RFs, and corticoclaustral pyramidal cells (L6-cl) which display elongated RFs. In order to determine the pattern of intra-cortical excitatory input sampled by L6 pyramidal neurons we performed paired whole-cell recordings between morphologically identified L6 pyramidal neurons and excitatory neurons in all layers of the visual cortex maintained in acute rat brain-slices (P22-P30). We first confirmed the morphological division of L6-ct and L6-cl pyramidal neurons by recording from neurons retrogradely labeled from the thalamus and claustrum. The dendritic arbor of L6-ct terminates in L4 where it arborizes densely where as the apical dendrite of L6-cl extends to layer 1 with limited bifurcations. To our surprise we found that L6-cl and L6-ct neurons exhibited similar electrical properties. Paired recordings revealed that L6-ct and L6-cl pyramidal neurons were reciprocally inter-connected. In contrast, paired recording between L4 excitatory neurons and L6 pyramidal neurons revealed unitary excitatory connections only in L6-cl neurons. Strikingly and despite numerous attempts (n= 728 putative pairs) we failed to detect any connection from L2/3 and 5 pyramidal neurons to either L6-cl or L6-ct neurons. However, minimal extracellular stimulation in layer 1 evoked EPSPs in L6-cl, but not L6-ct, neurons with slow rise times (7.24±0.27ms), thus likely to result from remote, distal synapses. The use-dependent dynamics of synaptic transmission were connection-specific. L6-ct neurons evoked uEPSPs in L6-cl or L6-ct neurons with high failure rate (64%), and facilitated on repetitive activation (mean paired pulse ratio, PPR (40Hz): 4.06±0.91). In contrast, connections from L6-cl and L4 were more reliable (L6-cl: 23%; L4: 26%) and uEPSPs mostly depressed (PPR L6-cl: 0.88±0.08; L4: 0.78±0.02). Our results suggest that the receptive field properties of L6 pyramidal neurons emerge as a consequence of the intra-laminar reciprocal innervation between L6 pyramidal neurons. Uniquely we find that L6-cl pyramidal neurons receive both local L4 intra-cortical excitatory input and long-range input conveyed in layer 1, which may help to explain their elaborate receptive field properties.

Title: Probing the synaptic effects of distal connectivity in mouse visual cortex

Authors: ***T. SATO**[1], B. HAIDER[1], M. HAUSSER[2], M. CARANDINI[1]
[1]UCL Inst. of Ophthalmology, [2]Wolfson Inst. for Biomed. Res., Univ. Col. London, London, United Kingdom

Abstract: Neurons in primary visual cortex (V1) receive inputs from remote cortical sites through networks of distal intracortical connectivity, which include horizontal connectivity within V1 and feedback connectivity from higher areas. The impact of this distal connectivity is flexible, and obeys divisive normalization (Sato et al, Nature Neurosci, 2014): When a neuron is at rest or weakly active, distal connectivity provides drive (summation), whereas when the neuron is strongly active, distal connectivity provides suppression (division). A possible cellular explanation for these findings is that distal connectivity causes depolarization or hyperpolarization in the absence or the presence of sensory cortical activation. Hyperpolarization, in turn, may be mediated by somatic inhibition. To test these hypotheses, we have used *in vivo* patch-clamp recording in area V1 of anesthetized mice to measure the membrane potential (Vm) of neurons in layer 2/3 in response to visual stimulation and to distal activation. We activated the binocular zone (BZ) of area V1 using optogenetic antidromic stimulation (Sato et al, 2014), which allows us to impose spiking activity regardless of subthreshold influences. We then performed patch-clamp recordings in the distal monocular zone (MZ). Preliminary results indicate that distal activation in the BZ caused depolarization in the MZ when neurons were not visually driven, and hyperpolarization during high-contrast visual stimulation. The depolarization is likely to be mediated by synaptic excitation. As for the hyperpolarization, current experiments seek to establish whether it is due to somatic inhibition. To assess whether we can measure somatic inhibition using a conventional current-clamp mode,

we performed experiments in a mouse line expressing Channelrhodopsin-2 in parvalbumin-positive (PV) interneurons, which are known to provide somatic inhibition. Optogenetic activation of PV interneurons caused hyperpolarization in pyramidal cells when Vm was at rest (68.3 ± 1.7mV), and depolarization when Vm was more negative than the reversal potential for chloride (~ -80mV, 6mM intracellular chloride). These results confirm that our somatic recording electrodes can measure the chloride-mediated hyperpolarization or depolarization of Vm caused by somatic inhibition. Ongoing studies use this method to probe the role of somatic inhibition in the hyperpolarization caused by distal connectivity during visual stimulation. These experiments will provide a better understanding of how intracellular mechanisms implement flexible effects of distal connectivity as divisive normalization.

Title: Distinct excitatory/inhibtory balance in subnetworks within mouse primary visual cortex (v1)

Authors: P. BISTA, *A. H. BURKHALTER
Washington Univ. Med. Sch., St. Louis, MO

Abstract: Mouse visual cortex is subdivided into multiple, functionally distinct, hierarchically organized areas that are interconnected through feedforward (FF) and feedback (FB) pathways (Dong et al., 2004; Wang and Burkhalter, 2007). Within cerebral cortex the vast majority of interareal FF and FB connections are formed by excitatory pyramidal cells (Pyr), which in the target area synapse onto Pyr and, most commonly on parvalbumin-expressing (PV) GABAergic neurons (Gonchar and Burkhalter, 1999; 2003). Thus, in both pathways monosynaptic excitation of Pyr is followed by disynaptic PV neuron-mediated inhibition of activated Pyr cells (Dong et

al., 2004). The strength of this, so called, feedforward inhibition is likely to play a key role in the selection and top-down modulation of inputs as well as the dynamics of communication across the cortical hierarchy. Recently, we have found that FF input to PV neurons is stronger than to Pyr, whereas FB inputs to both types of neurons are balanced (Yang et al., 2013). Here, we report that FF geniculocortical and FB projections from higher visual areas to layers 1 and 2 of V1are patchy, raising the question whether the E/I balance within and outside patches is different. To study the issue, we used subcellular Channelrhodopsin-2 assisted circuit mapping (Petreanu et al., 2009) in tangential slices of V1 in which PV neurons were genetically labeled with tdTomato. We found that inside and outside of geniculocortical patches inputs to PV neurons were stronger than to Pyr cells, but the overall excitation within patches was 2-3 more powerful. Similar to FF connections, FB inputs to labeled patches were stronger to PV than Pyr. In contrast, FB inputs to unlabeled patches were balanced. These results suggest that feedforward inhibition depends on both the bottom-up and top-down direction of pathways as well as the subnetwork within the circuit.

Title: In-vivo GABAergic parvalbumin interneuron contribution to cortical transforms is laminar dependent

Authors: *D. E. PAFUNDO, B. D. FEESE, S. J. KUHLMAN
Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Gain control of neuronal networks is achieved by divisive normalization mechanisms, likely mediated by local inhibition and allows networks to encode a wide dynamic range of input values (Carandini and Heeger, NatRevNeurosci 2012). In the visual system, a significant part of stimulus driven gain control takes place in layer 4 of primary visual cortex (V1) where the contrast invariant tuning of excitatory neurons is mediated by stimulus-dependent broadening of inhibition produced by parvalbumin positive (PV) GABAergic neurons (Li et al, J Neurosci

2012). The processed visual information is then forwarded to layer 2/3 pyramidal neurons (PC) and PV neurons. Given that transformation of the visual stimulus takes place in layer 4 and that layer 2/3 PC and PV neurons do not receive strong direct thalamic stimulus dependent drive we hypothesize that there are laminar differences in how PV neurons mediate contrast invariant tuning of excitatory neurons. We used 2-photon guided electrophysiological cell-attached recordings of PV neurons to assay PV neuron activity in primary visual cortex in response to visual stimuli of different intensities. Consistent with previous reports, we find that the tuning curves of layer 4 PV neurons are contrast modulated, displaying a two fold increase in the orientation selectivity index when visual stimulation contrast was reduced from 100% to 25%. However, in layer 2/3 we find tuning curves of PV neurons are largely contrast independent, similar to excitatory neurons. Notably, preliminary whole cell current clamp experiments show that the tuning curves of action potential firing and subtreshold potentials of layer 2/3 PV neurons are similar. These results indicate that there are significant laminar differences in stimulus driven gain control mediated by PV neurons. Interestingly, the feedback connections from secondary visual cortex (V2) to V1 that target PCs and PV neurons in supra and infragranular layers seemingly avoid layer 4. Consequently, in layer 2/3, contextual gain control may be engaged by V2 feedback onto PV neurons, a modulation which would be absent in layer 4. Future experiments will address the contribution of V2 feedback to PV neuron mediated gain control in layer 2/3 of V1.

Title: Very long-range disynaptic connections through layer 6 pyramidal neurons in macaque monkey V1

Authors: *D. C. LYON, Y.-J. LIU, M. ARREOLA
Anat. & Neurobio., Univ. of California, Irvine, CA

Abstract: Neurons in primary visual cortex (V1) integrate across the representation of the visual field through networks of long-range projecting pyramidal neurons. These projections which originate from within V1 and through feedback from higher visual areas are likely to play a key

role in such visual processes as low contrast facilitation and extraclassical surround suppression. The extent of the visual field representation covered by feedback is generally much larger than that covered through monosynaptic horizontal connections within V1; and, although it may be possible that multisynaptic horizontal connections across V1 could also lead to more widespread spatial integration, nothing is known regarding such circuits. Here we used injections of the CVS-11 strain of rabies virus to examine disynaptic long-range horizontal connections within macaque monkey V1. Injections were made around the representation of 5° eccentricity in the lower visual field. Along the opercular surface of V1, we found that the majority of connected neurons extended up to 8 mm in layers 3, 4A, 4B, 5 and 6, consistent with twice the typically reported distances of monosynaptic connections. In addition, mainly in layer 6, a steady presence of connected neurons within V1 was observed up to 16 mm away. A relatively high percentage of these connected neurons had large diameter somata characteristic of Meynert cells, which are known to project as far as 8 mm individually. Several neurons, predominantly in layer 6, were also found deep within the calcarine sulcus reaching as far as 20° of eccentricity, based on estimates, and extending well into the upper visual field representation. Thus, our anatomical results provide evidence for a wide-ranging disynaptic circuit within V1, mediated largely through layer 6 that accounts for integration across a large region of the visual field.

Title: The sparseness of excitatory lateral connections can account for the formation of species-dependent orientation representation in the mammalian primary visual cortex

Authors: *M. MIYASHITA[1], S. TANAKA[2]
[1]Numazu Natl. Col. of Technol., Numazu, Shizuoka, Japan; [2]Univ. of Electro-Communications, Tokyo, Japan

Abstract: In the primary visual cortex of monkeys, cats and ferrets, preferred orientations are arranged along the cortical surface in an orderly manner, forming orientation maps. Recently, 2-

photon calcium imaging has revealed that preferred orientations are randomly distributed in the rodent visual cortex. This finding raised a question of why orientation maps exist in some species and not in others. To address this question, we examined the activity-dependent self-organization of orientation representation for different degrees of sparseness of excitatory lateral connections in the visual cortex. We assumed that cortical cells send excitatory connections to neighboring cells with the connection probability p, whereas inhibitory connections are long-range and nonspecific. In addition, we normalized each synaptic weight to be proportional to 1/p, because without the normalization, small connection probability leads to relatively strong lateral inhibition and cortical cells tend to be silent. Computer simulations were conducted by changing the value of p. As a result, we found a certain value p* such that salt-and-pepper-like orientation representations emerge for $p < p^*$ and orderly orientation maps emerge for $p > p^*$. For any value of p, model cortical cells exhibited simple-cell-like receptive fields. Note that without the normalization of synaptic weight, receptive fields were disrupted. The value p* depended on the "temperature" that is interpreted to indicate the magnitude of fluctuation in synaptic modification within our mathematical framework. Although we cannot determine the exact value of the temperature in real systems, a fairly sharp transition between an orderly map representation and a salt-and-pepper-like representation occurred at $p=p^*$ for lower temperatures. Combining these theoretical results with species-dependent orientation representations, it is suggested that excitatory lateral connections are sparse and each synaptic weight is large in the rodent visual cortex, whereas excitatory connections are relatively dense and each synaptic weight is small in the visual cortex of monkeys, cats and ferrets.

Title: GABAergic interneurons form spatial clusters in the mouse visual cortex to enhance inhibitory actions on excitatory neurons

Authors: ***T. EBINA**[1], K. SOHYA[1], I. IMAYOSHI[2], S.-T. YIN[1], R. KIMURA[1], Y. YANAGAWA[3], H. KAMEDA[4], H. HIOKI[4], T. KANEKO[4], T. TSUMOTO[1]

Abstract: Neocortical neurons with similar functional properties assemble into spatially coherent circuits, but it remains unclear how inhibitory interneurons are organized in the spatial domain of the cerebral neocortex. Recent *in vitro* studies revealed the clusters of inhibitory interneurons originated from the same progenitor cells in the developing neocortex. However, it is still not clear how long such a clustered distribution persists during postnatal development, and even if it persists to the adulthood, it remains unknown what is the functional significance of spatial clustering of GABAergic interneurons in operation of cortical circuits. To address these questions, we applied *in vivo* two-photon functional Ca2+ imaging and whole-cell recording of synaptic currents to record visual responses of cortical neurons, and analyzed their spatial arrangements. GABAergic interneurons were clustered in the three-dimensional space of the adult visual cortex, and the three subtypes of interneurons, parvalbumin-, calretinin- and somatostatin-positive neurons also formed clusters with slightly overlapping each other. Excitatory neurons located within the clusters (insiders) had a lower amplitude and sharper orientation tuning of visual responses than outsiders, whereas the neurons near and far from non-clustered interneurons did not show the location-tuning/amplitude relationship. Furthermore, inhibitory synaptic currents recorded from the insiders were larger than those of the outsiders. These findings suggest that GABAergic interneurons form spatial clusters to make their inhibitory function more effective than isolated interneurons.

Title: Layer 6 corticothalamic neurons activate layer 5a pyramidal neurons

Authors: J. KIM[1], C. J. MATNEY[1], A. BLANKENSHIP[2], S. HESTRIN[2], *S. P. BROWN[1]
[1]Dept. of Neurosci., Johns Hopkins Sch. of Med., Baltimore, MD; [2]Dept. of Comparative Med., Stanford Sch. of Med., Stanford, CA

Abstract: Layer 6 corticothalamic (L6 CT) neurons are thought to modulate sensory processing through feedback projections to the thalamus and feedforward projections to the main input layer of the cortex, layer 4 (L4). Anatomical reconstructions of individual L6 CT neurons, however, have shown that their axonal processes ramify not only in L4 but also in layer 5 (L5), the major output layer of the cortex, raising the question of the relative synaptic impact of L6 CT neurons on L4 and L5. Using a combination of anatomical, electrophysiological and optogenetic approaches, we show that the intracortical axons of L6 CT cells densely ramify within layer 5a (L5a) in both visual and somatosensory cortex and activate L5a pyramidal neurons. Following injections of retrograde tracers into the thalamus of Ntsr1-Cre mice, we show that Cre expression is largely restricted to L6 CT neurons. By crossing Ntsr1-Cre mice with Cre-dependent reporter lines combined with injections of viral and retrograde neuronal tracers, we show that the intracortical axons of L6 CT neurons are primarily located in L5a rather than in L4. We next compared the relative synaptic impact of L6 CT neurons on L4 and L5a excitatory neurons. By selectively expressing channelrhodopsin-2 (ChR2) in L6 CT neurons while performing whole-cell recordings from a L4 and a L5a excitatory neuron simultaneously, we show that photostimulation of L6 CT neurons elicits strong, short-latency excitatory postsynaptic potentials (EPSPs) in L5a pyramidal neurons while eliciting weak EPSPs or disynaptic inhibitory responses in L4 cells. We next compared this input with L6 CT input to inhibitory neurons. We performed similar experiments with pairs composed of a L5a fast-spiking (FS) interneuron and a pyramidal neuron or a L4 FS cell and excitatory neuron. We found that L6 CT photostimulation evokes strong, short-latency EPSPs in FS cells in both L4 and L5a. Interestingly, L6 CT photostimulation evokes action potentials in L5a pyramids despite the strong input to FS cells. We next asked whether L6 CT neurons provide input selectively to FS cells input or to inhibitory neurons more generally. By recording from pairs composed of a L5a somatostatin-expressing (SOM) interneuron and a L5a pyramidal cell, we show that SOM cells receive only weak L6 CT cell input. Taken together, our results suggest that L6 CT neurons activate pyramidal cells and FS cells in L5a, an output layer of the cortex, via feedforward excitation, while inhibiting L4, the major input layer of the cortex, via feedforward inhibition.

Title: Cellular imaging of genetically defined populations in layer 4 of mouse primary visual cortex reveals functional diversity

Authors: *A. R. GARNER, A. CHENG, L. MADISEN, H. ZENG, R. C. REID
Allen Inst. For Brain Sci., Seattle, WA

Abstract: Pyramidal cells of primary visual cortex are a genetically and physiologically heterogeneous population. We have employed *in vivo* 2-photon calcium imaging using GCaMP6 in awake, active transgenic mice to examine the functional diversity of genetically defined populations of pyramidal cells during visual stimulation. We focused on layer 4 (L4) because in addition to its role as the primary cortical recipient layer of LGN afferent fibers, anatomical studies have shown that most excitatory input is from recurrently connected cortical neurons. These circuit features make L4 an intriguing candidate for investigating information processing on input signals from the external world en route for higher order downstream cortical computations. Our results suggest that in addition to processing of visual sensory input, the information content of a layer 4 pyramidal cell's output is highly dependent on its spatiotemporal relationship with the activity of the assembly in which the cell is embedded as well as the behavioral state of the animal.

Title: A comprehensive large-scale spiking model of cat primary visual cortex

Authors: J. ANTOLÍK, C. MONIER, Y. FRÉGNAC, *A. P. DAVISON
UNIC, Ctr. Nationale De La Recherche Scientifique (CNRS), Gif sur Yvette, France

Abstract: Neuroscience has produced a large body of data on the function and anatomy of early visual areas but the transformation of this knowledge into a general coherent understanding has been limited. Computational modeling can integrate such fragmented data into comprehensive models of brain structures that satisfy the broad range of constraints imposed by experiments, thus advancing our understanding of their computational role, and their implementation in the neural substrate. Unfortunately most studies have so far focused on small isolated models targeting only a few properties at a time. Here we introduce a comprehensive multiscale spiking model of cat primary visual cortex (V1/area 17) which satisfies a range of anatomical, statistical and functional properties. The model considers cortical layers 4 and 2/3, corresponding to a 5x5 mm patch of parafoveal V1. Thalamocortical connections are seeded based on orientation maps obtained in a developmental simulation of V1 (Antolík et al. 2010; Front Comp Neurosci 5:1-19). The inter and intra-layer connectivities are based on rules extracted from anatomical and functional studies (Binzegger et al. 2004; J Neurosci 24:8441-53): the thalamocortical pathways and local layer 4 connectivity follow a push-pull organization (Troyer et al. 1998; J Neurosci 18:5908-27), while the long distance horizontal connection probability falls off as a Gaussian curve with parameters derived from Stepanyants et al. (2008; Cereb Cortex 18:13-28). We assumed a slow propagation speed for horizontal connectivity and fast synaptic depression in both thalamocortical and corticocortical connections. We have subjected the model to a range of visual stimulation protocols including gratings and natural scenes animated with eye-movements (Baudot et al. 2014; Front Neural Circuits 7:206). The model expresses over multiple scales a large number of statistical and functional properties including: spontaneous activity with a physiologically plausible resting conductance regime; contrast-invariant orientation-tuning width; realistic interplay between visually evoked excitatory and inhibitory conductances, including the experimentally observed variations among neurons; surround modulation effects including size and orientation-contrast tuning; stimulus-dependent changes in firing precision; and a realistic distribution of Simple and Complex receptive fields. Overall we believe this

model offers the most comprehensive description of V1 to date from conductances to spikes. It offers numerous insights into how the properties studied interact, and thus contributes to a better understanding of visual cortical dynamics.

Title: Different cortical layers in V1 encode different visual information in different frequency bands

Authors: ***S. C. LOWE**[1], D. ZALDIVAR[2,3], Y. MURAYAMA[2], M. C. W. VAN ROSSUM[1], N. K. LOGOTHETIS[2], S. PANZERI[4]

Sch., Tübingen, Germany; [4]Ctr. for Neurosci. and Cognitive Systems, Italian Inst. of Technol., Rovereto, Italy

Abstract: We previously reported that the activity of primary visual cortex (V1) transmits information about complex naturalistic video stimuli in two distinct frequency bands: a low frequency band (1-24 Hz), and a high frequency (60-100 Hz) gamma oscillation range, with each range carrying its own independent information about the visual stimuli [1]. Here we ask whether these independent frequency channels originate from distinct cortical laminae. We used laminar electrodes with 150 micron spacing spanning the whole cortical depth to record extracellular field potentials from the primary visual cortex of opiate-anaesthetised macaques during presentation of a 2 minute long Hollywood colour movie clip. Using the recorded Local Field Potential (LFP), we computed the Current Source Density (CSD) for each trial. From the time-resolved power of the CSD in each trial, we estimated the mutual information that the power at each frequency carries about which section of the movie is being presented, and how

much information there is in frequency bands about different spatial resolutions of changes in luminance. We found, across depth and frequency, two distinct regions carrying large amounts of independent information about the movie stimulus: the low frequency (4-16 Hz) band had high information at depths corresponding to layers 4-6, whereas the high frequency (64-250 Hz) band had high information in layers 1-3. This suggests that different laminae of cortical circuits generate independent information channels that code information in separate frequency ranges. Furthermore, we found the low frequency band contained information about low spatial frequencies changes in luminance (<1 cycle per degree), whilst the high frequency band contained information about finer spatial details (1-6 cycles per degree). This suggests information about these two spatial frequency components arises through two different cortical mechanisms within V1, and information about them is encoded separately in two different frequency bands. Abstract: The pulvinar plays an important role in neural information processing, especially in facilitating the communication between cortical areas in response to attention demands (Saalmann et al., 2012). However, its functional connectivity with primary sensory cortices has remained unknown. We hypothesized that the different layers of primary visual cortex (V1) form distinct, frequency-specific functional connections with the pulvinar. To test this hypothesis, we presented artificial and naturalistic visual stimuli to anesthetized ferrets (Mustela putoris furo, 16-20 weeks, female, n=8) and simultaneously recorded multiunit activity (MUA) and local field potential (LFP) from the pulvinar and V1. We determined functional connectivity patterns between pulvinar and V1 cortical layers (supragranular, granular and infragranular layers) both for spontaneous network activity in absence of sensory input and for sensory processing of full-field visual stimuli. We found that naturalistic visual input caused most pronounced functional connectivity between the pulvinar and V1 measured by MUA spike correlations (ANOVA, main effect of stimulus type, $p=0.01$; no effect by layer, $p>0.05$). In agreement with our hypothesis, we found that the pulvinar and all three cortical layers exhibited highest correlations of LFP spectral power in the alpha frequency band (8-12 Hz) for spontaneous activity (main effect of frequency band, $p<0.001$). Furthermore, LFP coherence during visual stimulation exhibited layer- and stimulus-specific structure in distinct frequency bands: (1) supragranular and granular layers displayed higher coherence with the pulvinar than the infragranular layer in the delta (0.5-4 Hz) and alpha bands (main effect of layer, $p<0.001$) and (2) gamma coherence was suppressed by both artificial and naturalistic visual input (main effect of stimulus type, $p=0.003$). Cross-area coupling determined by phase preference of MUA as a function of LPF phase further confirmed layer-specific functional connectivity between pulvinar and V1. MUA in infragranular layers exhibited the strongest phase preference in the delta band of the pulvinar LFP. Differently, pulvinar MUA exhibited the strongest phase preference for all frequency bands of the supragranular V1 LFP. Together, our data suggest that, at the level of the LFP, several communication channels exist between the pulvinar and specific layers in V1 that are enabled by frequency-specific oscillatory activity patterns. Title: Modulation of spike rate by optogenetic control of GABAergic neurons alters contrast adaptation in mouse primary visual cortex

Authors: *N. A. CROWDER, K. R. STOVER, J. L. KING, K. M. GORDON
Dalhousie Univ., Halifax, NS, Canada

Abstract: Prolonged viewing of high contrast gratings alters perceived stimulus contrast, and produces characteristic changes in the contrast response functions of neurons in the primary visual cortex (V1). This phenomenon is referred to as contrast adaptation. The underlying cellular and network mechanisms mediating contrast adaptation are largely unknown. Therefore, having previously established broad similarities in V1 contrast adaptation between mice and higher mammals, we sought to use a mouse model of optogenetic perturbation to study the possible roles of intrinsic firing rate and/or GABAergic innervation in this form of short-term plasticity. We performed extracellular recordings from V1 neurons in transgenic mice that express channelrhodopsin-2 (ChR2) in GABAergic neurons, and coupled contrast adaptation stimulus protocols with V1 photostimulation. We found that optogenetic activation of GABAergic neurons when the adapting grating was present caused a decline in activity during this period that consistently altered the shape of adapted contrast response functions that were collected following cessation of photostimulation. The precise temporal control allowed by optogenetics shows promise in helping to unravel the mechanisms of visual adaption.

Title: No functional specialization of Calretinin-expressing neurons in the mouse visual cortex

Authors: D. CAMILLO[1], C. N. LEVELT[2], *J. A. HEIMEL[3]
[1]Cortical Structure & Function, [2]Mol. Visual Plasticity, Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [3]Netherlands Inst. Neurosci, Amsterdam, Netherlands

Abstract: Calretinin is a calcium-binding protein often used as a marker of a subset of inhibitory interneurons in the cerebral cortex. Using Calb2-ires-cre mice, we show that calretinin is also likely to be transiently expressed in cortical pyramidal neurons during development. In the mature visual cortex of the mice, only a minority of the cells that have expressed Cre is gabaergic and only about 13% stain positive for the Calretinin protein. To determine whether this group of cells share any functional characteristics, we recorded their visual response properties using GCaMP6s calcium imaging. The average orientation selectivity, size tuning, and temporal and spatial frequency tuning of this group of cells, however, match the response profile of the general neuronal population, revealing no functional specialization.

Title: Inhibition-stabilized balanced dynamics account for stimulus-induced changes of noise variability in the cortex

Authors: Y. AHMADIAN[1], G. HENNEQUIN[2], D. B. RUBIN[1], K. D. MILLER[1], *M. LENGYEL[2]
[1]Columbia Univ., New York, NY; [2]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Hypotheses about the dynamical regime in which cortical circuits may operate have traditionally relied on data about trial average responses and typically ignored across-trial variability, or at best considered its most basic aspect, the Poisson-like variability of single cell spike counts. However, there is now a growing body of data on more detailed patterns of variability and co-variability of neural responses, and how they change in a stimulus-dependent manner, both at the level of membrane potentials and spike counts. These data could be used to further constrain theories of cortical dynamics, but establishing a quantitative relationship between circuit dynamics and patterns of variability is challenging because it requires a formal understanding of how correlations arise mechanistically in recurrently connected networks of neurons. Unfortunately, existing theories provide a somewhat blurry picture, as they often connect some high-level statistics of the circuit connectivity to other summary statistics of the pairwise correlation distribution. More elaborate theories can predict pairwise correlations for any specific pair of neurons, but assume either small firing rate variability or weak correlations, which are unlikely to generally hold in cortical circuits. Here, we developed a novel theoretical framework to obtain the full correlational structure of a stochastic network of nonlinear neurons described by rate variables. Importantly, our theory requires neither the fluctuations nor the pairwise noise correlations to be weak, and works for several biologically motivated, convex single-neuron gain functions. We apply our formalism to visual area MT, for which data on how particular stimuli affect neuronal variability has been published recently (Ponce-Alvarez et al., 2013). We find that a balanced ring model network with a threshold-quadratic nonlinearity captures the stimulus-dependence of both the Fano factor and the noise correlations. Interestingly, this network operates in a regime very different from previous proposals for variability quenching which all relied on multistable attractor dynamics, but closer to the behavior of the inhibition-stabilized balanced networks (Murphy and Miller, 2009; Ahmadian et al. 2013; Hennequin et al. 2014).

Title: Modeling eye-position gain fields for population coding recovery of stimulus locations

Authors: *A. B. SERENO[1], M. E. SERENO[2], S. R. LEHKY[3]
[1]UT Houston Med. Sch., Houston, TX; [2]Univ. of Oregon, Eugene, OR; [3]The Salk Inst., La Jolla, CA

Abstract: We created a population of model neurons whose responses were modulated by eye position. This population was used to recover gaze angle, equivalent to recovering the location of a stimulus at fixation. An intrinsic population decoding method was used, namely multidimensional scaling. Each neuron in the population had a different function describing eye-position modulation, or a different gain field. We used quasi-planar gain fields, shaped like a curved sheet with a sigmoidal cross-section, defined by three parameters: *slope* (how steeply the gain field was tilted), *orientation* (direction of tilt), and *shift* (position of sigmoid inflection relative to receptive field center). When the population had broadly dispersed values for all three parameters it was able to do an accurate recovery of stimulus location. When the range of the slope parameter was held constant or restricted to having a small range of values close to some arbitrary value, the population was still able to accurately recover location. However, if the range of the orientation parameter was similarly restricted, the population was able to recover eccentricity of location, but not polar angle. Also, if the range of the shift parameter was similarly restricted, the population was able to recover polar angle of location, but not eccentricity. Using a broad range for all three parameters, it made no difference if the gain field was quasi-planar (sigmoidal) or planar, showing that linear and nonlinear gain fields fare equally well under this model. Populations of completely non-planar gain fields also performed good recovery of location, including gain fields that were parabolic, hyperbolic, or a complex shape that was a linear combination of planar, parabolic, and hyperbolic. An important requirement was that average neural response over the gain field (average response over all eye positions) was not identical for all neurons in the population. Thus, we have characterized how gain field properties can affect recovery of stimulus location and such modeling may be useful in understanding known stimulus mislocalization phenomena. Most importantly, we demonstrate that eye-position gain fields, even without retinal information, are sufficient to accurately recover fixated stimulus locations.

Title: The contribution of corollary discharge to perceived eye location for different movement orientations and amplitudes

Authors: *S. BANSAL[1], L. C. BRAY[2], M. S. PETERSON[3], W. M. JOINER[2]
[1]Neurosci., [2]Bioengineering, [3]Psychology, George Mason Univ., Fairfax, VA

Abstract: Both neural and behavioral studies have suggested that visual stability is mediated by a corollary discharge (CD) signal. This signal is hypothesized to inform the visual areas on the future eye position, but how it encodes impending saccade metrics, particularly for movements of different orientations and amplitudes, is still unclear. To investigate these properties we designed two experiments to determine the effects of amplitude and orientation on the CD-based ability to perceive trans-saccadic target displacements. In the first experiment (N=10) an initial target (T1) randomly appeared at one of three amplitudes (4º, 6º, 8º) and four orientations (upward, downward, leftward, and rightward) from the central fixation point. After a primary saccade to T1 there was a 250 ms blank period to reduce saccade suppression of displacement. T1 then reappeared at a shifted randomized position in-line with the movement (± 0.5º collinear increments) between ± 2.5º and the subject made a manual response to indicate displacement direction. Our results showed that there was a significant effect of amplitude, but for a given amplitude there was no significant effect of orientation ($p<0.01$ and $p=0.19$, 2-way ANOVA) in perceiving displacements when occurring in the direction of the saccade. We also confirmed that the threshold increased systematically with amplitude; mean thresholds were ~10% of movement amplitude. In addition, we found that in spite of the movement variability, subject performance remained greater than chance in perceiving the target displacement accurately (>70%) even when the displacement and saccade error were in conflict. As a consequence of these findings, we reduced our second experiment (N=8) to two amplitudes (4º or 8º), and three orientations (rightward, oblique (45º), or upward) to examine the ability to detect collinear, orthogonal and diagonal T1 shifts. We found that perceptual thresholds for both orthogonal and oblique shifts were lower than collinear displacements ($p\leq0.03$). Based on the different orientations, we also determined and compared the fields of sensitivity for the respective target locations. We find that the sensitivity fields are oriented (broader) along the saccade direction for horizontal and vertical movements, but less so for oblique saccades. However, for all saccade orientations, the

sensitivity field increased in size with movement amplitude while maintaining the original orientation. In summary, the CD-based ability to perceive changes in target displacement decreases with movement amplitude, and it is generally independent of movement orientation, but highly dependent on displacement direction.

Title: Gain and timing adaptation for smooth pursuit eye movements

Authors: *S. ONO
Washington Natl. Primate Res. Ctr., Univ. of Washington, Seattle, WA

Abstract: Visuomotor adaptation associated with gain and timing control is necessary for precise control of eye movements. It has been shown that smooth pursuit gain adaptation is induced by repeated trials of a step-ramp tracking with two different velocities (double-velocity paradigm) that step-up (10-30 °/s) or step-down (20-5 °/s). The most effective way to induce pursuit adaptation is to change the target speed at the time of pursuit onset (100-120 ms after target onset). Previous studies have shown an adaptive change in initial pursuit gain after repeated double-velocity trials (over 100-200 trials), revealed as overshooting or undershooting eye motion during control testing using single-speed ramp trials. However, it is still uncertain whether a double-velocity paradigm with different timing produces pursuit gain adaptation. Therefore, we use a double-velocity paradigm where target speed changes 400 ms or 800 ms after the target onset during a steady-state phase. After repeated presentation of this paradigm, overshooting eye motion did not occur on control trials using single-speed pursuit. The steady-

state paradigm affected neither initial pursuit gain nor steady-state gain. However, when a brief sinusoidal perturbation of target motion (2.5 Hz, ± 10 °/s) is introduced during a steady-state phase after the adaptation paradigm, a perturbation ocular response showed a significant adaptive change, which was associated with the time when the target speed changed. These results indicate that this gain adaptation occurs at a specific time, which could be due to adaptation mechanisms of visuomotor gain associated with timing control.

Title: What eye movements tell us about visual saliency in different states of awareness

Authors: *Y.-H. YANG[1,2], S.-L. YEH[2], A. BARTELS[1]
[1]Vision and Cognition Lab, Werner Reichardt Ctr. for Integrative Neurosci., Univ. of Tübingen, Tübingen, Germany; [2]Perception and Attention Lab, Dept. of Psychology, Natl. Taiwan Univ., Taipei, Taiwan

Abstract: The relation between attention and consciousness is a contentious issue. In the present study we tried to relate attention allocation to stimulus processing as a function of the conscious state of the observer. In particular, we asked whether attention is allocated to visual cues that are globally or locally salient as a function of awareness of the stimulus. We used a paradigm called continuous flash suppression (CFS) to render stimuli invisible to the observer, and measured eye movements to left or right half of the visual field that differed in stimulus content. We assumed that oculomotor responses are a good indicator of attention allocation during conscious as well as unconscious stimulus processing. During CFS, a critical stimulus presented to one eye is

interocularly suppressed by dynamic masks presented to the other eye. We presented the salient stimulus property in either left or right visual field, while the whole stimulus was suppressed by interocular masks. Oculomotor responses were measured online by an eye-tracker. The salient stimulus property was either a single pop-out feature (e.g., a red disk among green disks), or alternating local gradients (e.g., alternative red-green disks), thus forming a global or a local salient stimulus property, respectively. In each trial, we measured the level of awareness using an objective and a subjective criterion: the objective measure was the success rate with which observers judged whether the salient property was in left or right visual fields, and the subjective measure was the confidence rating of their judgment. We found that attention was allocated to the global or local feature depending on the state of awareness: in trials where objective performance was above chance level and subjective rating was high, eye position favored the local over the global stimulus feature. On the other hand, in trials where objective performance was at chance and confidence was low, eye position favored the global over the local stimulus feature. These results suggest that the state of awareness affects the type of visual features that attract attention.

Title: Effect of sensorimotor adaptation of saccades on covert exogenous attention

Authors: O. HABCHI, R. MATHIEU, C. URQUIZAR, A. FARNÈ, *D. PELISSON
INSERM U1028-CNRS UMR5292/CRNL, Lyon-Bron, France

Abstract: Acquisition of visual information relies on a close collaboration between overt movements of the eyes (saccades) and covert shifts of attention. The accuracy of saccades is controlled by sensorimotor adaptation processes based on neural plasticity. Despite the link between saccades and covert attention, the effects of saccadic adaptation on covert shifts of

exogenous attention have never been investigated. In this study we measured the performance of seventy-three healthy volunteers in a speeded visual detection task performed immediately before (pre) and after (post) an exposure phase. Participants were assigned to 8 groups (10 participants per group), each group performing during the exposure phase one combination of three experimental factors: saccade task (adaptation versus mere execution) x saccade type (voluntary versus reactive) x saccade direction (leftward versus rightward). In the saccadic adaptation task, a backward adaptation was induced by the double step target paradigm (McLaughlin 1967), whereas in the saccade execution (control) task, saccades were elicited in a single-step target paradigm. Note that throughout the visual detection task, subjects maintained their eyes on a central fixation point and had to manually press a response-button as soon as they detected the presentation of a visual target in either hemi-field. The results showed that, as expected, saccadic gain significantly decreased in the 4 adaptation groups and only in the "adapted" hemi-field. In contrast, detection reaction time decreased significantly between pre- and post-exposure specifically after adaptation of leftward reactive saccades, thus demonstrating that deployment of purely covert attention can be boosted by saccadic adaptation. Based on this specific effect of adaptation of leftward reactive saccades on covert attention and on the known asymmetrical specialization of cerebral hemispheres in oculomotor and attentional control, we propose a new neurophysiological model where the temporo-parietal junction (TPJ) plays a central role. To test this hypothesis, we currently perform a fMRI-guided Transcranial Magnetic Stimulation (TMS) study of the role of TPJ in adaptation of reactive saccades and in the associated change of covert attention.

Title: Temporal structure of population activity supplements the instantaneous rate code in gating saccade initiation

Authors: U. K. JAGADISAN[1], *N. J. GANDHI[2]
[1]Dept. of Bioengineering, [2]Dept. of Otolaryngology, Univ. of Pittsburgh, PITTSBURGH, PA

Abstract: The superior colliculus (SC) and frontal eye fields (FEF) are critical nodes in the network that facilitates the transformation of sensory input to orienting movements, e.g., saccadic gaze shifts. Crucial to this transformation are neurons in these regions that are activated both by the onset of a visual stimulus (visual burst) as well as prior to a saccade (premotor burst) in their response field. Intriguingly, these so-called visuomotor neurons also have direct projections to the burst generators in the brainstem that are involved in saccade initiation. This raises the question - why does the high frequency visual burst not trigger a saccade, unlike the premotor burst. Here, we record in monkeys performing the delayed saccade task and show that the temporal relationship between neurons in SC and FEF during the visual response is different from that during the premotor response. Specifically, the temporal structure fluctuates in the visual burst while remaining relatively stable in the premotor burst, specifying a code to distinguish between incoming sensory input and motor preparatory output. We propose this temporal inconsistency of the visual response as a putative explanation for why the high frequency visual burst does not initiate a saccade, although it may cross a firing rate threshold at the population level. Such gating of the visual burst is an important functional attribute because owing to the aforementioned direct projections to the brainstem, any increase in the incoming drive from these neurons is poised to trigger a premature (and potentially erroneous) gaze shift. We further show that during large saccades this pattern of temporal inconsistency is reversed in the population recorded from rostral SC, which is active during fixation and bursts for microsaccades. That is, the rostral SC population is temporally consistent during the visual burst occurring in caudal SC and fluctuates at the time of the (large) saccade. We also test the temporal inconsistency hypothesis in a condition where the visual and premotor bursts are not as well separated as in the delayed saccade task. Specifically, the visual burst which triggers express saccades in the gap paradigm had a relatively consistent temporal structure, whereas the visual burst for regular, non-express saccades was inconsistent. In the accompanying abstract, we develop a model of saccade initiation that takes into account temporal structure. We suggest that future studies need to look at the temporal structure of population activity along with measures such as instantaneous firing rate to examine its role in neuronal communication and correlation with behavior.

Title: Blinks and eye closures - More happening in the brain than meets the eye

Authors: *D. KONG, J. ONG, M. W. CHEE
Duke-Nus Grad. Med. Sch., Singapore, Singapore

Abstract: Blinks and eye closures are two commonly observed oculomotor activities that share similarities yet trigger largely distinct neural activities. Blinks transiently interrupt external visual input, but are rarely noticed, while sustained eye closures shut out external visual environment, altering sensory perception. Here, we tried to delineate functional differences between blinks and eye closure under a variety of visual conditions. 52 participants took part in 4 experiments that involved fMRI and eye-tracking. 1. Voluntary blinks with external visual inputs RSVP sequences of black letters appeared on a white screen. Participants blinked continuously or kept their eyes open for 20s blocks. 2. Blink in darkness or with constant retinal illumination Each 12s blink block was followed by an eyes-open period. Half the runs were conducted in darkness; while in the other half, pulsating light was delivered directly to the retina using a fiber-optic light source placed at the roof of the mouth. This kept retinal illumination constant regardless of blinks. 3. Spontaneous blinks in darkness Participants kept their eyes open in darkness. Spontaneous blinks were identified using eye tracking. 4. Eye closure in darkness or with constant retinal illumination Scans alternated between 12s eyes close and eyes open blocks. Similar to Exp. 2, visual stimulation was either absent or delivered through the fiber-optic system. Blinks, voluntary or spontaneous, consistently activated the parieto-occipital junction regardless of constancy or presence of visual stimulation. During extended eye closure, extensive deactivation was observed in thalamus, insula, frontal eye field, supplementary eye field and cuneus. Interestingly, increased activity was observed in extrastriate visual, somatosensory regions and hippocampus. Beta series connectivity analysis using thalamus as a seed showed that regardless of stimulation condition, thalamus connectivity with the attentional network and visual areas was preserved during blocks of blinking but was lost with extended eye closure. Activation observed during blinks may reflect engagement of compensation for the transient loss of visual input, giving the illusion of perceptual continuity. The co-activation of extrastriate visual, hippocampal and somatosensory areas in the absence of visual stimulation represents sensory activation dissociated from relevant external stimulation as evidenced by reduced thalamocortical functional connectivity. The basis for these latter observations remains unclear.

Title: Dissociation of pursuit eye movement and perception of visual motion under binocular and dichoptic condition

Authors: *B. CAO[1,3], E. EYUBOGLU[4], A. MECKEL[4], A. YAZDANBAKHSH[2,1]
[1]Programs in Cognitive and Neural Systems, [2]Ctr. for Computat. Neurosci. and Neural Technol., Boston Univ., Boston, MA; [3]Psychiatry and Behavioral Sci., Univ. of Texas Hlth. Sci. Ctr., Houston, TX; [4]Belmont Hill Sch., Boston, MA

Abstract: Our eyes are constantly moving. The brain uses both visual information and ongoing eye movements for future eye movement planning. However, our knowledge of how the brain integrates these information from two different sources and two eyes is still limited. We developed a presentation system that can show different images to separate eyes with large viewing angles and concurrently track both eyes. We conducted a series of psychophysical experiments, in which healthy human observers pursued a moving target on a moving background. The target and background could be seen by both eyes (binocular condition) or by separate eyes (dichoptic condition), i.e., the target was seen by one eye while the background by the other. We also systematically varied the background and target relative directions. The percept of the target's velocity was affected by the motion of the background in both binocular and dichoptic conditions. For example, when the background moves in the opposite direction of the target, the target appears to move faster subjectively (fast condition), and when the background moves with the same direction as of target's, the target's perceived velocity is slower (slow condition). Counter-intuitively, the eyes always moved slower in the fast condition than the slow condition, even when the target seemed to move faster due to background motion

in the fast condition. This effect remained even when there was no background for the eye seeing the target in the dichoptic condition. Thus, we found that the pursuit eye movement was subject to the background motion, but the pursuit eye movement was not following the perceived velocity of the moving target. Further, the planning of the pursuit seemed to be sent to both eyes, even when the visual information was separated from the two eyes.

Title: Target motion predictability determines the predictability of gaze decisions from retinal inputs

Authors: *L. C. OSBORNE[1], M. E. BATTIFARANO[2]
[1]Neurobio., [2]Neurobio. Dept., Univ. of Chicago, Chicago, IL

Abstract: In order to stabilize a moving target's retinal image, the brain must make continuous visual estimates of target motion and evaluate the trade-off between smoothly modulating eye movement and issuing a saccade. Pursuit offers the advantage of uninterrupted visual information but is not able to compensate for large retinal errors; saccades, on the other hand, are able to reduce large errors quickly, but they are likely to degrade visual information during the process. If target motion is unpredictable, gaze behavior must be driven by delayed visual estimates. But if the target trajectory can be extrapolated into the future because its motion is predictable, then pursuit and saccades may be coordinated to maximize both visual information and tracking performance. We investigate an existing formulation of the decision rule between pursuit and saccade introduced by Lefevre and colleagues (2002). This quantity, Eye-Crossing

Time (TxE), is defined as the time it would take the eye trajectory to cross the target. We tracked eye movements in human subjects with a Dual Purkinje Image eye tracker (Fourward Technologies) and in monkeys with scleral coils. We used three experimental paradigms: a 1D and 2D double step-ramp experiment, and a single-player version of the video game, Pong. In the double step-ramp paradigm, randomized trial presentation and a large parameter space minimized predictability. In Pong, the target dynamics - a small spot target with constant speed and elastic collisions with the arena walls - were predictable. We extend the existing definition of Eye-Crossing Time (TxE) to two-dimensions and show that there is a decision rule that captures gaze behavior across both experimental paradigms and both species. When conditioned on a saccade 125 ms in the future, TxE distributes equivalently for both the double step-ramp experiment and Pong, and is consistent between humans and non-human primates. Saccades are most likely when TxE is less than zero; pursuit is most likely when TxE is between 0-200 ms. That means that the occurrence of a saccade tells us something about the Eye- Crossing Time in the recent past. But is the converse true? Can we predict gaze behavior from TxE? We find that the likelihood of observing a saccade given the occurrence of an appropriate TxE is peaked at ~130 ms, as expected. But this only held true in the double step-ramp experiment, not in Pong. We find that a TxE based decision rule holds when gaze behavior is driven by feed-forward visual estimates. When motion becomes predictable, gaze behavior is no longer captured by the same decision rule. We apply information theoretic analysis to quantify the interaction between target, gaze, and time.

Title: The relation of perisaccadic perceived location to eye position and time

Authors: *J. POLA[1], E. MATIN[2], L. MATIN[3]
[1]Dept. of Biol. and Vision Sci., SUNY Col. Optometry, New York, NY; [2]Dept. of Psychology, LIU Post, Brookville, NY; [3]Dept. of Psychology, Columbia Univ., New York, NY

Abstract: The features and basis of the extraretinal (exR) signal involved in perisaccadic stability of visual space are far from being fully determined. One procedure for investigating the

exR signal consists of a subject making a saccade in the dark and reporting on the perceived location of a test flash presented around the time of the saccade. A general result coming from this sort of study is that the test flash is mislocalized just before, during and for a short time after the saccade (Matin, 1972, 1976; Honda, 1989, 1990, 1991; Dassonville, Schlag & Schlag-Rey, 1992; Bockisch & Miller, 1999). This mislocalization suggests the existence of an exR signal that begins to change prior to the saccade and continues to change more slowly than the eye movement. However, besides the slow change in exR signal, little is known about the quantitative properties of this signal, and especially in what manner it is influenced by eye position. In view of this, we explored the perceived location of a test flash presented in the dark during and following both normal and reduced amplitude saccades (reduced via an adaptation procedure) to see how, over a broader than usual range of eye positions, perceived location is related to eye position. A main finding of this work is that the perceived location of the flash varies as a linear function of eye position both during and after a saccade, and that the slope of the linear function changes over time. Of interest, the slope of the linear function is the same for both normal and reduced amplitude saccades. Along with these findings, an analysis of the features of the slope-intercept during and after the saccade indicates that besides the change in slope over time, another time varying component, not related to eye position, makes a contribution to perceived location. Together, these results suggest that perceived location is the consequence of a multifaceted exR signal. In traditional terms, this complex signal may come from some amalgam of "outflow signals" (such as "effort of will" and "efference copy") and "inflow signals." Associated neurophysiology may, in part, consist of a mix of receptive field remapping (as found in FEF, V1, V2 and V3) and eye position signals (occurring in LIP, VIP and MT).

Title: Dynamic network interactions of the human oculomotor system based on intrinsic connectivity

Authors: *A. ASHOURVAN[1], A. PUCE[3], N. L. PORT[2]
[1]Indiana Univ., BLOOMINGTON, IN; [2]Sch. of Optometry, Indiana Univ., Bloomington, IN; [3]Program in Neurosci., Indiana university, Bloomington, IN

Abstract: One of the biggest challenges in neuroscience is to understand how various diverging functions (such as perception, action and cognition) arise from the brain's fixed structural connections. Neuroimaging studies of the 'resting' brain consistently show that in timescales of 10-15 minutes brain structures with known high functional synchrony form distinguishable activation networks, such as the default mode network. White matter tractography studies have identified the structural links between the brain regions within these intrinsic connectivity networks (ICNs). However, synchrony between these brain regions over shorter timescales is not stable. This fluctuation in connectivity manifests as changes in community organization of these ICNs. Since the mental states of the subject are unknown in these resting state experiments, little can be learned about the role and significance of these short-scale modulations in these functional brain networks. Here, we studied the dynamics in short-scale modulations in connectivity and global functional organization of ICNs during a visually-guided task designed to activate the oculomotor system. Ten subjects, studied on a 3T Siemens Trio MRI scanner and an eye tracker, preformed a battery of 40s long blocks of alternating visually guided oculomotor tasks (fixation, smooth pursuit, saccades and voluntary cued blink conditions). Human and non-human primate oculomotor research has identified a network of cortical and sub-cortical structures involved in the control and execution of numerous subtypes of eye movements. Here, we asked how these structures within these oculomotor networks interact with other known functional networks. We decomposed our oculomotor task data using independent component analysis to identify and extract the active intrinsic connectivity networks (ICN). Number of structures involved in the control of eye movements, such as the frontal eye fields (FEF), supplemental eye field (SEF) and parietal eye field (PEF) were all part of a single ICN. However, other task activated areas such as lateral frontal eye field (latFEF) and inferior frontal gyrus (IFG) were each identified as separate ICNs. The well-known networks (e.g. the primary vis., higher vis., left executive control network (LECN), RECN, and salience network) were also identified. Utilizing graph analysis, we have studied the modulations of the functional community organization of these ICNs across our different task conditions. Our results showed similar condition-specific modular organizations of the ICNs across subjects. Additionally, most of the ICNs maintained a stable relationship throughout the task block.

Title: Accurate smooth pursuit eye movements improve hand movements in a manual interception task

Authors: J. FOOKEN[1], S.-H. YEO[3], D. K. PAI[1,4], *M. SPERING[2,4]
[1]Computer Sci., [2]Ophthalmology & Visual Sci., Univ. of British Columbia, Vancouver, BC, Canada; [3]Engin., Univ. of Cambridge, Cambridge, United Kingdom; [4]Brain Res. Ctr., Vancouver, BC, Canada

Abstract: Objective: Tracking a moving object with smooth pursuit eye movements enhances our ability to predict the object's trajectory in space (Spering et al., J Neurophysiol 2011) and time (Bennett et al., Exp Brain Res 2010). Intercepting a moving object, such as a flying ball, critically relies on motion prediction. Here we ask if accurately tracking a briefly presented target with smooth pursuit eye movements improves the ability to intercept its trajectory. Methods: We developed a novel paradigm in which human observers, 32 members of the UBC varsity baseball team, were asked to track a small moving dot, back-projected onto a translucent screen, and to intercept it as fast and accurately as possible. Observers were instructed to hit the target with their index finger as soon as it entered a designated "hit zone". During training, the target was shown for the entire trajectory. In experimental trials, the target trajectory was only shown briefly (100, 200 or 300 ms). Thus, observers had to extrapolate the target's trajectory after the dot disappeared from the screen and subsequently intercept the target at its assumed current position anywhere within the hit zone. Stimulus speed (25, 30 or 35 deg/s) and trajectory shape (curved or linear) were also varied. Eye and hand movements were recorded throughout each trial using an Eyelink 1000 and an Ascension TrakSTAR, respectively. We assessed the 2D position error of the finger end position as well as smooth pursuit quality (initial eye acceleration, position error, velocity error, steady-state velocity gain, catch-up saccade characteristics). Results: Eye and hand movement accuracy improved with increasing target presentation duration and were overall better for linear than for curved trajectories. Importantly, interception accuracy increased following more accurate pursuit; 2D finger position error was lower following trials with low eye position and velocity errors and high eye-velocity gain. Interception accuracy was also predicted by saccade characteristics: better interception was observed in trials with smoother pursuit, in which fewer catch-up saccades of smaller amplitude

were made. Conclusions: Smooth pursuit eye movements boost hand movement accuracy, indicating that accurate eye movements lead to a better velocity estimate. Enhanced motion estimation during pursuit may be due to efference copy information. We discuss potential practical implications for improving motor performance in sports and clinical rehabilitation through eye-movement training.

Title: Neural signatures of perceptual load during natural reading

Authors: *B. WEISS[1], B. KNAKKER[2], Z. VIDNYÁNSZKY[1,3]
[1]Brain Imaging Centre, Res. Ctr. for Natural Sci., Hungarian Acad. of Sci., Budapest, Hungary; [2]Fac. of Information Technol. and Bionics, Pázmány Péter Catholic Univ., Budapest, Hungary; [3]Dept. of Cognitive Science, Fac. of Natural Sci., Budapest Univ. of Technol. and Econ., Budapest, Hungary

Abstract: Letter spacing strongly affects the efficacy of natural reading and recently it has also been shown that increasing letter spacing improves reading in dyslexia. However, the neural basis of the effect of letter spacing on natural reading is unknown. Here we used concurrent eye-tracking (ET) and EEG recordings to investigate the neural correlates of letters spacing during natural reading. Twenty-four young adults were instructed to read text paragraphs at their own pace, while the text was presented line-by-line and the perceptual load was controlled by manipulating the letter spacing. Our novel methodological approach involved simultaneous recording of ET and EEG, adaptive analysis of ET data, artifact elimination using independent component analysis of EEG recordings with incorporated ET information, scalp current density transformation, time-frequency decomposition based spectral dynamics analysis, extraction of fixation-related potentials (FRPs) and fixation-related spectral perturbations (FRSPs), hierarchical single-trial analysis of FRPs and FRSPs. The obtained results revealed significant effects of letter spacing on FRP and FRSP features during natural reading while controlling for

confounding ET variables such as saccade amplitude and fixation duration. FRP amplitudes decreased in the 170-220 ms time interval with increase of letter spacing. Most significant effects were found in the right temporo-occipital and parietal brain regions. FRSP results showed a very similar trend for theta frequency band power, but in a broader spatio-temporal region. The power of theta oscillations exhibited a significant decrease with the increase of letter spacing with the strongest effect around 190 ms in the right temporo-occipital region. The same trend also appeared for beta band power, however, most significant effects were found around 100 ms in the right occipital and temporo-occipital regions in this case. Our results revealed the EEG signatures of the effect of letter spacing during natural reading and thus pave the way for future research aiming at understanding why decrease of letter spacing impairs reading in dyslexia.

Title: A recurrent excitation-inhibition model that captures population temporal structure explains saccade initiation

Authors: *U. K. JAGADISAN[1], N. J. GANDHI[2]
[1]Dept. of Bioengineering, [2]Otolaryngology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: It is difficult to reconcile popular models of movement initiation such as threshold-based gating and the optimal subspace hypothesis with the observed activity pattern of visuomotor neurons in the superior colliculus (SC) and frontal eye fields (FEF). We recently proposed an alternative hypothesis that uses the temporal structure of population activity to explain why downstream structures process the visual burst differently from the premotor burst in that the former does not trigger a saccade while the latter does (see accompanying abstract). Here, we develop rate-based models that incorporate the effects of temporal structure to explain saccade initiation. We explore various aspects of model design that enable the exploitation of population activity structure. We first demonstrate that an accumulator network with synaptic facilitation can distinguish between consistent and fluctuating population inputs. Heuristically,

this “decoder” keeps track of the short-term history of population activity, uses this memory to evaluate consistency of the inputs, and responds selectively when the activity pattern is deemed consistent over some time. This is achieved by using short-term facilitatory connections from the input population to a leaky accumulator, with a Hebb-like learning rule and weight normalization. We also look at whether a network with static synapses can use its leak time constants to achieve optimal temporal integration of consistent inputs over fluctuating inputs. In addition to these putative neural mechanisms for interpreting temporal structure, we also propose a mechanism for why the inconsistency arises in the visual burst and not the premotor burst. Independent, noisy inhibition on the recurrent networks in SC and FEF causes the activity bursts in single neurons in response to an incoming visual input to be relatively uncorrelated. Following the GO cue, reduced levels of inhibition coupled with correlated low-level activity allows the recurrent excitation to take over the dynamics producing correlated bursts that are temporally consistent. We examine the role of the balance between excitation and inhibition in creating experimentally observed attributes of population activity, including stable persistent activity during the delay period in the delayed saccade task.

Title: Illusory objects are altered by saccadic eye movement preparation

Authors: *W. J. HARRISON[1], G. MAIELLO[1,2], P. J. BEX[1]
[1]Dept. of Ophthalmology, Harvard Med. Sch., Harvard Med. Sch., Boston, MA; [2]Univ. Col. London, London, United Kingdom

Abstract: The human visual system continuously interpolates fragmented image features across space, time and eye movements to construct a coherent percept of rigid objects. We investigate how high-level brain areas that control the planning and execution of eye movements interact with other brain areas that integrate spatial information and encode structures. We employed Kanizsa figures, in which illusory contours are interpolated from isolated “pacmen” inducers to

form an apparent occluding shape that can appear lighter or darker than its background. Observers judged the apparent lightness of real and illusory Kanisza squares relative to a grey background. The pacmen inducers were dark (<1 cd/m2) and the physical luminance of the target square was higher than, lower than, or equal to the luminance of the background (15 cd/m2), according to a method of constant stimuli. The target was presented at 11° eccentricity for 80 ms while an observer fixated the center of the display, or within 200 ms of the onset of a saccade toward the center of the upcoming target. Perceived lightness was inferred from the 50% point of a cumulative Gaussian fit to the proportion of trials in which the observer reported that the target appeared lighter than the background as a function of the physical target luminance. For the no-eye-movement condition, the point of subjective equality (PSE) was biased toward darker targets: a square that was physically 3% darker than its background was judged to be equally light, suggesting a perceptual lightening of the target. When targets were presented immediately before a saccade, this perceptual bias doubled in magnitude: the PSE occurred when the target was 6% darker than the background. Therefore, the perceived lightness of the Kanisza figure was greater immediately before a saccade than when no eye movement was planned. Lightness discrimination sensitivity (the slope of the psychometric function) did not vary across conditions, ruling out the possibility that changes in perceived lightness were a corollary of previously reported changes in perceived contrast of features at the goal of a saccade. Our data thus reveal three important novel findings: 1) the systems involved in generating eye movements influence the computations involved in visual interpolation; 2) visual objects, not just their component features, are altered by saccadic preparation, and 3) the perceptual processes associated with saccadic preparation enhance illusory rather than veridical percepts. These observations identify an interaction between eye movement control and feature integration that promotes the representation of stable objects across the visual field.

Title: Perisaccadic perception of visual space in people with schizophrenia

Authors: *A. RICHARD, J. CHURAN, V. WHITFORD, G. O'DRISCOLL, D. TITONE, C. PACK
McGill Univ., Montreal, QC, Canada

Abstract: Background Corollary discharge signals are found in the nervous systems of many animals, where they serve a large variety of functions related to the integration of sensory and motor signals. In particular, this signal is thought to serve a number of purposes related to the maintenance of accurate visual perception. In humans, an important corollary discharge signal is generated by oculomotor structures and communicated to sensory systems in concert with the execution of each saccade. The properties of the oculomotor corollary discharge can be probed by asking subjects to localize stimuli that are flashed briefly around the time of a saccade, where the results of such experiments typically reveal large errors in localization. Here, we have exploited these well-known psychophysical effects to assess the potential dysfunction of corollary discharge signals in people with schizophrenia. **Methods** Using a standard paradigm (e.g. Lappe et al., 2000), we studied mislocalization in schizophrenic subjects and controls making horizontal 20° saccades. Subjects (8 patients and 6 controls) were instructed to report the perceived position a briefly (12 ms) flashed vertical bar presented over a range of horizontal positions in a time-window ± 200 ms around saccade onset. **Results** We found that, compared with controls, patients with schizophrenia exhibited larger errors in localizing visual stimuli. The pattern of errors could be modeled as an over-damped corollary discharge signal that encodes instantaneous eye position. **Conclusions** The dynamics of this signal predicted symptom severity among patients, suggesting a possible mechanistic basis for widely observed behavioral manifestations of schizophrenia.

Title: A meta-analysis of functional imaging studies of smooth pursuit eye movement abnormalities in patients with schizophrenia

Authors: M. YOUNG[1], D. GURLER[2], C. MOORE[1], *M. S. BOLDING[3]
[1]Psychology, [2]Radiology, Univ. of Alabama At Birmingham, Birmingham, AL; [3]Univ. of Alabama At Birmingham, Hoover, AL

Abstract: Abnormal smooth-pursuit eye movements (SPEM) are well documented in patients with schizophrenia (SZ). Studies show SPEM abnormalities in up to 80% of patients and 50% of their unaffected first degree relatives (Holzman et al., 1974; Chen et al., 2004). However, no conclusive evidence exists that can delineate the neural basis of dysfunctional SPEMs in patients with SZ. In the present study, we utilized activation-likelihood estimation (ALE) meta-analytic techniques to synthesize the results of many neuroimaging studies in order to identify common patterns of activation among them. Particularly, we focused on studies which compared the neural activation patterns of patients with SZ to healthy controls during a smooth-pursuit based task. We performed a literature search of the online databases PubMed and Google Scholar, using the keywords "smooth pursuit, schizophrenia, eye movement" to identify relevant studies. Any paper that directly compared patients to controls on a smooth-pursuit task, utilized whole brain analyses, and reported the foci of significantly different activation in a standard stereotactic space was included in ALE meta-analysis. ALE finds convergence of location between different experiments, and does not depend on author assigned labels (Turkeltaub et al., 2002). Instead, they utilize foci reported in a standard stereotactic space as raw data. All six studies we reviewed (O'driscoll et al., 1999; Tregellas et al., 2004; Hong et al., 2005; Lencer et al., 2005; Keedy et al., 2006; Nagel et al., 2007), used a horizontal smooth-pursuit task, and reported significantly different activation localized in the frontal eye fields and/or the V5 complex. However, our meta-analysis revealed a small cluster of significant ALE scores only in the right medial thalamus. These results are consistent with the finding of Cui et al. (2003) who suggested that the thalamus is involved in an efferent feedback loop of extra-retinal motion signals in primates, as well as a paper by Cronenwett and Csernansky (2010) that detailed thalamic pathology in patients with schizophrenia. Our finding of abnormal activity patterns in the right medial thalamus support the need for the use of whole brain imaging and analysis, instead of region of interest based analyses, in all future neuroimaging studies of patients with SZ. We believe that the differences between the tasks used in the experiments included in our meta-analysis confounded our results. Therefore, any future research of smooth-pursuit dysfunction in patients with SZ would benefit from the adoption of a standardized smooth-pursuit task, similar to the standardized anti-saccade task reported in Leigh et al. (2013)

Anderson Cancer Ctr., Houston, TX; [4]Ophthalmology and Visual Sci., [5]Pediatrics, [6]Neurobio. and Anat., The Univ. of Texas Hlth. Sci. Ctr. at Houston Med. Sch., Houston, TX

Abstract: Background: Reports conflict as to whether Tourette Syndrome (TS) confers deficits in executive function. This study's aim was to evaluate executive function in youths with TS using oculomotor tasks while controlling for confounds of tic severity, age, medication and severity of comorbid disorders. **Method:** Four saccade tasks requiring the executive functions of response generation, response inhibition, and working memory (prosaccade, antisaccade, 0-back and 1-back) were administered. Twenty youths with TS and low tic severity (TS-low), nineteen with TS and moderate tic severity (TS-moderate), and twenty-nine typically developing control subjects (Controls) completed the oculomotor tasks. **Results:** There were small differences across groups in the prosaccade task. Controlling for any small sensorimotor differences, TS-moderate subjects had significantly higher error rates than Controls and TS-low subjects in the 0-back and 1-back tasks. In the 1-back task, these patients also took longer to respond than Controls or TS-low subjects. **Conclusions:** In a highly controlled design, the findings demonstrate for the first time that increased tic severity in TS is associated with impaired response inhibition and impaired working memory and that these executive function deficits cannot be accounted for by differences in age, medication or comorbid symptom severity.

Title: Oculometric assessment of dynamic visual processing

Authors: *D. B. LISTON[1,2], L. STONE[1]
[1]NASA Ames Res. Ctr., Moffett Field, CA; [2]San Jose State Univ., San Jose, CO

Abstract: Eye movements are the most frequent (~3 per second), shortest-latency (~200 ms), and biomechanically simplest (1 joint, no inertial complexity) voluntary motor behavior in primates, providing a model system to assess sensorimotor disturbances arising from trauma, fatigue, aging, or disease (e.g., Diefendorf & Dodge, 1908). We developed a 15-minute test that derives ten metrics from the oculomotor response to visual motion, including pursuit initiation and steady-state tracking, as well as direction and speed tuning metrics that can be directly converted into psychometric thresholds (e.g., Stone et al., 2009). Methods. Subjects (N=41) fixated a central spot for a randomized duration. When the fixation spot was extinguished, a small peripheral target spot simultaneously appeared at 3.2 to 4.8 deg eccentricity and immediately began moving for 700-1000 ms back toward and past the initial fixation point (Rashbass, 1961). On each of the 180 trials, the velocity of the target spot was randomly drawn from a distribution of five speeds (16, 18, 20, 22, 24 deg/s) and of 180 possible directions sampled every 2 deg. The large temporal and spatial uncertainty minimized the utility of prior expectations and required a broad distribution of attention across space, time, and direction. Results. We observed a median pursuit latency of 180 ms, initial acceleration of 124 deg/s^2, and median steady-state gain of 0.82. We found median oculometric direction-discrimination thresholds of 2.7 deg (cardinal) and 6.0 deg (oblique), and speed-discrimination Weber fraction of 34%, consistent with psychophysical values for unpracticed observers under high-uncertainty

conditions (e.g., Krukowski and Stone, 2005). Although some of our metrics were correlated, some were not (e.g., the two oblique-effect metrics were uncorrelated with the others, r2 < 0.2) and all were uncorrelated with subject age and foveal acuity (r2 < 0.10. Conclusion. Our 15-minute clinical test delivers ten metrics that quantify multiple aspects of dynamic visual function that would require many hours or even days of psychophysical testing to measure using standard methods. Our test could serve as an efficient screening tool for neural disorders affecting visuomotor processing.

Title: Electrodermal activity and eye movements inform the usability of passwords

Authors: *J. C. ROMANO BERGSTROM[1], K. GREENE[2], D. HAWKINS[1], C. GONZALEZ[1]
[1]Fors Marsh Group, Arlington, VA; [2]Natl. Inst. of Standards and Technol., Gaithersburg, MD

Abstract: While measuring physiological responses is a common practice in the field of neuroscience, it is rare in the usability arena and in password usability studies, in particular. This is unfortunate, as the use of such implicit measures could complement more traditional, explicit metrics of performance like password entry times and errors. Capturing participants' electrodermal activity and eye-movement patterns during password entry can provide unique insights about users' intentions, perceptions of difficulty, and emotional state that would otherwise be impossible to gain via behavioral and self-report measures. Here, we build on prior work examining the usability of a set of complex, system-assigned passwords across input devices (Greene et al., 2014) and adherence to English grammatical rules (Romano Bergstrom et al., 2014). We maintain similar stimuli and methodology but expand upon previous research by additionally recording electrodermal activity (i.e., skin conductance response [SCR]) and eye movements, using fingertip electrodes and a desktop eye tracker. We expect SCR for more difficult passwords to be of greater amplitude, greater frequency, and shorter latency than easier passwords, where password difficulty is a function of multiple factors such as length, frequency and placement of special symbols, and linguistic and phonological difficulty. Additionally, more difficult passwords should result in more repeat fixations, fixations that are more frequent and of

longer duration than for easier passwords. Physiological measures may improve password difficulty classification accuracy of a naïve Bayesian classifier over and above behavioral measures of error rates and completion times. The potential to differentiate difficult from easy passwords based on SCR and fixation frequency and duration implies that we have indeed found a promising use for implicit indicators of stress, encoding, and retrieval processes associated with password learning and entry across devices. The current exploratory work demonstrates the potential practical value of combining physiological and behavioral measures in password usability research. This should be of interest to the usability, security, and neuroscience research communities, as it provides a novel measurement approach for the former and an interesting applied research problem for the latter.

Title: The cognitive control of gaze patterns when decoding the affordances of complex tool use

Authors: *N. NATRAJ[1], Y. M. PELLA[1], A. M. BORGHI[2], L. WHEATON[1]
[1]SCHOOL OF APPLIED PHYSIOLOGY, COLLEGE OF SCIENCES, GEORGIA INSTITUTE OF TECHNOLOGY, ATLANTA, GA; [2]Psychology, Univ. of Bologna, Bologna, Italy

Abstract: Tools are a unique class of objects as they automatically potentiate action knowledge (graspability, usability) during passive viewing, a property called affordances. It is thought that such affordances are decoded by parietofrontal regions that store motoric properties of tools and tool-use. However, overlapping parietofrontal networks also control eye movements; it is unclear if a relationship exists between exploratory oculomotor control and action understanding when viewing static images of complex tool-use, the predominant stimuli in affordance studies. To address this issue, we recorded eye movements in healthy human adults as they passively evaluated static tool-use images across a combination of three tool-use contexts and four types of tool-grasps, giving rise to 12 experimental conditions with varying affordances. We hypothesized that the control of exploratory eye movements (saccade initiation times, gaze patterns and scene feature biases) over distinct features of tool-use scenes across conditions to

either be maximally unpredictable/random or alternatively, always follow a predictable pattern independent of affordances. This would imply that parietofrontal responses to tool-use images represent action understanding alone rather than an additional control of fixations and saccades. Given the high dimensionality of the dataset and the multivariate time varying nature of eye movements, a novel statistical framework based on pattern recognition theories was developed to evaluate the hypothesis. While saccade initiation times were independent of affordances, contrary to our hypothesis participants exhibited differential gaze patterns and scene feature biases that were driven primarily by the intent of the tool-grasp and subsequently by the context of tool-use action with unique interaction effects. Additionally, a discrete Hidden Markov Model was developed that predicts a hierarchical control scheme of eye movements in each visual hemifield modulated by affordances. Results here show that gaze behavior is sensitive to affording properties in tool-use scenes, suggestive of a coupling between oculomotor control and action understanding over parietofrontal networks. This has potential implications to affordance studies evaluating neural and/or behavioral responses to tool-use understanding.

Title: Acute inflammation reveals potential nociceptive role of peripheral GABA A receptors

Authors: ***I. JANG**[1], Y. KIM[1], S. JUNG[2], H. FURUE[3], S. OH[1]
[1]Pain Cognitive Function Res. Ctr., Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Hanyang Univ., Seoul, Korea, Republic of; [3]Natl. Inst. of Physiological Sci., Okazaki, Japan

Abstract: Gamma-aminobutyric acid (GABA) depolarizes dorsal root ganglia (DRG) neurons through GABA A receptor activation. In the present study, we tested whether GABA A receptors are involved in nociceptive signaling and pain behavior during formalin-induced acute inflammatory pain in adult mice. We found that peripheral administration of the GABA A receptor agonist, muscimol, restored spontaneous licking behavior after subsidence of formalin-induced pain behaviour. We performed extracellular single-unit recordings from spinal cord wide

dynamic range neurons *in vivo* and showed that spike frequency was increased by muscmiol injection into hind paw after, but not before, formalin treatment. Using Ca2+ imaging *in vitro* we show that formalin, as well as the major inflammatory mediator prostaglandin E2, can potentiate GABA-induced Ca2+ transients in cultured DRG neurons, an effect that is blocked by the prostaglandin EP4 receptor antagonist AH23848. Taken together, these results demonstrated that GABA A receptors may contribute to excitation of peripheral sensory neurons in inflammation through PGE2-EP4 signaling.

Title: Investigating the role of TRESK in sensory afferent function using a selective opener

Authors: *L. CAO[1], A. LOUCIF[1], P.-P. SAINTOT[1], M. K. PATEL[2], C. ADAMS[1], K. KUAN[1], R. FISH[1], M. RIGBY[1], B. ANTONIO[3], K. OMOTO[1], D. PRYDE[1], E. B. STEVENS[1]
[1]Pain RU, Neusentis, Pfizer UK, Great Abington, United Kingdom; [2]Anesthesiol., Univ. of Virginia Hlth. Syst., Charlottesville, VA; [3]Pfizer Neusentis, Durhum, NC

Abstract: Two-pore-domain background potassium (K2P) channels are a unique structural group of ion channels with each subunit containing four transmembrane domains and two pore domains which assemble as functional dimers. K2P channels are important for the generation and modulation of the resting membrane potential and play an important role in regulating neuronal excitability. The calcineurin-regulated K2P channel, TRESK has been suggested as potential therapeutic target for pain due to a genetic association between a TRESK frameshift mutation and migraine with aura in a large pedigree, along with its unique expression pattern largely limited to sensory neurones. In this study we have used a highly selective TRESK opener alongside an immunohistochemical approach, using a TRESK antibody, to investigate the role of TRESK in sensory neuron excitability and neurotransmitter release. The TRESK opener was identified following an HTS campaign using a thallium flux assay. Using manual patch clamp technique, compound A caused a maximum enhancement of 226 ± 43 % and an EC_{50} of 0.6 μM for human TRESK (n=3) and a maximum enhancement of 394 ± 21 % and an EC_{50} of 0.9 μM for rat TRESK (n=3). No clear effect was observed against other potassium channels (TREK-1,

TASK-3, KCNQ1, BK and hERG) at 10 μM. Using current clamp recording, the firing frequency of rat dorsal root ganglion (DRG) neurones was reduced by 41.5 ± 17 % (n=7) when compound A was applied at 3 μM. A multi-unit *ex-vivo* rat skin-nerve preparation was used to test the effect of compound A on heat evoked (36-52^{o}C ramp) tibial nerve firing. Compound A had no significant inhibitory effect (11 ± 2.0 %, n=7) on the heat-evoked firing frequency, while the KCNQ2/3 opener, retigabine, significantly inhibited firing by 38.4 ± 2.0% (n=7), compared to their respective vehicle controls. In contrast, compound A at both 3 uM and 10 uM significantly reduced CGRP release from (lumbar L4-L6) spinal synaptosomes evoked by 10 μM veratridine. Using immunohistochemistry, expression of TRESK in peripheral and central compartments (rat skin, DRG and dorsal horn) was compared to the neuronal marker PGP9.5. TRESK antibody staining was detected in DRG neurons and dorsal horn, but was absent from peripheral nerve. In conclusion, using both a selective TRESK opener and immunohistochemistry, we have demonstrated that TRESK has a key role in regulating neurotransmitter release in the dorsal horn, but plays little or no role in regulating peripheral excitability.

Title: Effects of pharmacological agents on pain tolerance in lynx1 knockout mice through the manipulation of nicotinic acetylcholine receptors

Authors: *K. R. ANDERSON, C. M. GARRISON, K. L. ACKERMAN, J. M. MIWA
Lehigh Univ., Bethlehem, PA

Abstract: Pain management is a crucial yet challenging field that causes over 80 billion dollars in hospital costs annually. A subset of patients are resistant to the current treatment options, which are also often accompanied by adverse side effects. A search for alternative therapeutic avenues, therefore, is warranted. A potential alternative pain therapy is based upon nicotine receptors, which have a role in pain alleviation (antinociception). The binding of certain agonists, such as the exogenous drug of abuse nicotine, to nicotinic acetylcholine receptors (nAChRs) have been shown to produce analgesic effects. nAChRs are part of the cholinergic system which mediates a host of CNS functions, including pain tolerance. The cholinergic system exists on a gradient of activation, which can be influenced by several regulatory factors, one being a class of protein modulators, lynx proteins. The lynx1 gene codes for an allosteric modulatory protein which binds to nAChRs and inhibits its function, in order to balance neuronal activity and survival in the CNS. lynx1 acts as a brake on the cholinergic system and shifts the cholinergic gradient towards underactivation. lynx1 was not previously known to function in pain pathways but its relationship with the cholinergic system suggests a direct upstream function in pain thresholds and pain tolerance. In order to test the relationship between nicotine, lynx1, and pain tolerance lynx1 knockout and wildtype mice are given saline or nicotine and tested for pain thresholds on a thermal sensitivity test. It is predicted that in the presence of lynx1, the analgesic effects of nicotine will be reduced but in the absence of the lynx1 gene, cholinergic tone will be raised, thus increasing pain tolerance. This hypothesis was supported as the loss of the lynx1 gene in lynx1 knockout mice, resulted in an increase in pain tolerance which is further amplified by nicotine. Several inhibitors were given in conjugation in order to test which specific subtypes of nicotinic receptors are involved. Our data suggest a selective release on α4* receptor inhibition in lynx1 knockout mice, whereas an α4* component is not expressed in wild-type mice. This data suggests the lynx1 can act as a specific receptor modulator to regulate pain thresholds.

Title: Role of TASK-3 leak potassium channels in peripheral cold thermosensation

Authors: C. MORENILLA-PALAO[1], E. LUIS[1], C. FERNÁNDEZ-PEÑA[1], E. QUINTERO[1], J. L. WEAVER[2], D. A. BAYLISS[2], *F. VIANA[3]

Abstract: Animals sense cold ambient temperatures through the activation of peripheral thermoreceptors that express TRPM8, a cold- and menthol-activated transient receptor potential ion channel. These cold thermoreceptors can discriminate a very wide range of temperatures, from innocuous to noxious. The molecular mechanism responsible for the variable sensitivity of individual cold receptors to temperature is still unclear. Previous studies have suggested an important role of several potassium channels in cold thermotransduction, by acting as excitability brakes. However, the molecular and functional characterization of these potassium channels in thermoreceptors is still incomplete. To address this question, we performed a detailed ion channel expression analysis of cold sensitive neurons, combining BAC transgenesis with a molecular profiling approach in FACS purified TRPM8 neurons from mouse DRG. We found that TASK-3 (Kcnj9) leak potassium channels are highly enriched in TRPM8-positive neurons and expressed in a fraction of these thermoreceptors. Using whole-cell patch-clamp recordings we characterized leak potassium currents sensitive to low external pH (a signature for TASK-1 and TASK-3 channels) in TRPM8-expressing neurons. The density of pH-sensitive current was reduced in TRPM8-positive neurons of TASK-3 KO mice. Moreover, the thermal threshold of the population of TRPM8 cold neurons is decreased in mice lacking TASK-3. Behavioral studies showed that these mice display hypersensitivity to cold. Our results demonstrate a novel role of TASK-3 channels in cold thermosensation, and suggest that a channel-based combinatorial expression within TRPM8 cold thermoreceptors leads to their molecular specialization and functional diversity.

Abstract: Chronic pain is a major clinical problem, yet the mechanisms underlying the transition from acute to chronic pain remain poorly understood. We show that reduced expression of nociceptor G protein-coupled receptor kinase 2 (GRK2) promotes cAMP signaling to the guanine nucleotide exchange factor EPAC1 and prolongs the PGE_2-induced increase in pain sensitivity (hyperalgesia). Using a model of transition from acute to chronic inflammatory pain, we show that reduced GRK2 and/or increased EPAC1 in dorsal root ganglion (DRG) neurons promotes chronic pain. In addition, when we either increased GRK2 *in vivo* by viral-based gene-transfer or decreased EPAC1 *in vivo*, as was the case for mice heterozygous for Epac1 or mice treated with Epac1 antisense-oligodeoxynucleotides, the transition to chronic pain was prevented. In search for the underlying mechanism that promotes Epac1 signaling when GRK2 is low, we identified GRK2 as the first kinase known to phosphorylate Epac1. We identified the residue in Epac1 that is phosphorylated by GRK2. In addition, we demonstrate that phosphorylation of this residue in Epac1 by GRK2 inhibits Epac-mediated activation of the small G protein Rap1 and agonist-induced membrane association of Epac1. These findings add Epac1

to a growing list of non-G protein coupled receptor GRK2 substrate and further establish the key role of GRK2 in pain sensing neurons in protecting against chronic pain. Our data suggest that therapies targeted at balancing nociceptor GRK2 and EPAC1 levels have promise for the prevention and treatment of chronic pain.

Title: NMDA receptor-induced substance P release from primary afferent terminals is inhibited by μ and κ, but not δ, opioid receptors

Authors: ***W.-L. CHEN**[1], H. KIM[1], H. S. ENNES[1], W. WALWYN[1], J. A. MCROBERTS[1,2], J. G. MARVIZON[1,2]
[1]Dept. of Med., UCLA, Los Angeles, CA; [2]Veteran Affairs Greater Los Angeles Healthcare Syst., Los Angeles, CA

Abstract: Recently, we showed that BDNF acting on trkB receptors induces a gain of function of NMDA receptors in primary afferent terminals that occurs after the onset of neuropathic pain (Chen et al., Eur. J. Neurosci., 2014). Here we present evidence that μ opioid receptors (MORs) and κ-opioid receptors (KORs) induce a counterbalancing loss of function of these NMDA receptors. NMDA receptor function was assessed as the ability of NMDA + D-Ser (10 μM for 2 min) to induce substance P release in rat spinal cord slices. Substance P release was measured as neurokinin 1 receptor (NK1R) internalization in lamina 1 neurons. NMDA-induced NK1R internalization in spinal cord slices was abolished by 1 hr preincubation with the MOR agonists morphine (1 μM), DAMGO (0.1 μM) and endomorphin-2 (1 μM). DAMGO had no effect when applied together with NMDA and produced a maximum effect with preincubations of 15 min or

longer. A concentration-response for DAMGO yielded an IC50 of 14 nM and was right-shifted by the MOR antagonist CTAP with a KB of 215 nM (Gaddum-Schild analysis). The KOR agonist U50,488 (1 μM) inhibited NMDA-induced NK1R internalization by about 50%, and this inhibition was reversed by the KOR antagonist nor-binaltorphimine (1 μM) but not by the MOR antagonist CTAP (10 μM). The δ-opioid receptor (DOR) agonists DPDPE (1 μM), [D-Ala2]-deltorphin II (1 μM) and SNC-80 (1 μM) produced different levels of inhibition; however, their effect was eliminated by the MOR antagonist CTAP (10 μM) but not by the DOR antagonist naltrindole (10 μM), indicating that it was mediated by MORs. The GABAB agonist baclofen (30 μM) did not affect NMDA-induced NK1R internalization. DAMGO inhibited NMDA-induced NK1R internalization in slices preincubated with BDNF (20 ng/ml), but not in slices preincubated with the protein tyrosine phosphatase inhibitor BVT948 (10 μM), suggesting that MORs inhibit the NMDA receptors by increasing the dephosphorylation of the NR2B subunit by a protein tyrosine phosphatase. To determine whether MORs inhibit NMDA receptor-induced substance P release *in vivo*, rats were given intrathecal BDNF (0.3 μg) to increase NMDA receptor function, then intrathecal DAMGO (3 nmol) or saline 3 hr after BDNF and finally intrathecal NMDA + D-Ser (10 nmol each) 1 hr later. NMDA induced NK1R internalization after BDNF, and this effect was eliminated by DAMGO. Alternatively, NMDA receptor function was increased by chronic constriction injury of the sciatic nerve; 6 hr later, intrathecal DAMGO (3 nmol) also inhibited NMDA-induced NK1R internalization. These results show that MORs and KORs, but not DORs or GABAB receptors, decrease NMDA receptor function in primary afferent terminals.

Title: The TrkA receptor and not the p75NTR mediates thermal hyperalgesia from NGF in the rat hind paw

Authors: *A. KHODOROVA[1], G. NICOL[2], G. STRICHARTZ[1]
[1]Harvard Med. Sch. Brigham and Women's Hosp, BOSTON, MA; [2]Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Recently we have shown that p75 neurotrophin receptor ($p75^{NTR}$) and its activation of the sphingomyelin signaling cascade are essential for mechanical hypersensitivity resulting from NGF (Neuroscience, 2013). Here we evaluate the role of the same effectors in thermal hypersensitivity induced by NGF. Sensitivity of rats' plantar skin to thermal stimulation after local subcutaneous (s.c.) injection of NGF was measured using the Hargreaves method. Intraplantar injection of NGF (500ng/paw) resulted in ~40% reduction of paw withdrawal latency (PWL) that was measured through 22-24h and had recovered by 48h. Pre-injection of the paw with the $p75^{NTR}$ blocking anti-body (gift of L. Reichardt, UCSF) 4h before NGF did not affect the degree of acute thermal hyperalgesia over 0.5-3.5h, but shortened its duration such that the PWL fully recovered by 22h. In controls, pre-injections of IgG were without effect. Thus, whereas mechano-sensitizing effects of both Pro-NGF and NGF were prevented by pre-injection of the paw with the $p75^{NTR}$ blocking anti-body, that antibody failed to prevent the acute thermal hypersensitivity from NGF. In addition, GW4869 (2mM), an inhibitor of the nSMase enzyme on the $p75^{NTR}$ signaling pathway, that inhibited mechanical hyperalgesia from NGF, failed to prevent thermal hyperalgesia. Paw injection of a non-selective inhibitor of nSMase activation, glutathione, pre- and co-injected with NGF (1.8µmoles/paw total dose, at a 15min interval) prevented significant acute thermal- sensitization at 22-48min, but was without effect at later time points, or at lower doses. A wide spectrum inhibitor of the TrkA receptor, K252a, at 2mM fully prevented thermal hyperalgesia from NGF, at 200µM its development was delayed, and at 20µM it was unaffected. TrkA blocking anti-body (gift of L. Reichardt, UCSF) prevented the reduction of PWL from subsequently injected NGF. These findings suggest that TrkA receptor has a predominant role in the development of thermal hypersensitivity induced by NGF, while $p75^{NTR}$ may be engaged in its maintenance.

Title: Involvement of P2X3 in peripheral sensitization of UVB-induced inflammatory pain

Authors: E. KASAI, S. OMACHI, T. ASAKI, G. SAKAGUCHI, *S. SHINOHARA
Pain & Neurol., Shionogi & Co, Ltd, Toyonaka Osaka, Japan

Abstract: In the field of pain research, the importance of translational pain models become increasing. Among them, ultraviolet B (UVB)-induced skin inflammation model is one of the best characterized experimental pain models in the clinical. UVB-irradiation induces mechanical hyperalgesia at the site of irradiation (primary hyperalgesia), is thought to be elicited predominantly via peripheral sensitization. In this study, we investigated physiological changes and sensitivity to analgesics in UVB-irradiated rats. We also examined whether P2X3 receptors are involved in peripheral sensitization in UVB model.UVB-irradiation to the rat hind paws produced a significant dose-dependent reduction in mechanical paw withdrawal thresholds as reported in human. Slight erythema, mild edema, increase in blood flow and up-regulation of inflammatory factors are also observed in the rats. The sensitivity profile was evaluated using several analgesics such as ibuprofen, morphine and pregabalin. Ibuprofen (30 mg/kg, p.o.) and morphine (1 mg/kg, s.c.) significantly reduced mechanical hyperalgesia but pregabalin (10 mg/kg, p.o.) had little effect in the UVB-irradiated rats. These pharmacological findings are similar to those in human model. Injection of adenosine 5'-triphosphate (ATP) to rat hind paws produced mechanical hyperalgesia and it was potentiated in the UVB-irradiated rats. ATP-evoked hyperalgesia in UVB-irradiated rat was dose dependently attenuated by pre-administration of P2X3 antagonist (A317491, 1-100 mg/kg, s.c). Minimal effective dose of A317491 was lower in the UVB-irradiated rats than non-irradiated. Immunohistochemical analysis revealed that injection of ATP into UVB-irradiated skin induced phosphorylation of extracellular signal-regulated kinases 1/2 (ERK1/2), a potent marker of activated neurons, in L4/L5 dorsal root ganglion (DRG) neurons expressing P2X3. These results suggested that P2X3 receptors have critical contribution to ATP-evoked hyperalgesia and also contribute to peripheral sensitization in UVB model. In conclusion, rat UVB model shows similar pathophysiological and harmacological properties to those in human UVB model. The rat UVB model might be a good translational model for investigation of peripheral sensitization in pathological pain.

Title: Endovanilloids modulate synaptic transmission by three distinct mechanisms

Authors: *Y. WANG, B. D. BURRELL
Basic Biomed. Sciences, Ctr. for Brain & Behavior Res. (CBBRe), Univ. of South Dakota, Vermillion, SD

Abstract: Endovanilloids are endogenous ligands that act on TRPV channels in the central nervous system and play an essential role in cardiovascular and respiratory functions, emesis, locomotion, anxiety and pain modulation. Anandamide (AEA) and 2-arachidonoyl glycerol (2-AG) are examples of endogenous vanilloid neurotransmitters that act on both TRPV and cannabinoid receptors (Zygmunt et al. (2014), PLoS ONE 8: e61618). Using the well-characterized nervous system of the medicinal leech, it is possible to isolate the TRPV-mediated effects of 2-AG and AEA since invertebrates lack of CB receptors. In this project, we examined the role of Cl- homeostasis in determining the sign of endovanilloids-mediated synaptic modulation. Endovanilloids were observed to elicit three distinct forms of persistent (≈1hr) synaptic plasticity. In synapses made by polymodal nociceptive afferents, AEA, 2-AG and the TRPV1 agonist, capsaicin (CAP), depressed synaptic transmission via direct activation of a TRPV-like receptor as previously described (Yuan & Burrell (2010) J Neurophysiol 104: 2766). Pretreatment with the TRPV1 antagonist, SB 366791 (SB), prevented this endovanilloid-induced form of long-term depression (LTD). In synapses made by the non-nociceptive, pressure-sensitive afferents, AEA, 2-AG and CAP potentiated synaptic transmission. This endovanilloid-induced long-term potentiation (LTP) was due to a decrease in inhibitory GABAergic signaling (disinhibition) that could be blocked by pretreatment with either bicuculline (GABA receptor antagonist) or VU 0240551 (an inhibitor of the Cl- exporter KCC2). The polymodal nociceptive synapses that are directly depressed by endovanilloids are protected from this disinhibition due to an elevated intracellular Cl- concentration (they are excited, not inhibited, by GABA). Finally, in synapses made by mechanical nociceptive afferents, AEA, 2-AG and CAP also depressed synaptic transmission, but not due to the direct activation of the TRPV-like receptors, which these afferents lack. As in the case of polymodal nociceptors, mechanical nociceptive afferents are also excited by GABA due to an elevated intracellular Cl- concentration. In these synapses, endovanilloid-mediated LTD was found to be due to a decrease in this excitatory GABAergic input (disexcitation) given that it could be blocked by pretreatment with either bicuculline or bumetanide (an inhibitor of Cl- importer NKCC1). These results indicate that endovanilloids can modulate synapses by three distinct mechanisms and that Cl- homeostasis plays a critical role in determining the sign of this synaptic plasticity.

Title: AMPK-mediated control of P bodies as a novel mechanism of gene expression control in peripheral sensory neurons

Authors: G. L. MEJIA[1], O. K. MELEMEDJIAN[3], G. DUSSOR[4], *T. J. PRICE[2]
[1]Sch. of Behavioral and Brain Sci., [2]Pharmacol., UTD, Richardson, TX; [3]Pharmacol., Univ. of Arizona, Tucson, AZ; [4]Sch. of Behavioral and Brain Sci., Univ. of Texas at Dallas, Richardson, TX

Abstract: Changes in gene expression have long been recognized as a central mechanism for altered sensitivity and excitability of nociceptors. We, and others, have focused on translation control, in particular local, activity-dependent translation control as a novel means to modulate gene expression in response to injury. In this context, an increase in local translation, downstream of extracellular signal regulated kinase (ERK) and/or mechanistic target of rapamycin complex 1 (mTORC1) activation leads to an enhancement of pain sensitivity and an increase in measures of excitability. A possible mechanism to mitigate these effects is activation of adenosine monophosphate activated protein kinase (AMPK) because signaling via this kinase leads to inhibition of ERK and mTORC1 signaling to translation machinery. In addition to these effects, inhibition of translation via AMPK may also lead to changes in mRNA turnover. We have tested that hypothesis here examining major sites of mRNA repression and decay in cells, called P bodies, upon AMPK activation in trigeminal (TG) and dorsal root ganglion (DRG) neurons. We find that translation (using the sunset technique) and P body formation are reciprocally regulated upon pharmacological activation of AMPK in TG and DRG neurons. While AMPK activation leads to a decrease in puromycin incorporation into nascently synthesized peptides, it also causes a robust increase in P bodies (as revealed by rck/p54-positive puncta) suggesting mRNA sequestration from translation machinery and potentially mRNA degradation because P bodies are major sites for mRNA decapping in cells. Moreover, AMPK activation *in vivo* with metformin leads to enhanced P body formation in DRG neurons. Our

findings enhance our understanding of gene expression regulation in the peripheral nervous system and suggest a potential role for P bodies in pain plasticity.

Title: An essential role for eIF4E phosphorylation in peripherally-mediated pain plasticity

Authors: *J. K. MOY[1,2], M. N. ASIEDU[3,2], A. KHOUTORSKY[4], D. V. TILLU[3], O. K. MELEMEDJIAN[2], G. L. MEJIA[3,2], J.-Y. KIM[2], N. SONENBERG[4], G. DUSSOR[3,2], T. J. PRICE[3,2]

Abstract: An essential role for eIF4E phosphorylation in peripherally-mediated pain plasticity Jamie K Moy[1,2], Marina NK Asiedu[1,2], Arkady Khoutorsky[3], Dipti V Tillu[2], Ohannes K Melemedjian[1], Galo L Mejia[1,2], Ji-Young Kim[1], Nahum Sonenberg[3] and Gregory Dussor[1,2], Theodore J Price[1,2] [1]University of Arizona, Department of Pharmacology [2]University of Texas at Dallas, School of Behavioral and Brain Sciences [3]McGill University, Department of Biochemistry Translational control of gene expression is a key process for the regulation of plasticity in the nervous system. Multiple lines of evidence indicate that translation control plays a critical role in peripheral pain plasticity but precise mechanisms underlying this effect have not been elucidated. Here we have tested the hypothesis that eIF4E, which binds the 5'CAP of mRNAs, plays an important role in pain plasticity via upstream phosphorylation through the MAPK pathway, specifically ERK and MNK1/2. We used transgenic mice harboring a Ser209Ala mutation in eIF4E to assess the role of eIF4E phosphorylation in pain plasticity.

Behavioral studies were done on eIF4E^{S209A} mice and their wild-type (WT) littermates. We used biochemical techniques to assess changes in brain-derived neurotrophic factor expression in these mice. Finally, we used patch clamp electrophysiology to assess changes in excitability in nociceptors lacking eIF4E phosphorylation. eIF4E^{S209A} mice showed clear deficits in behavioral hypersensitivity induced by nerve growth factor (NGF) and protease activated receptor type 2 (PAR2) agonists. Although overall protein synthesis rates (measured with sunset assay) were not lower in these mice, BDNF protein expression was markedly reduced indicating that eIF4E phosphorylation selectively targets certain mRNAs in DRG neurons. Electrophysiological characterization of DRG neurons from eIF4E^{S209A} revealed no differences in baseline properties, however, hyperexcitability induced by NGF was abrogated in transgenic mice. eIF4E phosphorylation plays a crucial role in sensitization of the peripheral nervous system following injury. Therefore, targeting eIF4E phosphorylation via the ERK/MNK1/2 pathway is a novel target for the manipulation of pain plasticity. **Acknowledgements** Supported by NIH grants NS065926 and GM102575

Title: Cdk5 is an important modulator of pain signaling

Authors: M. PROCHAZKOVA[1], E. UTRERAS[2], A. TERSE[1], B. HALL[1], *A. B. KULKARNI[1]
[1]Functional Genomics Section, LCDB, NIDCR, NIH, BETHESDA, MD; [2]Dept. of Biol., University of Chile, Chile

Abstract: Cyclin-dependent kinase 5 (Cdk5), a unique member of the serine/threonine kinase family, plays an important role in brain development and functions. Deregulation of its activity is implicated in neurodegenerative and neuropsychiatric disorders. Considering this link between

Cdk5 and brain functions, we explored its role in the regulation of nociceptive signaling. Our initial studies revealed that the expression of Cdk5 and its activator, p35, is upregulated in nociceptive neurons during peripheral inflammation. Moreover, we observed in genetically altered Cdk5 mouse models that perturbation in Cdk5 activity in DRG correlated with altered peripheral thermal pain sensation. Cdk5 regulation of inflammatory pain involved crosstalk with different signaling pathways. Our current studies based on operant behavioral analysis link Cdk5 with orofacial mechanical, thermal, and chemical pain sensation. We found that this link is partly based on the ability of Cdk5 to phosphorylate some of the receptors of pain. All of these findings demonstrate that Cdk5 is an important modulator of pain signaling.

Title: Nociceptive sensitization by activation of Protease-Activated Receptor 2 (PAR-2) in rats

Authors: *K. KIDO, E. MASAKI
Tohoku Univ. Hospital, Dept. of Dent. Anesthesia, Sendai, Miyagi, Japan

Abstract: Background- It was reported that mast cell degranulation after incision induced hyperalgesia in a postoperative pain model. Proteinase-activated receptor 2 (PAR-2) is a G protein-coupled receptor, seven trans-membrane domain receptor family, which is expressed in the peripheral sensory neurons and may play an important role in development of inflammatory and injured pain by binding with tryptase from mast cells. In this study, we examined if activation of peripheral PAR-2 could modulate nociception, using behavioral testing and *in vitro* skin-nerve preparation in rats. Method- The PAR-2-activating peptide SLIGRL-NH2 was administered by the intraplantar route in the rat. Guarding behavior (biting and licking) was observed after administration of SLIGRL-NH2 for 30 minutes. Mechanical thresholds were assessed using von Frey filaments. Withdrawal latencies to heat were assessed applying a

focused radiant heat on the injected area of plantar skin. Using the rat glabrous *in vitro* skin-tibial nerve preparation, afferent activities from single mechanosensitive nociceptors were recorded. Spontaneous activities, and responses to mechanical stimuli were recorded before and after SLIGRL-NH2 application or phosphate buffered saline (PBS) control. Responses to heat and cold stimuli were recorded once after exposure to either with SLIGRL-NH2 application or PBS control. Results- The guarding pain increased after SLIGRL-NH2 injection within 30min. Mechanical and thermal hyperalgesia were also produced after administration. *In vitro* skin-nerve preparation, 100μM SLIGRL-NH2 increased spontaneous activities in 42.5 % C-fibers within 5 minutes. 100μM SLIGRL-NH2 application did not change the responses to mechanical stimuli in C- fibers but 1mM increased the responses. C-fibers were sensitized to heat and cold stimuli. Conclusion- PAR-2-mediated excitation and sensitization of peripheral primary nociceptors may contribute to PAR-2-mediated pain via TRPV1, TRPA1 and TRPV4.

Title: Epigenetic regulation of spinal cord gene expression controls opioid-induced hyperalgesia and tolerance

Authors: *D.-Y. LIANG[1], Y. SUN[2], P. SAHBAIE[2], X. SHI[2], W.-W. LI[2], D. J. CLARK[2]
[1]Anesthesiol., [2]Stanford Univ., Palo Alto, CA

Abstract: The long term use of opioids for the treatment of pain leads to a group of maladaptations which includes opioid-induced hyperalgesia (OIH). Previous studies show morphine-induced epigenetic alteration in spinal cord (SC) tissue regulates OIH. Specifically, OIH typically resolved within few days after cessation of morphine treatment but was prolonged for weeks following manipulation of histone deacetylase activity during treatment. The present work searches for gene targets of these epigenetic effects responsible for OIH prolongation. To investigate involvement of histone acetylation on OIH, selective HDAC inhibitor suberoylanilide hydroxamic acid (SAHA) was administered daily to groups of animals undergoing repeated

morphine exposure. After examining expression changes in implicated SC genes by qPCR, chromatin immuoprecipation (ChIP) of candidate genes were carried out, and complementary studies involved mechanical threshold determination, pharmacological assessments, ELISA and immunohistochemistry. Dose-response relationships and tolerance were assessed using the tail flick assay. The data show:1) HADC inhibitor and chronic morphine treatment enhanced OIH with significant SC up-regulation of BDNF and PDYN. Promoter regions of PDYN and BDNF exon-IV genes were strongly associated with aceH3K9 after morphine and SAHA treatment; 2) Selective TrkB receptor antagonist (ANA-12) treatment reduced mechanical hypersensitivity given one or seven days after cessation of morphine with/out SAHA treatment; 3)Treatment with single dose of selective KOR receptor (nor-BNI) antagonist was not sufficient to reverse sensitization due to prior morphine plus SAHA treatment, though it could reverse sensitization in mice treated with morphine; 4)The co-administration of either receptor antagonist agent daily with morphine or morphine plus SAHA resulted in attenuation of hyperalgesia one day after cessation of treatment. Seven days later ANA-12 or nor-BNI treated animals that had received morphine continued to exhibit less mechanical hypersensitivity. Only co-administered ANA-12 had lasting effects on sensitization after morphine plus SAHA treatment; 5) TrkB and KOR receptor antagonists have a different effects on morphine analgesic tolerance The present study identified two genes whose expression is regulated by epigenetic mechanisms during morphine exposure. Epigenetic processes may be responsible for integrating the effects of environmental factors (drug administration) with intrinsic processes like pain signaling pathways to cause alterations in neuronal function.

Title: The role of mechanosensitive ion channels in osteoarthritis pain

Authors: ***H. HE**[1], A. DAVIDOVA[2], R. SHARIF NAEINI[2]
[1]Physiol., McGill Univ., Montreal, Canada; [2]Physiol., McGill Univ., Montreal, QC, Canada

Abstract: Osteoarthritis (OA) is a disabling and prevalent condition affecting 27 million US citizens and 5 million Canadian citizens. Pain is the primary symptom of the disease and is largely manifested as mechanical hypersensitivity to joint palpation/movement. However, the underlying mechanisms are poorly understood. The enhanced mechanosensitivity can be due to changes in excitability of the pain sensing neurons (nociceptors), or to a sensitization of the mechanosensing apparatus. The central component of this apparatus is a mechanosensitive ion channel that converts mechanical inputs into electrical signals. This project aims at examining the changes that occur in the function of MSCs in knee joint nociceptors in naïve and osteoarthritic animals. Using a mouse model of OA (monoiodoacetate (MIA)), we will assess if the sensitivity of MSCs in joint-innervating nociceptors is altered in the setting of OA pain. We hypothesize that MSCs are sensitized to mechanical stimulation in OA and blocking their activity will not only reduce this hypersensitivity at the cellular level, but also behaviorally. Our initial behavioral observations from knee-injected mice validate our MIA model as mice become hypersensitive to knee flexion and extension. Electrophysiology recordings from acutely dissociated knee nociceptors indicate that there are no changes in the resting membrane potential. Furthermore, our preliminary data indicates that the activation threshold of MSCs in these nociceptors of OA mice is significantly lower than that of nociceptors from naïve mice. This suggests that the sensitivity of MSCs may contribute to the mechanical hypersensitivity observed in behavioral tests. In conclusion, our preliminary results suggest that MSCs in nociceptors may be a novel therapeutic strategy in the treatment of OA pain.

Title: Endocannabinoids/endovanilloids attenuate injury-induced hyperalgesia but not mechanical allodynia

Authors: *T. L. SUMMERS, B. HANTEN, W. PETERSON, B. D. BURRELL
Basic Biomed. Sci., Univ. of South Dakota, Vermillion, SD

Abstract: The endocannabinoid/endovanilloid system is thought to play an important role in modulating nociceptive signaling at both the central and peripheral levels, making it a potential therapeutic target for treating chronic pain. The central analgesic effects of these neurotransmitters are thought to be due, in part, to depression of excitatory synaptic transmission within nociceptive pathways. However, results from both clinical and laboratory-based studies have found that endocannabinoid/endovanilloid can also contribute to nociceptive sensitization (e.g. mechanical hyperalgesia or allodynia) due to a depression of inhibitory synapses resulting in disinhibition of pain circuits (Christie & Mallet, 2009; Pernia-Andrade et al., 2009). Using the medicinal leech as a model system, our lab has observed that while endocannabinoid/endovanilloid depress nociceptive synapses, they actually enhance non-nociceptive synaptic transmission (Yuan & Burrell, 2010; Higgins et al. 2013). Here, we examined the functional relevance of these synaptic effects by testing whether endocannabinoid/endovanilloid have similar bidirectional effects on behavioral responses to nociceptive vs. non-nociceptive stimuli. First, uninjured leeches were injected with either 2-arachidonoylglycerol (2-AG; 75μM) or anandamide (AEA; 100μM) and then tested for behavioral responses to nociceptive and non-nociceptive stimuli. Both AEA and 2-AG sensitized responses to non-nociceptive stimuli while simultaneously decreasing responses to nociceptive stimuli. Both the pro- and anti-nociceptive effects of AEA and 2-AG were blocked by co-injection of SB366791, an inhibitor of the transient receptor potential vanilloid (TRPV) channel (invertebrates lack CB1 & CB2 receptors). Next, experiments were conducted to determine the effect of 2-AG and AEA on non-nociceptive and nociceptive stimuli responses in an injury-induced sensitized animal. Animals received a crush injury to their posterior sucker which resulted in a significant increase in responses to non-nociceptive (allodynia) and nociceptive (hyperalgesia) stimuli. In a subgroup of these sensitized animals, injection of 2-AG (75μM) on the third day after injury restored nociceptive stimuli responses to pre-injury levels. However, 2-AG treatment did not attenuate the sensitized response to non-nociceptive stimuli. These results indicate that endocannabinoid/endovanilloid treatment may be effective in treating hyperalgesia, but is ineffective at treating or may even worsen mechanical allodynia.

Title: Allosteric interactions within delta opioid receptor - kappa opioid receptor (DOR-KOR) heteromers in peripheral sensory neurons

Authors: *B. A. MCGUIRE, T. A. CHAVERA, W. P. CLARKE, K. A. BERG
UT Hlth. Sci. Ctr., San Antonio, TX

Abstract: G-protein coupled receptor (GPCR) heteromers may have unique pharmacological properties, signaling characteristics and anatomical specificity. Thus, GPCR heteromers may provide a unique pharmacological target for the treatment of a variety of disease states. Due to methodological limitations, most of the work characterizing GPCR heteromers has been performed in heterologous expression systems, with few experiments in physiologically relevant systems. We have found that DOR-KOR heteromers form in peripheral nociceptors (i.e., pain-sensing neurons) and, when activated, produce robust antinociceptive responses (Berg et al., 2012, *Mol Pharmacol* 81:264-272). Further, selective KOR antagonists differentially alter the potency and efficacy of DOR agonists in both a rat behavioral model of thermal nociception and in primary cultures of peripheral nociceptors (i.e., *ex vivo* model). Here we sought to further demonstrate that DOR-KOR heteromers are functional in nociceptors by examining bidirectional allosteric interactions between protomers of DOR-KOR heteromers. We determined if the selective DOR antagonist naltrindole (NTI) altered responses to the KOR agonist ICI 199441 *ex vivo* and *in vivo*. In primary cultures of rat peripheral sensory neurons, ICI 199441- mediated inhibition of PGE_2-stimulated cAMP accumulation was determined in the presence and absence of NTI (2nM, 100 x Ki). Neither basal nor PGE_2-stimulated cAMP levels were altered by NTI, however, the concentration response curve to ICI 199441 was shifted to the left by more than 100-fold; the EC50 for ICI 199441 was 15 nM versus 0.12 nM in the absence or presence of NTI, respectively (n=4). Similarly, NTI shifted the dose response curve for ICI 199441-mediated inhibition of PGE_2-induced thermal nociception to the left by 10-fold. Rats were injected with NTI (40µg) or vehicle 15 min before intraplantar coinjection of varying doses (0.1-10 µg) of ICI 199441 along with PGE_2 (0.3 µg). Paw withdrawal latencies to thermal stimulation were measured for 20 min. The ICI 199441 ED_{50} for reduction of PGE_2-induced thermal allodynia was 2.7ug versus 0.24ug in the absence or presence of NTI, respectively (n=6 animals

per group). This demonstration of bidirectional allosteric interactions between the protomers of DOR-KOR heteromers provides strong evidence for functional DOR-KOR heteromers in peripheral nociceptors. We propose that the DOR-KOR heteromer may be a suitable target for pain pharmacotherapy.

Title: Cathepsin S induces peripheral and central activation of pain via biased agonism of Protease-Activated Receptor 2

Authors: *T. LIEU, P. ZHAO, N. BARLOW, D. P. POOLE, B. SEBASTIAN, N. W. BUNNETT
Monash Inst. of Pharmaceut. Sci., Parkville, Australia

Abstract: Proteases such as mast cell tryptase cleave protease-activated receptor-2 (PAR2) at R36/S37 and reveal a tethered ligand that binds to and activates the cleaved receptor. PAR2 can activate transient receptor potential (TRP) ion channels and thereby excite nociceptors to induce neurogenic inflammation and pain. Whether proteases that cleave PAR2 at distinct sites are biased agonists that also activate TRP channels to induce neurogenic inflammation and pain is unexplored. Cathepsin S (Cat-S) is a lysosomal protease secreted by antigen presenting cells such as macrophages and spinal microglial cells during inflammation. We used mass spectrometry to identify the Cat-S cleavage site, bioluminescence resonance energy transfer (BRET) to examine PAR2 and G protein coupling, in-vitro cell-based assays to characterize PAR2 signaling by Cat-S, *in vivo* assessment of Cat-S-induced inflammatory and pain mechanisms, and RT-PCR and immunofluorescence to localize PAR2 expression. We observed that Cat-S cleaves N-terminal fragments of PAR2 at E56/T57, down-stream from the canonical trypsin site, as determined by mass spectrometry. In contrast to trypsin, which cleaves PAR2 at the cell-surface and causes receptor internalization, PAR2 cleaved by Cat-S remained at the

plasma membrane. Cat-S and a decapeptide corresponding to the Cat-S-revealed tethered ligand stimulated PAR2 coupling to Gαs but not Gαq determined by BRET to examine the conformational change and interactions between PAR2 and G proteins. Cat-S stimulated PAR2-dependent formation of cAMP, but Cat-S was unable to activate mutant PAR2 lacking the Cat-S cleavage site. Unlike trypsin, Cat-S did not mobilize intracellular Ca2+, activate ERK1/2, recruit β-arrestins nor induce PAR2 endocytosis. This is evidence for agonist-dependent signaling bias for Cat-S activity for PAR2. Intraplantar injection of Cat-S caused inflammation and mechanical hyperalgesia in mice that was attenuated by deletion of PAR2 and TRPV4. The Cat-S inhibitor MV026031 and the PAR2 antagonist GB88 prevented inflammation and pain induced by intraplantar injection of formalin. Central mechanisms of Cat-S activation of spinal neurons are unexplored. We found that PAR2 is expressed throughout the murine spinal cord. Immunofluorescence revealed that PAR2-immunoreactivity is localized to lamina I of the dorsal horn and co-localizes with CGRP positive neurons. Intrathecal injection of Cat-S into the lumbar section of the spinal cord caused sustained mechanical hyperalgesia in wt-mice for up to 4 hours ($p<0.001$, $n=4$). Determination of Cat-S-dependent activation of PAR2 on dorsal horn neurons remains to be investigated.

Title: CXCL10 directly sensitizes a subset of cutaneous nociceptors through CXCR3 and contributes to itch in a murine model of allergic contact dermatitis

Authors: L. QU[1], K. FU[1,2], S. G. SHIMADA[1], *R. H. LAMOTTE[1]
[1]Dept Anesthesiol, Yale Univ. Sch. Med., New Haven, CT; [2]Jinan Univ., Guangzhou, China

Abstract: The role of the chemokine, CXCL10, and its receptor CXCR3, has been implicated in the pathophysiology of allergic contact dermatitis, but unexplored for the itch and pain that can accompany this disorder. We examined whether CXCL10 directly activated acutely dissociated,

small-diameter, cutaneous, sensory neurons through CXCR3, and contributed to itch- and pain-like behaviors in a murine model of allergic contact dermatitis (contact hypersensitivity or CHS) induced by a hapten, squaric acid dibutylester (SADBE). Calcium imaging revealed that CXCL10 directly evoked a Ca2+ increase in a subset of small-diameter, dorsal root ganglion (DRG) neurons, fluorescently tagged as cutaneous, via the activation of CXCR3. The larger proportion of neurons responsive to CXCL10 in CHS vs. control mice was suggestive of an increased number of cutaneous sensory neurons expressing CXCR3 after the development of CHS. The neurons from CHS mice exhibited a depolarized membrane potential accompanied by action potentials and a reduction in input resistance upon CXCL10 application. Pretreatment with a CXCR3 antagonist significantly attenuated the direct excitatory effects of CXCL10. CXCL10 activated a chloride channel in cutaneous sensory neurons from CHS mice, which may account for the depolarization induced by CXCL10. In behavioral tests, subcutaneous injection of a CXCR3 antagonist significantly attenuated the spontaneous itch- but not pain-like behaviors directed to the site of CHS. CXCL10 elicited site-directed itch-like but not pain-like behaviors when injected into a site of CHS but neither type of behavior in control mice, which is likely due to the paucity of functional CXCR3 expressed in cutaneous sensory neurons under normal conditions. The CXCL10-evoked itch-like behavior in CHS mice was attenuated by a CXCR3 antagonist or a chloride channel blocker. These results suggest that CXCL10/CXCR3 signaling directly activates a subset of cutaneous primary sensory neurons through chloride channels and may contribute to the itch accompanying allergic contact dermatitis.

Title: NMDA receptor-induced substance P release from primary afferent terminals is inhibited by α2A adrenergic receptors, lack of synergism with μ-opioid receptors

Authors: *H. KIM[1], W. CHEN[1], H. S. ENNES[1], W. WALWYN[1], J. A. MCROBERTS[1,2], J. G. MARVIZON[1,2]
[1]Med., UCLA, Los Angeles, CA; [2]Veteran Affairs Greater Los Angeles Healthcare Syst., Los Angeles, CA

Abstract: Recently, we showed that BDNF acting on trkB receptors induces a gain of function of NMDA receptors in primary afferent terminals, which occurs right after the onset of neuropathic pain (Chen et al., Eur. J. Neurosci., 2014). Here we present evidence that α2A adrenergic receptors induce a counterbalancing loss of function of these NMDA receptors. NMDA receptor function was assessed as the ability of NMDA + D-Ser (10 μM for 2 min) to induce substance P release in rat spinal cord slices. Substance P release was measured as neurokinin 1 receptor (NK1R) internalization in lamina 1 neurons. NMDA-induced NK1R internalization in spinal cord slices was inhibited by 1 hr preincubation with the α2A adrenergic receptor agonists clonidine (1 μM), guanfacine (10 nM), tizanidine (100 nM) and medetomidine (1 μM). A concentration-response for guanfacine yielded an IC50 of 0.22 nM and was right-shifted by the selective α2A receptor antagonist BRL44408 with a KB of 16 nM (Gaddum-Schild analysis). To determine whether α2A receptors inhibit NMDA receptor-induced substance P release *in vivo*, rats were given intrathecal BDNF (0.3 μg) to increase NMDA receptor function, then intrathecal guanfacine (0.3 nmol) or saline 3 hr after BDNF and finally intrathecal NMDA + D-Ser (10 nmol each) 1 hr later. NMDA induced NK1R internalization after BDNF, and this effect was eliminated by guanfacine. These results show that α2A receptors decrease NMDA receptor function in primary afferent terminals. We also investigated whether the inhibition of substance P release by α2A receptors was synergistic with its inhibition by μ-opioid receptors. Spinal cord slices were preincubated for 1 hr with different concentrations of guanfacine, DAMGO (a μ-opioid receptor agonist), or guanfacine and DAMGO combined at a ratio of 1:10. Slices were then stimulated for 2 min with NMDA and D-Ser. NMDA-induced NK1R internalization data obtained with each agonist alone or the two agonists combined were analyzed simultaneously by fitting two dose-response curves to the data. Akaike's Information Criterion was used to determine the probability that the IC50 was the same for each agonist alone compared to the two agonists combined. The probability that the IC50 was the same for the concentration-responses of guanfacine and guanfacine + DAMGO was 76%. The probability that the IC50 was the same for the concentration-responses of DAMGO and DAMGO + guanfacine was 48%. Therefore, there was no detectable synergy between α2A adrenergic receptors and μ-opioid receptors to inhibit substance P release in the spinal cord.

Abstract: Pharmacological evidence for a dominant role of NaV 1.7 in action potential regulation in guinea pig and human vagal afferent nociceptors. R. Adam Herbstsomer, Marian Kollarik, Sonya Meeker, Jeffrey Krajewski, Baolin Li, Kirk Johnson, Eric Nisenbaum, Bradley J. Undem We used an *ex vivo* guinea pig (GP) trachea-vagus nerve preparation to evaluate the effect of NaV1 blockers on the action potential (AP) response single tracheal afferent terminals with cell bodies in nodose and jugular ganglia. One nerve was studied per animal. In addition we evaluated the C-wave of the compound action potential (CAP) in human peribronchial vagus nerves. In 70% of the nodose and jugular afferent nerves, tetrodotoxin (TTX) potently (EC50 30-100nM) and effectively increased voltage threshold for AP formation. It abolished the action potential discharge in response to citric acid (1ml of a 1 mM solution applied directly to the receptive field) in all nodose Aδ fibers (n=19) and inhibited the acid response in jugular C-and Aδ afferent nerves by 80% (n=16). A selective NaV 1.7 blocker (Lilly's compound A) potently inhibited GP cloned NaV 1.7 current, and inhibited by 80% the TTX-sensitive current in GP isolated nodose neurons. It was nearly equipotent as TTX in increasing voltage thresholds in nodose (n=13) and jugular fiber terminals (n=20) in the trachea. It was slightly less effective than TTX in blocking citric acid responses, maximally (1 μM) blocking discharge in nodose and jugular fibers by 70% and 60%, respectively. ICA-121431 (10 μM), a selective blocker of human NaV1.1, 1.2 and 1.3 (*McCormack et al PNAS, 2013*) had no effect on the GP cloned NaV1.7 current, and had no effect on voltage threshold or citric acid response in nodose or jugular tracheal fibers. Likewise, A803467 (30 μM, a concentration that blocked the TTX-insensitive NaV 1.8 current in GP nodose neurons by 80%) was without effect on GP nodose and jugular terminals. TTX (0.1 μM) and Compound A (1μM) each reversibly blocked (~90% inhibition) the C-wave of the CAP in human peribronchial vagi, whereas ICA-121431 (10 μM) had little effect.

These data add pharmacological support to our previous work with NaV1.7 shRNA *(Muroi et al. J. Physiol 2011)* that NaV 1.7 is a dominant NaV1 involved in action potential formation in vagal afferent Aδ and C-fibers.

Title: Phosphorylation of mTOR maintains pain hypersensitivity after the tissue injury

Authors: Y. IZUMI[1], M. SASAKI[2], *F. AMAYA[2]
[1]Saiseikai Kyoto Hosp., Kyoto, Japan; [2]Anesthesia and Intensive care, Kyoto Prefectural Univ. of Med., Kyoto, Japan

Abstract: (Background) We previously showed that insulin-like growth factor 1 (IGF1) in injured tissue contributes to the maintenance of peripheral sensitization after a plantar incision. Mammalian target of rapamycin (mTOR) is activated by IGF1 and controls protein synthesis in the nervous system. Here, we investigated the role of IGF1/mTOR signaling in the dorsal root ganglion (DRG) for the development of pain hypersensitivity following plantar incision. (Method) Male SD rats were used for the experiments. Rats were treated with plantar incision procedure or intraplantar injection of IGF1 under deep isoflurane anesthesia. Behavioral analysis was performed to determine thermal and mechanical noxious threshold. L4 and L5 DRG were taken and processed for the immunohistochemistry. Phosphorylated mTOR (p-mTOR) and Vesicular glutamate transporter 2 (VGLUT2) expression were visualized by indirect immunofluorescence method. (Result) The number of p-mTOR-positive neurons was increased after the incision. Systemic Rapamycin treatment inhibited p-mTOR expression in the DRG and thermal hypersensitivity after the incision. Local injection of IGF1 increased p-mTOR expression in the DRG, and treatment with the IGF1 receptor inhibitor picropodophyllin alleviated incision-induced p-mTOR induction. VGLUT2 expression was increased after the plantar incision or local IGF1 treatment increased VGLUT2 expression in the DRG neurons. The

incision-induced increase in VGLUT2 expression was inhibited by rapamycin. (Conclusion) These results demonstrated that tissue injury induces phosphorylation of mTOR in DRG neurons via IGF1 dependent manner. Increased expression of VGLUT2 by the mTOR activation contributes to the maintenance of thermal hyperalgesia after tissue injury.

Title: Different effects of the cytokine Interferon-γ on slowly or fast conducting nociceptive nerve fibers in rat *in vivo*

Authors: *F. RICHTER, S. WANDT, J. FINK, M. RAUSCHELBACH, H. WITZENHAUSEN, H.-G. SCHAIBLE
Inst. of Physiol. I, Univ. Hosp. Jena, Jena, Germany

Abstract: Whether the cytokine Interferon-γ (IFN-γ) has proinflammatory or anti-inflammatory effects is still disputed. In this study we investigated whether IFN-γ has the potency to induce mechanical hyperalgesia in normal or in acutely inflamed (kaolin/carrageenan) knee joints and whether such effects are specific to an action on the IFN-γ receptor. Healthy adult WISTAR rats were anesthetized with sodium thiopentone (100 mg/kg, i.p.). The knee joint was mechanically stimulated by innocuous (20 mNm) or noxious (40 mNm) rotations of the lower leg against the fastened femoral bone for 15 sec each. Action potentials were recorded from nerve fibers that were classified as C- or as Aδ-fibers by their conduction velocity (<1.4 m/s or <10 m/s, respectively). Compounds were injected into the joint cleft at a volume of 0.1 ml each. In normal knee joints a single intraarticular injection of IFN-γ dose-dependently decreased the net response rate of C-fibers to noxious stimulation within three hours (0.1 ng by 21±51, 1 ng by 155±32, 10 ng by 171±56 APs/15 s; mean±SEM, respectively), but had no influence on the net response rate to innocuous stimulation. The response rates in Aδ-fibers were only insignificantly changed by IFN-γ. After 7 hours of acute knee joint inflammation in C-fibers a similar dose-dependent decrease in response rate was seen, the highest dose of IFN-γ caused a decrease by 211±61 APs/15 s after three hours of application of the cytokine. Interestingly, in Aδ-fibers recorded from inflamed knee, both 1 ng and 10 ng of IFN-γ caused rather an increase in the net response

rate (1 ng by 135±40, 10 ng by 195±64 APs/15 s, respectively). Simultaneous injection of 10 μg of a blocking IFN-γ receptor antibody together with 10 ng of IFN-γ in normal knee joints prevented the decreasing effect of the cytokine in C-fibers, responses in Aδ-fibers did not change. Thus IFN-γ in slowly conducting nerve fibers both in normal and in inflamed knee joints acts as an antinociceptive cytokine, whereas its effect on fast conducting fibers depends on the situation in the knee joint.

Title: Correlation of the electrophysiological profiles and sodium channel transcripts of individual rat dorsal root ganglia neurons

Authors: ***M. CHAHINE**, O. THÉRIAULT
Medecine, Inst. universitaire en santé mentale de Québec, Québec, QC, Canada

Abstract: Voltage gated sodium channels (Na+ channels) play an important role in nociceptive transmission. They are intimately tied to the genesis and transmission of neuronal firing. Five different isoforms (Nav1.3, Nav1.6, Nav1.7, Nav1.8, and Nav1.9) have been linked to nociceptive responses. A change in the biophysical properties of these channels or in their expression levels occurs in different pathological pain states. However, the precise involvement of the isoforms in the genesis and transmission of nociceptive responses is unknown. The aim of the present study was to investigate the synergy between the different populations Na+ channels that give individual neurons a unique electrophysical profile. We used the patch-clamp technique in the whole-cell configuration to record Na+ currents and action potentials from acutely dissociated small diameter DRG neurons (<30 μM) from adult rats. We also performed single cell qPCR on the same neurons. Our results revealed that there is a strong correlation between Na+ currents and mRNA transcripts in individual neurons. A cluster analysis showed that subgroups formed by mRNA quantification have different biophysical properties. In addition, the

firing frequency of the neurons was not affected by the relative populations of Na+ channel subtypes. The synergy between populations of Na+ channel subtypes in individual small diameter DRG neurons gives each neuron a unique electrophysiological profile. The Na+ channel remodeling that occurs in different pathological pain states may be responsible for the sensitization of the neurons.

Title: Systems view of axotomy with rna-seq analysis of dorsal root ganglion, dorsal horn and ventral horn

Authors: S. C. GOSWAMI[1], J. R. GROSS[1], *J. K. NEUBERT[2], A. J. MANNES[1], M. J. IADAROLA[1]

Abstract: The full-spectrum of molecules involved in nociceptive signaling involves many as yet unrecognized molecules. Depending on the cause of pain (e.g. inflammation or nerve injury) the signaling molecules involved may vary. This study focuses on nerve injury and examines the transcriptional changes within the DRG after axotomy. Spinal cord dorsal horn and ventral horn are also examined to elucidate broader system changes, differences, and commonalities between these tissues. In this study we employ RNA-Seq to obtain quantification of transcriptomes at maximal resolution and dynamic range. Rat L4-L5 DRG, lumbar DH, and VH at 0, 1, 3, 10, 30 and 90 day(s) after axotomy were collected and sequenced with the Illumina HiSeq 2000. The RNA-Seq data were mapped with RUM and statistical analyses performed using DESeq. The transcriptome data from the DRG axotomy revealed significant modulation of ~1700 genes (with an adjusted fold difference > 2 and above). Significantly regulated genes are subdivided into two categories: induced (basal expression below 1 RPKM) and upregulated (basal expression > 1 RPKM). Clustering within these categories disclosed several temporal patterns: Peak Day1, Peak

Day 3, Peak Day 10, Bimodal, Transient Decrease and Delayed Increase. Gene enrichment analyses were used to categorize nerve injury changes. GO terms such as negative regulation of catalytic activity, peptidase inhibitor activity for genes in the Peak Day 1 imply an initial attempt to stabilize injury-induced alterations. The DH and VH share some regulated genes with DRG and the general temporal clustering patterns. VH RNA-seq resulted in ~200 significantly regulated (2-fold and above) genes with a strong enrichment for mitotic and cell cycle transcripts at Day 3 consistent with microglial proliferation to effect displacement of synaptic terminals from motoneurons. The DH RNA-Seq dataset revealed ~400 regulated genes (>2-fold). Many of the DH genes regulated at Day 3 also were involved in mitosis. It is unclear however, whether the mitotic changes are due to the same processes in the two tissues. As expected, many other functional groups were discerned and included a strong representation of immune response genes in all three tissues. Understanding molecular changes after axotomy at a fine level of molecular resolution in both PNS and CNS is a key element in understanding the pathophysiological consequences of nerve injury and regeneration mechanisms. The present RNA-Seq study provides a rich repertoire of data to further elucidate the pathways and mechanisms involved nerve-injury models of pain.

Title: Aminooxyacetic Acid: An aspartate aminotransferase inhibitor with local analgesic properties during chronic inflammation

Authors: *B. R. BOLT, K. E. MILLER
Anat. and Cell Biol., Oklahoma State Univ. Ctr. For Hlth. Sci., Tulsa, OK

Abstract: Painful inflammation leads to a local increase in neurotransmitter Glutamate in the rat peripheral afferent terminals (skin). The primary sensory neurons of the dorsal root ganglia (DRG) are glutamatergic utilizing glutaminase (GLS) in the glutamine cycle as a source for

glutamate production, but aspartate aminotransferase (AST; GOT1) also plays a key role by transamination of aspartate and 2-oxoglutarate to produce glutamate along with oxaloacetate. We previously demonstrated that AST, GLS, and glutamate are elevated in the rat DRG and skin during the adjuvant-induced arthritis (AIA) model. Inhibition of GLS in the skin during AIA provides long-lasting analgesia. Since AST contributes to glutamate synthesis in peripheral nerve terminals, we hypothesized that the peripheral inhibition of AST using Aminooxyacetic acid (AOAA) would lead to analgesia during AIA. For the AIA model, peripheral inflammation was induced by intraplantar injection of Complete Freund's adjuvant in the right hind paw. After 4 days of inflammation, rats where treated with subcutaneous administration of AOAA. After AOAA administration, exaggerated thermal and mechanical responses in AIA rats were attenuated by 30 min and lasted for up to 5 hours. The current results further indicate that AST is a major contributor of glutamate synthesis in nociceptive peripheral nerve terminals. AST inhibition appears to be a viable target for producing long lasting local analgesia by decreasing glutamate production and release from peripheral primary afferents.

Title: Prolactin sex-dependently regulates peripheral and spinal postoperative hypersensitivity

Authors: *M. J. PATIL[1], V. GOFFIN[2], M. HENRY[3], A. AKOPIAN[3]
[1]Endodontics, UT Hlth. Sci. Ctr., SAN ANTONIO, TX; [2]Inserm and Univ. Paris Descartes, Paris, France; [3]UTHSCSA, san antonio, TX

Abstract: Aim of Investigation: Prolactin (PRL) is a multifaceted pituitary hormone dually regulated by estrogen and trauma/stress. PRL levels are sex-dependently elevated in serum and extra-pituitary after pain conditions such as tissue injury, inflammation, surgical procedure, burn and migraine. We recently reported that ablation of PRL receptor (PRLR) leads to reduction

postoperative and inflammatory hypersensitivity in a sex-dependent manner. However, mechanisms mediating these sex-dependent PRL effects are unknown. Here, we investigated how PRL regulates postoperative hypersensitivity at periphery and spinal cord of males and females. Methods: All described experiments were performed on adult males and estrous phase females, which contain moderate PRL levels in blood. Expression of PRLR in dorsal root ganglia (DRG) and spinal cord were assessed using immunohystochemistry (IHC). Functional expression of PRLR long form was assessed by labeling to phspho-STAT5. Classical hindpaw incision model was used as an acute postoperative model. Results: PRLR is expressed in subset of DRG and spinal cord neurons. PRL regulates phosphor-STAT5 in DRG and spinal cord neurons via PRLR long isoform. PRL is able to produce thermal and mechanical hypersensitivity upon injection in hindpaw of male and female naïve rats. These hypersensitivity effects are sex-dependent. We next evaluated role of peripheral and spinal PRLR in postoperative hypersensitivity in males and females using specific PRLR antagonist, αPRL. αPRL when injected peripherally or intrathecally 24h post-surgery did not have an effect on thermal or mechanical hypersensitivity in male rats. The female rats with incision showed significant reduction in both thermal and mechanical hypersensitivity post intrathecal administration of αPRL. The antagonist administration peripherally resulted in inhibition of thermal, but not mechanical postoperative hypersensitivity. Conclusions: Short and long forms of PRLR are expressed in subsets of DRG and spinal cord neurons. PRL is able to cause hypersensitivity in naïve animals, but the effect in sex-dependent. Importantly, peripheral and spinal inhibitory actions of the PRLR antagonist on postoperative thermal and mechanical hypersensitivity are exclusively restricted to females. Compression of presented data with results generated after global ablation of PRLR indicates that PRL can exhibit anti-nociceptive effects in males by acting on unknown brain regions. In contrast, peripheral and spinal mechanisms of PRL action are specific for females.

Sch. of Neural Information Processing, Univ. of Tuebingen, Tuebingen, Germany; [3]Visualization and Data Analysis, Zuse Inst. Berlin, Berlin, Germany; [4]Digital Neuroanatomy, Max Planck Florida Inst., Jupiter, FL; [5]Bernstein Ctr. for Computat. Neurosci., Tuebingen, Germany

Abstract: In order to gain a mechanistic understanding of sensory signal flow in the rat vibrissal system, it is necessary to determine the activity of neurons in response to sensory inputs, and to identify the spatial distribution of synapses to and from these neurons. While the responses of neurons to whisker stimuli have been characterized extensively, a complete quantitative description of connectivity in the vibrissal system is still lacking. Therefore, we aim to determine all inputs and outputs to and from neurons in rat barrel cortex. Two widely used techniques for investigating neural connectivity are electron-microscopic (EM) reconstruction of brain circuits and tracing of bulk injections. However, so far these approaches have been limited to small circuits of hundreds of neurons (EM reconstruction) or only allow limited extraction of quantitative connectivity data (bulk injections). Here, we present a third, statistical approach for obtaining dense synaptic connectivity of neural networks from representative samples of 3D morphologies of single neurons labeled *in vivo*. To do so, we measure (i) the 3D geometry of rat barrel cortex, (ii) the 3D distribution of excitatory and inhibitory neuron somata, and (iii) the 3D morphology of dendrites and axons of 11 excitatory and 6 inhibitory neuron cell types. Combining these data in a common 3D reference frame allows estimating the 3D distribution of 5 billion boutons from 6,000 thalamocortical and 500,000 intracortical neurons in a volume of 6.5 cubic mm, at a resolution of 50 μm. Putative synaptic innervation at subcellular resolution is predicted from the overlap between reconstructed dendrites and axons. In the past, a variety of results obtained by statistical mapping deviated from direct connectivity measurements. Comparing the resultant cell type-specific innervation probabilities and cell-specific subcellular innervation patterns with previously reported *in vivo* paired-recordings and EM data, we demonstrate the validity and appropriate spatial resolution of this statistical approach. Finally, we show how this statistical approach can be used to generate a dense cell-to-cell connectome of barrel cortex. Analysis of the resultant connectivity reveals cell type- and location-specific connectivity patterns from the microscopic, subcellular level up to the macroscopic scale of the entire barrel cortex, which form the structural basis underlying sensory-evoked signal flow.

Title: The relationship between microcircuit structure and dynamics in the rat barrel cortex

Authors: *I. D. LANDAU[1], R. EGGER[2], M. OBERLAENDER[3,2], H. SOMPOLINSKY[1,4]
[1]Edmond and Lily Safra Ctr. for Brain Sci., The Hebrew Univ. of Jerusalem, Jerusalem, Israel; [2]Computat. Neuroanatomy Group, Max Planck Inst. for Biol. Cybernetics, Tübingen, Germany; [3]Digital Neuroanatomy, Max Planck Florida Inst. for Neurosci., Jupiter, FL; [4]Ctr. for Brain Sci., Harvard Univ., Cambridge, MA

Abstract: In the study of the cerebral cortex, the roughly uniform six-layer structure and the prominence of functional columns have raised the question of the relationship between structure and function of cortical microcircuits. Nevertheless, experimental work has only slowly begun to systematically unveil the connectivity of local recurrent cortical circuits, and most theoretical work has until now dealt only with simple random connectivity. Even recent realistic numerical studies have used only cell-type connection probabilities accumulated from different experimental techniques, animals, species, and brain regions. The rodent barrel cortex has become an attractive site for experimental work on the structure-function relationship because of its anatomically observable somatotopy and readily isolatable sensory input channels. In this collaborative project, we combine recent anatomical work on the rat barrel cortex which has yielded a coherent, realistic, anatomically constrained cell-to-cell connectivity matrix, with both theoretical and numerical analysis in order to shed new light on the relationship between structure and function in cortical microcircuits. We explore the dynamics of a full-scale spiking neuron network model under realistic cell-to-cell connectivity and identify constraints imposed by the connectivity beginning with one complete Layer 4 Barrel. In particular, we use numerical and theoretical tools to explore the implications of the heterogeneity in the number of connections on the dynamical state. We simulate the network model alongside others with simplified connectivity schemes, and also apply dynamical mean-field theory to a connectivity model that reflects realistic heterogeneity in order to derive analytical results. We address the trade-off between sparsity and irregularity in the balanced state. Furthermore, we probe the signal propagation yielded by the realistic connectivity matrix, exploring the spatial distribution of spontaneous, primary whisker evoked, and secondary whisker evoked firing. We compare the

results of our network model to physiological findings and make further predictions. Our work is an important step toward bridging between theory and experiment, connecting the abstract study of the dynamics of cortical circuits to the increasingly detailed experimental account of their real connectivity structure and the biophysical properties of different cell types.

Title: A computational model for interacting assembly sequences

Authors: *W. MAASS[1], R. LEGENSTEIN[1], J. MACLEAN[2]
[1]Inst. of Theoretical Computer Sci., Graz Univ. of Technol., Graz, Austria; [2]Dept. of Neurobio., The Univ. of Chicago, Chicago, IL

Abstract: As multineuronal recordings have become more prevalent it is increasingly clear that spatiotemporally patterned spiking activity encodes sensory input (Luczak et al., 2007), motor output (Churchland et al., 2007), and behavioral choice (Harvey et al., 2012). Network dynamics takes the form of trajectories of network states as captured by the assembly phase sequence postulate (Hebb 1949). Despite the utility of attractor networks in computational models the repeated experimental observation of reliable and stereotyped time varying network activity is inconsistent with attractors being the most salient computational primitive. Here we employ a generative model that exhibits stereotyped transitions through network states to evaluate the type of network computations and computational models that are consistent with the existence of stereotypical sequences of network states, and how such sequences could support network computations. In a probabilistic framework, the familiar Hidden Markov Model (HMM) is a sufficient computational (and generative) model for a single assembly sequence. However experimental data indicates that several such sequences can be generated by the same local

neural circuit (Sadovsky and MacLean 2014), and it seems likely that any such sequence interacts with assembly sequences in other parts of a larger neural system. Therefore we propose an extension of the HMM that generates separate, yet potentially interacting, state sequences (Strands) that propagate in parallel. Each strand encodes a local network state and is combined with temporal information such as lifetime and strength of initiation. We show that our Strand Computing Model (SCM) is well-suited for integrating loosely aligned information streams and for supporting inference about a possible common cause of such as multi-modal input streams, or the contextualization of a whole scene. Computations of this type are likely taking place in higher cortical areas (e.g. parietal cortex), but a more abstract computational model has been missing to describe them and to test their utility. We show that the SCM can also be used as a generative model, to produce interacting assembly sequences in large-scale models for cortical systems. Churchland MM, Yu BM, Sahani M, & Shenoy KV (2007). Title: Circuit mechanisms underlying the thalamocortical transformation during active tactile sensation

Authors: ***J. YU**, D. GUTNISKY, A. HIRES, K. SVOBODA
HHMI Janelia Farm Res. Campus, Ashburn, VA

Abstract: A fundamental challenge in neuroscience is linking behaviorally relevant computations to mechanisms at the level of neural circuits. Tactile information from the whiskers flows from the periphery through the ventral posteromedial nucleus of the thalamus (VPM) to

layer 4 (L4) of the barrel cortex. The microcircuit of each L4 barrel is relatively simple: excitatory and inhibitory neurons within the same cortical column are connected with high probability; the only prominent long-range input originates in the VPM. Here we explored how sensory information is transformed from thalamus to cortex while mice performed an active tactile discrimination task. We recorded intracellularly from L4 neurons in the barrel cortex of mice performing a whisker-dependent tactile task. Whisker trajectories and touches were recorded with high-speed videography. Under baseline conditions during performance of the tactile task, L4 neurons were hyperpolarized, with small-amplitude high-frequency membrane potential fluctuations. Whisker movements produced only small depolarizations (~ 1 mV) that were usually below spike threshold. Membrane potential dynamics associated with spikes was dominated by large-amplitude (> 10 mV) deflections. These bumps occurred almost exclusively within 10 ms after touch. In contrast, GABAergic neurons, including fast-spiking cells, were driven to spike by both touch and whisker movements. The stimulus-selectivity of GABAergic neurons was similar to VPM neurons. We also directly recorded feed-forward inhibition onto excitatory neurons by holding them at the reversal potential for excitatory input. Large inhibitory inputs were coupled to touch and whisker movements. We propose that synchronous touch responses from VPM neurons drive L4 excitatory neurons. Feedforward inhibition, mediated by L4 fast-spiking neurons, selectively suppresses asynchronous input associated with whisker movements.

Abstract: Recent studies on optogenetic silencing of PV interneurons in the non-columnar mouse visual cortex suggest a prominent role of this subpopulation in gain control Atallah BV et al (2012). Here, we explore their impact on barrel cortex microcircuit activity *in vivo*, hypothesizing a more specific effect due to its columnar organization.We established a multimodal approach, combining optical and electrophysiological readouts with optogenetics. Excitatory and inhibitory opsins (ChR2 and ArchT) were expressed specifically in PV expressing interneurons in layer II/III of the barrel cortex. We use intrinsic optical imaging (IOI) to target the virus expression to defined barrel related columns. This allowed us to achieve a barrel specific expression of opsins. The synthetic calcium indicator Oregon-green Bapta-1 (OGB-1) was then injected in barrel related columns identified by IOI upon single whisker deflection, typically B1/B2. Employing a custom-built 2 photon microscope, equipped with two independent scanning mirrors for spatio-temporally independent optogenetic modulation, the suprathreshold activity of up to 100 neurons can be imaged at 30 Hz. Electrophysiological recordings from layer V identify the brain state of the animal. This combination of techniques allows us to assess the temporal dynamics and spatio-temporal properties of whisker-evoked activity upon manipulation of PV interneuron activity.

Title: Technology innovations for leveraging supercomputers for reconstruction and simulation of large-scale detailed tissue models

Authors: J. G. KING[1], F. DELALONDRE[1], B. MAGALHAES[1], P. KUMBHAR[1], T. EWART[1], A. OVCHARENKO[1], F. CREMONESI[1], M. HINES[2], E. MULLER[1], *F. SCHUERMANN[1], H. MARKRAM[1]

Abstract: The Blue Brain Project (BBP) aims to simulate a large-scale morphologically detailed and biologically accurate model of neocortical tissue that includes millions of neurons. Such an endeavor must leverage state-of-the-art high performance computing technology for simulation, as well as at many stages of the model building process, to attain the desired level of biological detail and model fidelity, and a usable time-to-solution at the intended model scale. We describe recent developments of our supercomputer-based software and hardware infrastructure to support these objectives in two directions: Increased problem scale via increased neuron and synapse counts along with greater biological complexity, and exploration of longer biological times allowing better introspection of biological accuracy over longer simulated durations. Increased problem scale: Recent endeavors in our circuit building process have increased the biological complexity of our reconstructed models and require increased capabilities in our simulation software to handle the increased feature set. We describe the latest algorithmic improvements (problem distribution, more efficient memory usage and layouts, and on node/core parallelisms) and present scaling numbers, and continuous efforts to build and simulate increasingly larger models using our recently acquired hardware platform. The later, referred to as BBP4 hosted by the Swiss National Supercomputing Centre (CSCS), ranking 47th in the world top500 ranking (Nov. 2013), consists of a 4-rack IBM Blue Gene/Q (65'536 cores and 64TB of DRAM) as well as a companion analysis and visualization cluster (40 nodes with 16 Intel Xeon cores and 2 K20 GPU per node). Using such a facility we were able to respectively build and simulate circuits of millions morphologically detailed neurons at the time of writing of this abstract. Exploration of longer biological times: We describe a newly developed "SaveState" feature which allows simulations to be saved and resumed. This facilitates common parameter sweep use cases, but also allows the chaining of short blocks of simulations in periods of low demand to attain time-scales relevant for studies of microcircuit plasticity and learning. In addition, performance modeling of the simulation software are used to drive low-level optimizations to reduce time to solution.

Title: Multiscale model of glia metabolism linked to an electrical model of cerebral cortex

Authors: *D. KELLER[1], J. S. COGGAN[1], J. G. KING[1], C. CALI[2], H. LEHVASLAIHO[2], H. MARKRAM[1], F. SCHUERMANN[1], P. MAGISTRETTI[2]

Abstract: Glia cells are essential for maintaining proper concentrations of metabolically significant molecules in the extracellular space of neural tissue. Of particular interest to energy balance between glia and neurons is the flux of lactate, an anaerobic product of glycolysis. We present a system for modeling the metabolic interaction of glia cells with a large-scale network of spiking neurons. The system models lactate and glucose metabolism within the neurons and glia and tracks their extracellular concentrations, as well as those of pertinent ions such as Na+, Ca2+, and K+. Extracellular concentrations of these ions influence the reversal potential of neurons and release processes. The system also accommodates diffusion of extracellular molecules. Glutamate released from spiking cortical neurons is taken up by glia cells and through this process it modulates metabolism in the glia. Calcium concentrations within neurons and glia are also included in the model and used to predict the production of vasoactive substances. We subject the circuit to various stimuli in order to observe location- and stimulation-dependent effects.

Title: Morphological analysis and classification of neuronal types in the neocortical microcircuit

Authors: *L. KANARI, G. ATENEKENG, J. W. GRAHAM, R. HATELAND, Y. SHI, J. SHILLCOCK, F. SCHUERMANN, H. MARKRAM
Blue Brain Project, EPFL, Lausanne, Switzerland

Abstract: Abstract: The ability to build and simulate models of the mammalian neocortex relies fundamentally on accurate neuronal morphologies. The shape of neuronal arborizations is a key feature for the classification of neurons and defines amongst other aspects, their physical connectivity and, as a consequence, their functionality (Kalisman, 2003). The extreme diversity of neuron types in the brain renders the direct reconstruction of large numbers of cells from microscopic images infeasible. Generating *in silico* copies of neurons is therefore necessary for modeling large brain regions. For the consistent use of the artificial morphologies in a simulation it is important to ensure that they are statistically close to the biological reconstructions. A workflow has been developed for the extraction of statistical measurements from biological reconstructions of different neuronal types that are used as input for the validation and the classification of artificial or biological morphologies. This morphological analysis process is

implemented in a software tool that allows the user to perform a variety of anatomical operations, ranging from detecting and correcting artifacts in the reconstructed morphologies to viewing, analyzing, comparing and classifying neurons. Here we present the process of measuring the morphological characteristics of a single neuron, comparing them with the statistics of different neuronal populations and objectively classifying the cell into the appropriate morphological class, based on the extracted features. This tool simplifies and automates many of the tasks needed before large-scale neuronal synthesis for brain simulation can become a routine procedure. **References:** 1) *Kalisman N, Silberberg G, Markram H.* **Deriving physical connectivity from neuronal morphology**. Title: Predictive in silico reconstruction of neuronal input-output organization in the neocortical microcircuit

Authors: *S. RAMASWAMY, M. REIMANN, J. G. KING, E. B. MULLER, H. MARKRAM
Blue Brain Project, Brain Mind Institute, EPFL, Lausanne, Switzerland

Abstract: The neocortical microcircuit contains a rich diversity of excitatory and inhibitory neurons. Although previous research has revealed the fundamental characteristics of neocortical neuron types, knowledge of their synaptic, laminar, and columnar organization remains very limited. The Blue Brain Project has developed a data-driven process for the in silico reconstruction of a neocortical microcircuit. The reconstruction integrates a vast body of

biological data on ion channel kinetics and distributions, neuronal morphologies and electrical types, synaptic kinetics and dynamics from juvenile rat somatosensory cortex. These data were used to parameterize and validate the in silico anatomy and physiology of monosynaptic pathways arising from the incidental axo-dendritic overlap of diverse pre-post morphological combinations. Experimental protocols of glutamate uncaging through photo-stimulation *in vitro* were mimicked in silico to uncover a gamut of predictions on the complement of intrinsic synapses impinging onto major neocortical neuron types. The reconstruction predicts functional maps for 55 identified neuron types based on afferent and efferent morphological, electrical, and synaptic types showing a high degree of asymmetry in their input-output organization. We describe key organizing principles of neuronal input-output in the local neocortical microcircuit and discuss their roles in governing global circuit activity.

Title: Towards an integrated sensory-motor model of a mouse

Authors: *M.-O. GEWALTIG, C. EROE, B. DENIZDURDURAN, H. MARKRAM
Blue Brain Project, Brain Mind Institute, EPFL, Lausanne, Switzerland

Abstract: We present the first integrated sensory-motor model of a mouse, including a central and a peripheral nervous system, as well as a body. The latter comprises a skeleton along with muscles, skin, and sensory organs. The virtual mouse is embedded in a simulated environment with realistic physics and can therefore be used in a wide range of *in silico* experiments. Thus, we can observe the entire range of neural activity, from the peripheral sensors to the central nervous system, while the virtual mouse is engaged in an experiment. The central nervous system is a brain model that is semi-automatically generated from different data-sets. Cell

positions and inter-region connectivity are generated from the Allen Brain Atlas [1]. Cortical cell types and cell-type specific connectivity are generated from the Blue Brain Project's neo-cortical column model [2]. The final brain model comprises 70 million integrate-and-fire neurons, connected by some 10^{11} synapses, but the precise number can be adjusted. The peripheral nervous system is composed of a spinal-cord, modeled at the population level, and connections between the brain and the sensory organs (whiskers, eyes, ears, and skin). We present a technique to map spatially distributed sensors, such as touch sensors on the skin, to their corresponding regions on the sensory cortex. The result is the first integrated data-driven model of a mouse which also serves as a seed model for the Neurorobotics Platform of the EU-backed Human Brain Project [3]. The model is the starting point for a perpetual refinement cycle where new data is integrated on demand and where each iteration will further our understanding of the nervous system within a closed action-perception loop. At the poster, we will present videos demonstrating the modeling workflow as well as results showing the emergent brain activity of the mouse as it is immersed in a dynamic environment. Title: Incorporating synthesized meso-scale pyramidal axons into a reconstruction of neocortical tissue

Authors: Y. KIM, J. DYNES, J. KING, *E. B. MULLER, M. REIMANN, J. SHILLCOCK, H. MARKRAM
Blue Brain Project, Brain Mind Institute, EPFL, Lausanne, Switzerland

Abstract: Neuronal morphologies are a vital component of biophysical models of the nervous system because they determine potential connectivity, and provide the geometrical framework for synaptic integration. Pyramidal axons in particular have extensive axonal arborizations extending beyond the local microcircuit (>300µm from soma) which cannot be obtained from standard *in vitro* brain slices. Such axonal morphologies can be obtained from in-vivo labeled neurons, but are significantly more labor-intensive, and are therefore too few in number to allow circuit reconstructions. Here we present a solution to this problem by synthesizing axonal arbors based on available data from in-vivo labeling. We developed a two stage synthesis algorithm where first, spatial clusters of the axons of individual neurons are extracted, and second, axonal arbors are synthesized by employing a wiring/delay cost balancing algorithm, extending previous work to multiple axonal clusters. Employing this technique, we synthesize and incorporate axons of cortical pyramidal cells in layers 2-5 of rat P14 somatosensory cortex into reconstructions of the somatosensory microcircuit. We compare microcircuits with synthesized pyramidal axons to those with axon reconstructions from slice, and highlight differences in multi-synaptic connectivity, long-range connectivity, and effects on in silico simulations of spontaneous and evoked network activity.

Title: Embedding gap junctions in high fidelity models of neocortical microcircuitry

Authors: O. AMSALEM[1], *J. G. KING[2], W. VAN GEIT[2], B. MAGALHAES[2], E. MULLER[2], H. MARKRAM[2], I. SEGEV[1]
[1]Inst. of Life Sciences, Hebrew Univ., Jerusalem, Israel; [2]Blue Brain Project, Brain Mind Institute, EPFL, Lausanne, Switzerland

Abstract: Inhibitory neurons in the neocortex are electrically interconnected through gap junctions (GJs). These connections are established mostly among interneurons of the same type. The function of GJs in the neocortex, and in particular the class-specificity of GJs, is not yet fully understood. Here we present a process for utilizing morphological and physiological data for the parvalbumin+ (PV) basket-cell class (% electrically coupled, coupling strength, number of GJs per cell, spikelet delays, etc.) as constraints for establishing realistic GJs among PV neurons in an in silico reconstruction of a microcircuit of rat P14 somatosensory cortex. Using realistic 3D morphologies, number and distribution for basket cells within the volume of layer 2/3, we found that, when assuming "touch detection" distance of 0 μm between dendrites-to-dendrites and dendrites-to-soma, the number of GJs per basket cell ranged between 40 - 80 with an average of 1.4 GJs per connected cells, both in close agreement with the experimental range. Namely, in this case, Peter's rule holds, in contrast to our previous findings for chemical synapses. Comparing experiments to the in silico reconstruction enabled us to extract the structural connectivity pattern of GJ's in the basket cell network, estimate the conductance of an individual GJ, and of the impact of the GJs load on the soma input resistance. We employ this unique opportunity to explore the effect of GJs, in a major inhibitory sub-network, on spontaneous and evoked dynamics/synchronization in biologically accurate large-scale simulations of neocortical microcircuitry.

Title: The HBP unified portal: Collaborative data-driven multi-scale reconstruction and simulation of neural tissue

Authors: *J. MULLER[1], J. G. BJAALIE[2], L. CORBEIL[3], J.-D. COURCOL[1], D. DARINE[2], F. DELALONDRE[1], S. HILL[1], D. MALLMAN[4], C. MCMURTRIE[3], C. MEZZANOTTE[3], E. MULLER[1], R. NIEDERBERGER[4], B. ORTH[4], F. SCHUERMANN[1], B. SCHULLER[4], M. TELEFONT[1], S. ZANINETTA[1], H. MARKRAM[1]
[1]Blue Brain Project, Brain Mind Institute, EPFL, Lausanne, Switzerland; [2]Inst. of Basic Med. Services, UNIVERSITETET I OSLO, Oslo, Norway; [3]EIDGENOESSISCHE TECHNISCHE HOCHSCHULE ZURICH, Zurich, Switzerland; [4]FORSCHUNGSZENTRUM JUELICH GMBH, Juelich, Germany

Abstract: A central tenant of the EU-FET Flagship “Human Brain Project” (HBP) is that a comprehensive understanding of the brain requires study of the structure and function across all levels of brain organization and cannot be obtained by the study of one level alone. The only approach today that can in principle be developed to simultaneously study the brain across all levels is brain simulations using biophysical in-silico reconstructions of the brain composed of embedded models at each level. Since this effort requires expertise across the spectrum of neuroscience, computer science, physics and mathematics, a massively collaborative scientific effort is crucial to reconstruct such multi-level models. The impact of the social internet and the success of opensource software communities shows that ICT has the capacity to enable the massively collaborative efforts needed. To enable large-scale collaborations in neuroscience, the HBP is developing the Unified Portal (HBP-UP), a web-based collaborative scientific platform intended to bring together all HBP activity. The HBP-UP will be equipped with a layer of powerful collaboration functions and extension frameworks to allow integration of the 6 HBP ICT Platforms. Built on this foundation and leveraging cutting edge HPC facilities, the HBP-UP will allow fluid sharing of data, theories, applications and models prior to publication while still maintaining proper attribution. It is expected that this sharing will be a key factor in the acceleration of neuroscience and the eventual achievement of the HBP’s ambitious goals. We present the current architecture for the HBP-UP along with a tech preview of a number of the key use cases it is meant to address. With this presentation we hope to solicit early feedback from the community.

Title: Sensory and Cognitive electrophysiology in rats: Tactile stimulation and micro-ECoG recordings in freely moving animals

Authors: ***G. DIMITRIADIS**, A. M. FRANSEN, E. MARIS
Donders Inst. For Brain, Cognition and Behaviour, Nijmegen, Netherlands

Abstract: We have developed a setup for rats that allows for controlled sensory input to an animal engaged in a task while recording both electrophysiological signals and behavioral output. We record electrophysiological signals using a novel high-density micro-electrocorticography (micro-ECoG) grid that covers almost the whole somatosensory system. We dealt with the well-known difficulty that the rat uses its whisker system in an active (motor-controlled) way to explore its environment by designing a head-mounted device that stimulates the rat's snout in a way unaffected by whisker movements. We replicate the spatial specificity of early evoked responses in somatosensory and auditory cortex. We validate our setup by replicating (1) the functionally nonspecific spread of neural activity following tactile stimulation, and (2) the effects of anesthesia on the tactile evoked responses. We also demonstrate for the first time that the ECoG can be used to record evoked responses in a signal that reflects neural output (spiking activity), and illustrate the usefulness of our setup by demonstrating that these evoked responses are modulated by both the phase of pre-stimulus oscillations and by

expectation. Compared with high-density wire recordings, micro-ECoG offers a much more stable signal without readjustments, and a much better scalability. Compared with head-fixed preparations, our head-mounted stimulator allows to stay closer to the rat's natural way of collecting sensory information. For perceptual and cognitive research, our setup provides a unique combination of possibilities that cannot be achieved in other setups for rodents.

Title: Effect of bicuculline on the temporal dynamics of the evoked local field potential: Implication on the interpretation of EEG

Authors: M. BRUYNS-HAYLETT[1], J. LUO[1], A. KENNERLEY[3], S. HARRIS[3], L. BOORMAN[3], N. VAUTRELLE[3], C. MARTIN[3], B. WHALLEY[1], M. JONES[4], J. BERWICK[3], *Y. ZHENG[2]
[2]Sch. of Systems Engin., [1]Univ. of Reading, Reading, United Kingdom; [3]Univ. of Sheffield, Sheffield, United Kingdom; [4]Univ. of Sheffield, sheffield, United Kingdom

Abstract: Increasing evidence from *in vivo* intracellular studies has demonstrated that proportionally balanced neural excitation and inhibition is a fundamental principle underlying a wide range of cortical activities. In particular, it has been shown that excitatory and inhibitory synaptic inputs are co-tuned, with inhibition lagging excitation by several milliseconds. However this temporal lag has not yet been demonstrated conclusively in extracellular field potential recordings. In this study, we investigated neural excitatory and inhibitory post-synaptic activity in the barrel cortex of anaesthetised rodents in response to electrical stimulation of the contra-lateral whisker pad. We manipulated the balance between neural excitation and inhibition by micro-injection of bicuculline, a competitive gamma-aminobutyric acid (GABAA) receptor antagonist at subconvulsive concentrations using a laminar linear 16-channel electrode array with an 'infusion-port' connected to a syringe pump. This multi-channel electrode allowed measurement of changes in the stimulus-evoked local field potential (LFP) before and after local

cortical bicuculline infusion *in vivo*. We found that for a range of dosages of bicuculline (6.25-50mM), the temporal dynamics of the evoked LFP did not change within the first 7-8 ms after the onset of stimulation and suggests that this initial segment of the evoked LFP reflects evoked temporal dynamics of excitatory post-synaptic activity of the local neural population alone. As the onset latency of the LFP response is ~4 ms, our data imply that, at the neural population level, inhibitory post-synaptic activity lags that of the excitatory activity by ~3-4ms and agrees well with findings from single neuron, patch clamp recordings (Wehr and Zador 2003, Okun and Lampl 2008). Furthermore the evoked LFP from the uppermost channel of the 16-channel micro-electrode (~50μm below the cortical surface) exhibited similar temporal characteristics as the event related potential (ERP) observed in human electroencephalography (EEG), with well-defined positive (e.g., p1, p2) and negative deflections (e.g., n1). Bicuculline had little effect on the amplitude and latency of p1 in the uppermost LFP channel, indicating, for the first time, that p1 may be solely associated with the excitatory post-synaptic activity of the local neural population.

Title: Investigating the shift in balance between neural excitation and inhibition due to bicuculline infusion using a two-compartment model of local field potentials

Authors: ***J. LUO**[1], M. BRUYNS-HAYLETT[1], J. BERWICK[2], A. KENNERLEY[2], L. BOORMAN[2], S. HARRIS[2], E. MILNE[2], D. COCA[3], S. BILLINGS[3], Y. ZHENG[1]
[1]Sch. of Systems Engin., Univ. of Reading, Reading, United Kingdom; [2]Dept. of Psychology, The Univ. of Sheffield, Sheffield, United Kingdom; [3]Automatic Control and Systems Engin., The university of Sheffield, Sheffield, United Kingdom

Abstract: Abstract Local field potentials (LFPs) reflect the synaptic activity of neural assemblies surrounding the recording electrode. Using a single compartment configuration, we previously derived a model of the LFP which decomposed LFP into co-tuned and temporarily shifted excitatory and inhibitory components. However the model was only applicable to LFP recorded in layer IV of the neocortex where cortical pyramidal neurons receive most of their synaptic inputs (Zheng et al 2012). In the present study, we extended the LFP model using a two-compartment (2C) representation. The model was used to fit simultaneous LFP recordings from both layer I and IV of the neocortex, decomposing the signals into their respective excitation and inhibitory components. Model validation was performed using the LFP data recorded after the infusion of bicuculline, a competitive gamma-aminobutyric acid (GABAA) receptor antagonist, which diminishes or reduces the fast inhibitory post-synaptic activity in the vicinity of the infusion site. In other words, the estimated excitatory component of the LFP by the 2C LFP model prior to bicuculline infusion was compared to the LFP recording immediately after the administration of bicuculline as inhibition was mostly eliminated by the manipulation. Furthermore the change in the balance between neural excitatory and inhibitory post-synaptic activities over the recovery phase of bicuculline infusion was captured by the 2C LFP model parameters, both in terms of the amplitude of each component, and more interestingly in terms of the temporal lag of inhibition with respect to excitation. Title: *In vivo* optogenetic manipulation of cells within the neurovascular unit leads to local changes in neural activity

Authors: *T. C. BROWN, C. BURLEY, K. SALEHI, T. KISHKOVICH, C. DEISTER, C. MOORE
Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: Communication and plasticity within or between cells in the neurovascular unit (neurons, glia, vascular endothelial and smooth muscle cells, and pericytes, among others) may play an important role in how neural networks adapt during sensory processing, encode synaptic changes, and/or contribute to the maintenance of cerebral metabolism. Disrupted signaling within the neurovascular unit has been linked to breakdown of the blood-brain barrier (BBB), and several pathological conditions, including diabetes, multiple sclerosis, Alzheimer's disease, epilepsy, and stroke. However, the mechanisms and precise role that neurovascular coupling plays in neural processing remains unclear. To this end, we have developed and further characterized multiple Vascular Optogenetic (VasOpto) and two-photon imaging methods that allow simultaneous visualization and bidirectional manipulation of cells within the neurovascular unit. Preliminary data show that bidirectional optogenetic manipulation of neocortical vascular endothelial or smooth muscle cells can lead to dilation and/or constriction of cerebral vessels comparable to the vascular changes evoked by physiological sensory input to the mouse primary somatosensory cortex. Utilizing these tools, experiments have revealed that somatosensory and VasOpto evoked vascular events lead to rapid changes in local neural activity, and that neurons can be tuned to unique aspects of the vascular response (dilation, constriction, peak, or other vascular specific parameters). Approximately 15-20% of neurons (N = 227 cells labeled w GCaMP5 under control of the synapsin promoter, all localized to layer I/II) were significantly modulated in firing by vibrissal stimulation, and a comparable number were similarly driven by VasOpto dilation. Ongoing and future studies are aimed at teasing apart the cell-type specificity of these interactions and comparing the neural responses associated with different VasOpto evoked vascular events, including dilation and constriction.

Title: Orexin-dependent activation of layer vib enhances cortical network activity and integration of non-specific thalamocortical inputs

Authors: *A. H. HAY[1,2], S. ANDJELIC[2,3], S. BADR[2], B. LAMBOLEZ[2]

Abstract: The deepest part of neocortical layer VI (layer VIb) is the only lamina reactive to orexins. Furthermore, layer VI of the parietal cortex receives dense projections from the orexin-sensitive rhomboid, a non-specific thalamic nucleus involved in cortical arousal. This convergence of structures involved in arousal onto layer VIb neurons prompted us to investigate how layer VIb modulates cortical arousal. We used patch-clamp and single cell reverse transcription-polymerase chain reaction to explore the sensitivity to neurotransmitters of arousal and the intracortical projections of layer VIb neurons. We found that the majority of neurons were excited by nicotinic agonists and orexin B through the activation of nicotinic receptor subunits α4, α5 and β2 and the OX2R orexin receptor, respectively. We found that a low dose of nicotine potentiated orexin effect specifically on layer VIb neurons and used this paradigm to explore their cortical projections. Co-application of nicotine and orexin increased the frequency of excitatory post-synaptic currents in ipsilateral layers I, II/III, V and VIa neurons and in contralateral layer V, with a minimal effect in ipsilateral layer IV. The ability of layer VIb to relay rhomboid thalamocortical inputs was tested using optogenetics. In infragranular layers of the parietal cortex, photostimulation of channelrhodopsin-expressing rhomboid fibers induced robust reponses that were not pre-synaptically affected by orexin. Activation of layer VIb neurons by orexin enhanced the reliability of layer VIa responses to rhomboid inputs and increased spike timing precision. These results indicate that layer VIb acts as an excitatory feedforward loop in the neocortex that potentiates cortical arousal.

Title: Synaptic properties of inverted pyramidal cells in layer vi of the rodent barrel cortex

Authors: *R. STEGER[1], L. BLACHORSKY[2], J. C. BRUMBERG[3,4]
[1]Grad. Ctr., Forest Hills, NY; [2]Neurosci. Major, [3]Psychology and Neurosci. Major, Queens College, CUNY, Flushing, NY; [4]Psychology and Biol., The Grad. Center, CUNY, New York, NY

Abstract: Within the nervous system, the cortex is the area of the brain where higher order sensory, motor and cognitive processing occurs. Around 70% of the neurons found in the mammalian cortex are upright pyramidal cells (UPCs). However, some of these pyramidal cells have their dendrites pointing in the opposite direction (towards the white matter); they appear inverted. Thus far, there has only been very limited research concerning the function of these inverted pyramidal cells (IPCs). Previous research in our lab has revealed numerous differences in the intrinsic physiology between IPCs and UPCs including input resistance and action potential threshold. In the present study, we characterized the synaptic inputs onto IPCs and UPCs. Coronal slices from mouse barrel cortex were prepared and whole cell recordings were done from layer VI IPCs and UPCs. Minimal stimulation techniques were used to activate axons passing through the underlying white matter. Single pulse experiments revealed that while the peak amplitude of the evoked excitatory postsynaptic potentials (EPSP) is similar in both IPCs and UPCs, the EPSP rise time was significantly shorter in UPCs than IPCs. Both pairs of electrical stimulation, and stimulus trains (8 pulses) delivered to the cortical white matter demonstrated synaptic depression over a wide range of frequencies (2-20Hz) in both IPCs and UPCs. These results may indicate that IPCs and UPCs may receive similar synaptic inputs but due to their intrinsic differences may process them differently.

Title: Cebus monkeys have a relatively complex somatosensory cortex: An architectonic study of the anterior parietal cortex and area 5 of Broadmann

Authors: *A. MAYER[1], M. N. S. LUIZ[1], N. B. KEHER[1], R. E. BITTENCOURT-NAVARRETE[2], R. GATTASS[1], J. G. FRANCA[1]
[1]Inst. de Biofísica Carlos Chagas Filho, Federal Univ. of Rio De Janeiro, Rio De Janeiro, Brazil; [2]Federal Univ. of Juiz de Fora, Governador Valadares, Brazil

Abstract: Cebus monkeys stand out from other New World monkeys by their ability to perform fine hand movements and use tools. Those behaviors are dependent on the processing and integration of somatosensory information performed by different areas of the parietal cortex. Although a few studies have examined and parceled the areas of cebus monkey parietal cortex, mainly using electrophysiological criteria, very little is known about its anatomical organization. In this study, we used SMI-32 immunohistochemistry, myelin and Nissl preparations to characterize the architecture of the cortical areas of the anterior parietal cortex, plus area 5, in the cebus monkey. Six adult cebus monkeys had their brains sectioned parasagitally, coronally or horizontally at 40 or 50 μm. In all cases, alternate sections were stained with cresyl violet (Nissl). In two cases, additional histological series were processed for myelin and/or for immunoreactivity against SMI-32 antibodies (SMI-32 IR). The analysis was performed on images of the whole section, collected using a 5x objective in a microscope equipped with the Neurolucida system (MBF, Inc). Six cortical areas were identified between the precentral gyrus and the anterior bank of the intraparietal sulcus. Area 3a showed moderate SMI-32-IR cell bodies and thin apical dendrites in layer 3, very strong myelination in layers 4-6, and a distinctive homogenous appearance in Nissl preparations, with a poorly developed layer 4. Area 3b exhibited light SMI-32-IR, moderate density of horizontal myelinated fibers in layer 4, dense horizontal fibers in infragranular layers (IG), and well-developed layers 4 and 6 in Nissl preparations. Area 1 presented a typical palisade-like appearance, especially in SMI-32-IR and myelin stained sections, due to dense immunolabeled cell bodies with long apical dendrites in supragranular layer (SG), and dense thick vertical fibers in IG. Area 2 showed moderate density of SMI-32-IR cell bodies with short apical dendrites in layer 3, moderate density of thick and short vertical fibers in IG, and a relatively homogeneous appearance in Nissl stained sections. Area 5d presented an immunostaining pattern and myeloarchitecture similar to area 2, but with much higher density of SMI-32-IR cell bodies and myelinated fibers. In contrast, area 5v exhibited a moderate density of SMI-32-IR cell bodies with characteristic long apical dendrites in SG and visible bands of Baillarger. Our results show that cebus monkeys have a relatively

complex somatosensory cortex, comparable to that of humans. This certainly is one of the key neurobiological features that allow cebus monkeys to perform outstanding manual behaviors.

Title: Tyrosine-protein kinase Kit (c-Kit) protein as a marker for supragranular neurogliaform cells in the neocortex

Authors: I. KRUGLIKOV[1], Z. TALBOT[1], L. BAYER[1], A. Z. AHMED[1], R. MACHOLD[1], *B. RUDY[2]
[1]NYU Neurosience Inst., New York, NY; [2]Physiol. & Neurosci., NYU Sch. of Med., NEW YORK, NY

Abstract: Layer 1 (L1) is an enigmatic layer of cerebral cortex that has been suggested as a site for integration of information carried by local, inter-areal and subcortical projections. L1 is populated exclusively by inhibitory interneurons whose activity controls electrogenesis in dendrites of deeper pyramidal cells. Neurogliaform cells (NGFCs) are known to be enriched in L1; however their function is not completely understood in part because of a lack of a specific genetic marker. Here we characterize cortical eGFP expression in c-Kit (CD117) BAC transgenic mouse line (Tallini et al. PNAS 2009). In supragranular layers of somatosensory cortex of adult animals, c-Kit eGFP expression does not overlap with Satb2 marker of pyramidal cells in immunohistochemical assay. It also does not overlap with three major markers of cortical interneurons -- parvalbumin, somatostatin and VIP. Taken together these data suggest labeling of a separate population of interneurons. To clarify this further, we performed whole-cell electrophysiological recordings of intrinsic properties and synaptic outputs of c-Kit interneurons.

Majority of c-Kit interneurons exhibited firing pattern characterized by a stuttering action potential discharge with or without delay to the first spike. A minority of c-Kit cells exhibited a firing pattern characterized by an initial burst of a few spikes. Anatomically, interneurons with stuttering firing patters display both elongated and local NGFCs morphologies, while bursting cells have sparser local as well as multiple translaminar downward axons. Synaptic outputs of c-Kit interneurons, assessed by paired recordings in L2 pyramidal cells, displayed properties of slow GABAA inhibitory currents. Preliminary recordings of c-Kit interneurons in awake behaving animals, using 2-photon targeted patching, show correlation of spiking activity as well as sub-threshold inputs with voluntary whisker movement. In conclusion, expression of c-Kit eGFP in supragranular cortical layers is biased towards NGFCs. L1 c-Kit cells in somatosensory cortex show motor-related activity.

Abstract: The input module of one presumed cortical column, the layer 4 “barrel” of mouse primary somatosensory cortex, contains about 2,000-3,000 neurons, of which more than 90% are spiny excitatory neurons. Their pairwise synaptic connectivity is about 30 percent. Beyond this statistical knowledge, the circuit structure of this neuronal ensemble is unknown. Here, we used serial blockface scanning electron microscopy to acquire a dataset of about 575 µm x 600 µm x 250 µm size and a nominal voxel size of about 11 nm x 11 nm x 28 nm of fully stained tissue targeted to the C2/C3 barrels in mouse S1 cortex. We are currently investigating the specificity of inhibitory innervation, the targets of thalamocortical axons and the structure of excitatory circuitry in this dataset.

Title: Structural distinguishability of neocortical circuit models

Authors: *E. KLINGER[1], T. KRETSCHMAR[1], F. THEIS[2], M. HELMSTAEDTER[1]
[1]Max Planck Inst. of Neurobio., Martinsried, Germany; [2]Inst. of Bioinformatics and Systems Biol., Helmholtz Zentrum, München, D-85764 Neuherberg, Germany

Abstract: Despite almost 100 years of intense research on neuronal circuits in the cerebral cortex, knowledge about the structure and computational capacity of cortical circuits is still poor today. Many largely varying types of such models have been proposed and studied, ranging from strictly layered feed-forward connectivity to largely randomly wired random-pool models. With novel high-resolution circuit mapping techniques being available, circuit models should become testable. Here, we analyzed three types of previously proposed cortical circuit models for their realistic implementation in a concrete cortical circuit, layer 4 of one cortical column in mouse somatosensory cortex. We find that only for a limited range of network parameters such models can be stably implemented under biologically plausible constraints. We are developing structural descriptors of such circuit models and investigate their distinctive power given densely mapped neocortical circuit data. We identified a set of observables that distinguish between feed-forward and random circuit types in the presence of connection noise. Such circuit analysis tools will allow coarse class distinctions of cortical models when dense connectomics data becomes available for networks in the cerebral cortex.

Title: Target-specificity of long-range cortical input to mouse barrel cortex

Authors: *F. P. DRAWITSCH, Y. HUA, M. HELMSTAEDTER
Max Planck Inst. of Neurobio., Martinsried, Germany

Abstract: Long-range cortico-cortical projections are known to target pyramidal neurons at their apical dendrites in layer 1. Little is known about the cellular specificity of such long-range projections. In mouse barrel cortex, all pyramidal neurons from layers 2, 3 and 5 extend their dendrites into layer 1, where they receive long-range input from other cortical regions such as primary motor cortex (M1) and secondary somatosensory cortex (S2). Here, we investigate the specificity of such long-range projections to the ensemble of pyramidal cells in one cortical column. We develop methods for correlated viral-injection based long-range axon labeling and light-microscopic imaging with high-resolution SBEM-based dense circuit reconstruction in layer 1. These methods include a fixation protocol for combined LM and EM imaging and large-volume staining, and computational methods to correlate light and EM images at the level of single axons. We are investigating whether long-range input from one cortical source is target-specific for subgroups of pyramidal neurons, and whether clustered innervation of dendritic branches occurs.

Title: Comparative analysis of local circuits in six- and three-layered sensory cortices

Authors: *P. BASTIANS[1], M. HEMBERGER[2], G. LAURENT[2], M. HELMSTAEDTER[1]
[1]MPI of Neurobio., Martinsried, Germany; [2]Max Planck Inst. for Brain Res., Frankfurt am Main, Germany

Abstract: Primary visual, auditory and somatosensory mammalian cortices are six-layered, and receive topographically organized sensory input. In contrast three-layered cortices are non-focally innervated from the sensory periphery. Some animals only possess three-layered cortices, such as turtle. Here we analyze by which principles local cortical circuits differ between six-layered and three-layered sensory cortices. Using serial block-face electron microscopy (SBEM), we compare neuronal circuits in six-layered primary somatosensory "barrel" cortex from mouse with dorsal cortex from turtle. As one focus, we investigate the innervation specificity of inhibitory neurons in both systems, testing whether non-topographic sensory innervation is mirrored by non-local inhibition.

Title: Influence of area 5 on motor cortical excitability during the pre-movement phase of a GO/NO-GO task in humans

Authors: *T. N. MACKENZIE, A. J. NELSON
McMaster Univ., Hamilton, ON, Canada

Abstract: Anatomical and physiological studies have implicated Brodmann's area 5 in fine motor control in the upper limb. However, the relationship between area 5 and ipsilateral motor cortex (M1) during movement planning remains unclear. The present study investigated the functional connectivity between putative area 5 and ipsilateral M1 in humans using paired-pulse Transcranial magnetic stimulation (TMS). Twelve right-handed individuals were studied. The right arm was engaged in the task while the left arm remained at rest. The GO/NO-GO task

involved an auditory warning cue followed at various intervals by a second auditory 'GO' or 'NO-GO' cue. For 'GO' trials participants were instructed to make a mouse click while 'NO-GO' trials required participants to withhold their response. Paired-pulse TMS involved a conditioning stimulus (CS) over putative area 5 followed by a test stimulus (TS) over M1. Both the CS and TS were delivered using customized 50 mm figure-of-eight branding coils, each connected to a Magstim 2002. Paired-pulse TMS was delivered at two timeframes (125 and 175 ms) and at two interstimulus intervals (ISIs) (6 and 8 ms) for GO and NO-GO trials. Eight conditions were tested in total: Task (GO/NO-GO) x timeframe (125, 175 ms) and ISI (6, 8 ms). Ten CS-TS trials were performed for each condition. In addition, TS alone trials were obtained for GO/NO-GO x timeframe. CS was set at 90% RMT. TS was set at the intensity to achieve ~ 1 mV motor evoked potential (MEP) in the first dorsal interosseous. The peak-to-peak amplitude of MEPs were averaged for each condition and normalized to TS alone (i.e. MEPCS-TS/MEPTS). Preliminary data indicate that MEPs are modestly facilitated for 'GO' compared to 'NO-GO' at the 125 ms timeframe for both 6 and 8 ms ISIs. These data suggest that area 5 modulates the excitability of M1 in a task-dependent manner and at specific time intervals within the pre-movement period, similar to the relationship found between right inferior frontal cortex and M1.

Title: Neurotensin decreases the frequency of the cortical slow oscillation and excites a neuronal population residing in the white matter

Authors: *L. CASE, C. BROBERGER
Karolinska Institutet, Stockholm, Sweden

Abstract: The peptide, neurotensin (NT), has been ascribed a wide variety of CNS actions, including analeptic effects. Within the cortex, where vigilance state is ultimately set, NT receptors are abundantly expressed. There is little information available, however, on direct NT actions within the cortical network. One prominent cortical manifestation of deep sleep is the so-called “slow oscillation” (SO; <1Hz) consisting of alternating UP- and DOWN-states. The SO can be reproduced in cortical slice preparations. We have explored electrophysiological actions of NT in slices of somatosensory and visual cortex prepared from 2-13 week-old rats. Robust SO activity was observed in extracellular multi-unit recordings from slices maintained in an interface chamber. In the presence of NT (0.2-1μM), UP-states decreased in frequency and eventually disappeared but returned upon washout. To determine the site of action of NT on the SO, NT was next focally applied. A decrease in SO frequency was seen only when NT was applied in the deepest layer, L6b, and in the white matter (wm). Cortical responsiveness to thalamic input differs between states of vigilance. To test if NT can induce such differences the peptide was bath applied to thalamocortical slices. The ventrobasal thalamus was electrically stimulated with two pulses at 50Hz and whole-cell recordings of pyramidal and fast spiking (FS) interneurons were performed in L6 of the somatosensory cortex. Thalamic stimulation reliably evoked UP-states in control conditions. In the presence of NT, however, all spontaneous and evoked network activity was abolished. In addition, the decay slope of the thalamic input was significantly increased during NT application providing greater temporal separation of inputs. Whole-cell recordings were performed to characterize the cells responsive to NT. Single cell responses to NT were rare in most cortical layers. Robust excitation in the form of depolarization and induction of action potentials could, however, be recorded in a subpopulation residing within the wm. In L6, pyramidal cells did not respond to NT but FS cells exhibited a small depolarization and increased synaptic input. These data suggest that NT-ergic regulation of vigilance state involves direct actions on discreet components of the cortical network. These actions may comprise recruitment of wm neurons leading to decorrelation of the cortical network. Decreased global synchrony may facilitate accurate sensory information processing associated with wakefulness.

Title: Layer 2/3 neurons in mouse barrel cortex receive direct synaptic input from the posterior-medial nucleus of the thalamus

Authors: *N. AUDETTE[1], J.-S. JOUHANNEAU[2], J. F. A. POULET[2], A. L. BARTH[3]
[1]Dept. of Biol. Sci., Pittsburgh, PA; [2]Dept. of Neuroscience, Max Delbruck Ctr. for Mol. Med., Berlin-Buch, Germany; [3]Dept. of Biol. Sci. and Ctr. for the Neural Basis of Cognition, Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Neurons in somatosensory (barrel) cortex respond to stimulation of principal (center) and adjacent (surround) whiskers. Although principal whisker stimulation is an effective stimulus for many neurons, neurons within a column can also respond to stimulation of multiple surround whiskers, and surround responses are not restricted to a single non-principal whisker. The source of inputs that generates multiwhisker, surround responses has been debated: this information could arise through horizontal connections between barrel columns in the cortex, or could be generated directly from thalamic inputs from the posterior medial nucleus of the thalamus (PoM) that exhibit multiwhisker, surround responses. *In vivo* under urethane anaesthesia, layer 2/3 neurons show short-latency subthreshold responses to optogenetic stimulation of PoM. To test whether layer 2/3 neurons receive direct synaptic input from PoM, whole-cell voltage-clamp recordings were carried out during optogenetic stimulation of PoM fibers in acute brain slices. In the presence of the Na channel blocker TTX to block recurrent activity and the K channel antagonist 4-AP to assist in axon depolarization, short-duration (5 ms) light stimulation elicited glutamatergic responses, evidence for PoM synapses onto layer 2 neurons. The strength of PoM input varied across different cell populations within and across layers. Thus, the multiwhisker receptive field properties of PoM neurons recorded *in vivo* may be sufficient to generate surround receptive field responses in neurons from barrel cortex.

Title: In rats with transection of the dorsal column ascending tract soleus H-reflex conditioning impairs locomotion

Authors: *L. CHEN, Y. CHEN, Y. WANG, J. R. WOLPAW, X. Y. CHEN
Lab. Neural Injury and Repair, Wadsworth Ctr, NYS Dept Hlth. & SUNY, Albany, NY

Abstract: In normal rats, right soleus H-reflex (HR) conditioning affects locomotor EMG activity and kinematics but does not disturb key locomotor features (e.g., right/left symmetry in timing and hip height (J Neurosci 25:6898-6906, 2005)). According to the *negotiated equilibrium* hypothesis (Neuroscientist 16:532-549, 2010), these features are preserved through an iterative process, a *negotiation*, in which the old behavior (i.e., locomotion) repeatedly induces compensatory plasticity that preserves its key features despite the plasticity induced by the new behavior (i.e., a larger or smaller H-reflex). Ascending sensory input is thought to guide the brain in inducing this compensatory plasticity. If this is correct, HR conditioning in rats in which transection of the dorsal column ascending tract (DA) has abolished much of this sensory input should disturb key locomotor features. We have tested this prediction. In 18 anesthetized Sprague-Dawley rats, the DA was transected bilaterally at T8-9, EMG electrodes were implanted in both solei, and a stimulating cuff was placed on the right posterior tibial nerve. At least 40 days later, control HR data were collected, and then for 50 days rats were exposed to right soleus HR up- or down-conditioning (HRup and HRdown rats) or continued in the control mode (Control rats). Locomotor EMG activity, H-reflexes, and kinematics were assessed before and after the 50 days. The results show: (1) DA transection itself does not disturb key locomotor features; (2) In DA rats as in normal rats, prolonged control-mode exposure does not affect the HR or locomotion, and HR up- or down-conditioning increases or decreases, respectively, the HR in the conditioning protocol and during locomotion and the right locomotor burst; (3) Unlike in normal rats, HR up- or down-conditioning in DA rats causes right/left asymmetry in locomotor timing and hip height. Thus, HR conditioning in DA rats disrupts key features of locomotion. These results are consistent with the prediction of the negotiated equilibrium hypothesis that when a new behavior (e.g., a larger or smaller HR) changes spinal neurons and synapses that also serve an old behavior (e.g., locomotion), the compensatory plasticity that

preserves the key features of the old behavior is guided by sensory input to the brain. When DA transection has removed much of this input, HR conditioning produces abnormal (i.e., asymmetrical) locomotion. A related abstract (Y Chen et al) addresses the locomotor impact of DA transection after HR conditioning has occurred.

Title: Impact of dorsal column ascending tract transection on locomotion after successful H-reflex conditioning in rats

Authors: *Y. CHEN, L. CHEN, R. L. LIU, Y. WANG, J. R. WOLPAW, X. Y. CHEN
Lab. Neural Injury and Repair, Wadsworth Ctr, NYS Dept Hlth. & SUNY, ALBANY, NY

Abstract: In normal rats, right soleus H-reflex (HR) conditioning affects locomotor EMG activity and kinematics but does not disturb key locomotor features (e.g., right/left symmetry in step-cycle timing and hip height (J Neurosci 25:6898-6906, 2005)). According to the *negotiated equilibrium* hypothesis (Neuroscientist 16:532-549, 2010), key features are preserved through an iterative process, a *negotiation*, in which the old behavior (i.e., locomotion) repeatedly induces compensatory spinal cord plasticity that preserves its key features despite the plasticity induced by the new behavior (i.e., a larger or smaller HR). Ascending locomotor sensory input guides the brain in inducing this compensatory plasticity. The hypothesis is supported by our recent finding

that, in rats in which dorsal column ascending tract (DA) transection has eliminated much ascending locomotor sensory input, HR conditioning disrupts key locomotor features (L Chen et al. abstract). We are now studying the locomotor impact of DA transection after HR conditioning has occurred. In anesthetized Sprague-Dawley rats, EMG electrodes are implanted in both solei, and a stimulating cuff is placed on the right posterior tibial nerve. At least 30 days later, control HR data are collected, and rats are exposed to right soleus HR up- or down-conditioning (HRup or HRdown) for 50 days. The DA is then transected bilaterally at T8-9 under anesthesia, and up- or down-conditioning continues for 50 more days. Locomotor EMG activity, H-reflexes, and kinematics are assessed before conditioning, just before DA transaction, and 50 days later. The initial results are consistent with previous data indicating that HR conditioning in normal rats does not disrupt key locomotor features; and they suggest that, when the DA is transected and conditioning continues, key locomotor features are disturbed. Confirmation of these early results by further data would provide additional support for the hypothesis that ascending sensory input is essential for inducing the compensatory plasticity in the spinal cord that ensures preservation of an old behavior (i.e., locomotion) when a new behavior (i.e., a larger or smaller HR) changes the spinal cord.

Title: Inferior olive to cerebellum to sensorimotor cortex to spinal cord: A hierarchy of plasticity probably underlies down-conditioning of the H-reflex

Authors: *X. Y. CHEN, Y. CHEN, L. CHEN, Y. WANG, J. R. WOLPAW
Lab. Neural Injury and Repair, Wadsworth Ctr, NYS Dept Hlth. & SUNY, ALBANY, NY

Abstract: Monkeys, humans, rats, and mice can gradually increase or decrease the soleus H-reflex (HR) in response to an operant conditioning protocol. This simple motor skill is associated with multi-site plasticity in the spinal cord and brain. Physiological and anatomical studies, primarily in down-conditioned animals, indicate that this plasticity operates as a hierarchy in which plasticity in the brain guides and maintains plasticity in the spinal cord that is directly responsible for the HR change. These studies (recently reviewed in Front Integr Neurosci (doi: 10.3389/fnint.2014.00025)) suggest that acquisition and maintenance of an operantly conditioned decrease in the HR may occur as follows: 1: Before conditioning, sensorimotor cortex (SMC) produces continually varying corticospinal tract (CST) activity that excites GABAergic interneurons (INs) in the ventral horn that have terminals on soleus motoneurons (MNs). Via $GABA_B$ receptors, this input affects voltage-gated Na channels in the MN membrane and thereby affects MN firing threshold, which affects the probability that the primary afferent EPSP (which is largely responsible for the HR) will excite the MN to contribute to the HR. CST collaterals provide efference copy input to the cerebellum (CB) via mossy fibers (MFs). 2: With the onset of down-conditioning, the reward network in the cerebrum sends a reward/no reward signal to the inferior olive (IO), which produces corresponding climbing fiber (CF) input to the CB (and/or CB nuclei). 3: The conjunction of MF input (reflecting the CST activity) and CF input (indicating whether reward occurred) induces CB plasticity. This plasticity can survive ~7 days without the IO input. 4: The CB plasticity produces input to SMC that induces plasticity that increases the probability of CST activity that leads to a positive shift in MN firing threshold and thus reduces the HR. This plasticity can survive ~40 days without the CB input. 5: The altered CST activity induces plasticity in the GABAergic INs and their terminals and in MN Na channels that results in the positive shift in MN firing threshold that reduces the HR and increases reward probability. This spinal cord plasticity can survive 5-10 days without the CST activity. In sum, the data support the hypothesis that the reward contingency produces IO input to the CB that combines with CST-induced MF activity to induce and maintain CB plasticity that induces and maintains SMC plasticity that induces and maintains spinal GABAergic IN plasticity that induces and maintains MN plasticity that is directly responsible for the smaller HR. Similar hierarchies may underlie other motor learning that involves spinal cord plasticity.

Title: H-reflex conditioning appears to affect motoneuron axon initial segment size and voltage-gated sodium channel labeling

Authors: *Y. WANG, L. CHEN, Y. CHEN, J. R. CHEN, X. Y. CHEN
Wadsworth Ctr. NYS Dept Hlth. & SUNY, Albany, NY

Abstract: Monkeys, humans, rats, and mice can gradually increase or decrease H-reflex (HR) size in response to an operant conditioning protocol (Encyclopedia of Neuroscience 7:225-233, 2009 & Front Integr Neurosci (doi: 10.3389/fnint.2014.00025) for review). HR down-conditioning is associated with a positive shift in motoneuron firing threshold (and a decrease in axonal conduction velocity) that could reflect a change in voltage-gated sodium (Na_v) channels in the motoneuron membrane (J Neurophysiol 74:867-871, 1995). To further evaluate this possibility, we are exploring the effects of HR conditioning on axon initial segment (AIS) size (measured as AIS length and hillock diameter) and on AIS Na_v content. Rat soleus motoneurons are labeled by retrograde transport of a fluorescent tracer; and AIS size and Na_v content are determined by blinded assessment of immunofluorescent labeling of the anchored protein ankyrin G (ANK3) and Na_v channels, respectively. To date, four groups of rats have been studied: rats in which down-conditioning has reduced the H-reflex by ≥20% (successful HRdown) (n=9); rats in which down-conditioning has not reduced the H-reflex by ≥20% (failed HRdown) (n=6); rats in which up-conditioning has increased the H-reflex by ≥20% (successful HRup) (n=7); and unconditioned (naïve control) rats (n=7). Analysis of these initial results (i.e., ANOVA followed by Tukey Test) indicates that: (1) In successful HRdown rats, AIS hillock diameter and Na_v labeling are significantly less ($p<0.001$ and $p<0.0001$, respectively) than in naïve rats. (2) In failed HRdown rats, AIS length, hillock diameter, and Na_v labeling are not significantly different ($p>0.06$ for all) from those of naïve rats. (3) In successful HRup rats, AIS length is significantly greater ($p<0.01$) than in naïve rats. These initial results may provide new insight into the mechanisms directly underlying operantly conditioned decrease in H-reflex size. Their connections to the corticospinal tract activity that is essential for acquisition and

maintenance of down-conditioning, and to the increases in GABAergic interneurons in the ventral horn and GABAergic terminals on motoneurons that are associated with successful down-conditioning (reviewed in Encyclopedia of Neuroscience 7:225-233, 2009 & Front Integr Neurosci (doi: 10.3389/fnint.2014.00025)), remain to be defined.

Title: Long-term single-neuron data from behaving rats undergoing operant conditioning of the H-reflex: Initial data

Authors: *J. R. WOLPAW, W. T. BAXTER, Y. CHEN, J. S. CARP, X. Y. CHEN
Lab. Neural Injury & Repair, Wadsworth Ctr, NYS Dept Hlth., ALBANY, NY

Abstract: H-reflex (HR) operant conditioning changes the spinal cord and brain (Front Integ Neurosci (doi: 10.3389/fnint.2014.00025) for review). It depends on the corticospinal tract, and thus on neuronal activity in sensorimotor cortex (SMC). To define this activity and explore corticospinal interactions during conditioning, we have developed automated methods for recording and analyzing single-neuron and local field potential (LFP) data from rat SMC 24 hr/day throughout one or more exposures to HR conditioning. Sprague-Dawley rats are implanted under anesthesia with EMG electrodes in right soleus, a stimulating cuff on right posterior tibial nerve, and a 32-microwire array (2.1x0.9 mm; 300-μm interelectrode spacing)

fixed to the skull over left hindlimb area of SMC and extending 1.3-1.5 mm into cortex. EMG and nerve-cuff wires pass subcutaneously to a flexible head-mounted tether and through a commutator to amplifiers and stimulator; and EMG activity is stored (5 kHz). The array wires pass to a head-mounted preamplifier/digital-multiplexer (Blackrock), the output of which passes through the tether and commutator to a digital demultiplexer and then to a Cerebus NSP unit (Blackrock) for online visualization and to a computer for storage (30 kHz). The tether, which allows the rat to move freely about the cage, is in place continuously. Beginning 10-15 days after implantation, whenever EMG activity remains in a given range for 2.3-2.7 s, nerve stimulation just above M-response threshold elicits the HR. In control mode (first 10-20 days), no reward occurs. In HRup or HRdown mode (next 50 days), reward occurs when HR size is > or < criterion, respectively. The rat may then be switched to the opposite mode for 50 more days. EMG and cortical data from 0.5 s pre- to 0.2 s post-stimulation are stored. To date, data have been collected from 8 rats exposed to the HRup or HR down mode and 0-3 reversals over 88-297 days. While action potentials (spikes) are most frequent and largest in the first 2-4 weeks, they are generally detectable throughout data collection. After 400-5000 Hz bandpass filtering, trials in which pre-stimulus RMS averages 4-40 μV are analyzed for spikes, which are defined as negative deflections 0.1-0.5 ms wide and ≥5 times the average trial RMS. We are determining pre-stimulus firing rates and post-stimulus responses, their correlations with concurrent background EMG level and H-reflex size, and the relationships among these parameters; and we are assessing the impact on these measures of HRup or HRdown conditioning. The results should help to illuminate the role of SMC in acquisition and maintenance of this simple motor skill (i.e., a larger or smaller H-reflex).

Abstract: The purpose of this study was to systematically examine the variability of soleus (SOL) spinal stretch reflex (SSR) size within and across days in neurologically normal subjects. First, we evaluated the variability in the SSR size in 12 different stretch conditions using coefficient of variation (CV). Then, with one of the 12 stretch conditions, the SSR was measured at 4 different times within a 24-hour period (8:00, 12:00, 16:00, and 20:00) and across 4 different days at the same time of day. All the measurements were made while the sitting subject maintained a fixed stable level of SOL and tibialis anterior background EMG. At the beginning of each session, a recruitment curve of SOL H-reflex and M-wave was obtained. Then, for the first part of the study, twenty SOL SSRs were elicited in each of the 12 stretch conditions (4 deg of dorsiflexion at a velocity of 150 deg/sec, 6 deg at 75, 150, 200, 250, and 280 deg/sec, 8 deg, 10 deg, and 12 deg at 200 and 250 deg/sec), using a custom joint perturbation device. The mean rectified values were obtained for first ("M1") and second ("M2") components of the SSR. M1 is originated primarily from group Ia afferents and typically occurs 46-57ms after the onset of perturbation; M2 is presumably mainly mediated by group II afferents, and typically occurs 59-78ms after perturbation onset. The M1 and M2 SSR sizes were normalized by the maximum M-wave size, and the mean and CV were calculated for each condition. For the second part, the evaluation of the within- and across-day variability, the SSR was elicited using 6 deg perturbation at 250 deg/sec. Twenty responses were averaged together to calculate the average M1 and M2 SSR sizes for each time or day. We found that the M1 with 6 deg perturbation at 200, 250, and 280 deg/sec was significantly larger that that with 6 deg at 75 deg/sec. The M1 with 6 deg at 280 deg/sec was significantly larger than that with 6 deg at 150 deg/sec. The CVs of 6 deg at 150, 200, 250, and 280 deg/sec were significantly smaller than that of 6 deg at 75 deg/sec. The CV of 6 deg at 280 deg/sec was significantly smaller than that of 6 deg at 150 deg/sec. M2 did not present any significant size or variability differences among tested conditions. There was no difference in the extent of M1 or M2 size variation within- or across-days ($p>0.05$, 2-way ANOVA); the mean CVs of 6 deg perturbation at 250 deg/sec over 8 measurement times were 0.21(±0.01) for M1 and 0.40(±0.02) for M2. The present study shows that SOL SSR sizes do not change systematically within- or across-days. It also suggests that a stretch parameter should include ≥6 deg of dorsiflexion at a ≥200 deg/sec to elicit reliable SOL SSRs. This study provides a framework for the evaluation of human SOL SSRs.

Title: Phrenic motoneuron loss and diaphragm function following cervical spinal cord injury

Authors: *L. N. LITTLE[1], S. HUSSEY[1], E. E. GONZALEZ-ROTHI[2], L. M. MERCIER[1], D. D. FULLER[2], M. A. LANE[1], P. J. REIER[1], P. J. REIER[1]
[1]Neurosci., [2]Physical Therapy, Univ. of Florida, Gainesville, FL

Abstract: White matter injury and repair is a dominant emphasis in spinal cord injury (SCI) research. In contrast, the functional contributions of gray matter damage to post-SCI outcomes, especially at cervical or lumbar enlargements, are less well understood. We and others have described respiratory deficits following cervical contusions at the level of the phrenic nucleus (C3-C5/6) which could be attributed to a significant loss of phrenic motoneurons (PhMNs) by 24hrs post-injury (p.i.). To determine the potential for using a neuroprotective treatment, the initial goal of this study was to determine the early time-course of PhMN loss. Lateralized C3/4 spinal contusions were performed on adult, female Sprague-Dawley rats with the Infinite Horizon pneumatic impactor preset to 200 kilodynes (i.e., moderate injury). Ipsilateral PhMN cell counts were obtained at 0, 4, 8 and 24 hours after injury by retrograde labeling with Cholera Toxin β applied to the corresponding hemidiaphragm. Immediately after injury, there is an ~15% loss of PhMNs with no further significant decline thereafter. This result demonstrates an absence of secondary PhMN degeneration during the first 24hrs post-injury. Other published data also suggest minimal PhMN loss between 24 and 6wks (p.i.). The second goal of this study is to establish a model of restricted ventral gray matter damage at the level of the phrenic nucleus without concomitant direct white matter involvement. The antimetabolite, 6-aminonicotinamide (6-AN), has been shown to cause initial astrocyte toxicity and considerable destruction of spinal ventral gray matter. Intraspinal injection of 6-AN (0.025 M) was performed at the level of C3/4. Preliminary histological examination revealed loss of neurons, including cells in the region of the PhMN pool, within the targeted ventral horn 2 weeks later. Ventilatory data are currently being obtained to test the hypothesis that a focal gray matter lesion alone can contribute to respiratory insufficiency.

Title: Electrical stimulation of the diaphragm following cervical spinal cord injury in rats

Authors: *K. A. STREETER[1], E. J. GONZALEZ-ROTHI[1], G. FITZPATRICK[1], G. ARMSTRONG[1], P. J. REIER[2], E. J. FOX[1], D. D. FULLER[1]
[1]Physical Therapy, [2]Neurosci., Univ. of Florida, Gainesville, FL

Abstract: Respiratory insufficiency and complications are the leading causes of death following cervical spinal cord injury (SCI), presenting a large clinical problem within the human population. The traditional approach for managing severe hypoventilation post-SCI is mechanical ventilation (MV). However, an emerging therapy utilizing direct diaphragm pacing via intramuscular electrical stimulation appears to offers advantages over MV. Indeed, pacing is highly likely to mitigate diaphragm muscle atrophy and result in improved quality of life. However, a careful study examining the impact of diaphragm pacing on respiratory motor output and if diaphragm pacing can provide a neurorehabilitative impact following SCI, is lacking. Thus, we aimed to: 1) develop an anesthetized rat model of diaphragm pacing, and 2) examine the impact of diaphragm pacing on respiratory motor output following incomplete SCI. Initial results established the feasibility of direct diaphragm stimulation in rats in phase with respiratory activity (by triggering of off inspiratory activity) and optimized pacing parameters (frequency of 40Hz; stimulation intensity 1-15MA). To test the hypothesis that direct diaphragm stimulation restores activity to the paralyzed hemi-diaphragm and intercostals following C2 spinal hemi-section (C2Hx), rats were studied at 1 or 6 weeks post-C2Hx. At each time point rats were anesthetized and ventilated and bilateral diaphragm and intercostal (T2/T3) EMG activity was recorded. Our preliminary results indicate that intermittent diaphragm pacing while being ventilated (3 x 10 min pacing -in phase with respiratory activity-separated by 10 min no pacing)

at 1 week post-C2Hx induces a small, but highly variable recovery of left diaphragm and intercostal EMG activity compared to controls not receiving intermittent pacing. However, at 6 weeks post-C2Hx, intermittent diaphragm pacing elicits a robust recovery of left diaphragm and intercostal EMG activity while right diaphragm and intercostal EMG activity remains relatively unaffected. Together these results indicate that direct diaphragm pacing has the potential to influence the neural control of respiratory muscles following cervical SCI.

Title: Impact of high frequency epidural stimulation on respiratory function following incomplete cervical spinal cord injury

Authors: *E. J. GONZALEZ-ROTHI[1], S. M. TURNER[1], K. A. STREETER[1], G. M. FITZPATRICK[1], P. J. REIER[2], D. M. BAEKEY[3], D. D. FULLER[1]
[1]Physical Therapy, [2]Neurosci., [3]Physiological Sci., Univ. of Florida, Gainesville, FL

Abstract: Injury to the cervical spinal cord disrupts descending bulbospinal pathways innervating the phrenic motor pool (C3-C5/6), resulting in diaphragm paralysis and impaired ventilatory function. High frequency epidural stimulation (HF-ES) is a promising therapy for activating paralyzed muscles after spinal cord injury (SCI), and can effectively drive the phrenic motor system in a physiologic respiratory pattern following spinal transection. However, the impact of HF-ES on phrenic motor output has not been examined in cases of incomplete spinal lesion. This is an important translational consideration, as incomplete SCIs are far more common clinically. We hypothesize that thoracic HF-ES will enhance respiratory motor output when descending drive to the phrenic motor pool is partially spared. Thus, in ongoing studies, we are

using our established rodent model of cervical SCI (C2 hemisection) to evaluate the effects of thoracic (T2) HF-ES on respiratory motor output. In terminal neurophysiology experiments, phrenic and hypoglossal motor output were recorded from anesthetized, vagotomized, and mechanically ventilated rats at 2 or 12 weeks post-injury. Using a bipolar silver wire electrode, short duration (60s) bouts of HF-ES (300Hz) were administered to the ventrolateral spinal cord (ipsilateral to the side of injury). Preliminary results indicate that HF-ES enhances both tonic and phasic bursting in the ipsilateral phrenic nerve. The magnitude of this response correlates with the intensity of stimulation, and facilitation of medullary (hypoglossal) output occurs only high stimulation intensities. These initial results indicate that HF-ES can increase phrenic motor output after incomplete cervical SCI. This approach may be paired with conventional respiratory rehabilitation approaches or with pharmacological interventions to improve respiratory function in individuals with chronic cervical SCI.

Title: Ampakine administration potentiates intermittent hypoxia-induced long-term facilitation in mice

Authors: *S. TURNER[1], M. K. ELMALLAH[1], E. J. GONZALEZ-ROTHI[1], J. GREER[2], D. FULLER[1]
[1]Univ. of Florida, Gainesville, FL; [2]Univ. of Alberta, Edmonton, AB, Canada

Abstract: Respiratory plasticity is a persistent change in the neural control system based on prior experience which may involve structural and/or functional alterations arising from mechanisms distributed throughout the respiratory control system. One well-studied model of respiratory

plasticity is long-term facilitation (LTF). LTF is triggered by intermittent hypoxia and induces a long-lasting (>60 min post-hypoxia) increase in respiratory motor output. More recent work indicates that hypoxic exposure paradigms and LTF have rehabilitative value in conditions associated with respiratory compromise (e.g., spinal cord injury). We are investigating if a novel pharmacological approach can enhance the functional impact of intermittent hypoxia on respiratory motor activity. Ampakines are compounds that have been used in clinical trials to stimulate breathing during conditions associated with impaired respiratory neuromotor activity. Ampakines selectively enhance function of glutamatergic AMPA receptors, and these receptors are widely distributed in brainstem and spinal respiratory control networks. In ongoing experiments we are using an anesthetized mouse model to test the hypothesis that ampakine pretreatment can enhance the functional impact of intermittent hypoxia on respiratory motor output. Preliminary results suggest that intermittent hypoxia (3 x 1 min hypoxia, 10% O_2; separated by 3 min of hyperoxia, 50% O_2) enhances respiratory motor output 60 min post-hypoxia compared to time controls receiving a similar surgery but not experiencing intermittent hypoxia. Delivery of ampakine CX717 (15mg/kg) 10 min prior to intermittent hypoxia considerably increases the magnitude of LTF. These preliminary data suggest that ampakines may synergistically increase respiratory motor output following intermittent hypoxia.

Title: Supraspinal respiratory neuroplasticity within reticular nuclei following cervical spinal cord injury

Authors: *T. BEZDUDNAYA, V. MARCHENKO, T. J. WHELAN, M. A. LANE
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Spontaneous respiratory recovery after spinal cord injury (SCI) has been reported in a multitude of studies, demonstrating the neuroplastic potential of the respiratory network. These changes appear throughout the entire central and peripheral nervous system. However, the extent of respiratory recovery is minor and long-term deficits persist post-SCI. Understanding the mechanisms of recovery is an important step in developing new therapeutic strategies to improve breathing following cervical SCI. The present work attempts to elucidate the anatomical and functional changes that occur within medulla that are associated with respiration following high cervical SCI. Specific focus is on the phrenic motor system that mediates diaphragm activity, using the adult Sprague-Dawley rat. To first define the spinal and supraspinal circuitry associated with phrenic function, a retrograde transynaptic tracer (pseudorabies virus; PRV) was applied to the hemi-diaphragm, and animals perfuse-fixed 60-72 hours later. Analysis of tissue revealed neuronal labelling throughout the spinal cord, brainstem and brain. The earliest labelling within brainstem was seen within the raphe and reticular nuclei suggesting a close synaptic integration with spinal phrenic circuitry. For electrophysiological studies we used decerebrate, unanesthetized and artificially ventilated rats. We systematically mapped medulla for the presence of inspiratory and expiratory activity. To examine the extent of supraspinal plasticity following cervical SCI, animals received a C2 lateral hemisection (C2Hx). This injury disrupts descending bulbospinal and ascending spinobulbar pathways between the medulla and spinal phrenic neurons, resulting in immediate hemidiaphragm paralysis. Acute partial recovery of ipsilateral phrenic activity was observed at 4-6 hours after C2Hx. In injured animals, electrophysiological mapping was conducted once recovery of ipsilateral phrenic nerve activity reached a plateau. These experiments revealed an increase in respiratory activity within the reticular nuclei after C2Hx. Ongoing studies are using retrograde and anterograde tracing methods to define connectivity between respiratory neurons in the medulla and the spinal cord. The recruitment of respiratory activity within reticular nuclei may indicate their involvement with post-injury respiration and neuroplastic changes within respiratory network after cervical spinal cord injury.

Title: Assessment of sensory function after human spinal cord injury

Authors: *R. A. MACKLIN[1], P. H. ELLAWAY[2], M. A. PEREZ[1]
[1]Dept. of Physical Med. and Rehabil., Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA; [2]Imperial Col. London, London, United Kingdom

Abstract: The current gold standard for assessing sensory function in humans with spinal cord injury (SCI) is the International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI). However, increasing evidence supports the view that new and more sensitive quantitative outcome measurements of sensory function are needed to supplement the ISNCSCI. The purpose of our study was to compare sensory deficits revealed by the ISNCSCI and by the sensory electrical perceptual threshold (EPT) test in individuals with chronic incomplete cervical SCI. The ISNCSCI examines responses of cutaneous afferents to light touch and pin prick and the EPT examines cutaneous sensitivity to electrical stimulation. During EPT testing, electrical stimulation was delivered using a constant current high voltage electrical stimulator (model DS7A, Digitimer, Ltd.) at a repetition rate of 3 Hz (monophasic pulses of 0.5 ms duration). Threshold was defined as lowest stimulus intensity at which subjects reported sensation in dermatomes C2 to T4. In age-matched controls, we found that female subjects required less stimulus intensity compared to males, regardless of age and the dermatome tested. Older males required more stimulus intensity that younger males in all conditions tested. In SCI participants, the EPT test detected asymmetries between left and right dermatomes in all patients tested, which were not revealed using the ISNCSCI. Importantly, the EPT test revealed deficits between 2 to 5 segments lower than what was found with the ISNCSCI examination. Our findings highlight the need of combining ISNCSCI scores with additional outcome measurements to increase the sensitivity of sensory testing after human SCI.

Title: Reduced motor cortical maps during voluntary activity after incomplete spinal cord injury

Authors: *T. TAZOE, M. A. PEREZ
Dept. of Physical Med. and Rehabil., Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Motor cortical representations are reorganized after spinal cord injury (SCI). However, the extent to which voluntary muscle contraction influences the reorganization of muscle representations in motor cortex after SCI is unknown. Here we examined motor cortical maps in distal and proximal upper limb muscles in patients with chronic incomplete cervical SCI and age-matched controls at rest and during ~5% of isometric maximal voluntary contraction (MVC). Transcranial magnetic stimulation was guided by the Brainsight Frameless Nagivation system to acquire cortical motor maps of the first dorsal interosseous (FDI) and biceps brachii (BB) muscles. At rest, SCI patients exhibited larger cortical motor maps of both FDI and BB compared with controls. The overlap between the FDI and BB motor maps was also larger in SCI patients than controls. We found that the area of cortical motor maps was not affected by voluntary muscles contraction in controls. In contrast, in SCI patients, the areas of individual FDI and BB motor maps and their overlap were decreased during 5% of MVC compared to rest. In either group, the center of gravity of the motor maps was not different at rest or at 5% of MVC regardless of the muscle tested. Our findings demonstrate that a different form of reorganization takes place in motor cortical representations of upper-limb muscles at rest and voluntary activity after incomplete SCI. We speculate that the reduced size of motor cortical maps during voluntary activity may represent maladaptive plasticity during a motor behavior.

Title: Impaired corticospinal excitability during inhibition of voluntary movement after tetraplegia

Authors: *P. FEDERICO, M. A. PEREZ
Dept. of Physical Med. and Rehabil., Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The ability to stop voluntary movement is impaired in individuals with incomplete spinal cord injury (SCI). The extent to which the corticospinal system is involved in this process after SCI remains unknown. Here, we tested patients with chronic (≥1 year) incomplete cervical (C4 to C7) SCI and uninjured age-matched controls during a GO and NOGO task. Using transcranial magnetic stimulation we examined motor evoked potentials (MEPs) in the first dorsal interosseous (FDI) muscle during 5-10% of maximal voluntary contraction into index abduction and instructed by a visual stimulus on a computer screen to increase voluntary activity with the index finger as fast as possible (GO trial - green light) or not at all (NOGO trial - red light). During GO trials, index finger reaction time was shorter in controls (303.2 ± 48.6 ms) compared to patients (372.8 ± 54.4 ms) at matched levels of background electromyographic activity. The number of errors during the task did not differ between patients (2.9 ± 2.7 %) and controls (1.7 ± 1.1 %). Importantly, we found that the size of MEPs in the FDI muscle decreased significantly during NOGO compared to GO trials in control subjects but to a lesser extent in SCI patients. Thus, our findings indicate that the ability to suppress corticospinal drive during an ongoing voluntary visuomotor task is impaired in humans with SCI. Since changes in MEP size might involve cortical and subcortical mechanisms it is possible that impaired modulation at these levels contributed to our results.

Title: Temporal pattern of corticospinal volleys influences motor function after tetraplegia

Authors: *J. CIRILLO, F. J. CALABRO, M. A. PEREZ
Dept. of Physical Med. and Rehabil., Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: How do corticospinal volleys descend from the cerebral cortex and reach spinal motoneurones in humans with incomplete spinal cord injury (SCI)? In an intact system, a single shock over the primary motor cortex evokes temporally organized descending volleys in the corticospinal tract, which can generate a burst of activity in spinal motoneurons. Using noninvasive cortical stimulation, we measured indirect (I) wave corticospinal volleys targeting an intrinsic finger muscle in surface electromyographic recordings in humans with chronic anatomically incomplete SCI. We demonstrate that corticospinal discharge frequency and amplitude decreased in all corticospinal volleys after SCI. Late but not early corticospinal volleys had increased latencies and duration, which correlated with the magnitude and onset of hand voluntary motor output. Our results for the first time identify deficits in specific I-wave corticospinal volleys after SCI, which influence residual voluntary motor output. We argue that dysfunction of these volleys may underlie some functional deficits in motor disorders affecting corticospinal tract function.

Title: Molecular adaptations in the periaqueductal gray in a rat model of chronic neuropathic pain: Focus on dopamine D1 receptors

Authors: *P. J. VOULALAS, Y. JI, L. JIANG, R. MASRI
Div. of Prosthodontics, Univ. of Maryland Sch. of Dent., Baltimore, MD

Abstract: Spinal cord injury (SCI) in humans often leads to the development of chronic neuropathic pain, due to persistent changes in brain areas mediating the behavioral, sensory, and affective components of pain. We have used a rat model of neuropathic pain to investigate molecular alterations in the periaqueductal gray (PAG) following SCI. We hypothesized that chronic neuropathic pain is associated with maladaptive changes in receptor expression and phosphorylation in the PAG. Male Sprague-Dawley rats were subjected to SCI or sham surgery. Electrolytic lesions to the spinal cord (10 μA DC pulses, 4 X 10s) were at C6, designed to lesion parts of the spinothalamic tract. Von Frey filaments and the Rat Grimace Scale were used to assess pain-like behaviors in animals following surgery. At 21 days post SCI or sham surgery, rats were sacrificed and the PAG isolated from 2 mm punches from frozen sections. Semi-quantitative western blot analysis was conducted on cytoplasmic and membrane fractions isolated from PAG extracts to assess changes in the expression of the following proteins: Glutamate receptor type A, subunit 1 (GluA1), phosphorylated GluA1 at serine 831 (GluA1-pS831), cannabinoid receptor 1 (CB1), metabotropic glutamate receptor 5 (mGlu5), phosphorylated ERK2 (pERK2), protein phosphatase 1 (PP1), and D1 dopamine receptor (D1). Data were statistically analyzed using ANOVA: $p < 0.5$ was considered significant. Immunoblot analysis revealed a significant decrease in synaptosomal GluA1 protein in SCI rats compared to Shams (Sham: 100 ± 7; SCI: 64 ± 2; $p = 0.003$; $n = 4$), with GluA1-pS831 significantly elevated in the same SCI rats ($p = 0.02$). There were no detectable changes in CB1 or mGlu5 protein, but D1 levels were reduced 3-fold in SCI rats compared to Shams (Sham: 100 ± 16; SCI: 33 ± 4; $p = 0.017$; $n = 7$). In addition, two mediators of D1 signaling exhibited different expression profiles following SCI. While pERK2 levels were unchanged ($p = 0.32$; $n=4$), PP1 levels were significantly increased after SCI, compared to Shams ($p = 0.0004$; $n = 4$). These results suggest that glutamatergic and dopaminergic neurotransmission in the PAG may be compromised due to reduced expression of D1 and GluA1 following SCI. Since dopaminergic and glutamatergic neurotransmission increases activity of output neurons in the PAG and enhances descending inhibition, we hypothesize that this reduction in D1 and GluA1 may contribute to suppression of descending pain pathways, and the emergence of pain-like behaviors in SCI animals. These results derived from a rat model of neuropathic pain are predicted to advance our mechanistic understanding of neuropathic pain, facilitating development of therapies for humans.

Title: Post-translational modifications of cortical GluA1 receptors in a rat model of spinal cord injury pain

Authors: *L. JIANG[1], P. VOULALAS[1], Y. JI[1], R. MASRI[1,2]
[1]EPOD, Univ. of Maryland Dent. Sch., Baltimore, MD; [2]Anat. and Neurobio. Dept., Univ. of Maryland Med. Sch., Baltimore, MD

Abstract: Injury to the spinal cord (SCI) is devastating and leads to catastrophic consequences including the development of chronic neuropathic pain (SCI-pain). Previous studies suggested that SCI is associated with maladaptive plasticity not only at the site of injury (spinal segments) but also in supraspinal structures (thalamus and cerebral cortex) involved in pain processing. Little is known about the molecular and cellular mechanisms leading to maladaptive plasticity in the cortex and how they contribute to the development of SCI-pain. Here, we study changes in AMPA-type glutamate receptor (GluAR) expression in conditions of SCI-pain. We hypothesize that SCI-pain results from *maladaptive homeostatic plasticity caused by post-translational modifications of GluARs in the primary somatosensory cortex (S1).* To test our hypothesis, we used an animal model of SCI-pain and injured the anterolateral quadrant of the spinal cord at the level of C6. In these animals, we extracted brain tissue from the hindlimb representation of S1 before surgery, and at 3, 7, 14, 21, and 35 days after SCI or sham surgery (control). We performed western blot analysis to quantify total protein levels of GluA1 subunits relative to a loading control (β-actin) and to quantify protein levels of phosphorylated serine residue 831 (pS831) and pS845 relative to total GluA1. In all animals we also assessed pain-like behaviors using the Grimace Scale test at the same 6 time points post SCI. ANOVA followed by Dunnett's multiple comparison test was used for statistical comparison. A $p < 0.05$ was considered significant. We found that pS831 levels gradually reduced after SCI and pS831 was maximally dephosphorylated at day 21 (>2-fold) compared to controls. No significant changes were found in pS845 levels or in pS831 levels in S1 of control animals ($p > .05$). The temporal pattern of changes in pS831 levels mimicked the temporal pattern for the development of pain-like

behaviors suggesting that the dephosphorylation of pS831 is causally related to the development of SCI-pain. Our results suggest that SCI-pain is associated with maladaptive plasticity caused by dephosphorylation of pS831 in S1. We propose that this dephosphorylation preferentially affects inhibition, which will result in hyperactivity in cortical pain networks.

Title: Unilateral, but not bilateral motor cortex electrical stimulation promotes corticospinal function after injury

Authors: *T. T. BETHEA[1], Y. HAROONIAN[1], G. DRUMMOND[1], A. KHALILI[1], J. B. CARMEL[1,2]
[1]Burke-Cornell Med. Res. Inst., White Plains, NY; [2]Weill Med. Col. of Cornell Univ., New York, NY

Abstract: In our previous studies, we have applied electrical stimulation to the motor cortex on the uninjured hemisphere after unilateral corticospinal tract (CST) injury. Stimulation promoted axon outgrowth, functional connections, and behavioral recovery even after chronic injury. Here we hypothesized that stimulation of the injured CST would also promote CST function by causing collateral sprouting of axons above the lesion or in sparse spared axons below the lesion. We performed two studies. For both studies, we used ladder-walking as an assay of skilled motor function. Female rats were trained on the task, and baseline error rates were recorded. Performance was measured each week thereafter without additional training. Electrical stimulation was performed after lesion using epidural electrodes over forelimb area of motor cortex. Real or sham stimulation was delivered 6 hours per day for 10 days, using our published paradigm. In the first study, we completely severed the CST at the medullary pyramid and stimulated motor cortex in the lesioned hemisphere. Electrical stimulation was performed four weeks after CST injury. The error rates of rats with electrical stimulation diminished over the four weeks after starting stimulation and fell to the baseline error rates. The error rate in rats with

sham stimulation remained high. In the second study, we stimulated the motor cortex bilaterally after dorsal column injury. This lesion severs 95% of CST axons in the spinal cord, as well as sensory axons. Real or sham stimulation was initiated 2 weeks after injury. The error rates were variable, and there was no change in rats with either real or sham stimulation. Anatomical analysis of spared axons below the lesion showed no difference between groups. Lengths above the lesion, counted using stereological techniques also show no difference. Thus, there was striking discord in the positive effects of unilateral stimulation after unilateral CST injury and the null effects of bilateral stimulation after bilateral injury. The difference in patterns of injury and stimulation need to be compared directly to better understand the effects and potential use of motor cortex electrical stimulation.

Title: PIAS1 may play a role in repetitive acute intermittent hypoxia induced down-regulation of spinal inflammatory gene expression in rats

Authors: *B. J. DOUGHERTY[1], S. S. SPRINGBORN[1], A. S. ROOPRA[2], K. K. BOWEN[1], G. S. MITCHELL[1], J. J. WATTERS[1]
[1]Comparative Biosci., [2]Neurosci., Univ. of Wisconsin - Madison, Madison, WI

Abstract: Repetitive acute intermittent hypoxia (rAIH; 10 episodes of 10.5% O2/day, 3 days/wk, 4 wks) promotes spinal motor plasticity and elicits functional recovery of breathing capacity after cervical injuries. rAIH also elicits anti-inflammatory effects, down-regulating cyclooxygenase-2, tumor necrosis factor family members, chemokines and interleukins-1β and -6 (plus others) in the ventral cervical spinal cord of adult rats. To explore possible transcriptional drivers of these changes, whole genome Vista analyses were utilized to identify over-represented transcription factor binding sites in the upstream 5kb promoter regions of rAIH down-regulated genes. Binding sites for Signal Transducer and Activator of Transcription 1 and 2 (STAT1/2) and nuclear factor kappa B (NF-κB) were over-represented ($p<0.005$), suggesting that rAIH may decrease STAT1/2 and NF-κB transcriptional activity. Here we localize expression of protein inhibitor of activated STAT-1 (PIAS1) within the ventral cervical spinal cord; PIAS1 is a small ubiquitin-related modifier E3 ligase known to negatively regulate DNA binding activities of STAT1/2 and NF-κB. PIAS1 was highly expressed in identified phrenic motor neurons, suggesting a potential role in the anti-inflammatory actions of rAIH and, quite possibly, in rAIH-induced spinal motor plasticity. An understanding of mechanisms giving rise to the anti-inflammatory actions of rAIH may broaden its therapeutic potential in diverse clinical disorders associated with either systemic or neural inflammation.

Title: Chronic morphine exposure activates mTOR pathway through μ-opioid receptor in dorsal horn neurons

Authors: *L. SUN[1], L. LIANG[2], S. WU[2], X. GU[2], B. LUTZ[2], A. BEKKER[3], Y. TAO[2]
[1]Anesthesiol. Department, NJMS, Rutgers, Newark, NJ; [2]Rutgers New Jersey Med. Sch., Newark, NJ; [3]Rutgers New Jersey Med. Sch., Demarest, NJ

Abstract: Our previous research found that blocking spinal mTOR activity dramatically attenuated morphine-induced tolerance and hyperalgesia. This observation led us to hypothesize that spinal mTOR is activated during chronic morphine exposure. Here, we first investigated the phosphorylation levels of mTOR and its downstream effectors S6K1 and 4E-BP1 in dorsal horn after repeated morphine injections. Results showed that phosphorylated mTOR (p-mTOR), p-S6K1, and p-4E-BP1 were undetectable or expressed at low levels in saline-treated rats, while intrathecal morphine led to significant, time-dependent increases in the levels of p-mTOR, p-S6K1, and p-4E-BP1 in lumbar enlargement segments. Total expression of mTOR, S6K1, and 4E-BP1 protein in dorsal horn was not altered during the observation period. The number of cells positive for p-mTOR, p-S6K1, and p-4E-BP1 was also dramatically increased exclusively in dorsal horn neurons. Then, we defined which opioid receptors triggered this morphine-induced activation of mTOR and its downstream effectors in dorsal horn neurons during chronic morphine exposure. Intrathecal co-injection of CTOP (1 ng, a selective μ opioid receptor antagonist) blocked morphine-induced increases in p-mTOR, p-S6K1, and p-4E-BP1 in dorsal horn. μ opioid receptor knockout mice failed to display an increase in dorsal horn p-mTOR after repeated subcutaneous injections of morphine. Furthermore, cultured dorsal horn neurons exposed to morphine (20 μM) or DAMDO (20 μM) exhibited time-dependent increases in p-mTOR, p-S6K1, and p-4E-BP1, but not total expression of these three proteins. These increases were attenuated by CTOP (10 μM), but not η-BNI (20 μM; a selective κ opioid receptor antagonist) or naltrindole (20 μM; a selective δ opioid receptor antagonist). Double labeling revealed that μ opioid receptor mRNA co-expressed with mTOR and morphine-induced p-mTOR in dorsal horn neurons. Our findings indicate that the μ opioid receptor triggers activation of the dorsal horn mTOR pathway during chronic morphine exposure. This previously unknown μ opioid receptor-triggered mTOR pathway in dorsal horn neurons may be involved in morphine-induced spinal protein translation changes under the conditions of chronic morphine tolerance and hyperalgesia. Thus, inhibiting mTOR pathway may have potential clinical implications.

Title: Pharmacological inhibition of histone deacetylase-6 as a treatment for spinal cord injury

Authors: *M. METCALFE
Biol., Burke Med. Res. Inst., White Plains, NY

Abstract: Metcalfe MJ, Tanner J, Rivieccio MA, Brochier CA, Brown J, Hill CE, and Langley B. During spinal cord injury ascending and descending axonal pathways are damaged resulting in interrupted motor and sensory communication between the brain and body and functional loss. In addition to this, neuronal death and limited axonal regeneration restricts the amount of functional repair that takes place. Few therapeutic options exist for treatment after spinal cord injury and they are not very successful in promoting regeneration and the recovery of function. Histone deacetylase 6 (HDAC6) is a class IIb deacetylase that has preference for non-histone proteins, including -tubulin, HSP90 and cortactin. We previously showed that chemical or genetic inhibition of HDAC6 allows axons to grow on non-permissive substrates *in vitro*, in a manner independent of transcription (Riveccio et al., 2009); however, the molecular mechanisms that lead to this growth, and whether it occurs *in vivo* have yet to be determined. In this study we investigate -tubulin, a constituent of microtubules, as a molecular target of HDAC6 deacetylase activity in mediating the growth potential of CNS neuron axons, and whether HDAC6 inhibition can promote functional recovery after spinal cord injury. For spinal cord injury studies, we use a rat contusion model and we assess functional recovery by Basso, Beattie, Bresnahan open field locomotor test (BBB), grid walk, and catwalk tests. After 8 weeks post-injury, treated rats showed promising improvements in locomotor paradigms compared to control rats. We propose that inhibiting HDAC6 could promote axon growth and functional recovery following mechanical injury.

Abstract: Neuropathic pain caused by traumatic spinal cord injury is an important clinial problem. The aim of this study was to investigate the changes in the number of neurons containing Fos protein after HBO treatment following spinal cord injury (SCI). Rivlin and Tator clip method was used to induce SCI at T9-T11 in Sprague-Dawley male rats (n=16). Rats received HBO at 2.80 ATA for 60 min daily. Groups were: 1)Control(SCI, no HBO), 2)Preoperative HBO for 5 days, 3)Postoperative HBO for 5 days, 4)preoperative and postoperative HBO(5 days and 5 days after SCI). HBO applied preoperatively, postoperatively and pre+postoperatively induced Fos expression significantly in spinal cord sections 1cm proximal and 1 cm distal to SCI. The increase was in proportion with the duration of HBO treatment. Fos expression was mostly found in laminae 1-2, followed by laminae 3 -4, and laminae 7-8. In a previos study on oxidative stress following SCI (Dayan et al., 2012), we found that HBO treatment decreased superoxide dismutase, glutathione peroxidase, catalase and nitric oxide synthase in the spinal cord tissue, and significantly improved BBB scores. In this project, we had expected a decrease in Fos expression parallel to these improvements; however, we have observed an increase. This leads us to the conclusion that HBO treatment induced Fos expression following SCI is related to other mechanisms, not due to mechanisms related to pain.

Title: Plasticity of indirect cortico-motoneuronal excitations in relaxed hand muscles in humans

Authors: *T. NAKAJIMA[1], S. SUZUKI[2], H. OHTSUKA[4], T. ENDOH[5], Y. MASUGI[6], S. IRIE[1], T. KOMIYAMA[3], Y. OHKI[1]

Abstract: We previously reported that repetitive combined stimulation (RCS) of pyramidal tract and peripheral nerve could induce long-term potentiation (LTP) in indirect cortico-motoneuronal (C-M) excitations in biceps brachii (BB) of human subjects, which are mediated by cervical propriospinal neurons (PNs). However, the LTP could be induced only when the target muscle was voluntarily contracted, which limits possible clinical use. In animal studies, PNs are known to project various forelimb motoneurons. Because RCS could induce plastic changes in synapses from pyramidal tract to PNs, we hypothesized that the LTP of C-M excitations could also be induced in non-target muscles in upper limb, which are relaxed during RCS. RCS intervention (0.2 Hz, 10 min) was the same as in the previous study. With EMG recording from right BB under weak contraction, transcranial magnetic stimulation (TMS) to the arm area of left motor cortex (M1) was delivered with right ulnar nerve stimulation. Inter-stimulus interval for the combined stimulation was set at 10 ms, where inputs by both stimuli to reach PNs simultaneously. Stimulus strengths were determined to observe the maximum spatial facilitation in BB by the simultaneous inputs. To observe LTP in non-target muscles, motor evoked potentials (MEPs) were obtained from flexor digitorum superficialis, extensor digitorum communis and first dorsal interosseous muscles, by TMS to the optimal point in M1, which was ~1 cm lateral to the arm area. As previously reported, MEPs in BB were potentiated after RCS, which lasted for ~65 min. Furthermore, the potentiation could be observed in hand muscles, which showed similar time course to that in BB. When the stimulation point in M1 was moved laterally by 2-3 cm, where MEPs could be evoked in hand muscles but less efficiently, the potentiation was not observed after RCS. These results show that LTP could be induced in muscles without contraction, if RCS induces LTP in another muscle under weak contraction. Differences between stimulation positions indicate that the LTP was caused by plastic changes in synapses, which are activated by TMS during RCS.

Title: Decreased spinal inhibition during muscle lengthening in humans with incomplete spinal cord injury may contribute to increased central activation during eccentric contractions

Authors: *H. E. KIM[1], D. M. CORCOS[3], T. G. HORNBY[2]
[1]Grad. Program in Neurosci., [2]Dept. of Physical Therapy, Univ. of Illinois At Chicago, Chicago, IL; [3]Physical Therapy & Human Movement Sci., Northwestern Univ., Chicago, IL

Abstract: Recent data suggest individuals with chronic motor incomplete spinal cord injury (SCI) generate greater central activation of the knee extensors during eccentric maximal voluntary contractions (MVCs) than during isometric or concentric MVCs. This activation pattern is markedly different from that of healthy adults, who demonstrate reduced central activation during eccentric MVCs in several different muscle groups. Inhibition of Ia-α motoneuron excitability during muscle lengthening in healthy adults, as determined by H-reflex testing, may contribute to central activation deficits. Currently, there are no published data on H-reflex modulation during dynamic muscle length changes in humans with SCI. The aims of the current study are to assess patterns of central activation in the ankle plantarflexors using the interpolated twitch technique, and to compare modulation of soleus H-reflexes during isometric, shortening, and lengthening muscle actions between SCI and healthy subjects. We hypothesize that differences in muscle activation patterns between the two groups are associated with divergent modulation of Ia input onto motor pools. Preliminary results in 5 males with incomplete SCI demonstrate central activation ratios (CARs) in the plantarflexors are greater during eccentric MVCs (0.78±0.13) than isometric (0.64±0.17) or concentric (0.55±0.29) MVCs. In addition to CAR testing, H-reflex modulation during isometric, shortening, and lengthening muscle actions was assessed in a subset of the SCI subjects (n=3) and 3 healthy males. SCI subjects demonstrated decreased spinal inhibition of H-reflexes during muscle lengthening compared to controls. These data suggest contrasting patterns of muscle activation between SCI and healthy subjects may be related to differences in modulation of Ia-α motoneuron excitability

across different types of muscle length changes. Increased understanding of mechanisms underlying altered muscle activation patterns in SCI patients may aid future development of more effective training protocols.

Title: Locomotor training modifies soleus motoneuron excitability in human spinal cord injury

Authors: ***M. KNIKOU**[1], A. C. SMITH[2], W. Z. RYMER[3]
[1]The Grad. Ctr., City Univ. of New York, STATEN ISLAND, NY; [2]Interdepartmental Neurosci. Program, [3]Sensory Motor Performance Program, Northwestern Univ., Chicago, IL

Abstract: The objective of this study was to describe changes in soleus motoneuron excitability after locomotor training in humans with spinal cord injury (SCI). We hypothesized that locomotor training alters spinal reflex excitability in a body position-dependent manner. Fifteen people who had either chronic motor complete or incomplete SCI received an average of 45 daily locomotor training sessions. The soleus H-reflex and M-wave recruitment curves were assembled using data collected in the right and left legs, with subjects seated and standing, before and after training. The soleus H-reflexes and M-waves, measured as peak-to-peak amplitudes, were normalized to the maximal M-wave (Mmax). Stimulation intensities were normalized to the 50 % Mmax stimulus intensity. A sigmoid function was also fitted to

normalized soleus H-reflexes on the ascending limb of the recruitment curve. Locomotor training modified the reflex excitability of soleus motoneurons in people with motor complete and incomplete SCI, while seated and during standing. After training, H-reflex excitability was decreased during seated position testing, and was increased during standing, in both limbs. Changes in reflex excitability coincided with changes in H-reflex stimulation threshold, and at 50 % maximal H-reflex, while the slope remained unaltered. Adaptations of the intrinsic properties of soleus motoneurons and Ia afferents, excitability profile of the soleus motoneuron pool, oligosynaptic inputs, and corticospinal inputs may all contribute to these changes. The findings of this study demonstrate that the injured human spinal cord can adjust reflex excitability levels after locomotor training, based on demands of the motor task.

Title: Operant up-conditioning of the tibialis anterior motor evoked potential in neurologically normal subjects

Authors: *J. A. BRANGACCIO[1], B. M. FAVALE[2], G. FIORENZA[2], A. THOMPSON[2,3,4,5]
[1]OP Neurol. and Pediatrics, [2]Helen Hayes Hosp., West Haverstraw, NY; [3]Wadsworth Center, NYS Dept Hlth., Albany, NY; [4]Dept. of Neurology, Neurolog. Institute, Columbia Univ., New York, NY; [5]Dept. of Biomed. Sciences, State Univ. of New York, Albany, NY

Abstract: The corticospinal tract (CST) plays a key role in motor control and motor skill learning and re-learning after CNS damage. The corticospinal motor evoked potential (MEP) to transcranial magnetic stimulation (TMS) that reflects the excitability and connectivity of CST is decreased after CNS damage, and increases during recovery of motor function. Thus, strengthening remaining CST function might help restoring motor function in people after CNS damage. As the first step in testing the hypothesis that operant up-conditioning of the ankle dorsiflexor MEP can strengthen CST connectivity and alleviate foot-drop in people with CNS damage, we are up-conditioning the tibialis anterior (TA) MEP in people with no known neurological conditions. The protocol consists of 6 baseline (3/wk) and 24 up-conditioning or control sessions (3/wk), similar to a human soleus H-reflex conditioning protocol previously used (J Neurosci 2009:29:5784-92). In all sessions, TA MEPs are measured while the sitting subject provides 15-20% maximum voluntary contraction (MVC) level of TA background EMG with ankle, knee, and hip joint angles fixed. In all the trials of baseline sessions, all the trials of control sessions, and the first 20 trials of conditioning sessions, the subject is given no feedback as to MEP size (i.e., control MEPs). In 225 conditioning trials of conditioning sessions (i.e., conditioning MEPs), the subject is encouraged to increase the TA MEP, and receives immediate feedback as to whether MEP size was above a criterion (i.e., whether the trial was a success). TMS is kept at 10% above threshold. To date, 6 subjects have completed the up-conditioning protocol and 4 subjects have completed the control protocol. Four of 6 up-conditioning subjects increased the TA MEP significantly. Among these subjects, the final MEP size (averaged over conditioning sessions 22-24) was 147±12(SE)% of the baseline value. In contrast, MEP size did not change in the 4 control subjects; the final MEP size was 92±12(SE)% of the baseline value. Initial gait analysis indicates that locomotor EMG activity and kinematics did not change in either up-conditioning subjects or control subjects. The absence of locomotion change after MEP conditioning in normal subjects is different from our preliminary findings in people with

multiple sclerosis (Favale et al., SfN abstract, 2014), in whom successful TA MEP up-conditioning alleviated foot drop, increased TA MVC, and increased walking speed. Lack of functional impact in normal subjects may reflect compensatory plasticity that prevents the plasticity underlying MEP change from disturbing normal locomotion (Neuroscientist 2014: Epub ahead of print)

Title: Operant up-conditioning of the tibialis anterior motor evoked potential in neurologically normal subjects

Authors: *B. FAVALE[1], J. VELEZ[1], P. FALIVENA[1], A. K. THOMPSON[1,2,3,4]
[1]Helen Hayes Hosp. NYS Dpt Hlth., W HAVERSTRAW, NY; [2]Wadsworth Center, NYS Dept Hlth., Albany, NY; [3]Dept. of Neurology, Neurolog. Institute, Columbia Univ., New York, NY; [4]Dept. of Biomed. Sciences, State Univ. of New York, Albany, NY

Abstract: The corticospinal tract (CST) is important in motor control and in guiding the spinal cord plasticity that is associated with learning motor skills and re-learning them after CNS trauma or disease (Neuroscientist 2010:16:532-549; 2014:Epub ahead of print). Damage to the corticospinal pathway often results in weak ankle dorsiflexion and spasticity, and thereby limiting the mobility of people with multiple sclerosis (MS). Thus, strengthening the corticospinal function may improve locomotion. This pilot study investigated whether operant up-conditioning of the tibialis anterior (TA) motor evoked potential (MEP) can enhance the corticospinal excitability and connectivity and alleviate locomotor problems in people with chronic stable MS. MEP up-conditioning protocol consisted of 6 baseline and 24 up-conditioning sessions (3/wk for 10 wks). In all sessions, TA MEPs at 10% above threshold were measured

while the sitting subject provided a pre-set level (typically 30% of maximum voluntary contraction (MVC) level at the beginning of study) of TA background EMG with ankle, knee, and hip joint angles fixed. During the baseline sessions, MEPs were simply measured. During 225 conditioning trials of each of the 24 conditioning sessions, the subject was encouraged to increase MEP, and was given immediate feedback indicating whether MEP size was above a criterion (i.e., whether the trial was a success). In 3 of 4 subjects with MS, over the course of conditioning, TA MEP and MVC increased significantly by 35-77% and 28-61%, respectively, and locomotor EMG activity improved bilaterally and their foot drop became less severe. All three of them spontaneously reported better leg movement during walking. Twenty-five-feet walking times improved more than 20% in all but one subject. To our pleasant surprise, these improvements were also observed in one of the subjects, whose disease progress was noted near the end of the conditioning period. In addition, in one of them, extensive follow-up sessions occurred for the following 3 years, during which increases in TA MEP and MVC were maintained. These case studies suggest that while the disease itself may continue to gradually progress, CNS plasticity can be induced and maintained, and thereby generate functional improvement in people with chronic stable MS. Operant up-conditioning of MEP could provide a promising new therapy for improving locomotion in people with MS or other CNS disorders.

Title: Operant conditioning of spinal reflexes in people with chronic CNS damage

Authors: *A. THOMPSON[1,2,3,4], J. R. WOLPAW[1,2,3,4]
[1]Helen Hayes Hosp NYS Dept Hlth., W HAVERSTRAW, NY; [2]Wadsworth Center, NYS Dept

Hlth., Albany, NY; [3]Dept. of Neurology, Neurolog. Institute, Columbia Univ., New York, NY; [4]Dept. of Biomed. Sciences, State Univ. of New York, Albany, NY

Abstract: People with chronic CNS damage often suffer motor disabilities due to spasticity and poor muscle control, even after conventional therapy. Abnormal spinal reflex activity commonly contributes to these problems. Operant conditioning protocols can modify specific spinal reflex pathways and thereby restore more normal reflexes. We recently showed that down-conditioning the soleus H-reflex during standing can markedly improve locomotion in people with spasticity due to chronic incomplete spinal cord injury (SCI) (J Neurosci 2013:33:2365-2375). Furthermore, the beneficial reflex change initiates widespread plasticity that improves locomotor function in both legs (Neuroscientist 2014:Epub ahead of print). We are currently testing several different reflex conditioning protocols in people with chronic CNS damage: (1) We are down-conditioning the soleus H-reflex during walking in people with spastic hyperreflexia due to chronic incomplete SCI to test the hypothesis that down-conditioning during the mid-late swing phase (when the H-reflex is very small or absent normally but very large in these individuals) will restore more normal locomotor reflex modulation, and thereby improve locomotion. (2) We are down-conditioning the soleus H-reflex in people after stroke to determine whether reflex conditioning is possible after stroke. (3) We are down-conditioning the soleus stretch reflex in people with chronic incomplete SCI to compare the effects and time course of stretch reflex conditioning with those of H-reflex conditioning. All three protocols consist of 6 baseline and 30 conditioning sessions (J Neurosci 2013:33:2365-2375). Each session includes 3 blocks of 75 reflex trials, without (control trials in baseline sessions) or with (conditioning trials in conditioning sessions) encouragement to reduce reflex size with the aid of visual feedback. Before and after the 30 conditioning sessions, 10-m walking speed and locomotor EMG are assessed. To date, 3 of 4 Protocol-1 subjects >3yrs after incomplete SCI, 2 of 3 Protocol-2 subjects >2yrs. after stroke, and 1 of 2 Protocol-3 subjects >10yrs after incomplete SCI successfully reduced the reflex. Their 10-m walking speeds improved by 8-30%, and their locomotor EMG modulation improved. We are currently studying additional subjects with each protocol. Confirmation of these initial results should increase understanding of reflex conditioning protocols and broaden the range of their potential therapeutic applications.

Title: Afferent regulation of the upper limb motor cortex following incomplete cervical spinal cord injury

Authors: *A. BAILEY, P. MI, A. J. NELSON
Kinesiology, McMaster Univ., Hamilton, ON, Canada

Abstract: Aaron Bailey*, Peter Mi, and Aimee J. Nelson Department of Kinesiology, McMaster University, Hamilton, Ontario Incomplete spinal cord injury (SCI) to the cervical spine impairs the transmission of afferent and efferent volleys along the remaining neural pathways. Impairment in somatosensory afferent transmission can alter the gating effect on the Transcranial magnetic stimulation (TMS) elicited motor evoked potential (MEP) seen in uninjured participants (i.e. short and long-latency afferent inhibition). The purpose of the present study was to investigate the afferent regulation of the flexor carpi radialis (FCR) muscle in individuals with incomplete SCI. Eight individuals with incomplete SCI (mean age = 31±7.13, 7 males, ASIA range B,C,D with lesions between C4-C7) and aged-matched uninjured controls (mean age = 30.67±7.09, 3 males) were studied. Afferent regulation was studied bilaterally by electrical stimulation of the median nerve at the elbow (1.2x motor threshold) followed by TMS pulses delivered over the FCR representation to evoke MEP at half-maximum amplitude. Afferent regulation was studied while FCR was at rest and also during 15-20% of maximum voluntary contraction. The interstimulus intervals between the nerve stimulation and TMS pulse included: 15, 20, 25, 35, 45, 55, 65 and 200 ms. Ten trials were recorded at each ISI and the resulting MEP was normalized to those obtained in the absence of conditioning (i.e. TS alone). Afferent regulation was measured using the area of the MEP and calculated as the $MEP_{nerve-TMS}/MEP_{TMSalone.}$ Preliminary results indicate that afferent input elicits greater inhibition of the MEP in controls versus SCI at latencies of ~15 ms corresponding to the short-latency afferent inhibition interval for the FCR muscle. Afferent modulation of MEPs is similar for controls and SCI at intervals from 35 - 65 ms. These results indicate alterations in the afferent regulation of the motor cortical output to FCR muscle that coincide with the cortical arrival of the somatosensory afferent volley.

Title: Short and long-interval intracortical inhibition in flexor carpi radialis muscle in incomplete spinal cord injury

Authors: *Y. P. MI, A. BAILEY, A. J. NELSON
Kinesiology, McMaster Univ., Hamilton, ON, Canada

Abstract: Peter Y. Mi*, Aaron Bailey, Aimee J. Nelson. Corticospinal output as measured using Transcranial magnetic stimulation (TMS) is typically reduced in individuals with spinal cord injury (SCI). These changes may be due to alterations at the spinal level and possibly by changes within primary motor cortex. Two TMS-evoked circuits, short- and long-interval intracortical inhibition (SICI and LICI) are measures of the intracortical inhibitory mechanisms within primary motor cortex. The present study measured SICI and LICI in 8 individuals with incomplete SCI (mean age = 31±7.13, 7 males, ASIA range B,C,D with lesions between C4 and C7) and aged-matched controls (mean age = 30.67±7.09, 3 males). SICI and LICI measures were obtained from the flexor carpi radialis (FCR) muscle bilaterally in SCI and in the dominant limb in controls. SICI and LICI were obtained with the muscle at rest and also during a 15 - 20% maximum voluntary contraction i.e. active. SICI recruitment curves were generated using six conditioning stimulus (CS) intensities: 60, 70, 80, 90, 100, 110% of rest and active motor threshold. For SICI the ISI between the CS and the test stimulus (TS) was set at 2 ms. LICI recruitment curves were generated using five CS intensities: 90, 100, 110, 120, 130% of rest and active motor threshold. For LICI the ISI between the CS and the TS was set at 150 ms. For both circuits, 30 trials were obtained at each CS intensity (15 with test stimulus alone, 15 with conditioning preceding test stimulus). SICI and LICI were measured using the area of the MEP using the formula: $MEP_{CS\text{-}TS}/MEP_{TSalone}$. Preliminary data reveals a decrease in SICI at rest in SCI compared to controls. However, in ‘active’, SICI appears to be similar across groups. LICI obtained at rest is similar between SCI and controls. However, LICI appears to be greater in SCI compared to controls during ‘active’. The data suggests some degree of reduction in $GABA_A$ function in the cortex resulting in the reduction of SICI as well as a persistent $GABA_B$ function during movement which causes dysfunction of the LICI circuit.

Title: Effects of zolmitriptan and N-methyl-D-aspartate on the sensory input processing of deep dorsal horn neurons in mice with acute spinal cord injury

Authors: *T. THAWEERATTANASINP[1], C. J. HECKMAN[2], V. M. TYSSELING[3]
[1]Physiol., Northwestern University, Feinberg Sch. of Medici, Chicago, IL; [2]Physiology, Physical Med. and Rehabilitation, Physical Therapy and Human Movement Sci., [3]Physiology, Physical Therapy and Human Movement Sci., Northwestern University, Feinberg Sch. of Med., Chicago, IL

Abstract: Spinal cord injury (SCI) results from a physical insult to the spinal cord, which can cause various motor dysfunctions. A muscle spasm is one of the common dysfunctions sustained in chronic SCI patients. It is characterized by a sudden, involuntary contraction of a muscle, which can interfere with standing, seating, walking, and other physical movements. SCI causes loss of tonic serotonin (5-hydroxytryptamine; 5-HT) inhibition of the excitatory deep dorsal horn neurons (DHN), likely contributing to the exaggerated excitatory drive to the spinal motoneurons. The enhancement of excitatory input over inhibitory one to spinal motoneurons then results in muscle spasms. Recent studies in rodents and humans with chronic SCI revealed that activation of 5-HT1B/1D receptors can reduce muscle spasms without affecting the intrinsic properties of spinal motoneurons. Moreover, the majority of 5-HT1 receptors concentrate highly in the spinal dorsal horn, where the early processing of sensory input from the body occurs. This evidence suggests the involvement of DHNs in producing muscle spasms after chronic SCI. We hypothesize that DHNs become hyperexcitable after SCI by showing prolonged plateau potentials and strong persistent inward currents, thus amplifying synaptic input to the downstream motoneurons. Moreover, if the 5-HT deficiency is the cause of the hyperexcitable DHNs, the selective 5-HT1B/1D receptor agonist zolmitriptan should reduce the neuron hyperexcitability. We have tested these hypotheses by using the *in vitro* sacral cord preparation from the adult mice (Mus musculus) for the model of acute SCI. We analyzed the effects of zolmitriptan and N-methyl-D-aspartate (NMDA) on the extracellularly recorded responses of DHNs located in spinal lamina III-V and ventral root activity. The synaptic activation of DHNs and ventral root activity was achieved via dorsal root stimulation at four stimulus strengths. Compared with controls, bath application of zolmitriptan (1 μM) increased spike threshold of DHNs, thus generating fewer spontaneous or evoked spikes at a given stimulus strength. However, not on all DHNs did we observe the inhibitory effect of zolmitriptan. Surprisingly,

NMDA had dual effects on the firing activity of DHNs. While NMDA (100 μM) facilitated bursting in one DHN population, it suppressed the evoked responses in the other. These preliminary results suggest the differential sensory input processing of DHNs in acute SCI. A future study of chronic SCI is necessary to see how sensory processing of DHNs would change when muscle spasms arise. It is also interesting to see how the interplay between 5-HT and NMDA receptor systems would affect DHNs in SCI.

Title: Proteolytic cleavage of sodium channels and co-transporters KCC2: Mechanism leading to spasticity after spinal cord injury

Authors: V. PLANTIER, F. GACKIÈRE, C. BROCARD, S. LIABEUF, L. VINAY, *F. BROCARD
Inst. de Neurosciences de la Timone, CNRS, Marseille, France

Abstract: Pathophysiological mechanisms of spasticity are quite diverse but alterations in intrinsic properties of motoneurons play a central role. Aside an upregulation of the persistent sodium current (I_{NaP}) in motoneurons, disinhibition of motoneurons due to of the down-regulation of the co-transporter KCC2 appears to be an important substrate for spasticity. We postulated that the up- and down-regulation of I_{NaP} and KCC2 respectively not only have a synergistic effect in generating spasticity but also share a common upstream mechanism responsible for their dysregulations. In this study, neonatal Wistar rats underwent a T8 spinal cord injury at birth. One week later, characteristic spastic-like responses were observed. This hyperexcitability of the spinal cord emerged with a concomitant upregulation of I_{NaP} and depolarization of the chloride equilibrium potential (E_{Cl}), that were both associated with a

proteolytic cleavage of voltage-gated sodium channel (Nav) and a down-regulation of KCC2 expression, respectively. In uninjured rats, the pharmacological inhibition of KCC2 by DIOA (25 μM) combined with an upregulation of I_{NaP} by veratridine (75 nM) reproduced spastic-like responses. The *in vitro* biochemical assays identified the calcium-dependent protease, calpain, to be the main proteolytic factor. Acute or chronic administration of the calpain inhibitor MDL28170 decreased proteolytic cleavage of Nav channels, rescued KCC2, reduced I_{NaP} in motoneurons, hyperpolarized E_{Cl}, and attenuated spastic-like responses. Altogether, this study establishes a causal link between the proteolytic cleavage of Nav channels and KCC2 and the alterations of I_{NaP} and E_{Cl} in motoneurons. These two mechanisms act synergistically to induce spasticity.

Title: Injury discharge immediately following a T10 spinal contusion is critical for the development of DRG neuron hyperexcitability

Authors: *J. DU[1], E. T. WALTERS[2], S. M. CARLTON[1]
[1]Neurosci and Cell Biol., Univ. Texas Med. Br., Galveston, TX; [2]Integrative Biol. and Pharmacol., UT Hlth. Sci. Ctr., Houston, TX

Abstract: Spinal cord injury (SCI) patients often live with chronic pain and mechanisms underlying its generation are unknown. Our previous studies using a rat T10 contusion model demonstrated that the dorsal root ganglion (DRG) cells, including nociceptors, at and below the

level of the injury, are hyperexcitable 3 days and 1-5 months post-contusion, with a significant increase in the number of fibers with spontaneous activity (SA). The goal of the present study was to elucidate whether aberrant electrical activity initiates DRG neuron hyperexcitability. We investigated in male SD rats whether signals coming to the DRG from the spinal cord via the dorsal roots (DRs) contribute to development of SA in the DRG after SCI. To determine whether electrical activity generated in the spinal cord is transmitted to the DRG, we recorded from DRs immediately (within 5 min), 30 min, 7 weeks, and 2 months following contusion. The greatest electrical activity (generated in the cord, recorded in the DR) occurred immediately following contusion; at all other time points, SCI activity was not different from sham activity. To determine whether intact DRs are necessary for the development of SA in the DRG, L4/5 DRs were cut on one side and then rats were contused. SA was recorded in ipsilateral and contralateral DRs on days 3, 7 and 35 post-injury. At all time points, the percentage of units with SA in the rhizotomized DRs was significantly decreased compared to contralateral intact DRs, and was not different from sham. These data suggest that signals conveyed from the cord in the DRs play a major role in inducing the SA that develops in DRGs after contusion. To determine whether injury discharge is key to the induction of SA in the DRG, lidocaine (LIDO) was applied to the DRs from 45 min before to 45 min after contusion. Compared to vehicle, 3 days post-contusion the LIDO rats showed a significant decrease in the proportion of units with SA and their discharge rate was not different from sham. These findings strongly suggest that an electrical signal, generated in the spinal cord at the time of contusion and transmitted to the DRG via the DRs, is critical for the development of SA in the DRG after spinal contusion.

Title: Cardiovascular responses to cutaneous nociceptive input after cervical spinal cord injury: Role of pain afferent types and their plasticity

Authors: *H. LEE[1,2], J. CHUNG[1,2], K. E. TANSEY[1,2,3]
[1]Dept. of Neurol., [2]Dept. of Physiol., Emory Univ., Atlanta, GA; [3]Spinal Cord Injury Clin., VAMC, Atlanta, GA

Abstract: In normal, anesthetized rats, stimulation of segmental (T6 - L1) dorsal cutaneous nerves (DCNs) generates different cardiovascular responses depending on which pain afferent types are activated. Stimulation of A delta fibers alone (0.5 mA) generates increases in heart rate (HR) but relatively limited decreases in blood pressure (BP), with this effect on BP being greater at higher stimulation frequencies (10 Hz vs 1, 2 or 5 Hz). Stimulation of both A delta and C fibers together (5 mA) generates the same increase in HR but now a greater drop in BP, especially at higher stimulation frequencies (2, 5, & 10 Hz). The temporal relationships between BP and HR changes show an initial drop in BP followed by an increase in HR followed by a recovery in BP and then a recovery in HR. Following C7 crush spinal cord injury (SCI), we have found three cardiovascular responses based on BP, a depressor (normal) response where DCN stimulation at A delta and C fiber strength (5 mA) almost always generates a drop in BP, a pressor (autonomic dysreflexia) response where DCN stimulation almost always generates an increase in BP, and a dysautonomia response where there are mixed depressor and pressor responses to DCN stimulation at different spinal levels. We have now investigated the BP vs. HR relationships within these groups and found that the depressor response after injury is different than the normal response in that the final recovery of increased HR is delayed. This finding is also true in the dysautonomia response. In the pressor response, there are simultaneous increases in both BP and HR and both BP and HR are delayed in their return to baseline. In this last group, the effect is much greater in response to rostral DCN stimulation than to caudal DCN stimulation. To relate these cardiovascular responses to pain afferent anatomical plasticity in the spinal cord dorsal horn, we transganglionically labeled A and C fibers with CTB and IB4 respectively in the T7 and T13 DCNs. In all injury cardiovascular responses, we found increased A fiber sprouting from both DCNs relative to uninjured animals. C fibers were fewer than, or the same as, in uninjured animals in both the depressor and dysautonomia response groups but showed sprouting in the pressor response group, significantly more so at T7 than at T13. Taken together, the normal animal data and the spectrum of cardiovascular responses and anatomical plasticity after cervical SCI, it would seem that A delta afferent input and plasticity preferentially affect HR responses and C fiber input and plasticity preferentially affect BP responses. This may mean that A delta effects could be predominantly cardiac while C fiber effects could be predominantly on vascular tone.

Abstract: Deprivation of spinal serotonin after spinal cord injury (SCI) causes significant plasticity in spinal circuitry. Recent studies demonstrated an increase in the expression of the constitutively active isoform of the 5-HT2c receptor following chronic sacral SCI in rats. This increase was functionally tied to the development of tail spasms. Most clinical cases of SCI, however, involve incomplete injuries in which some descending systems, including raphespinal systems, remain partially intact. In this study we examined whether such clinically relevant cases of incomplete SCI also involve the development of constitutively active 5-HT2c receptors. We also asked whether the development of constitutively active 5-HT2c receptors might be modulated by chronic inhibition of serotonergic reuptake with SSRIs. To test this, we used both *in vivo* and *in vitro* testing on two groups of mice with incomplete thoracic SCIs, one control group and one with chronic treatment of Prozac. *In vivo*, we used open field locomotor scores and EMG responses to the flexor withdrawal stimulus to examine behavior and hyperreflexia/spams. *In vitro*, we recorded sacral spinal reflexes to assess the presence of constitutive activity. We show that constitutive activity does increase in mice with incomplete thoracic SCI, but to a lesser degree as compared to the previously published complete studies. In addition, we show that chronic treatment with SSRIs significantly alters adaptations in 5-HT receptors following incomplete SCI. These results reinforce previous work showing an increase in 5-HT2c receptor constitutive activity after spinal cord injury and also suggest that this increase can be modulated through pharmacological intervention.

Abstract: Following incomplete spinal cord injury (SCI) some spontaneous recovery of function occurs. In rodent models of SCI, particularly in mice, the degree of spontaneous recovery exceeds that observed in humans, or even in other animal models of SCI (eg. cat). The specific cellular mechanisms underlying this spontaneous recovery of function, as the animals transition from the acute to chronic stages of injury, are unknown. For mice such information is important as this species is increasingly used to study the involvement of various genes in recovery from SCI. Here we characterize the changes to intrinsic cellular and synaptic properties of spinal interneurons occurring in the acute (4 wks post SCI) and chronic (10 wks) stages of SCI in an adult mouse hemisection model of injury. Male mice (C57Bl/6; ~P63) received a spinal hemisection (T9-10) and were allocated to acute and chronic groups. After the recovery period, mice were sacrificed and horizontal spinal cord slices (T6-T12, 250 μm) were prepared for whole cell patch clamp analysis. Recordings were made from deep dorsal horn (DDH) interneurons located within two spinal segments of the SCI. Input resistance and rheobase current were decreased in chronic (n=108 neurons) versus acute (n=65) SCI mice and resting membrane potential was more depolarized in interneurons from chronic SCI mice ($p<0.05$). In response to square step depolarising current injection DDH interneurons exhibit four action potential discharge patterns: tonic firing, initial bursting, delayed firing and single spiking. The proportion of neurons exhibiting each discharge pattern differed significantly in acute versus

chronic SCI mice; specifically the proportion of tonic firing neurons is increased and delayed firing neurons decreased in chronic SCI. Moreover, the expression of several voltage-gated ion channels (I_{Ar}, I_{As} and I_{Ca}) known to underlie differences in AP discharge categories in DDH interneurons also differed in acute versus chronic groups. Acute SCI mice exhibit a higher proportion of I_{Ar} and chronic mice a higher proportion of I_{Ca}. Spontaneous excitatory postsynaptic currents (sEPSCs) were recorded to assess excitatory synaptic drive. sEPSC amplitude decreased, sEPSC rise and decay time increased, while sEPSC frequency did not change over time post-injury. Together these data indicate that DDH interneurons in the chronic stages of SCI are characterized by altered excitability, reduced excitatory synaptic drive, and either altered expression of glutamate receptor subtypes or receptor location on their somatodendritic trees.

Title: Assessment of Hebbian plasticity in the spinal cord

Authors: ***A. J. FUGLEVAND**[1], M. J. RAMIREZ[2]
[2]Physiol., [1]Univ. Arizona, Tucson, AZ

Abstract: A fundamental process underlying learning and memory is a long-lasting change in the effectiveness of synaptic communication among neurons. One principle that governs such changes in synaptic 'strength' was proposed by Hebb in the 1940s. Hebb postulated that synaptic connections among neurons that are co-active become stronger whereas synaptic connections among neurons that are active at different times are weakened. While a substantial body of research has largely confirmed aspects of Hebb's rule underlying plasticity in various brain structures, little is known about the capability of neurons in the spinal cord to exhibit Hebbian plasticity. The goal of this project was to determine whether the strength of synaptic connections between corticospinal neurons and spinal motor neurons (MNs) could be changed by a period of

training that involved their repetitive co-activation. As such, we measured the extent of short-term synchronized spiking between MNs supplying two hand muscles before and following 4 weeks of training on a computer game that required precise matching of the forces exerted by the two muscles. Because such synchronization reflects the strength of synaptic inputs projecting across the two motor nuclei, training-related increases in synchrony were assumed to reflect Hebbian-like increases in the strength of common synaptic inputs. Despite marked improvements in game performance, no changes in synchrony were observed. Given the constraints of the training protocol and the indirect assay to evaluate changes in synaptic strength, these results should not be taken to indicate that synapse-specific and activity dependent changes in synaptic strength cannot occur in the spinal cord. Nevertheless, it still seems feasible that the molecular machinery needed to support Hebbian plasticity is absent at MN synapses.

Title: The use of F-response in defining interstimulus intervals appropriate for LTP-like plasticity induction in lower limb spinal paired associative stimulation

Authors: *A. SHULGA[1,2], P. LIOUMIS[1], E. KIRVESKARI[1,2], S. SAVOLAINEN[3], J. P. MÄKELÄ[1], A. YLINEN[1,2]

Abstract: In spinal paired associative stimulation (PAS), orthodromic volleys are induced by transcranial magnetic stimulation (TMS) in upper motor neurons, and antidromic volleys by peripheral nerve stimulation (PNS) in lower motor neurons of human corticospinal tract. The volleys arriving synchronously to the corticomotoneuronal synapses induce long term potentiation -like plasticity in the spinal cord. For clinical use of spinal PAS, it is important to develop protocols that reliably induce facilitation of corticospinal transmission. Due to variability in conductivity of neuronal tracts in neurological patients, it is beneficial to estimate

interstimulus interval (ISI) between TMS and PNS on individual basis. Spinal root magnetic stimulation has previously been used for this purpose in spinal PAS targeting upper limbs. However, at lumbar level this method does not take into account the conduction time of spinal nerves of the cauda equina in the spinal canal. For lower limbs spinal PAS, we propose estimating appropriate ISIs on the basis of F-response and motor-evoked potential (MEP) latencies. The use of navigation in TMS and ensuring correct PNS electrode placement with F-response recording enhances the precision of the method. Our protocol induced over two-fold MEP amplitude facilitation in healthy subjects, being effective in all subjects and nerves tested. We report for the first time the individual estimation of ISIs in spinal PAS for lower limbs. Estimation of ISI on the basis of F and MEP latencies is sufficient to effectively enhance corticospinal transmission by lower limb spinal PAS in healthy subjects.

Title: Comparison of two TMS plasticity protocols across two TMS labs

Authors: ***A. D. WU**[1,2], D. J. EDWARDS[4,5], M. IACOBONI[2,3], C. DEBLIECK[1,2], M. CORTES[4,5], R. R. RATAN[4,5], B. DOBKIN[1]

Abstract: Transcranial magnetic stimulation (TMS) can be used in many modulation protocols to induce lasting changes in motor evoked potentials (MEP). These effects resemble changes seen with plasticity paradigms in animal models and have been proposed as probes of plasticity in human subjects. However, data on reproducibility of protocols between TMS labs are sparse, but essential if these tools are to be used in study of plasticity changes in patients. We tested a standard (paired-associative stimulation, PAS) and a novel (dual-TMS) modulation protocol across two TMS labs (UCLA, Burke-Cornell). The goal was to establish uniform methods of

assessing plasticity in human subjects which can be applied to the study of candidate drugs, manipulating plasticity, for brain and spinal cord injury recovery studies. PAS protocol involved 200 pairs of ulnar nerve stimulation and contralateral motor cortex TMS with an interstimulus interval (ISI) of 25 msec at 0.25 Hz. Dual-TMS protocol involved 90 pairs of TMS over right posterior parietal cortex (PPC) followed by left dorsal premotor cortex (PM) with 1 msec ISI at 0.1 Hz. Outcome MEPs were recorded from right FDI muscle for 60 min every 10 min after each protocol. For PAS, 24 control subjects (mean 26yo [18-56 yo], 11M) were tested. MEP amplitudes increased over baseline following PAS (20, 30, 40 min, p=0.02, 0.005, 0.04). However, we found no significant MEP facilitation analyzing data from each site separately. No significant differences between sites were found at any time point. For dual-TMS, 19 control subjects (mean 27 yo [18-47 yo], 8M) were tested. MEP amplitudes increased over baseline following dual-TMS (30, 40, 50 min, p=0.04, 0.03, 0.04). We found significant MEP facilitation at 40 min (p=0.03) and trends without significance at 50, 60 min (p=0.08, 0.05) at UCLA (n=11) and at Burke at 30 min (p=0.09, n=8). No significant differences between sites were found at any time point. Data suggest PAS and dual-TMS modulation as tests for plasticity effects in producing post-modulation MEP facilitation using combined data from both sites. PAS effects are compatible with spike-timing mechanisms. The short ISI cortico-cortical dual-TMS effects support a hypothesis of increased synchrony and functional connectivity in a parietal-premotor circuit and its downstream influence on the motor cortex. Data suggest that MEP data from two sites are comparable, but limited sample size make this tentative. Future work will increase sample sizes to ensure between site reliability of the protocol across sites and compare within-subject reliability between sites in anticipation of looking at plasticity following stroke in humans.

Title: Characterization of thoracic (Th9), complete transection spinal cord injury model of muscle spasticity in the rat

Authors: *J. A. CORLETO[1], M. BRAVO-HERNANDEZ[3], O. KAKINOHANA[2], M. HEFFERAN[4], M. MARSALA[2]
[2]Anesthesiol., [1]UCSD, La Jolla, CA; [3]Farmacobiologia, Ctr. de Investigacion y de Estudios Avanzados, Mexico, Mexico; [4]Neuralstem Inc., San Diego, CA

Abstract: José A. Corleto, Mariana Bravo-Hernández, Osamu Kakinohana, Camila Santucci, Michael P. Hefferan, Martin Marsala University of California, San Diego, La Jolla, CA, USA
The development of muscle spasticity is a serious complication associated with traumatic spinal cord injury. It is believed that the mechanism leading to development of muscle spasticity is the result of the loss of descending facilitatory inhibition, increased sensory input and/or loss of local segmental inhibitory interneurons. Here, we characterize a thoracic 9 (T9) complete transection model in Sprague-Dawley (SD) rats to study the onset of muscle spasticity following SCI. Adult SD rats were used to perform a T8 laminectomy followed a complete, T9 transection of the spinal cord. To identify the presence of spasticity, two different qualitative tests were employed: i) changes in ankle resistance and corresponding EMG activity were measured in the gastrocnemius muscle in fully awake animals using a computer-controlled ankle rotational system, and ii) gastrocnemius muscle EMG response was recorded after applying a progressively increased paw pressure using von Frey filaments. The changes in H-reflex and rate dependent depression (RDD) in T9-transected rats were also measured. In the pharmacological part of the study, the effect of systemic (IP) treatment with: i) Baclofen (10 mg/kg), ii) Tizanidine (1 mg/kg), or iii) NGX424 (1 mg/kg) was studied. A time-dependent and muscle stretch-velocity-dependent development of spasticity response was seen between 1-3 months after spinal transection. Treatment with baclofen, tizanidine, and NGX424 led to significant suppression of otherwise increased EMG activity measured during ankle rotation. Analysis of the H-reflex showed a significant increase in the H wave at 3 months post-transection when compared to naïve non-injured animals. Similarly, an average 60% loss in rate dependent depression was measured at high stimulation frequencies (3, 5, and 10 Hz) in spastic animals. Analysis of tactile stimulus-evoked EMG response showed the presence of tactile hypersensitivity at intervals longer than 4 weeks after spinal transection. This hypersensitivity was effectively blocked by systemic treatment with baclofen (10-20 mg/kg, ip). These data demonstrate that rats with complete spinal transection develop a consistent and prominent muscle spasticity/spinal hyper-reflexia at intervals of 1-3 months after injury. The potent anti-spastic effect measured after treatment with clinically effective antispastic agents also demonstrates the validity of this model in screening new anti-spasticity agents.

Title: Multi muscle neuromuscular stimulation of the lower limbs: Effect on Motor Pools

Authors: *G. F. FORREST[1], E. JOHNSON[1], A. RAMANUJAM[2], E. GARBARINI[2], R. LAMB[2]
[1]Kessler Fndn. Res. Ctr., West Orange, NJ; [2]Kessler Fndn. Inc., West Orange, NJ

Abstract: Acute spinal cord injury often leads to rapid muscle atrophy in the paralyzed limbs. Recently we have shown that an intense novel form of multi-muscle neuromuscular stimulation combined with dynamic stand retraining task may potentially restore muscle structure and function after sub acute to chronic, motor-complete SCI. Recovery of stepping and standing after spinal cord injury is often measured by studying motor pool activation of the lower extremity during standing or stepping with very little attention given to the importance of the amount of leg muscle mass and its corresponding effect on neuromuscular control for the reorganization of the lower or upper extremity neural circuitry. Recently, we have also shown that a large dose of repetitive task specific stand and step training can improve trunk function as well as standing, stepping or walking overground for sub acute to chronic SCI. However, little is known on the flexor and extensor motor pool recruitment changes or neural changes during stepping when there has been an significant increase in lower limb muscle volume/strength (through multi muscle neuromuscular stimulation with mechanical loading) of a previous atrophied muscle. We will present data for several individuals with a cervical and thoracic, motor complete spinal cord injury who have undergone a large number of standardized repetitive task specific training sessions with mechanical loading combined with lower extremity multi neuromuscular stimulation. These data will evaluate the changes in leg and trunk extensor and flexor muscle activation pools or motor patterns during active standing perturbations and stepping concomitant with the changes in lower limb muscle volume. In addition, these data will be compared to those individuals who received the lower extremity multi neuromuscular stimulation without mechanical loading. For an increase in muscle volume in the lower extremity extensors and flexors in both the neuromuscular stimulated groups (loaded and unloaded groups) it was found

that there was a significant increase in flexor and extensors muscle activation amplitude during continuous stepping in the neuromuscular stimulated and mechanical loaded group only. It was noted that the the phasic coordination of the flexor and extensor muscle activation pools were inappropriate for stepping. Multi muscle lower limb hypertrophy/strength gains may require repetitive task specific training to benefit the reorganization of the neural circuitry after severe human spinal cord injury.

Title: Optogenetic mapping of forelimb movement in the rat cervical spinal cord

Authors: *S. E. MONDELLO[1,2], M. D. SUNSHINE[2], P. J. HORNER[1], C. T. MORITZ[2]
[1]Neurolog. Surgery, [2]Rehabil. Med., Univ. of Washington, Seattle, WA

Abstract: In a previous study, the Moritz Laboratory meticulously mapped the responses of forelimb muscle activation and movements in response to intraspinal stimulation at various sites along the cervical spinal cord. A variety of complex movements were elicited depending on the site of stimulation. In the current study, we perform a similar assessment using a novel type of

stimulation called optogenetics. This technique allows for the targeted activation of cells stably transfected with the light-activatable channel channelrhodopsin (Chr2) with blue light. In the current study, rats were pre-transfected with AAV-CamkII2alpha-Chr2-mcherry virus with a viral injection into the gray matter of the hemicord along spinal segments C3 through T1. Several weeks later, rats underwent a mapping procedure in which forelimb muscle activation and movements were assessed across a systematic range of sites along the surface of the cord while stimulating those sites optogenetically. Similar to what was reported in our previous work, we found that optogenetic stimulation activated different muscles and elicited different movements depending on the site being stimulated. Further, we found that this optogenetic system has the intriguing capability to elicit movements when stimulated with a two micron microLED from above the surface of the spinal cord. In combination, these findings will assist in our future plans to use optogenetics as therapeutic stimulation for enhancing functional recovery after spinal cord injury.

Title: Inhibition of Nav1.8 channels reduces pain-related behavior after spinal cord injury

Authors: *M. A. ODEM[1], J. K. HADDEN[1], R. J. CROOK[1], J. DU[2], S. M. CARLTON[2], Q. YANG[1], E. T. WALTERS[1]
[1]Integrative Biol. and Pharmacol., UT Hlth. Sci. Ctr., Houston, TX; [2]Neurosci. and Cell Biol., Univ. of Texas Med. Br., Galveston, TX

Abstract: Chronic pain is an intractable problem for many people with spinal cord injury (SCI). Unexpectedly, we found in a rat model of contusive SCI at T10 that this central neuropathic pain is associated with persistent hyperexcitability and spontaneous activity (SA) in the cell bodies of primary nociceptors recorded *in vitro* and *in vivo* below the injury level (Bedi et al. J Neurosci, 30:14870, 2010; Wu et al. Pain, 154:2130, 2013). Primary afferent neurons, including most

nociceptors, are the only neurons that express the voltage-gated sodium channel, Nav1.8. We found recently (Yang et al., unpublished) that chronic hyperreflexia and nociceptor SA induced by SCI can be reversed by antisense knockdown of Nav1.8 channels, and that SCI-induced SA in dissociated nociceptors can also be suppressed by the selective Nav1.8 antagonist, A-803467. We are now testing the prediction that A-803467 will also ameliorate hyperreflexia and other pain-related behavioral changes after SCI. Injection of A-803467 (100 mg/kg i.p.) caused a significant reversal of hindlimb hyperreflexia assessed with heat and mechanical test stimuli 6-8 weeks after SCI, but had no significant effect on hindlimb reflexes in control rats given sham surgery. Ongoing experiments are testing the effects of A-803467 on operant tests of spontaneous pain and evoked pain. Spontaneous pain is assessed with a conditioned place preference test. Evoked pain is assessed with an operant task in which a rat has to choose between escaping from an aversive bright light and crossing a floor of potentially painful probes. In addition, preliminary results indicate that application of A-803467 to exposed DRG in an anesthetized rat reduces chronic SCI-induced SA generated in lumbar DRG *in vivo*. These results suggest that drugs selectively inhibiting Nav1.8 channels may provide a promising approach for treating persistent neuropathic pain after SCI.

Title: Sympathetic preganglionic and afferent stimulation-evoked responses in paravertebral thoracic chain ganglia

Authors: *M. HALDER[1], M. SAWCHUK[2], S. HOCHMAN[3]
[1]Emory Univ., Atlanta, GA; [3]Physiol., [2]Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Paravertebral sympathetic postganglionic neurons (SPNs) located in thoracic chain sympathetic ganglia represent the predominant sympathetic control of vascular function in the upper and middle extremities. These ganglia are practically inaccessible for *in vivo* studies, and

consequently have barely been studied directly (Blackman and Purves J Pysiol 1969; Lichtman et al J Physiol 1980). We developed an *in vitro* adult mouse model to examine evoked population responses following stimulation of segmental sympathetic preganglionic and primary afferents axons. The approach retains the adult mouse thoracic sympathetic chain ganglia *in situ* with connections to dorsal root ganglia, dorsal roots and ventral roots. Dorsal roots were stimulated to examine primary afferent evoked responses, and ventral root stimulation was used to recruit axons of sympathetic preganglionic neurons. Responses in individual ganglia were recorded with suction electrodes attached to cut inter-ganglia nerve bundles. We first characterized the multisegmental axonal composition in individual chain ganglia. When recording from T12 ganglia, we observed orthodromic responses following stimulation of T7-T12 ventral roots and antidromic responses from T4-T12 dorsal roots. In addition to recordings of compound action potentials, dorsal and ventral root stimulation evoked synaptically-mediated spiking responses were seen and subsequently blocked in a high Mg2+/low Ca2+ solution or in the presence of ionotropic receptor antagonists. Both dorsal and ventral root stimulation evoked responses both showed sensitivity to ionotropic glutamatergic and cholinergic receptor antagonists while ventral root-evoked synaptic actions were also facilitated in the presence of the nitric oxide donor DEANO. The observation of considerable synaptic actions arising from visceral afferents was unexpected. To further support this observation, we undertook post-experiment immunolabeling within the chain and found CGRP+ puncta in a position to interact synaptically with SPNs. Overall, we conclude that most thoracic ganglia receive widely divergent input from multiple spinal segments. Moreover, the visceral afferents that within chain ganglia can project many spinal segments prior to entry into spinal cord and also appear to issue collaterals within the ganglia and have synaptic actions on SPNs.

Title: Conditional silencing of adult rat spinal locomotor circuitry induces hopping

Authors: *A. POCRATSKY[1], A. S. RIEGLER[2], J. R. MOREHOUSE[2], D. A. BURKE[2], J. T. HARDIN[3], R. M. HOWARD[2], D. S. K. MAGNUSON[2], S. R. WHITTEMORE[2]

Abstract: Identifying the functional role of spared neural pathways post-spinal cord injury can help design targeted rehabilitation strategies to enhance recovery. Methods to functionally dissect locomotor circuitry primarily consist of non-specific spinal lesions or a limited number of neuron-specific, fate-mapped transgenic strains. A conditional two viral vector system was recently developed, allowing specific neuronal pathways to be functionally silenced based solely on their anatomy. Targeted neurons are silenced *in vivo* through reversible expression of enhanced tetanus neurotoxin (eTeNT) that proteolytically cleaves vesicle-associated membrane protein 2, which is essential for synaptic vesicle exocytosis. Here, we conditionally silenced L2 interneurons with descending projections to L5. Those neurons were double-infected by bilateral injections of HiRet-TRE-EGFP.eTeNT at L5 and the tetracycline-responsive AAV2-CMV-rtTAV16 at L2. Doxycycline (DOX, 15 mg/ml) was given ad libitum to induce eTeNT expression. Behavioral, kinematic, gait, and electrophysiological assessments were performed pre-injections, before DOX-induced neurotransmission silencing, during DOX treatment (DOXON), and post-DOX. DOXON was repeated one month later to assess reproducibility. Silencing descending L2 interneurons induced a hop-like phenotype in the hindlimbs. Hopping was quantified by a significant increase in average hip excursion and changes to locomotor-related measures, including hindlimb swing, stance, and stride during volitional and treadmill-based stepping. L2-L5 interneuron silencing switched the step sequence pattern from alternate to cruciate wherein forelimb stepping precedes hindlimb, as opposed to alternation. These DOXON functional changes were replicated one month after DOX washout. Current studies focus on long ascending propriospinal neurons (LAPNs), a neural pathway thought to functionally interconnect hind- and forelimb central pattern generators. Bilateral injections of eTeNT at C6 and rtTAV16 at L2 doubly-infected LAPNs. DOX treatment induced a symmetrical hop-like gait involving both fore- and hindlimbs during volitional locomotion. Ongoing behavioral, kinematic, gait, and electrophysiological analyses are being performed to quantitatively describe this locomotor behavior. This approach enables delineation of the functional contribution of propriospinal pathways in normal locomotor function, after spinal cord injury, and importantly after targeted rehabilitative therapy.

Title: Proprioceptive feedback affects antidromic activity in sensory afferents of crayfish legs

Authors: B. CHUNG[1], J. BACQUE-CAZENAVE[1], D. CATTAERT[2], *D. H. EDWARDS[1]
[1]Neurosci. Inst., Georgia State Univ., Atlanta, GA; [2]Univ. of Bordeaux I, Bordeaux, France

Abstract: In both vertebrates and invertebrates, primary afferent depolarization (PAD) leads to antidromic excitation of afferents. Antidromic afferent spikes serve as a hallmark of PAD and may act to inhibit generation of orthodromic spikes in the afferent axon. Antidromic spikes have been recorded in the coxobasal chordotonal organ (CBCO) stretch receptor afferents of the crayfish leg during walking, but their role in producing or modifying the crayfish walking motor program is unclear. We have recorded antidromic spikes in CBCO afferents in an *in vitro* preparation of the thoracic nerve cord in which one of the leg proprioceptive feedback loops has been closed. Spikes in the leg levator and depressor motor nerves drive levator and depressor muscles of a computational neuromechanical model of the crayfish leg, and movement of the leg stretches and releases the intact CBCO stretch receptor organ to produce appropriately timed feedback to the central nervous system. This preparation can be in either a quiescent state, where neurons fire tonically and imposed leg lifts evoke downward resistance reflexes, or in an active state, where Levator/Depressor (Lev/Dep) burst pairs occur and leg lift evokes an assistance reflex. In six preparations, spikes from the Lev, Dep, and CBCO nerves were recorded when the feedback loop was closed and when it was open during both quiescent and active states. After sorting spikes among 18 motorneurons (MNs) in the Lev nerve, 13 MNs in the Dep nerve, and 36 afferents in the CBCO nerve, we used cross-correlation analysis to identify afferents excited antidromically by MNs. We found that nearly all CBCO afferents (e.g., 28/36 in one preparation) were excited antidromically, and that a single Lev MN excited all of them, while a few other Lev and Dep MNs and the Common Inhibitor MN each excited only a few afferents (<5). Twice as many afferents were excited antidromically when the preparation was quiescent (25/36) than when active (12/36), and in both states only the larger units were excited when the feedback loop was closed. In the active state under closed loop, the preparation produced rhythmic pairs of

Lev/Dep bursts at a frequency of 1/10s, and antidromic excitation was restricted to larger afferents firing strongly at the onset of each Lev MN burst. All these afferents were sensitive to CBCO release and excited Dep MNs in quiescent preparations to produce resistance reflexes. This result suggests that antidromic excitation of these afferents at the beginning of the Lev burst in closed loop will prevent resistance reflexes that would interfere with the leg rise. In open loop, antidromic activity was weaker and more evenly distributed throughout the burst duration.

Title: Experimental and theoretical studies concerning an inter-segmental neuronal network controlling locomotion, and application of the results to locomotion with more than six legs

Authors: *M. J. GRABOWSKA, T. I. TÓTH, A. BÜSCHGES, A. BORGMANN, S. DAUN-GRUHN
Animal Physiol., Univ. of Cologne, Cologne, Germany

Abstract: In legged animals, inter-segmental coordination is required to perform locomotion. This is true for insects, e.g. the stick insect, as well as for invertebrates with more than six walking legs, like crabs and crayfish. In all of these animals, inter-segmental neural connections, as well as local sensory signals, are assumed to play a crucial role (Barnes 1974; Sillar, Clarac and Bush 1987; Cruse and Müller 1986; Clarac 1982). Daun-Gruhn and Tóth (2011) designed an inter-segmental network model to mimic some basic aspects of the inter-leg coordination in the stick insect. As an initial step, they focused on the local segmental networks with central pattern generators (CPG) as their core elements that generate rhythmic activity of the thoraco-coxal motoneuron pools, i.e. the protractor-retractor neuro-muscular system (ThC-CPG), in three adjacent segments. The three ipsilateral segmental ThC-CPGs are connected rostro-caudally, and the connections are modulated by excitatory sensory signals from anterior segments and by local inhibitory ones from the same segment. It was found that, in order to obtain smooth transitions

between different coordination patterns, a neural connection from the meta-thoracic CPG to the pro-thoracic had to be assumed, making the connections cyclic. We present experimental evidence for this caudo-rostral inter-segmental neural connection in the stick insect. A walking hind leg was found to be able to entrain a pilocarpine-induced rhythm in the ThC-CPG of the pro-thoracic segment. Hence, the related assumption in the model could be confirmed. In addition, we used this model to test whether it could serve as basic module of an inter-segmental neuronal control network of n-legged (n>6) walking animals. To this end, we extended the model by additional segmental CPGs that had the same properties as the existing ones in the original model. We changed phase relations between the CPGs by varying appropriate system variables (e.g. excitatory and inhibitory sensory inputs), or model parameters (e.g. drive to the CPGs). In this way, we could simulate different coordination patterns, as well as transitions between them, that were similar to those observed in 8-legged animals. These results show that the inter-segmental network model, which is supported by experimental data gathered in the stick insect walking system, might serve as a fundamental module to simulate walking in animals with more than six legs.

Title: Electrical coupling influences the synchrony and pattern of spiking in identified peptidergic neurons

Authors: *C. C. BEEKHARRY, N. S. MAGOSKI
Biomed. and Mol. Sci., Queen's Univ., Kingston, ON, Canada

Abstract: Electrically-coupled neurons communicate through an assembly of channels called gap junctions, which connect one cell to another and mediate the transfer of metabolites and current. Coinciding with an ability to permit current flow, often in both directions, electrical coupling is involved in the synchronization and rapid transmission of action potentials within

circuits. In turn, this is believed to influence the bursting pattern and firing frequency of coupled neurons. The present study concerns an electrically-coupled two-neuron circuit within the CNS of the gastropod mollusc, Lymnaea stagnalis. The two neurons, designated Visceral Dorsal 1 (VD1) and Right Parietal Dorsal 2 (RPD2) are readily identifiable, peptidergic, strongly-coupled, and innervate the heart. Using dual sharp-electrode current-clamp recording in isolated brain preparations, we investigated how the disruption of electrical coupling influences action potential firing frequency and synchrony within the VD1/RPD2 network. Initially, axotomy was performed by cutting the connective linking VD1 and RPD2. This completely uncoupled the neurons, but only disrupted the firing rate and pattern of RPD2, consistent with prior reports indicating VD1 is the master and RPD2 is the follower in the network. Neurons were also exposed to gap junction blockers, assayed by hyperpolarizing current injection into either VD1 or RPD2 to determine the coupling coefficient before and after drug application. The addition of niflumic acid (NFA) and 5-nitro-2-(3-phenylpropylamino) benzoic acid (NPPB) significantly decreased the coupling coefficient, whereas meclofenamic acid, quinine, α- glycyrrhetinic acid, and carbenoxolone had no effect. However, although NFA and NPPB significantly lowered coupling, the drugs typically did not desynchronize the VD1/RPD2 network. Nevertheless, there were instances where NFA and NPPB resulted in RPD2 inappropriately exciting VD1 and causing it to temporarily fire out of sync. Moreover, in the presence of these uncoupling agents, supressing the activity of VD1 with hyperpolarizing current revealed a distinct firing pattern and frequency in RPD2, with some similarities to the pattern seen following axotomy. This suggests that in a continuously active or bursting network, consisting of a master/follower arrangement, strong electrical coupling appears to be a requirement for the network to maintain both synchronous output and rhythm. Perhaps in Lymnaea, such output influences cardiovascular function and heart rate.

Abstract: Spinal central pattern generators are a challenge to unravel due to the multitude of cell types which may be playing critically different roles yet operating simultaneously. The zebrafish larva offers the advantage of a small, transparent, genetically tractable organism with a vertebrate organization with which to deconstruct the function of particular cell types during locomotion. Glycinergic interneurons have been shown in mammals to play a critical role in left-right alternation as well as in modulating locomotor speed. Multiple glycinergic spinal interneuron classes in the zebrafish are anatomically characterized, and some have known mammalian homologues, but less is known about their functional roles. We aim to genetically target specific interneuron types by performing gene trap and enhancer trap screens and identifying specific spinal expression in glycinergic cell classes. We have chosen two stimuli to evoke locomotion at different speeds: slow locomotion during the optomotor response, and fast locomotion evoked by escape-inducing stimuli. Utilizing these two stimuli we assess the participation of different spinal cell types in the slow or fast locomotor circuits. Our approach combines two-photon *in vivo* calcium imaging of genetically-encoded GCaMP calcium indicators with fictive locomotion to record neuronal activity while the circuit is active. By combining genetic access to specific cell classes, calcium imaging, and recordings of fictive locomotion, we can investigate the selective recruitment of glycinergic cells for different speeds of locomotion.

Title: Organization of the descending locomotor drive from the mesencephalic locomotor region to reticulospinal neurons in salamanders

Authors: *D. RYCZKO[1,2], F. AUCLAIR[1], J.-M. CABELGUEN[3], R. DUBUC[1,2]

Dis. Team, Bordeaux, France

Abstract: In salamanders as in other vertebrates, the Mesencephalic Locomotor Region (MLR) finely controls forward locomotion (Cabelguen et al 2003 J Neurosci 23:2434-9). However the mechanisms by which the MLR controls locomotion in salamanders are not known. Here we examined the anatomy and physiology of MLR outputs to the reticular formation (RF) in the salamander Notophthalmus viridescens, with special reference to the reticulospinal (RS) system known to receive MLR inputs in other species. Tracer injections in the hindbrain RF coupled with immunofluorescence against choline acetyltransferase (ChAT) revealed double-labelled cells in the laterodorsal tegmental nucleus (LDT) that were located in the MLR. ChAT-negative cells located in close proximity to the LDT were found to project to the RF as well. We then recorded intracellularly the activity of reticular cells in a semi-intact preparation in which the brain is exposed and the body is left intact and free to move. Trains of unilateral MLR electrical stimulation elicited alternating limb movements together with spiking activity in reticular cells. Spiking and stepping frequencies were positively correlated with the intensity of MLR stimulation. Single shocks applied to the MLR evoked excitatory synaptic responses in reticular cells. We confirmed that MLR stimulation activated RS neurons by using calcium (Ca2+) imaging of the RS cells of the middle and inferior reticular nuclei retrogradely labelled from a Ca2+ green dextran injection in the spinal cord. Trains of unilateral MLR stimulation elicited bilateral Ca2+ increase in RS cells. Again, MLR stimulation intensity finely controlled RS Ca2+ responses. We explored the contribution of glutamatergic (Glu) and cholinergic (Ach) neurotransmission in these responses. Bath-applied Glu antagonists (CNQX + AP5) reduced RS responses evoked by trains of MLR stimulation. Local microinjections of glutamate onto RS neurons precisely controlled RS responses. Microinjections of Glu antagonists onto RS neurons decreased RS responses elicited by trains of MLR stimulation. Furthermore, bath-application of the acetylcholinesterase inhibitor eserine increased the RS responses elicited by trains of MLR stimulation and microinjections of Ach onto RS neurons elicited Ca2+ responses, though smaller than those elicited by glutamate. The anatomical and physiological organization of this descending locomotor drive seems to be strikingly similar to that previously reported in lamprey.

We thus suggest that the dual Ach/Glu drive from the MLR to RS cells could constitute a blueprint of the locomotor drive in vertebrates.

Title: The anatomy and physiology of the diffuse chemosensory system in the sea lamprey

Authors: *G. DAGHFOUS[1,2], F. BLUMENTHAL[1], F. AUCLAIR[1], M. MANSOURI[1], B. ZIELINSKI[3], R. DUBUC[1,2]
[1]Groupe de Recherche sur le Systeme Nerveux Central, Dept. of Neurosci., Univ. Sci., Univ. of Windsor, Windsor, ON, Canada

Abstract: In addition to the olfactory and gustatory systems, vertebrates possess another chemosensory system, the diffuse chemosensory system. Its receptors, the so-called “solitary chemosensory cells” (SCCs), are specialized epithelial cells that are associated with a nerve fiber and share some features with taste receptor cells. Solitary chemosensory cells have been reported in all vertebrate lineages examined so far, including mammals. It was shown that their localization vary widely from one species to the other. For instance, in fish, SCCs are present in the oropharynx, gills and skin, whereas they seem to be restricted to the airways in mammals. Physiological studies pointed out that their function differs as well. In fish, SSCs serve as food or predator detectors, while in mammals SCCs appear to act as toxins detectors. Consequently, despite a wide phylogenetic distribution, the diffuse chemosensory system is still poorly

understood. Knowledge of its anatomy and physiology in lampreys, the most basal lineage of vertebrates, can shed light on this problem. Putative SCCs, referred to as “oligovillous cells”, have already been reported on the body surface and on cutaneous finger-like extensions named “papillae” of brook lampreys [Whitear and Lane, 1983, J Zool Lond]. Our anatomical investigation, in the sea lamprey, revealed the presence of papillae around the oral hood, on the dorsal fins, and on the posterior rim of the gill pores. For the present report, investigation was limited to the gill papillae. Extracellular recordings from individual gill papillae showed multiunitary action potentials in response to chemical stimulation, confirming that they contain chemosensory cells. Among the substances tested, food-related stimuli (trout washing water and amino acids) produced the most potent responses. Examination of the epidermal surface of the papillae under environmental and conventional SEM showed the presence of tufts of several microvilli protruding from cell apices surrounded by epidermal cells. Their location and morphology support a chemosensory role. Immunofluorescence directed against acetylated tubulin, a reliable marker of nerve fibers in the peripheral nervous system of lampreys, demonstrated that gill papillae are well innervated structures. *In vivo* injections of axonal tracers in the gill papillae labeled glossopharyngeal (IX) and vagal (X) ganglion cells with central projections forming an ascending limb that reached the mesopontine border area and a descending limb that reached the rostral spinal cord. Our study constitutes the first step in the characterization of the diffuse chemosensory system in lampreys.

Title: ChannelRhodopsin mediated mapping of CerebroSpinal Fluid Contacting Neuron connectivity in the zebrafish spinal cord

Authors: *J. HUBBARD, C. STOKES, S. NUNES-FIGUEIREDO, C. WYART
Inst. Du Cerveau Et De La Moelle Epiniere, Paris, France

Abstract: Locomotion in vertebrates relies on central pattern generators (CPGs) located in the ventral spinal cord. While most sensory information is thought to project on the dorsal spinal cord, CerebroSpinal Fluid contacting neurons (CSF-cNs) exhibit the morphology of sensory cells in the ventral spinal cord. CSF-cNs are specialized GABAergic neurons which protrude a ciliated brush into the central canal. Optogenetic activation of CSF-cNs can modulate swimming behavior in larval zebrafish, suggesting these cells signal to elements of the CPGs (Wyart et al., 2009). However, to date the connectivity pattern of CSF-cNs remains a mystery. Here we combine fluorescence-guided patch clamp of identified spinal neurons and optogenetic activation of CSF-cNs *in vivo* to uncover neuronal cell types receiving monosynaptic input from CSF-cNs in the spinal cord. Taking advantage of a library of transgenic lines, we record from spinal neuron subtypes with identified morphology, genetic markers and neurotransmitter phenotype. A short pulse of blue light leading to the ChannelRhodopsin2 (ChR2) mediated activation of CSF-cNs reveals the existence of monosynaptic connectivity from CSF-cNs to the recorded cells. In order to restrain the activation to single cells, we have developed optical setups to spatially pattern the blue light in 2D with Digital Mirror Devices and in 3D with Digital Holography. We show that CSF-cNs exhibit redundant and diverse patterns of neuronal innervation, suggesting that subtypes of CSF-cNs preferentially target distinct classes of spinal neurons. Altogether our work reveals part of the functional connectivity diagram of spinal CSF-cNs and provides critical insight on how these neurons can modulate locomotor activity.

Title: Effect on intrinsic bursting on restoration of rhythmic activity in respiratory network

Authors: *N. TOPORIKOVA[1], N. MELLEN[2]
[1]BIology, Washington and Lee Univ., Lexington, VA; [2]Univ. of Louisville, Louisville, KY

Abstract: Rhythmic inspiratory movement of a diaphragm is initiated by neuronal activity of the pre-Botzinger(pre-BotC) complex in ventrolateral medulla. This rhythm is remarkably stable and capable of restoring itself after physiological or pharmacological perturbations. If excitatory

connections among pre-BotC neurons are blocked, the rhythmic respiratory output ceases. However in this condition of synaptic block a small fraction of neurons still produce rhythmic bursting. It is currently unclear if these intrinsic bursting properties are relevant to generation or maintenance of respiratory rhythm generation. In this computational study we tested the effect of intrinsic neuronal properties on restoration and maintenance of transient disturbance in synaptic connectivity. We conducted a series of numerical experiments with several types of network connectivities and varying fractions of intrinsic bursters to compare how fast such networks can fully recover after brief perturbation. Our simulation shows that networks with larger fractions of pacemakers recovers faster from transient synaptic blockade. These results indicate a possible role of intrinsic bursters in restoring respiratory rhythmicity after brief perturbation.

Title: Network properties underlying vocal production in the African clawed frog, Xenopus laevis

Authors: K. LAWTON, J. PERRY, *E. ZORNIK
Biol., Reed Col., Portland, OR

Abstract: Central pattern generators (CPGs) are ubiquitous self-sustaining circuits crucial for the production of rhythmic motor behaviors. The diversity of cell types and network connections provide both precision and flexibility in behavior. Investigations of many CPGs controlling both vertebrate and invertebrate behaviors have elucidated general functional principles across neuronal circuits. The male advertisement call in the frog *Xenopus laevis*, is a powerful model for understanding vertebrate behaviors because the active CPG can be studied *in vitro* in a "singing brain in a dish". Xenopus calls are produced by a two-part CPG: 1) cranial motor nucleus IX-X (n.IX-X) containing motor neurons that project to the larynx and 2) the dorsal tegmental area of the medulla (DTAM) which contains neurons that generate the fast trills: fast trill neurons (FTNs). Two major lines of evidence suggest that an efferent motor copy from n.IX-X is necessary for normal FTN function. First, transections between n.IX-X and DTAM caused FTNs to fire with a variable pattern and faster frequency. Second, blockade of motor neurons (by

backfilling with the intracellular Na^+ channel blocker QX-314) also disrupted normal FTN spiking rates in the functioning circuit. Together, we conclude that an efferent copy from n.IX-X motor neurons to DTAM regulates FTN firing. No direct anatomical connection from n.IX-X MNs to DTAM has been observed, suggesting the existence of an intervening interneuron. Electrical stimulation of the laryngeal motor nerve produced inhibition in the majority of the recorded FTNs. Because motor neurons are cholinergic, we predicted the connection from n.IX-X to DTAM may be mediated via excitatory acetylcholine receptors. Low concentrations (1 – 10 μM) of the nAChR blocker tubocurarine altered fast trill rates. Higher concentrations blocked song production, but induced fast bursting of FTNs as observed during QX-314 and n.IX-X transections. Together results suggest that n.IX-X motor neurons are providing synchronizing inputs to DTAM neurons via activation of nAChR-expressing n.IX-X interneurons.

Title: Computational modeling and qualitative analysis of spinal circuits underlying locomotor pattern generation and frequency-dependent left-right coordination

Authors: ***B. BACAK**[1], Y. MOLKOV[2], I. RYBAK[1]
[1]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Mathematical Sci., Indiana Univ. - Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: Coordination between left and right neural activities in the spinal cord during locomotion is controlled by commissural interneurons (CINs). Several CIN types have been genetically identified, including the excitatory V3 and excitatory and inhibitory V0 types. Talpalar et al. (2013) reported that genetic elimination of the V0 CINs caused switching from a normal left-right alternating pattern of motor activity to a left-right synchronized “hopping” pattern. Furthermore, ablation of only the inhibitory V0 neurons ($V0_D$ subtype) resulted in a lack of left-right alternation at low locomotor frequencies and preservation of this alternation at high frequencies, whereas selective ablation of the excitatory V0 neurons ($V0_V$ subtype) maintained

the left-right alternation at low locomotor frequencies and switched the motor output to a left-right synchronized ("hopping") pattern at high frequencies. To explain the above findings we developed a simplified mathematical model of neural circuits consisting of four pacemaker neurons representing left and right flexor and left and right extensor half-centers interacting via the commissural pathways representing V3, $V0_D$, and $V0_V$ CINs. The “locomotor” frequency in the model was controlled by a parameter defining the excitability of neurons (via the leak reversal potentials) and commissural pathways, whose changes represented the corresponding changes induced by changing the concentration of N-methyl-D-aspartate (NMDA) applied in to control the locomotor frequency in the isolated rodent spinal cord preparations. The model demonstrated: (1) a typical left-right alternating pattern under control conditions; (2) switching to a synchronized hopping activity at any frequency after removing commissural connections representing both V0 ($V0_D$ and $V0_V$) neurons; (3) a synchronized pattern at low frequencies with alternation at high frequencies after removing commissural connections representing $V0_D$ neurons; (4) an alternating pattern at low frequencies with synchronized hopping at high frequencies after removing commissural connections representing $V0_V$ neurons. We used bifurcation and fast-slow decomposition methods to analyze the behavior of this network in the above states/regimes and transitions between them. The model reproduced a series of experimental phenomena and generated multiple predictions available to experimental testing.

Title: Computational modeling of neural circuits in the mammalian spinal cord involved in left-right coordination of neural activity during locomotion

Authors: ***N. A. SHEVTSOVA**[1], A. E. TALPALAR[2], S. N. MARKIN[1], R. M. HARRIS-WARRICK[3], O. KIEHN[2], I. A. RYBAK[1]

Abstract: Left-right interactions in the spinal cord are mediated by the commissural interneurons (CINs) whose axons cross the midline and affect neural circuits on the contralateral side of the cord. Several types of CINs have been genetically identified, including the excitatory V3 CINs and the inhibitory ($V0_D$) and excitatory ($V0_V$) V0 CINs. Talpalar et al. (2013) have recently demonstrated that: (a) removal of both V0 CIN types leads to a left-right synchronized, "hopping" pattern at all locomotor frequencies; (b) selective ablation of the excitatory $V0_V$ CINs maintains alternation at low frequencies but switches to synchronized activity at high frequencies; (c) ablation of only the inhibitory $V0_D$ CINs leads to a lack of left–right alternation at low frequencies, but maintains alternation at high frequencies. The ipsilaterally projecting V2a interneurons are recruited with the increasing locomotor speed (Zhong et al. 2011) and are necessary for left-right alternation at high frequencies (Crone et al. 2008, 2009). Our objective was to construct a computational model of bilaterally interacting central pattern generators (CPGs) that could reproduce and explain the above findings. In our model, the CPG on each side of the cord consisted of flexor and extensor half-centers. Each neural population consisted of 50-200 neurons modeled in the Hodgkin-Huxley style. The rhythmic locomotor activity was generated by an intrinsic neural mechanism involving the persistent sodium current present in CPG neurons. The left-right coordination was dependent on the balance between the three CIN pathways: a V3-mediated pathway that supported left-right synchronization, and $V0_D$- and $V0_V$-mediated pathways that supported left-right alternation. The activity of the inhibitory $V0_D$ CINs was driven by the ipsilateral flexor half-center. The activity of $V0_V$ neurons was mediated by the ipsilateral V2a neurons recruited with the increasing locomotor speed. The model demonstrates: (1) a left-right alternating pattern under control conditions; (2) a synchronized hopping pattern at any frequency after removing both V0 populations; (3) a synchronized pattern at low frequencies with alternation at high frequencies after removing the $V0_D$ populations; (4) an alternating pattern at low frequencies with synchronized hopping at high frequencies after removing either $V0_V$ or V2a populations. The model closely reproduces multiple experimental data, suggests the organization of commissural interactions in the spinal cord defining the left-right alternation at different locomotor speeds, and generates predictions for future experimental studies.

Title: Synaptic modulation of spinal motoneurons during locomotor-like rhythmic activity in the alpha-chimaerin knockout mouse *in vitro*

Authors: *H. NISHIMARU[1], R. KOBAYASHI[2,3], S. ITOHARA[5], T. IWASATO[6,4]

Abstract: In the developing mammalian spinal cord, tyrosine kinase receptor EphA4 is expressed on the tip of the extending axon of a population of ipsilaterally projecting neurons and its ligand ephrinB3 is localized in the midline. The interaction of these two molecules functions as a barrier preventing EphA4+ axons from crossing the midline. Deletion of the EphA4 or its downstream-signaling molecule alpha-chimaerin causes aberrant midline-crossing of these ipsilateral-projecting axons in the spinal cord and leads to a hopping gait in mice (Kullander et al., 2003, Iwasato et al., 2007). We have recently shown that in mutants in which these molecules were selectively deleted from excitatory vesicular-glutamate-tranporter-type-2-positive neurons, a similar hopping gait was observed indicating that the alteration of excitatory connections in the spinal circuit is one of the main causes of the hopping locomotor phenotype (Borgius et al. 2014). In this study we examined the synaptic modulation of lumbar motoneurons (MNs) during drug-induced locomotor-like rhythmic activity in the isolated spinal cord preparation taken from alpha-chimaerin knockout (Chn1-KO) neonates. Similar to wildtype MNs, membrane oscillation of an individual Chn1-KO L2-flexor-related-MN was time-locked with the ipsilateral flexor activity but not with that of the contralateral side indicating that it is unlikely that the firing pattern of Chn1-KO MNs is shaped by direct synaptic inputs from the contralateral network. Furthermore, we estimated the instantaneous frequency of excitatory and inhibitory synaptic inputs during the rhythmic activity from the membrane voltage trace based on the Ornstein−Uhlenbeck model (Kobayashi et. al. 2011). Our estimation showed that MNs were modulated by balanced excitatory and inhibitory synaptic inputs during the locomotor activity. These preliminary results suggest that Chn1-KO MNs are synaptically modulated in a similar way to wildtype MNs during locomotion and alteration of the connections between the bilateral

premotor networks may be responsible for the hopping gait in the EphA4 - alpha-chimaerin signaling mutants.

Title: Corollary discharge informs cranial motor systems about locomotor activity

Authors: R. BANCHI, S. HÄNZI, H. STRAKA, *B. P. CHAGNAUD
Dept. of Biol. II, Ludwig Maximilians Univ., Planegg-Martinsried, Germany

Abstract: Corollary motor discharges are traditionally considered as predictors of self-generated sensory inputs. By interfering with the central processing, motor efference copies are able to counter unwanted consequences of an animal's own actions. In addition, intrinsic signals, generated during locomotion, serve as prospective substrate for assisting self-motion derived sensory feedback by directly activating image-stabilizing compensatory eye movements. The direct coupling between the spinal locomotor and the extraocular motor system opens the possibility that other brainstem motor systems are also influenced by intrinsic spinal efference copies during locomotion. Here, we studied in Xenopus laevis the impact of locomotor corollary discharge on the trigeminal motor system, which controls a number of cranial muscular elements in the rostral head region, including the motility of mechanosensory appendages. Pre-metamorphic tadpoles were used to monitor the movements of the bilateral pair of mobile rod-like tentacles, located at the corner of the mouth during locomotor activity. Free undulatory swimming caused a tonic lateral deflection of both tentacles that lasted throughout the entire locomotor event. Head-fixed semi-intact preparations of larval Xenopus with intact sensory appendages and isolated brainstem/spinal cord were used for quantitative video analysis of tentacle motion dynamics and trajectory during fictive locomotor episodes. In the absence of swimming-related sensory inputs, the tentacle motion exhibited a stereotyped motion pattern

with a reliability that increased with swimming strength. Tract-tracing experiments demonstrated a trigeminal nerve innervation of the single tentacle muscle and outlined a specific cluster of motoneurons in rhombomere 2 and 3. Multiple-unit recordings of the tentacle nerve close to the muscular insertion during fictive swimming revealed a tonic trigeminal motor discharge that closely coincided with the duration of the entire locomotor event. The clear phase-locking of the activity in some trigeminal motoneurons with the rhythmic locomotor commands, suggests a spinal origin of the corollary discharge. Potential consequences of the tentacle retraction during swimming include prevention of reafferent stimulation of touch-receptive Merkel cells and reduction of the hydrodynamic drag caused by extended appendages. The influence of spinal corollary activity on brainstem motor systems appears to be a general feature that ensures spatio-dynamic appropriate tuning of all motor effectors during locomotion as well as subtractive influences on reafferent sensory signals.

Title: Developmental modifications of premotor excitatory drive match changes in motoneuron properties

Authors: ***C. M. VANDUNK**, S. KISHORE, D. L. MCLEAN
Neurobio., Northwestern Univ., Evanston, IL

Abstract: The first behavior zebrafish embryos produce is spontaneous ‘coiling’, involving bends of the entire body. This behavior is generated by spinal circuits that ultimately control fast escapes in larvae after they hatch. During this period, the earliest born axial ‘primary’ motoneurons (pMNs) migrate dorsally in the spinal cord and nearly double in size, resulting in substantial decreases in excitability. One question that arises is how the early premotor elements responsible for driving movements adjust to these changes to allow for continued expression of

motor behavior through life. Here, we have focused on changes in a major source of premotor excitatory drive in all vertebrates, which arises from Chx10-positive V2a neurons. Using *in vivo* time-lapse imaging of stochastically-labeled V2a cells in a transgenic line labeling the motoneuron pool, we find that the earliest born V2a cells, which will ultimately occupy the dorsal-most positions in the larval spinal cord (dV2a), are initially ventrally located. At this early embryonic stage, putative connections to pMNs at the same ventral location arise from en passant synapses along the main axon. As dV2as and pMNs migrate dorsally during development, this initial contact is apparently maintained locally by secondary axonal branching from the initial site of contact with the main axon. Next, to examine the potential functional impact of this maintained connection, we performed whole-cell voltage clamp recordings of excitatory drive to pMNs during 'fictive' swimming in 2-day old embryos and 4-day old larvae. At both stages, pMNs received phasic excitation driving the cyclical bursts of motor activity and tonic excitation providing a background source of depolarizing drive. However, there was a substantial increase in both phasic and tonic drive commensurate with a decrease in input resistance (Rin) from day 2 to 4, consistent with the idea that synaptic inputs compensate for decreases in cellular excitability to maintain functional output. To examine the contribution of cellular excitability to this process, we are using the bacterial voltage-gated sodium channel, NaChBac, and the inward-rectifying potassium channel, Kir2.1, to provide genetically-targeted increases and decreases in cell excitability, respectively. Whole-cell patch clamp recordings from individual pMNs expressing these constructs have confirmed their utility. Our work thus suggests there are changes in dV2a morphology and excitatory drive that compensate for changes in pMN location, size and Rin, and we are now in a position to examine the contribution of cell autonomous features, like excitability, to this process.

Title: Investigating weakly coupled oscillators in the stick insect locomotor system

Authors: A. BORGMANN, C. MANTZIARIS, N. ROSJAT, S. GRUHN, *A. BUSCHGES
Zoology/Animal Physiol, Univ. Koln, Koln, Germany

Abstract: Walking movements result from a complex interplay of central pattern generating networks (CPGs), local sensory feedback about movements and forces generated in the legs and coordinating signals from neighboring limbs. In the stick insect, the antagonistic muscles of each leg joint are driven by one CPG that can be activated by the muscarinic acetylcholine agonist pilocarpine (Büschges et al. 1995). Sensory information plays a crucial role in coordinating the different CPGs of one leg and appears to play a major role in inter-segmental coordination of the different legs as well. However, hardly anything is known about the role and contribution of intersegmental interactions between CPG networks. Preliminary evidence (Büschges et al. 1995) suggested some intersegmental influence between CPGs. In this study we aimed to investigate in more detail the influences between the Coxa trochanter (CTh-) joint CPGs of the three thoracic segments. We analyzed the coordination of the CTh-joint CPGs in and between the three thoracic segmental ganglia in the completely deafferented nervous system of the stick insect, Carausius morosus. Rhythmic motor activity was induced by bath application of pilocarpine. Activity of ThC-motoneuron pools supplying the levator and depressor trochanteris muscles of a leg was recorded by means of extracellular electrodes from lateral nerves C1 and/or C2 in each thoracic ganglion. We used a new method for analyzing time series of several rhythmic systems in order to (i) identify time intervals of coupling between the MN-output of the different CTh-joint CPGs, (ii) provide a measure for coupling strength and (iii) determine if coupling was present with preferred phase relations between the different CTh-joint CPGs. We first focused on contralateral coordination between intra-segmental CPGs of the same ganglion. Phase analysis revealed a weak intra-segmental coupling for each thoracic ganglion. Interestingly, the intra-segmental coordination was affected by inter-segmental signals. This was revealed by preparations in which rhythmicity in a chain of two or three rhythmically segmental ganglia was studied. Our results clearly indicate for the first time that there exist weak intra- and intersegmental neural coupling between the CTh-CPGs in the stick insect thoracic nerve cord.

Title: Using dynamic causal modeling in the study of the stick insect locomotor system

Authors: *N. ROSJAT, T. TÓTH, C. MANTZIARIS, A. BORGMANN, S. GRUHN
Animal Physiol., Univ. of Cologne, Cologne, Germany

Abstract: Walking results from a complex interplay of central pattern generating networks (CPGs), local sensory feedback signalizing position, velocity and forces generated in the legs, and coordinating signals from neighboring limbs. In the stick insect, the neural basis of inter-segmental coordination, and the precise effects of sensory information on the central networks in establishing coordinated motor output are largely unknown. The antagonistic muscles of each leg joint are driven by one CPG that can be activated by the muscarinic acetylcholine agonist pilocarpine. Sensory information plays a crucial role in coordinating the different CPGs of one leg and appears to play a major role in inter-segmental coordination of the different legs, too. However, precious little is known about the interactions between the different CPG networks. Büschges et al. 1995 could show that there appear to be episodes when CPGs of different segments tended to be active in phase. Here, we aimed to investigate potential coupling between CPGs at the CTr-joint in the different segments, in more detail. To uncover putative coordination in and between the three thoracic segmental ganglia we analyzed the activity in the completely deafferented nervous system of the stick insect, Carausius Morosus. Rhythmic motor activity was induced by bath application of the muscarinic receptor agonist pilocarpine. The activity of the motoneuron pool supplying the depressor trochanteris muscles of a leg was recorded by means of extracellular electrodes from the lateral nerves C2 in each thoracic ganglion. We used dynamic causal modeling (DCM) to investigate the coupling structure and strength of two coupled ganglions. We first focused on the influence of different pilocarpine concentrations on inter-segmental coupling strengths on the ipsilateral side. The analysis revealed that anterior segments were stronger coupled to posterior segments when the pilocarpine concentration has been increased. Then, we integrated the contralateral side into our model. We set up different coupling schemes for DCM and compared them using Bayesian model selection methods. There was a clear preference to models with lateral connections in each segment and ipsilateral connections on both sides to all other tested models. DCM for preparations in which the connectives between two segmental ganglia were cut showed a clearly decrease in coupling strength between the CPGs of different ganglions. Our results show a high probability for the existence of ipsilateral intra- and lateral inter-segmental coupling between the CPGs controlling the coxa-trochanteral joint musculature in the stick insect thoracic nerve cord.

Title: Reconstructing the connectivity of the larval zebrafish spinal cord

Authors: ***F. SVARA**, J. KORNFELD, J. BOLLMANN, W. DENK
Max Planck Inst. For Med. Res., Heidelberg, Germany

Abstract: Motoneurons in the vertebrate spinal cord can be activated both by interneurons of spinal central pattern generator (CPG) circuits and by direct inputs from the hindbrain reticulospinal (RS) system. While the spinal cord can show sustained neuronal activity without inputs from the brain, it is the brain that selects which patterns are produced, as appropriate for the animal in a given situation. In the larval zebrafish brain, the dominant pathway that sends commands to the spinal cord is the RS system in the hindbrain. How exactly different patterns are selected is not clear, not least because it is unknown how exactly the brain is wired to its spinal cord targets. With 3D Electron Microscopy, and more specifically Serial Block-Face Electron Microscopy (SBEM), that question can be addressed directly. In the larval zebrafish, different patterns of tail motion can be parametrized by bend amplitude and beat frequency, where low-amplitude, low frequency swims are used when swimming slowly and high-amplitude, high-frequency swims are used when swimming fast. Motoneurons and spinal interneurons have been shown to be activated following different principles: Increasing numbers of motoneurons are activated with increasing speed, progressing from small ventral to large dorsal motoneurons. In the case of spinal interneurons, there is a specificity of different cells for different movement speeds, where a cell's activation depends on the interneuron's dorso-ventral position. To clarify how these activity patterns are selected as a function of descending commands, we reconstructed the connectivity between motoneurons and their presynaptic partners, i.e. RS axons, excitatory (CiD, MCoD) and inhibitory (CiA, CoBL) spinal interneurons.

We asked whether motoneuron recruitment principles can be explained by specific RS axons wiring to specific motoneuron subsets or whether it is mostly governed by motoneuron-intrinsic properties, with unspecific wiring. Further, the observed recruitment principles of excitatory interneurons could either lead to the recruitment of appropriate motoneuron pools through an unspecific interneuron to motoneuron wiring scheme, with specific cell-intrinsic and synaptic properties, or through selective wiring between subsets of interneurons and motoneurons. Our data can help to explain the mechanisms by which the brain activates distinct networks in the spinal cord that generate the motor patterns required for the animal's survival and opens up new questions about the physiology and connectivity of spinal neuronal networks.

Title: Investigating the cellular basis of the differential recruitment of motoneurons in the *Drosophila* larval locomotor system

Authors: *M. ZWART[1,2], S. R. PULVER[1], R. D. FETTER[1], A. CARDONA[1], M. LANDGRAF[2]
[1]HHMI Janelia Farm, Ashburn, VA; [2]Dept. of Zoology, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: The precise execution of behaviors requires the generation of the appropriate patterns of motoneuron activity. In the locomotor system of *Drosophila* larvae, the peristaltic waves that underlie crawling are generated by sequential contraction of longitudinal and transverse muscle groups. This sequence of activation is caused by the differential recruitment of the two classes of motoneurons in the CNS that innervate these muscle groups. The mechanisms responsible for such group-specific activity patterns are unknown. There are at least two, not necessarily mutually exclusive, possibilities: first, the two different classes of motoneurons may receive input from different presynaptic interneurons; second, differences in motoneuron recruitment may be due to differences in the intrinsic excitable properties of the two classes of motoneurons.

Here, we describe our progress towards resolving this question. We have taken two approaches: first, EM-based reconstruction of the neural network presynaptic to the class of motoneurons innervating the transverse muscles followed by a comparison to the network presynaptic to motoneurons innervating longitudinal muscles; second, patch clamp recordings of identified motoneurons that are differentially recruited during larval crawling to determine their intrinsic and synaptic properties. Our results delineate the precedence of the connectivity of the neural network ("extrinsic properties") versus the physiology of its constituent neurons ("intrinsic properties") in the generation of patterned neural activity in the *Drosophila* larval locomotor system.

Title: The role of glycinergic inhibition in the locomotor rhythm of the lamprey hindbrain

Authors: *J. T. BUCHANAN, A. A. RASMUSSEN, K. M. KENNEY, J. M. SCHEEL
Marquette Univ., Milwaukee, WI

Abstract: Although it is well-established that the central pattern generator (CPG) for locomotion in vertebrates resides within the spinal cord, we have found that the hindbrain of lamprey also has a locomotor CPG. When isolated from the spinal cord, the last segment of hindbrain is capable of generating rhythmic bursts of action potentials in the spino-occipital (S-O) nerves, which are the efferent nerves of a column of somatic motor neurons that innervate several muscles of the head. Like the spinal cord, the S-O nerves burst with left-right alternation. The goals of the present study were 1) to determine whether the alternating bursting of the hindbrain locomotor CPG is dependent upon glycinergic inhibition as it is in the spinal cord and 2) to identify the target muscles of the S-O motor neurons and the distributions of motor neuron cell bodies within the S-O motor column. To determine whether the alternating bursting of the hindbrain locomotor CPG is dependent upon glycinergic inhibition, we used an *in vitro* hindbrain

preparation that was isolated from the spinal cord by a complete spinal transection midway between the caudal S-O nerve and the first spinal ventral root. Motor activity was elicited by bath application of either D-glutamate or NMDA while recording the S-O nerves on each side of the hindbrain with extracellular suction electrodes. When the glycine receptor antagonist strychnine was bath applied, all 8 preparations in which rhythmic activity was present both before and after strychnine (of 10 total preparations) showed a statistically significant switch from left-right alternation (181 ± 7 deg) to synchronous (358 ± 11 deg) bursting. To identify the target muscles of the S-O motor neurons, a combination of intracellular/extracellular electrophysiology and retrograde/anterograde axon tracing was used. Based on electrophysiology, five head muscles were found to be innervated by the S-O motor neurons. Two of these muscles are rostral representatives of segmental body muscles: the epibranchial and hypobranchial muscles. It was found that up to four segments of these two muscle groups received innervation from the S-O motor neurons. With retrograde tracing, the S-O motor column was found to contain about 300 motor neurons on each side. While the motor neurons to each muscle had distinct locations within the motor column, there was considerable overlap with the motor neurons of other muscles. In conclusion, the locomotor CPG of the hindbrain switches to synchronous bursting in the presence of strychnine, indicating that glycinergic inhibition is required for the alternating left-right pattern of locomotion, similar to findings in the spinal cord.

Title: V3 spinal interneurons are crucial in regulating weight-loading movement

Authors: *H. ZHANG, H. HAMODAT, Y. ZHANG
MEDICAL NEUROSCIENCE, Dalhousie Univ., Halifax, NS, Canada

Abstract: V3 interneurons (INs) are the major excitatory commissural interneurons in the mouse spinal cord. Our previous work has shown that genetic deletion of V3 INs caused the animal to exhibit an unstable and incoherent gait. In order to further understand the functional role of V3 INs in the locomotor circuits, we selectively blocked the synaptic transmission of V3 INs by deleting the expression of vesicular glutamate transporter 2 (VGLUT2). The mutant mice could survive and didn't show obvious behavior defects in the cage. When they were put on a treadmill with various speeds, however, these mutant mice couldn't run faster than 15 cm/s, while wild-type mice could run at a rate of above 60 cm/s. On the other hand, during swimming, the mutant mice could reach the same high speed as wild types. Furthermore, electromyography (EMG) recordings in different hind limb muscles have shown that some extensor muscles, such as gastrocnemius and vastus lateralis muscle, showed little change of activity in mutant mice when they altered from running to climbing or to swimming, while there was a significant increase in the activity of these muscles in control animals under the same condition. These results indicate that V3 INs may be involved in regulating the activity of extensor muscles of the hind limbs in controlling animal's locomotor activity, instead of directly setting the rhythms of limb movement.

Title: Unraveling the leech connectome

Authors: ***J. PIPKIN**, W. B. KRISTAN
Univ. of California At San Diego, La Jolla, CA

Abstract: The medicinal leech is a segmented annelid with 21 stereotyped midbody ganglia each responsible for sensing, communicating with the other ganglia, and producing behavior relevant to the segment it innervates. These ganglia all contain the same complement of approximately

400 neurons. Each neuron possesses a large cell body arranged on the exterior of the ganglion, and a central region of neuropil where the synaptic circuitry is established. To begin unraveling this circuitry, we are applying a connectomic approach relying on serial blockface electron microscopy (SBEM). Here we present data collected from an entire ganglion collected from a smaller but still behaviorally-mature juvenile leech. Within this volume of data, we have segmented several motor neurons and identified the connections between them. With this dataset, we show that we can identify known synapses (identified via previous experiments using intracellular electrophysiology) and that we can begin answering questions about the number and spatial distribution of these synapses in the neuropil.

Title: Neuronal cerebrospinal fluid-contacting cells in lamprey are sensitive to fluid movement

Authors: E. JALALVAND, B. ROBERTSON, *P. WALLEN, S. GRILLNER
Karolinska Inst, Dept Neurosci., Stockholm, Sweden

Abstract: Cerebrospinal fluid-contacting (CSF-c) cells are found in all vertebrates but their function has remained elusive. In the lamprey spinal cord they surround the central canal and have processes passing the gray matter to the lateral margin of the spinal cord. We have recently characterized lamprey CSF-c cells according to their morphology, phenotype, and electrophysiological properties, and identified two distinct types (Jalalvand et al., J Comp Neurol 522:1753-68, 2014). Type 1 cells have a bulb-like ending that protrudes into the central canal and a lateral process that ramifies ventrolaterally and laterally in the gray matter, and that ends in a dense plexus surrounding the mechanosensitive dendrites of edge cells located at the spinal cord margin. Type 1 cells are GABAergic (also somatostatin), have neuronal membrane

properties and express both glutamate and GABA receptors. Type 2 cells, on the other hand, have a flat ending protruding into the central canal and a laterally projecting process that only ramifies at the lateral margin. Type 2 cells do not show active membrane properties, and may represent a type of glia cell. These findings suggest that type 1 CSF-c cells may play a modulatory role by influencing edge cells and thus the locomotor-related sensory feedback (Viana Di Prisco et al., Brain Res 530:161-66, 1990). We here address the question of how type 1 cells are activated. Their bulb-like endings have cilia protruding into the central canal, and it is therefore possible that type 1 cells may sense the movements of the CSF occurring for instance during swimming. Using a longitudinally sliced, isolated preparation of the lamprey spinal cord, we patched CSF-c cells and applied brief pressure pulses via a fluid-filled micropipette close to the cilia. In type 1 cells, a short pressure pulse reliably elicited receptor- or action potentials. The receptor potential amplitude increased with increasing pulse magnitude, and action potentials were evoked with even higher pressure pulse settings. These responses remained after application of GABA and glutamate antagonists, suggesting that they were due to movements of the cilia and not to synaptic input. In contrast, type 2 cells did not show any responses to pressure pulse stimulation. These results suggest that the GABAergic type 1 CSF-c cells in the lamprey spinal cord can be activated by fluid movements in the central canal during body undulations, and thereby in turn regulate the sensitivity of the mechanosensitive dendrites of the edge cells, and thus their movement-related feedback to the locomotor CPG. The type 1 CSF-c cells may also influence the interneuronal network in the gray matter directly.

Title: Membrane resonance influences the frequency of an electrically coupled network

Authors: ***Y. CHEN**, F. NADIM, H. ROTSTEIN
biological department, New Jersey Inst. of Technol., Newark, NJ

Abstract: Neurons often exhibit membrane potential resonance, a maximal voltage response to sinusoidal current inputs at a non-zero frequency (f_{res}). Resonance in individual cells has been implicated in determining the frequency (f_{net}) of the oscillating networks in which they are embedded. The functionality of resonance is still an open question. We examine the hypothesis that f_{net} monotonically changes with f_{res} in electrically coupled networks. We test this hypothesis in a two-cell model network consisting of an oscillator (with endogenous frequency f_O), electrically coupled to a biophysically-inspired linear resonator, for which different attribute of the impedance profile (*f-Z* curve) can be varied independently (Rotstein & Nadim, *J Comput Neuro*, 2014). We find that shifting the resonant frequency of the resonator positively influences f_{net}, and that this effect is enhanced by increasing the maximal impedance of the resonator. The influence of the resonator on the oscillator is independent of oscillator properties, but is enhanced when f_O is larger than f_{res}. We also find that f_{net} remains constant upon changes in the linear resonator parameter values provided the impedance profile remains unchanged. This result implies that the impedance profile, and not the specific details of the resonator, determines the network frequency. We confirm these results using biophysical nonlinear resonator models. To our knowledge, these results are the first direct demonstration of the influence of membrane resonance of non-oscillating neurons on the frequency of an oscillatory network and show an important role for impedance profile of individual neurons in shaping the output of electrically coupled networks. *Figure:* 30 random resonators with same impedance profile (f_{res}=1), but different parameters, coupled with the same oscillator, show the same f_{net}. Shifting the resonance profile of all resonators to f_{res}=1.5 also increases f_{net} in all cases.

Title: Eupnea, tachypnea, and autoresuscitation in a closed-loop respiratory control model

Authors: *C. O. DIEKMAN[1], C. G. WILSON[2], P. J. THOMAS[3]
[1]Dept. of Math. Sci., New Jersey Inst. of Technol., Newark, NJ; [2]Ctr. for Perinatal Biol., Lloma Linda Univ., Lloma Linda, CA; [3]Dept. of Mathematics, Applied Mathematics and Statistics, Case Western Reserve Univ., Cleveland, OH

Abstract: Incorporation of sensory feedback is essential to guide the timing of rhythmic motor processes. How sensory information influences the dynamics of a central pattern generating circuit varies from system to system, and general principles for understanding this aspect of rhythmic motor control are lacking. It has been realized for sometime, however, that the mechanisms underlying rhythm generation in a central circuit when considered in isolation may be different from the mechanisms underlying rhythmicity in the intact organism (Bässler, Biol Cybern 54:65-69, 1986). Here we investigate the mechanisms of rhythmogenesis in a minimal model incorporating a central pattern generator (CPG) in a respiratory control loop, a preliminary version of which was introduced in Diekman et al. (Conf Proc IEEE Eng Med Biol Soc, 2012:6669-72). We show that the closed-loop system has bistability corresponding to coexistence of a eupneic-like breathing rhythm with normal minute ventilation and blood oxygen level, and a tachypneic-like state with pathologically reduced minute ventilation and critically low blood oxygen, consistent with a similar model developed independently in Ben-Tal and Smith (J Theor Biol, 251:480-497, 2008). We show that an artificially imposed bout of hypoxia can cause the system to leave the basin of attraction for the eupneic-like state and enter the basin of attraction for the tachypneic-like state. In addition, we investigate the relationship between rhythms in the intact (closed-loop) and isolated CPG (open-loop) systems, and find that eupneic-like oscillations with similar time courses nevertheless appear to arise from two distinct mechanisms in the open and closed-loop systems. Finally, we show that conductances endogenous to the Butera-Rinzel-Smith model of the respiratory CPG (Butera et al., J Neurophysiol 82:382-397, 1999) can lead to spontaneous autoresuscitation after short or mild bouts of hypoxia.

[4]Physiotherapy, UNIANCHIETA-Jundai, Jundiai, Brazil

Abstract: Motor nervous system interacts with musculoskeletal metabolism. Denervation of peripheral nerves has been associated with skeletal disorders and limited rehabilitation of skeletal system. Preview studies have shown that nerve damage reduces P substance and calcitonin gene-related peptides, also known as neuropeptides that may have a key role on bone healing. In surgical conditions or extensive traumas when a bone defect is critical, implants of synthetic biomaterials have been employed to favour bone growth. Considering that hydroxyapatite implants are widely used in complex injuries associated with peripheral nerve rupture, this study investigated the effects of unilateral sciatic nerve injury on osseointegration after hydroxyapatite implant within a bone defect in rat's tibia. The present study was approved by the ethics committee and all procedures conducted to reduce suffering of animals. Young male wistar rats (n=10) were divided into two groups: the control group having both functioning sciatic nerves (CRT) and an experimental condition for a complete injury of the left sciatic nerve (INJ). All animals were surgically submitted to a bone defect in the left tibia and subsequently filled with hydroxyapatite granules. Housing and handling of animals were standardized for both groups. Two months after the implant, the animals were sacrificed and the samples analyzed by means of histomorphological and radiological analysis. Radiological signs of bone healing were observed in all cases, proving that the hydroxyapatite previously implanted within the bone defect was integrated with the surrounding bone favorably. Histomorphological findings have shown increased bone neoformation adjacent to the hydroxyapatite granules in the CRT group, which

was in minor proportion to the INJ group. The latter have shown predominant connective tissue proliferation in the bone defect, rather than young bone. It may be concluded that osteosynthesis were stimulated by hydroxyapatite within the bone defect and it was further facilitated by peripheral nerve functioning in terms of bone volume and speed of bone formation. These findings suggest that the trophism of peripheral nerves helps bone reconstruction after hydroxyapatite implant within a bone defect. Moreover, a denervation of peripheral nerve may not impede osseointegration or bone growth expected in implants of hydroxyapatite.

Title: Video based behavioural analysis of rodents on the rotarod provides additional parameters to discriminate between drug effects

Authors: *R. WILLEMS, M. MAHIEU, L. VER DONCK
Neurosci., Janssen Res. & Development, A Div. of Janssen Pharmaceutica NV, Beerse, Belgium

Abstract: Impaired motor coordination due to medication can have an important impact on the patient's quality of life. Extrapyramidal motor symptoms, induced by antipsychotic drugs, and muscle relaxant effects of benzodiazepines both disturb coordination of body movements. The rotarod test is widely used to evaluate drug effects on motor coordination in rodents. We have developed an automated version of the rotarod, using image analysis software to identify secondary parameters, such as turnaround behaviour and time on back of the rod. These may help in differentiating side effects of compounds on motor coordination. OBJECTIVE: To compare the effects of the typical antipsychotic haloperidol and the benzodiazepine diazepam on performance in rats and mice on the automated version of the rotarod. METHODS: Male mice (NMRI) and rats (Sprague Dawley) were trained to walk on a rotating rod at constant speed and then tested for baseline performance on the accelerating rotarod. The next day, animals were treated with a dose of haloperidol, diazepam or vehicle, and performance on the rod was determined 30, 60 and 90 min after treatment. RESULTS: In a series of studies in mice and rats, haloperidol showed dose dependent impairment in time on the rod and increased time at the back

of the rod. Time on the rod in mice was restored at 90 min, but time in back was increased. In addition, increased turning behaviour was observed in mice but not in rat. Diazepam impaired time on rod in rats and mice during the 90 min period, however only increased time in back was observed 30 min after treatment. No turning behaviour was seen. CONCLUSION: With automated measurement of rodent behaviour on the rotarod, we are able to define new parameters to assess the performance of rats and mice. Effects of haloperidol differed between rats and mice: i) Time in the back in mice was increased at doses that were without effect on time on rod, wheras both measures were in-line in the rat. ii) In contrast to mice, the turnaround parameter does not appear to be relevant for rats because they are too heavy to turn around. Diazepam revealed no differences between rats and mice. Testing of other pharmacological classes will further evaluate the added value of these additional parameters.

Title: Nerve crush induces a smaller loss of central IA afferent synapses (VGLUT1) on injured motoneurons than complete nerve transection

Authors: *T. M. ROTTERMAN[1], A. DWARAKANATH[2], P. NARDELLI[3], T. C. COPE[3], F. J. ALVAREZ[2]
[1]Physiol., [2]Emory Univ., Atlanta, GA; [3]Wright State Univ., Dayton, OH

Abstract: Peripheral nerve injuries affect nearly one million people annually leaving them with permanent motor deficits, such as a loss in the stretch reflex. After complete nerve transections there is a permanent loss of the central synaptic arbors of IA afferent axons and motor axon recurrent collaterals inside the spinal cord. By difference to the regeneration that occurs peripherally, central changes are permanent. The synaptic connections of Ia afferents with MNs, as defined by vesicular glutamate transporter 1 (VGLUT1), are reduced by 62% on dendrites and 87% on somata of injured MNs after they regenerate and reinnervate muscle. This reduced input explains the loss of stretch-evoked EPSPs in 40% of regenerated MNs and their low amplitude in

the remaining 60%, as well as the reduced connectivity of single IA afferents across the MG motor pool. These morpho-functional changes help to explain the loss of stretch reflexes in rodents and possibly in other species, including humans. In contrast, when the nerve is crushed there is an enhancement in stretch-evoked EPSPs and the stretch reflex is preserved and augmented. We therefore analyzed VGLUT1 inputs on injured MNs after crush and whether GABAergic presynaptic control through terminals expressing the 65 kDa isoform of glutamic acid-decarboxylase (GAD65) was reduced. Adult rats underwent a tibial nerve crush and regenerated from 21 days to 3 months after injury. The medial gastrocnemius (MG) muscle was injected with cholera toxin b (CTb) to retrogradely label the MNs. We did not find significant differences between 21 days and 3 months in coverage of CTb labeled MG MNs by VGLUT1 synapses or the coverage of these synapses by presynaptic GAD65 boutons; therefore data from both ages were pooled together. The results indicate fewer VGLUT1 losses on the cell bodies (41% depletion) and dendrites (10% depletion) of MNs after crush compared to complete nerve transections. Furthermore, the incidence of VGLUT1 synapses covered by GAD65 synapses did not significantly change (range 85-89% of synapses in both control or after nerve crush) although there was a small reduction in the number of GAD65 synapses per VGLUT1 terminal. In control MNs we found on average 2.4±0.4 and 2.8±0.5 GAD65 synapses per VGLUT1 terminal making synaptic contacts respectively on dendrites and cell bodies of MNs. This coverage was reduced by 21-29% after nerve crush. We concluded that there is better preservation of VGLUT1 IA afferents after nerve crush compared to total nerve transection; however the small change in presynaptic inhibition does not seem sufficient to explain the large increase in monosynaptic transmission from stretch sensitive IA afferents.

Title: GAL-160, a peripheral chemoreceptor stimulant, selectively increases hypoglossal nerve and genioglossal muscle activities during unobstructed and obstructed breathing in rats

Authors: *S. M. BABY[1], S. I. MARDIROSIAN[2], T. SCHEMM[2], S. PENG[2], F. J. GOLDER[1], D. E. MACINTYRE[1]
[1]Galleon Pharmaceuticals,Inc, HORSHAM, PA; [2]Chem., Galleon Pharmaceuiticals, Inc, Horsham, PA

Abstract: Peripheral chemoreceptor stimulation preferentially increases genioglossal muscle (GG) inspiratory activity compared to the diaphragm (DIA) (Bruce et al., 1982, J Appl Physiol). Thus, drugs that stimulate the carotid bodies may improve upper airway patency without causing adverse hyperventilation and be useful in the treatment of obstructive sleep apnea (OSA). GAL-160 is an orally active compound that stimulates the carotid body and decreases the frequency and duration of spontaneous obstructive apneas (OAs) in an anesthetized rat model of OSA. We hypothesized that in this model GAL-160 decreases the frequency of OAs by increasing GG electromyogram (EMG) activity during unobstructed breathing and decreases the duration of OAs by increasing the GG response to airway obstruction. We further hypothesized that GAL-160 does not increase diaphragm activity. To test these hypotheses, we recorded hypoglossal and phrenic neurograms from urethane anesthetized, mechanically ventilated rats before and during biphasic infusions of vehicle (saline) or GAL-160 to achieve GAL-160 plasma concentrations between 60-90 ng/ml. Baseline $PaCO_2$ was set at 3 mmHg above the $PaCO_2$ at apneic threshold for each individual animal and maintained at this level throughout the experiment. GAL-160 dose-dependently increased hypoglossal nerve activity (to 67 ± 10% above baseline) without altering phrenic nerve activity (13 ± 8% above baseline). Vehicle infusion had not effect on either neurogram. Genioglossus and diaphragm EMGs were recorded from urethane anesthetized, spontaneously breathing rats. The peak EMG responses to standardized 10 second airway obstructions were quantified before and during a similar biphasic infusion vehicle or GAL-160. GAL-160 increased the peak GG EMG response to obstruction (before GAL-160: 214 ± 74%; after GAL-160: 589 ± 146%; above baseline) without altering the DIA EMG response (before GAL-160: 60 ± 13%; after GAL-160: 79 ± 19%; above baseline). Vehicle had no effect on the EMG response to obstruction. These data support the hypothesis that GAL-160 selectively increases GG inspiratory activity during unobstructed and obstructed breathing and is the likely mechanism whereby GAL-160 is efficacious in the rat model of spontaneous OAs.

Foundation for Physical Therapy

Title: Measuring twitch interpolation and motor evoked potentials in the first dorsal interosseous muscle: Transcranial magnetic stimulation versus peripheral nerve stimulation

Authors: *M. R. RAFFERTY[1], H. E. KIM[1], D. M. CORCOS[3], S. MADHAVAN[1,2]
[1]Grad. Program in Neurosci., [2]Physical Therapy, Univ. of Illinois at Chicago, Chicago, IL; [3]Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL

Abstract: The extent to which neural drive is translated into muscle force is measured with the twitch interpolation technique. The purpose of this study was to investigate the utility of the twitch interpolation technique in the first dorsal interosseous (FDI) muscle, comparing the use of peripheral nerve stimulation (PNS) and transcranial magnetic stimulation (TMS). Fourteen healthy participants (7 male, age 21-33 years) received 28 stimuli with PNS and with TMS while performing isometric finger abduction through a range of contraction strengths. This protocol was repeated 2-14 days later. Superimposed twitch amplitudes were measured, and two muscle activation estimates were compared: central activation ratios (CAR) and voluntary activation (VA). There were no significant differences for any measure between the two testing sessions. Superimposed twitch amplitudes were significantly larger with TMS than with PNS ($p=0.0021$). Thus, muscle activation estimates were larger with PNS compared to TMS ($p<0.0001$). Maximal muscle activation estimates were larger when calculated with the CAR formula than with VA formula, with both stimulation techniques (PNS: $p=0.0005$; TMS: $p=0.0012$). Measuring maximal VA with TMS resulted in low and variable muscle activation estimates ($68.4 \pm 27.5\%$) compared to the other muscle activation estimates (VAPNS = $95.4 \pm 6.5\%$; CARPNS = $99.1 \pm 1.5\%$; CARTMS = $93.4 \pm 6.3\%$). During submaximal contractions at 75% MVC, CARPNS was 96.4% and CARTMS was 87.8%. Motor evoked potentials (MEPS) and M-waves were also analyzed, and shown to be repeatable. In conclusion, the twitch interpolation technique is repeatable in the FDI with both PNS and TMS. The VAPNS, CARPNS, and CARTMS formulas appear to be more appropriate measures of maximal muscle activation than the VATMS formula. However, the collapsed range of activation values above 75% MVC with CARPNS indicate that twitch interpolation with PNS may have limited responsiveness to change in the FDI. Technical, anatomical, and physiological limitations of performing the twitch interpolation technique in the FDI are discussed. Future studies of twitch interpolation in the FDI should explore measurement with TMS rather than PNS and/or focus on EMG outcome measures rather than force.

Title: Circadian modulation of neuromotor control

Authors: *H. O. DE LA IGLESIA[1], J. J. GILE[2], O. JOHNSON[2], B. SMARR[3], H. CHIZECK[2]
[1]Biol., [2]Univ. of Washington, Seattle, WA; [3]UC Berkeley, Berkeley, CA

Abstract: The circadian system controls daily rhythms of behavior and physiology, including locomotor activity and motor-task performance. The master regulation of these rhythms is achieved by a circadian clock located in the suprachiasmatic nucleus of the hypothalamus. Motor tasks are the result of neuronal programs within the primary motor cortex (PMC) but it is not known whether these programs are modulated by the circadian system. Our hypothesis is that similar motor tasks executed at different times of the day may require different motor programs to account for the predictable daily variance introduced by the circadian system. How and where in the brain this variance in motor control manifests itself has not been established. To identify specific primary motor cortex activity patterns associated with specific motor outputs across the 24-hour day we implant electrocorticographic (ECoG) electrodes onto the motor cortex of mice and record brain wave activity during wheel running and rest at different circadian times. Our results indicate a broad-spectrum power increase in the frequency of PMC electrical signals associated with wheel running. Furthermore, the spectrum frequency associated with wheel running changes predictably throughout the circadian cycle. The decoding of motor cortex signals is at the core of the design of brain-machine interfaces (BMIs). These devices decode signals from the conscious brain to drive the execution of specific tasks by a machine, such as an artificial limb. Our work will directly contribute to the understanding of how the motor cortex

decodes circadian time. This knowledge is essential to create BMIs that can operate effectively throughout the 24-hour day to execute tasks by brain-operated artificial devices.

Title: Functional implications of anterograde tracing in the mouse corticospinal tract

Authors: *H. SCHRODER[1], S. TOCHMAFSCHAN[1], B. DENGLER[1], S. ARNDT[2]
[1]Dept. II of Anat. / Neuroanatomy, Univ. of Cologne, Köln, Germany; [2]Dept. of Animals in Sci. & Society, Div. of Animal Welfare & Lab. Animal Sci., Utrecht Univ., Utrecht, Netherlands

Abstract: Today there is a plethora of tracing studies available. To the best of our knowledge, however, functional consequences of stereotactic tracer application have not been studied. We here report on an anterograde tracing approach (Miniruby BDA) of the mouse (C57BL/6OlaHsd [Harlan], female, 8-12 weeks old) corticospinal tract by tracer injection into the primary motor cortex. Mice motor functions were assessed by use of Rotarod and Fitness Center before and after the operation (2d / 7d post OP). Animals were perfusion-fixed 14 days post OP and coronal brain sections (50µm) were prepared. The fluorescent microscopic examination showed the typical course of the corticospinal tract from the motor cortex via the internal capsule and the cerebral peduncles to the pyramids of the medulla oblongata and further to the pyramidal decussation and the contralateral dorsal funiculus. The preliminary evaluation of the test data does not show any significant differences in motor function comparing pre- and postoperative testing. The results show that the application of an anterograde tracer into the primary motor cortex does not lead to overt short-term motor impairment.

Title: Motor-execution network activity following stroke and rehabilitation

Authors: ***S. BAJAJ**[1,2], D. DRAKE[2], A. BUTLER[3,2], M. DHAMALA[4]
[1]Dept. of Physics & Astronomy, Georgia State Univ., Atlanta, GA; [2]Byrdine F. Lewis Sch. of Nursing & Hlth. Professions, Georgia State Univ., Atlanta, GA; [3]Dept. of Veteran's Affairs, Atlanta Rehabil. Res. and Develop. Ctr. of Excellence, Decatur, GA; [4]Dept. of Physics and Astronomy, Georgia State Univ., Atlanta, GA

Abstract: Functional neuroimaging studies have demonstrated that even when people are not subjected to explicit stimulation or tasks, several cortical and subcortical areas of the motor system interact in the low frequency range (< 0.1 Hz). It has been found that the interaction among these areas might be functionally disturbed following stroke. Very few studies have discussed the role of rehabilitation to functionally reorganize the network in order to recover the motor ability of stroke patients. Here, we investigated the activity of five core areas in the motor-execution network consisting of the left primary motor area (LM1), the right primary motor area (RM1), the left pre-motor cortex (LPMC), the right pre-motor cortex (RPMC) and the supplementary motor area (SMA) in patients following stroke and rehabilitation. The fMRI data were collected from a total of 30 participants (17 able-bodied participants and 13 stroke participants). Stroke participants had either mental practice or combined mental practice and physical therapy within 14-51 days. Using directed functional connectivity approach, we found that (i) the network activity dominated in the frequency range 0.06 Hz - 0.08 Hz for all the regions and for both able-bodied and stroke participants (ii) causal flow between the regions (LM1 and SMA, RPMC and SMA, RPMC and LM1, SMA and RM1, SMA and LPMC) was reduced following stroke (iii) causal flow did not change significantly after mental practice alone and (iv) the causal flow among the regions during combination of mental and physical practice increased tending towards approaching the values for able-bodied people. In conclusion, this study helps us to understand the reorganization of motor-execution networks in stroke survivors. These findings suggest that a combination of mental practice (MP) and physical therapy (PT) can be an effective treatment for stroke survivors to recover the functionality of motor networks.

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a progressive neurodegenerative disease known to target a variety of cells, in particular neurons and glial cells in the spinal cord. In this study, we sought to determine if sensory neurons are also affected by ALS causing mutations. We have found that sensory neurons are compromised in the SOD1-G93A and TDP43-A315T mouse models for the disease. In animals harboring SOD1-G93A, there is an early and significant delay in the response to cold and hot stimuli. Along with these sensory deficits, fewer sensory neurons take up fluorescently labeled cholera toxin (fCTB), a retrograde tracer, from hind limbs. The inability to take up the retrograde tracer is due to loss of peripheral sensory axons. Proprioceptive nerve endings, marked with YFP, undergo early and significant structural alterations in SOD1-G93A mice, and follow a similar degenerative pattern and time course as motor axons. We then asked if sensory projections to the spinal cord were similarly affected. We found a significant decrease in the number of vesicular glutamate transporter 1 (VGLUT1) positive synapses in the ventral horn of presymptomatic and symptomatic SOD1-G93A and TDP43-A315T animals. Surprisingly, degeneration of central and peripheral nerve endings did not culminate in loss of sensory soma. Importantly, these alterations are likely due to intrinsic changes in sensory neurons. Consistent with their degeneration *in vivo*, the axons of cultured sensory neurons expressing SOD1-G93A grow slower and are more susceptible to a microtubule-destabilizing drug than neurons from control animals. These results demonstrate that proprioceptive and likely other sensory neurons are vulnerable to ALS causing mutations.

Title: Pacific Ciguatoxin-1 modulates motor function and EEG activity in mice

Authors: *G. KUMAR[1], Y. WANG[2], N. P. B. AU[1], Y. L. MAK[3], L. L. CHAN[3], P. K. S. LAM[3], L. L. H. CHAN[2], C. H. E. MA[1,3]

Abstract: Ciguatera fish poisoning (CFP) is a common foodborne illness causing chronic and persistent neurological effects on peripheral nervous system. Pacific ciguatoxin-1 (P-CTX-1), the most potent CTX isolated thus far, acts on the sodium channel in mouse peripheral neurons directly (i.e. dorsal root ganglion). The modification of sodium channel gating activity provides strong evidence for the cause of sensory disturbances observed in patient; however, the effect of CTX on motor function is largely unknown. In the present study, we investigate the effect of P-CTX-1 on electroencephalogram (EEG) and the correlation with motor function after acute and repeated exposure to P-CTX-1. Male adult C57BL/6 mice were used for neurobehavioral and EEG study. Motor function was assessed by grip strength and rotarod test. EEG electrodes were implanted on right parietal cortex and reference electrode over cerebellum and fixed with dental cement. Sub-lethal dose of P-CTX-1 (0.26ng/g) was administered intraperitoneally twice on day 0 and day 3. EEG signals were amplified, digitally filtered, sampled at 256 Hz, and stored. EEG recording was done at baseline, day 0, 7, 14 and 21 after the second injection. The power spectral analysis for each spectral band was calculated and compared with baseline. Grip strength and rotarod test showed statistically significant decreases as compared with vehicle control after first exposure to P-CTX-1 and returned to normal after 72 hours. However, second exposure to P-CTX-1 showed significant decreases and then returned to the normal in about two weeks. EEG power spectral analysis showed reduction of theta power (4-7 Hz) after one hour of P-CTX-1 (first exposure) and returned to normal after 3 hours. However, second exposure to P-CTX-1 (1 hour post injection) caused significant power reduction of delta (0.1-3 Hz) & theta (4-7 Hz) as

compared with base line and remains decreased till day 7 and returned to normal on day 14. In summary, P-CTX-1 reduces motor function and EEG activity in mice after repeated exposure to P-CTX-1. We show, for the first time, that P-CTX-1 affects not only the motor function but also the temporal dynamic of EEG activity in mouse brain.

Title: Age-related strength loss is due to peripheral muscle weakness

Authors: *Y.-J. CHANG, N.-J. HUANG, F.-Y. CHANG, Y.-F. CHUANG
Dept. of Physical Therapy and Grad. Inst. of Rehabil. Sci., Chang Gung Univ., Tao-Yuan, Taiwan

Abstract: Muscle weakness is a major cause of frailty in old people. The muscle weakness might start to progress from pre-old age. Investigating the mechanism of muscle weakness in mid-age people is important for early intervention on preventing sever weakness in old age. Twenty six young and 16 mid-age people with a sedentary lifestyle were recruited. Maximal voluntary isometric contraction (MVC), electrical stimulation elicited twitch force of quadriceps, and interpolated twitch technique (ITT) were used to measure the total strength, activation level, and the peripheral component of strength, respectively. The cortical excitability was measured by transcranial magnetic stimulation (TMS). The mid-age group had significant lower MVC and twitch forces than young group ($p<0.05$). No difference was found in activation level, MEP amplitude, intracortical facilitation, or inhibition, In conclusion, the age-related weakness is

significant from mid-age. The cause of age-related weakness is mainly caused by the peripheral muscle weakness.

Title: An investigation of the mirror neuron system activation in expert dancers and their performance on a novel task

Authors: *L. PACKARD[1], C. J. KETCHAM[2]
[2]Exercise Sci., [1]Elon Univ., Elon, NC

Abstract: Recent research on the Mirror Neuron System (MNS) has indicated that experts have increased mirror neuron activity compared to non-experts when observing people perform their skill of expertise (Kim et al., 2011; Orgs et al., 2008; Calvo-Merino et al., 2006; Cross et al., 2006). Little research has been done to determine if this activation transfers to learning of novel skills. The present study investigates mirror neuron activation differences between experts and novice individuals in observation of known and novel skills. Additionally, performance on a novel task was assessed to determine if experts have better transference of motor skills. In this study, EEG activity at the Mu frequency was used to record MNS activity in expert dancers and non-experts and compare the MNS activity to the individual's ability to perform a novel movement. 20 participants (10 expert dancers and 10 novice individuals) were recruited from the local community. The participants watched a randomized series of video clips of upper body movement, either ballet phrases or American Sign Language (ASL) phrases during EEG recording. Participants were then asked to perform a novel movement (a new ASL phrase) where performance was measured in speed and accuracy. Preliminary results showed a positive correlation between MNS activity level during observation and ability to correctly perform a novel ASL phrase. These results support evidence that MNS activity is related to transference of motor skills, which may be a mechanism for observational learning.

Title: Nerve injury-induced mitochondrial fission is an essential adaptive response to maintain neuronal survival and promote axonal regeneration

Authors: *S. KIRYU-SEO[1], H. TAMADA[1], Y. KATO[1], N. ISHIHARA[2], M. NOMURA[3], K. MIHARA[4], H. KIYAMA[1]

Sci., Fukuoka, Japan; [4]Dept. of Mol. Biol., Kyushu University, Grad. Sch. of Med. Sci., Fukuoka, Japan

Abstract: Successful nerve recovery from injury requires huge energy supply by mitochondrial response. Our previous studies have demonstrated that mitochondria could play a critical role to determine the fate of injured motor neurons by losing or maintaining the mitochondrial integrity. Recently, multiple findings have suggested that mitochondrial dynamics including morphology and motility is strictly controlled for neuronal maintenance and axonal integrity. In line with this, the models for neurodegenerative diseases observe the irregular shape, accumulation and altered transport of mitochondria in damaged neurons and axons prior to clinical onset. However, most of evidences about mitochondrial dynamics have been derived from *in vitro* studies, and there remains controversy in functional consequences of mitochondrial dynamics under physiological and pathological conditions *in vivo*. To address this issue, particularly the functional significance of mitochondrial dynamics in injured neurons, here we have successfully created a unique transgenic mice using bacterial artificial chromosome (BAC) technology in which we designed to label mitochondria by GFP and simultaneously express cre recombinase in response to nerve injury. To ensure the nerve injury responsiveness, we employed the BAC clone containing entire

genome region of the activating transcription factor 3 (ATF3), which is known as a marker for axonal injury in nervous system. Using this newly obtained BAC Tg mice, we found that the length of axonal mitochondria became shorter and the turnover was accelerated in regenerative injured motor nerve, suggesting the increased fission activity of mitochondria. To evaluate the functional relevance of the increased fission activity in response to nerve injury, we crossed the BAC Tg mice with the floxed mice of dynamin-related protein (Drp1), which is responsible for mitochondrial fission, and succeeded in the specific ablation of mitochondrial fission in nerve-injured motor neurons. The injured motor neurons lacking mitochondrial fission showed round and gigantic mitochondria in soma and longer tubular mitochondria in axon. The quality and axonal transportation of mitochondria became apparently worse, and eventually leading to neuronal death and axonal degeneration. These findings suggest that mitochondrial fission is an essential adaptive response for injured neurons to maintain mitochondrial integrity and trafficking and consequently to accomplish successful regeneration.

Title: Altered overlapping pattern of hand movement representation by electromyogram triggered neuromuscular stimulation in humans

Authors: *W. TSUCHIHASHI[1], T. ONO[3], S. KASUGA[2], J. USHIBA[2]
[1]Grad. Sch. of Sci. and Technol., [2]Dept. of Biosci. and Informatics, Fac. of Sci. and Technology,, Keio Univ., Yokohama/Kanagawa, Japan; [3]Saiseikai Kanagawa-ken Hosp., Yokohama/Kanagawa, Japan

Abstract: Repetition of a simple movement can produce changes in the motor response evoked by transcranial magnetic stimulation (TMS), leading to a transient reorganization in motor connectivity (Classen et al. J Neurophysiol 1998). Moreover, active involvement in task performance leads to a substantial increase in cortical excitability, yet remains unchanged after non-skilled or passive training (Perez et al. Exp Brain Res 2004). It is, however, an open question how repetition of corporative muscle movement in multiple muscles changes motor

representation of each muscle. Furthermore, it is unclear whether cortical plasticity can be induced after repetition of passive movement evoked by electrical stimulation, corresponding with voluntary activation of another muscle. To address these questions, we examined whether artificial corporative movement of two muscles can reorganize motor representation of these muscles in short-time scale, with using Electromyogram Triggered Neuromuscular Stimulation (ETMS), a technique to apply a certain intensity of electrical stimulation to a muscle depending linearly on the amplitude of electromyogram (EMG) recorded in another muscle. Fourteen healthy adults participated this study. The participants received electrical stimulation to right flexor pollicis brevis muscle (FPB) when they performed a voluntary right wrist-extension with contraction of the extensor carpi radials muscle, ECR) repeatedly in 10 minutes. In other words, ECR was electrically activated contingent to FPB contraction. Before and after this motor task, we evaluated the TMS-based motor maps of FPB and ECR to see its alteration (7 x 7 cm grid configuration was used; Each grid point were 1 cm apart; the stimulus intensity of 110% of the lowest resting motor threshold at the target muscle was employed; 6 times of stimulation at each grid point). The averaged MEPs were then summed for each muscle to represent the net excitability. Overlapping area, defined as the number of the grid points where MEPs were elicited in both ECR and FPB, was also calculated as a representative value of the shared motor representation. The results showed that the excitability of ECR motor area included in overlapping area significantly increased after ETMS ($P < .01$). Moreover, overlapping ratio between ECR and FPB motor areas is also significantly increased ($P < .05$). Our results suggest that ETMS altered cortical motor representation of ECR and FPB through the reorganization of neural networks controlling these muscle activities.

Title: Optogenetic inhibition of peripheral nervous system circuitry

Authors: *C. GORINI[1], S. M. IYER[1], K. L. MONTGOMERY[1], S. YOUNG[1], H. SCUTT[1], A. CHRISTENSEN[1], D. J. CLARK[2], K. DEISSEROTH[1], S. L. DELP[1]

Abstract: Many neural circuits in the peripheral nervous system are amenable to optogenetic modulation. These include primary motor neurons in disorders such as spasticity, as well as primary afferent nociceptors in chronic pain. One of the primary challenges involved in achieving optogenetic inhibition is establishing sufficiently strong expression of the opsin in the desired neuronal population. This is particularly relevant if opsin transduction is to be conducted using viral means, as different virus types can produce dramatically different levels of opsin expression and trafficking. We first examine the question of virally mediated optogenetic inhibition of motor neurons, which we have previously achieved in transgenic NpHR-expressing mouse lines (Liske, et al. 2014). We describe a broad scan of AAV serotypes and injection routes, as well as different opsins, and discuss the degree of transduction observed. Preliminary results indicate anterograde transduction of AAV2-eGFP to the mouse sciatic nerve following intraspinal injection of L4/L5. Additionally, we demonstrate significant retrograde trafficking of AAV8 following intrasciatic nerve injections. More work is necessary to characterize different AAV serotypes for potential inhibitory opsin trafficking. We then turn to optogenetic inhibition of nociceptors. We reported previously (Iyer, Montgomery, et al. 2014) that intrasciatic injections of AAV6-hSyn-eNpHR-eYFP resulted in specific expression of halorhodopsin in primary afferent nociceptors, and that transdermal illumination of injected mice could raise mechanical and thermal pain thresholds, both in uninjured mice, and in mice with the chronic constriction injury model of neuropathic pain. We examine whether this inhibitory capacity extends to other models of chronic pain, and in particular, examine a model of incisional pain. Preliminary results indicate that transdermally delivered yellow light may also reverse mechanical allodynia induced by an incisional pain model, indicating the generalizability of the optogenetic inhibition approach used.

Title: Effect of acute upside down body posture on human respiratory control

Authors: *J. E. BUTLER[1,2], A. L. HUDSON[1,2], F. JOULIA[3], A. A. BUTLER[1,2], R. C. FITZPATRICK[1,2], S. C. GANDEVIA[1,2]
[1]Neurosci. Res. Australia, Randwick, NSW, Australia; [2]Univ. of New South Wales, Sydney, Australia; [3]Univ. of Toulon, Toulon, France

Abstract: Introduction: During quiet breathing, there is coordinated and efficient contraction of the obligatory inspiratory muscles. The neural drive to these muscles is distributed in a way that is coupled to their relative inspiratory mechanical advantage. This has been termed 'neuromechanical matching' (1,2). However, it is not known whether the neural drive to the inspiratory muscles adapts with alterations in the mechanics of the muscles or respiratory system. Here, we aimed to alter inspiratory muscle mechanics by altering body posture. We hypothesised that in the upside down posture the inspiratory mechanical advantage of the scalene muscles and diaphragm may be altered by gravitational effects on the rib cage and this would bring about a redistribution of neural drive to the inspiratory muscles. Methods: In 14 healthy human subjects, we determined the effect of the upside down posture on ventilation, thoracoabdominal expansion, inspiratory pressures and inspiratory muscle activity during quiet breathing, compared with standing and lying supine. Subjects breathed with a mouthpiece through a pneumotachometer with calibrated inductance bands around the chest wall and abdomen. Electromyographic activity (EMG) was recorded from scalene muscles with surface electrodes. Crural diaphragm EMG and oesophageal and gastric pressures were also measured with a purpose-built catheter (in a subset of 6 subjects). Thirty seconds of quiet breathing, maximal manoeuvres and standard lung function manoeuvres were performed in each posture. Results: The effect of the upside down posture was to increase inspiratory capacity and reduce end-expiratory lung volume. However, during quiet breathing, tidal volume, mean inspiratory airflow and inspiratory time were similar across all postures. While upside down, the ribcage contribution to tidal volume was less and the abdominal contribution was greater than when standing. Transdiaphragmatic pressure increased by ~ 230% in the upside down posture. Despite this, crural diaphragm EMG was unchanged, whereas scalene muscle EMG was significantly reduced ($p<0.05$). Conclusion: We have shown that the mechanical effects of the acute upside down posture modifies the activation of the inspiratory muscles. This could reflect an acute adaptation of neural drive to the changes in respiratory muscle mechanics; such has been demonstrated for a muscle in the hand (3). 1. Butler et al. Title: Sensory-parietal cortex stimulation for enhancing motor recovery in chronic subcortical capsular infarct model

Authors: *R. KIM[1], J. CHO[1], D. KIM[1], J.-Y. PARK[1], M.-C. LEE[2], H.-I. KIM[1]
[1]Gwangju Inst. of Sci. and Technol., Gwangju, Korea, Republic of; [2]Chonnam Natl. Univ., Gwangju, Korea, Republic of

Abstract: Introduction: Subcortical capsular stroke leaves severe long-term motor disability, which demands alternative treatment other than traditional treatment. We stimulated sensory-parietal cortex (SPC), where diaschisis was markedly observed in our preliminary studies, to test whether cortical stimulation may contribute to restoring the motor fundtion. Using microPET, behavioral study and analysis of c-Fos protein, we aimed to identify the dynamic changes of the neural substrates coupled with SPC stimulation leading to motor recovery and to elucidate the better strategy of rehabilitation in the subcortical capsular infarction (SCI) model. Material &Methods: Adult male Sprague Dawley rats (n=33) underwent the unilateral photothrombotic subcortical lesioning in the posterior limb of internal capsule (PLIC) and were divided into continuous-stimulation group (CSG: n=20), intermittent stimulation group (ISG: n = 10) depending on the mode of stimulation and non-stimulation group (NSG: n=13). Stimulation groups received cortical stimulation for 2 weeks concurrently with daily single pellet reaching tests, and was subjected to [18F-FDG] microPET static images were obtained longitudinally at 4 day, 1 week and 2 weeks of stimulation. Reconstructed PET images analyzed in voxel-wise fashion. The distribution of c-Fos immunopositivity following stimulation was measured. Results: The rats that received continuous SPC stimulation showed significant improvement of single pellet reaching scores compared to NSG from 3rd day of stimulation ($p<0.01$). On the

other hand, ISG showed motor recovery from 6th day of stimulation but degree of motor recovery was much less than CSG ($p<0.05$). The c-Fos was expressed bilaterally in significantly recovered CSG whereas only in ipsi-lateral cortex in ISG. MicroPET images shows the disappearance of diaschisis in SPC, activation of ipsilateral SPC and hippocampus, contralateral SPC and striatum. Conclusions: This study suggests that SPC stimulation is likely to reverse the diaschisis of the bilateral sensory-parietal cortex, leading to motor recovery. Further coactivation of cortical subcortical network is considered to contribute to the functional reorganization in chronic SCI models.

Title: Group Ia reciprocal excitation between ankle antagonists in a plantigrade animal

Authors: *A. S. DEARDORFF[1], R. E. W. FYFFE[2], T. C. COPE[3]
[2]VP for Res., [3]Chair, Dept of Neuroscience, Cell Biology, & Physiol., [1]Wright State Univ., DAYTON, OH

Abstract: Rodents are increasingly used for morphologic and genetic analysis of spinal motor circuitry, yet data on rodent segmental circuit function are not well established. For example, a wealth of information exists on the ontogeny and synaptic connectivity of rodent 1a inhibitory interneurons, but physiologic analyses of reciprocal antagonist connections, which are so well documented in the cat, are scarce in the adult rat. Digitigrade operation of the ankle joint in cats requires plantar and dorsiflexors adopt a role in ankle stabilization distinct from plantigrade posturing of the rat or human. We speculate these obvious differences in hindlimb movements to manifest species difference(s) in their segmental circuit function, including the 'classic' 1a reciprocal inhibitory pathway. Nichols & Koffler-Smulevitz (1991) assign an important task in stabilizing the feline ankle joint to reciprocal Ia inhibition; Hongo et al (1984) propose species differences in this segmental circuit may, in part, relate to plantigrade vs digitigrade limb use.

We tested these notions by studying the Ia reciprocal pathways, which are so well documented in cat, for the first time in the adult rat. Intracellular records of synaptic potentials were obtained *in vivo* from motoneurons of acutely decerebrated or ketamine/xylazine anesthetized adult rats. Following selective physiological activation of tibialis anterior Ia afferents, we observed few instances of reciprocal inhibition in rat medial gastrocnemius motoneurons. Rather, we frequently observed marked reciprocal excitation at latencies consistent with a tri-synaptic pathway. Our results demonstrate a pathway for Ia excitation of antagonist muscles which may represent a useful adaptation for species (eg: human) exhibiting plantigrade gait.

Title: Effects of 60-min sciatic nerve stimulation immediately after cut and repair of feline soleus and lateral gastrocnemius nerves on locomotor EMG activity of ankle muscles

Authors: *A. PANTALL[1], R. J. GREGOR[2], R. MEHTA[3], B. I. PRILUTSKY[3]
[1]Michigan State Univ., East Lansing, MI; [2]USC, Los Angeles, CA; [3]Georgia Inst. of Technol., Atlanta, GA

Abstract: Patients with peripheral nerve injury do not fully recover motor function after surgical nerve repair (Taylor et al. 2010). The major contributory factor to poor functional recovery is the slow regeneration of nerves (1-3 mm/day; Brushart et al. 2002). Therapeutic interventions being investigated to mitigate this factor include electrical stimulation to the proximal stump of the repaired nerve. Animal studies show this markedly enhances regeneration of severed axons (Gordon et al. 2009). However, it has also been reported that such stimulation increases reinnervation of inappropriate targets (English 2005). Little information is available on functional consequences of this intervention. The aim of this study was to determine the effect of electrical stimulation of axons of soleus (SO) and lateral gastrocnemius (LG) nerves on the locomotor EMG intensity and mean frequency of ankle muscles following reinnervation of SO and LG. EMG fine wire electrodes were implanted into four or more muscles of the hindlimb

including SO, LG, medial gastrocnemius (MG) and tibialis anterior (TA) in several cats. After recording baseline EMG activity and mechanics of overground walking, the nerve innervating SO and LG was cut and repaired using fibrin glue (English 2005). Immediately after LG-SO nerve repair, the sciatic nerve was stimulated through an implanted cuff electrode during four 15-min bouts of stimulation (2T, 7 Hz) with 5-min rest period between each bout. We recorded hindlimb mechanics and EMG during overground walking prior to surgery and weekly for 3 to 9 months following surgery. Mean EMG intensities and frequencies pre-surgery, determined by non-linear wavelet analysis, were similar to our previous findings (Hodson-Tole et al 2012; Pantall et al. 2014). For example, the mean EMG frequency of slow-twitch SO was lower than that of fast-twitch LG, MG and TA ($p<0.05$). However, post-reinnervation, there was a greater EMG intensity increase and reduction in frequency in reinnervated SO and LG and in intact MG compared to non-stimulated cats (Pantall et al 2014). EMG of non-reinnervated antagonist TA (not reported previously) decreased in intensity but increased in frequency. The greater increase in EMG intensity after nerve stimulation could result from greater enlargement of motor units (Krarup et al. 2002) and enhanced reduction in collaterals and inhibitory synapses from Renshaw cells on motor neurons of self-reinnervated and intact synergists (Havton and Kellerth 1990). The greater frequency decrease may be caused by smaller nerve fiber diameter and slower conduction velocity after nerve repair (Krarup et al. 2002).

Title: Dependence of the nociceptive withdrawal response of the tail on initial angle in intact, unanesthetized rats

Authors: *J. KIM, S. B. DONAIRE, R. E. MULLINS, J. J. YANG, C. L. CLELAND
Biol., James Madison Univ., Harrisonburg, VA

Abstract: Heat stimuli delivered to the tail of the intact, unanesthetized rat evokes a nociceptive withdrawal response (NWR) of the tail (Cleland & Bauer 2002). Previous studies from our

laboratory have shown that the response depends on the circumferential and rostral-caudal location of the stimulus (Bence & Cleland 2012). Although there is some evidence that the human NWR varies with initial posture, such as hip angle, weighting of the leg or ongoing movements, there is little information in animal models. The specific aim of this study was to determine if the NWR of the rat tail in intact, unanesthetized rats depends on the initial angle of the tail in the rostral-caudal/left-right plane. Adult male rats were restrained in a darkened acrylic tube from which only their tail emerged. The tails were marked with 13 black bands distributed evenly from the base to the tip of the tail. The angle of the tail at its base was varied between 0 degrees (parallel to the long axis of the body) through 30 degree intervals to 90 degrees (perpendicular to the long axis of the body). Heat stimuli were delivered with a laser diode (980nm; BWTek) to each side of a band roughly 30% caudal to the base of the tail. The resulting NWR of the tail was recorded using high speed video (650 fps; Redlake/IDT). The 13 marks were tracked in software (Proanalyst, Xcitex) to describe the movement of the entire tail in the horizontal plane over time. The response to the heat stimulus consisted of several components. First, a local bend moved the site of stimulation away from the stimulus. Next, muscles acting on the base of the tail moved the entire tail away from the stimulus. When the tail was bent at the base to the most extreme position (90 degrees) and the stimulus was directed from a caudal position, the local bend away persisted; however, the response of the base tail was now directed toward the stimulus. These results suggest that the NWR of the tail depends on the initial angle at the base of the tail, allowing the rat to adapt movements that might be blocked by the body of rat.

Title: Rat hind limb nociceptive withdrawal response to heat stimuli depends on initial paw posture but not stimulus location

Authors: *K. SEAMON, M. HARTMANN, C. A. CHRZAN, M. N. KABORE, K. A. MOORE, C. L. CLELAND
Biol., James Madison Univ., Harrisonburg, VA

Abstract: Rats rapidly withdraw their hind limb in response to a noxious heat stimulus applied to the plantar surface of their paw, which is an example of the Nociceptive Withdrawal Response (NWR). Previous studies in spinalized or lightly anesthetized non-human mammals have shown that the direction of response depends on stimulus location. The goal of this study was to determine if stimulus location, or other factors such as initial posture or response latency, determines the direction of withdrawal in the intact, unanesthetized rat. Rats were placed on a glass plate through which an infrared laser beam (980 nm) was directed to heat a small (1mm) localized portion of the plantar surface of the foot. The resulting withdrawal response was recorded with three conventional camcorders (60 fps @ 1080p), one on the left, one on the right, and the third underneath the rat. From the video beneath the rat, the initial location and angle of the stimulated paw was recorded. In response to the stimulus, the rat then withdrew and rapidly (~40ms) replaced its paw on the glass, at which point the final location and angle of the paw were recorded. Rats withdrew and then replaced their paw on the glass in all possible directions. To determine if the location of the stimulus influenced response direction, the rat's paw was stimulated in five locations (three aligned rostral-caudal and three aligned left-right). Unexpectedly, we found no dependence on stimulus location. However, we did notice the initial position of paw varied in both location and angle. Consequently we explored if initial position (left-right and rostra-caudal) and paw angle influenced final location and angle. Correlation between initial and final locations and angles did reveal a highly significant linear relationship ($p<0.001$), regardless of response latency. These results demonstrate, in contrast to studies in spinalized or anesthetized non-human animals, that initial posture plays a greater role in the programming of the NWR than stimulus location.

Title: Combination electrical stimulation and pulsatile acetylcholine release therapy to preserve neuromuscular juntion health in peripheral nerve injury

Authors: *J. R. ELES[1,3], C. L. KOLARCIK[2], K. A. CATT[2], X. T. CUI[2,3,4]

Abstract: Despite advances in regenerative medicine and scaffolding therapies for peripheral nerve repair and regrowth, functional recovery of large nerve injuries is still limited. Of of the contributing factors to this is the atrophy of neuromuscular junction (NMJ) targets distal to damaged peripheral nerves. We present a novel solution to preserving downstream NMJ targets that involves 1) chronic electrical stimulation to distal NMJs and 2) pulsatile acetylcholine (Ach) release from poly(3 4-ethylenedioxythiophene)/ graphene oxide-acetylcholine complex (PEDOT/GO-Ach) coatings on NMJ-contacting electrodes. To our knowledge, this is the only therapy system that combines the well-established benefits of chronic electrical stimulation with local, on-demand release of therapeutic agents. To optimize our system, we electropolymerized PEDOT/GO-Ach coatings onto gold electrodes. By allowing GO and Ach to interact prior to electropolymerization, cationic Ach can be readily incorporated into the growing PEDOT coat, which improves upon previously used methods of cationic drug incorporation that rely on loading post-polymerization. We have shown that biphasic, low-frequency stimulation of PEDOT/GO-Ach electrodes yields consistent, physiologically relevant amounts of Ach release (5.3 ± 1.7 ng/mm^2 electrode surface area/10 minute stimulation period) for thousands of stimulation cycles. Further, our PEDOT/GO-Ach coatings improve electrical properties of our electrodes, lowering 1Hz-1KHz band electrical impedance, which can improve the charge injection limit. We found that applying our therapeutic electrical stimulation with 5µM Ach to an *in vitro* innervated muscle co-culture model (NSC34/C2C12 cell lines) led to trending improvements in NMJ clustering as labeled by Ach receptor staining (48.8 ± 8.8 v 90.9 ± 22.5 NMJ/mm^2, control v. stimulation + added Ach). Thus, our therapy system presents as a viable candidate for improving functional nerve repair.

Title: Time course "dose" of cross-education of strength after handgrip training

Authors: *Y. SUN[1,2,3], T. BARSS[1,2,3], T. KLARNER[1,2,3], E. ZEHR[1,2,3,4]
[1]Rehabil. Neurosci. Laboratory, Univ. Victoria, Victoria, BC, Canada; [2]ICORD, Vancouver, BC, Canada; [3]Ctr. of Biomed. Research, Univ. of Victoria, Victoria, BC, Canada; [4]Div. of Med. Science, Univ. of Victoria, Victoria, BC, Canada

Abstract: Cross-education is a neural adaptation defined as the increase in strength or functional performance of the untrained contralateral limb after unilateral training. This phenomenon has been found in both neurologically intact and clinical (e.g. stroke, orthopedic injury) populations. Limitations for clinical translation include knowledge on the minimum time course for emergence of the crossed effects. Currently, little is known about the time-course of strength increase in each limb during training. Therefore, the major purpose of this study was to characterize the time-course of strength changes in both the trained and untrained limbs during handgrip training. An anticipated outcome was the determination of the minimum training weeks required to induce cross-education in the upper limb. Neurologically intact right-handed participants were recruited for a 6 weeks of thrice-weekly training. During each training session, participants performed 5 sets of 5 maximal isometric contractions (MVC) by gripping a dynamometer with their right hand. To evaluate the changes in strength and muscle functions, MVC force during handgrip, pinchgrip force, and MVC wrist extension and flexion torque, were measured in both trained and untrained limbs before and after training. In order to assess neurological adaptations, electromyography (EMG) of extensor carpi radialis (ECR), flexor carpi radialis (FCR), biceps brachii (BB) and triceps brachii (TB) muscles were recorded along with H-reflex and M-wave recruitment curves and cutaneous (superficial radial nerve)-conditioned recruitment curves of ECR muscle were also measured during pre and post-training. To track the time course of force changes the trained limbs, handgrip MVC force of all training repetitions were recorded and EMG of ECR and FCR were measured during one session each week. For the untrained limb, MVC of handgrip force and EMG of ECR and FCR were measured once a week from a single contraction. After six weeks of training, handgrip and pinchgrip force and wrist extension and flexion torque increased in both untrained and trained limbs. Changes in the maximal muscle activation and amplitude of the H-reflex were observed. This results of this study emphasize the importance of establishing effective "dose" for time course of functional and neurological adaptations in strength for effective translation to rehabilitative interventions.

Title: Phase-dependent cutaneous reflex reversal during walking emerges from reflex signs produced by afferents in discrete foot sole regions

Authors: *T. KOMIYAMA[1], T. NAKAJIMA[2], E. P. ZEHR[3,4,5], S. SUZUKI[1], R. A. MEZZARANE[6], H. OHTSUKA[7], G. FUTATSUBASHI[1], T. KLARNER[3], T. S. BARSS[3]

Sci., Univ. of Victoria, Victoria, BC, Canada; [6]Lab. of Signal Processing and Motor Control, Univ. of Brasília, Brasília, Brazil; [7]Hlth. Sci. Univ. of Hokkaido, Sapporo, Japan

Abstract: During human locomotion, cutaneous reflexes in ankle flexor muscles following distal tibial nerve (TIB) stimulation are predominantly facilitatory at the end of stance but reverse to suppression at heel strike. Explanatory mechanisms underlying this phase-dependent reflex reversal include the presence of "distinct" facilitatory or inhibitory interneuronal reflex pathways converging on alpha motoneurons. Because the TIB nerve innervates much of the skin of the foot sole, it remains unclear whether specific foot sole regions contribute to the bidirectional reflex actions during walking. Indeed, we previously showed that electrical stimulation of discrete foot sole regions could evoke inhibitory and facilitatory cutaneous reflexes during walking. Therefore, here we investigated possible regional contributions of cutaneous afferents innervating the foot sole on bidirectional reflexes following TIB nerve stimulation during walking.Cutaneous reflexes (MLR: 70-120 ms) in tibialis anterior (TA) muscle were elicited by delivering electrical stimulation to 3 foot sole regions (heel site: HL, fore foot medial site: f-M, fore foot lateral site: f-L) and TIB nerve and recorded during 16 different phases of the step cycle. In addition, we examined summation effect of reflex amplitudes after combined stimulation of each foot sole region (f-M or HL) and TIB nerve. MLRs after TIB stimulation

were strongly facilitatory during the late stance to mid swing phases and reversed to suppression around heel strike. Both f-M and f-L stimulation induced facilitation during the late stance to mid swing phases, but HL stimulation evoked strong suppression during the late stance to end of swing phases. Within each region of foot sole stimulation no evidence of phase-dependent reflex reversal could be found. We also investigated whether there was a summation effect following combined nervetrunk and f-M or HL stimulation. At the stance to swing transition a summation of MLR amplitude occurred during combined f-M (facilitatory) and TIB (facilitatory) stimulation. However, the same was not true for the combined HL (inhibitory sign) & TIB stimulation. At the swing to stance transition, there was a reflex summation during HL (inhibitory) & TIB (inhibitory) stimulation. In contrast, this summation was not observed after the f-M (facilitatory) & TIB (inhibitory) stimulation. Thus, our results suggest that reflex reversal observed during whole nerve stimulation (e.g. TIB) is an emergent property of the distinct effects produced by afferent populations innervating specific regions of the foot sole.

Title: Arm and leg cycling training to improve neurological function and walking ability after stroke

Authors: *T. KLARNER[1,2,3], T. S. BARSS[1,2,3], Y. SUN[1,2,3], C. KAUPP[1,2,3], P. LOADMAN[1], E. ZEHR[1,2,3]

Abstract: Rhythmic arm and leg (A&L) movements found in walking, cycling, and stepping share elements of central neural control. While it is reasonable to expect some transfer between locomotor tasks, the extent to which training in rhythmic A&L cycling can transfer to improved neurological function and enhanced ability to perform walking remains untested. The purpose of this study was to test the efficacy of A&L cycling training as a modality to improve locomotor function after stroke. Chronic stroke participants (i.e. greater than six months post infarct) were recruited and performed A&L cycling training (Sci-Fit Pro 2 ergometer) three times a week, with 30 minutes of aggregate activity time per session, for a total duration of 5 weeks. To evaluate the physiological cost of activity heart rate and rating of perceived exertion were collected. The progressive element of this training included increasing the resistance of the ergometer over the five weeks in order to maintain the same relative perceived exertion. To assess the strength of arm and leg coupling, interlimb cutaneous reflexes were evoked by simultaneous electrical stimulation (5x1.0ms trains @ 300Hz) to the cutaneous nerves in the hand (superficial radial) and foot (superficial peroneal) during A&L cycling and treadmill walking. Responses recorded in all four limbs were evaluated across all phases of the walking cycle. Changes in walking function were gauged via a customized analysis of muscle activity patterns and lower limb joint kinematics. Functional and clinical walking ability were assessed with the Ambulation Index, Functional Walking Scale, the timed up and go test, and the ten meter and six minute walking tests. Also, to assess possible suppression of exaggerated reflex excitability associated with spasticity, stretch reflexes in the soleus muscle were evoked and the modified Ashworth test and the Tardieu scale were used. Multiple pre-test sessions were used to establish a meaningful baseline of all outcome measures prior to the intervention. Our preliminary data show that after a stroke A&L cycling improves neurological function leading to improved walking ability seen in reflex function, gait analysis, and in an increased distance walked in the six minute walk test. These results suggest that arm and leg cycling could be used as an additional modality to improve interlimb coupling, walking ability, and clinical presentation of spasticity after stroke.

Title: Effects of presynaptic inhibition on bilateral fluctuations of H- and T-reflexes of the soleus muscle

Authors: *R. A. MEZZARANE[1], F. MAGALHÃES[2], A. KOHN[3]
[1]Univ. of Brasilia (unb), Sao Paulo, Brazil; [2]Sch. of Arts, Sci. and Humanities, EACH, [3]EPUSP, PTC, Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract: The stretch reflex of the soleus muscle is a useful tool employed in spinal cord neurophysiology studies. Its amplitude presents an intrinsic trial to trial variability associated with both pre and post-synaptic mechanisms. Previous studies showed that this modulation occurs for both legs and the correlation of bilateral H-reflex fluctuations can be changed according to the task. However, to date, the influences of a higher level presynaptic inhibition (PSI) on bilateral H-reflex fluctuations have not yet been explicitly inspected. Moreover, no study examined bilateral T-reflexes. The present work aimed at investigating bilateral fluctuations of both H and T-reflexes under different conditions: 1) at rest; 2) during soleus voluntary contraction (10% MVC); 3) with PSI conditioning; 4) contraction + PSI. Fifteen subjects, aged 32.2 ± 6.2 years (mean ± STD), were seated in an armchair with the legs immobilized. The mechanical stimulus was 1 cycle of a sine wave with 10 ms duration applied to the Achilles tendon through a vibratory transducer. The electrical stimulus was a rectangular pulse (1 ms duration) applied to the posterior tibial nerve. Five hundred electrical or mechanical test stimuli were applied to both legs simultaneously at 1Hz to elicit H or T-reflexes (20%Mmax) in conditions 1-4. A 1 ms conditioning electrical pulse was applied to the neck of the fibula 100 ms before either the mechanical or electrical test stimulus (conditions 3 and 4). Sequences of cross-covariance (CCV) were calculated in each condition to detect bilateral fluctuations in the peak-to-peak amplitudes of the reflexes obtained from both legs. To avoid the occurrence of false positives, both reflex sequences were whitened by means of an inverse auto-regressive filter. This procedure allows specifying the critical limit for the CCV peaks (at $p<0.05$). Two way ANOVA detected significant effect of voluntary contraction (increased amplitude) (condition 2) and PSI conditioning (decreased amplitude) (condition 3) on both T and H-reflex as compared to condition 1 (rest) ($p<0.05$). There were no differences in the frequency of occurrence of significant CCV peak across conditions for T-reflex. However, H-reflex showed lower number of significant CCV peaks in condition 4 as compared to other conditions (chi-squared test; $p<0.05$). These results seem to reinforce the hypothesis of the existence of an interaction between post and presynaptic mechanisms acting on H-reflex bilateral fluctuations as previously suggested. Further, it is currently suggested that the fusimotor drive can counteract the disruption in bilateral fluctuations caused by this interaction.

Title: Effects of enhanced sensory feedback on cross-education of strength in the wrist extensors

Authors: *T. S. BARSS[1,2,3], T. KLARNER[1,2,3], K. INOUYE[1], E. ZEHR[1,2,3,4]
[1]Rehabil. Neurosci. Laboratory, Univ. of Victoria, Victoria, BC, Canada; [2]ICORD, Vancouver, BC, Canada; [3]Ctr. for Biomed. Research, Univ. of Victoria, Victoria, BC, Canada; [4]Div. of Med. Sciences, Univ. of Victoria, Victoria, BC, Canada

Abstract: An increase in strength of the untrained limb after training of the opposite homologous limb is commonly referred to as "cross-education". Strength training involves forceful contractions that activate cutaneous receptors in the skin, producing widespread and powerful effects between limbs. Providing "enhanced" cutaneous stimulation during unilateral contractions may alter excitability of interlimb reflex pathways, modifying the contralateral increase in strength. To date, no study has directly assessed the possible contribution of afferent pathways to cross-education. Therefore, the purpose of this study was to determine the contribution of cutaneous input in cross-education. This was assessed by determining if unilateral cutaneous stimulation altered ipsilateral and contralateral strength gains. Right handed participants were randomly assigned to either a voluntary contraction (VOL), cutaneous stimulation (CUT), or cutaneous stimulation during voluntary contraction with cutaneous stimulation (VOL+CUT) training group. Each participant completed 6 sets of 8 reps 3x/week for 5 weeks. VOL training included unilateral maximal voluntary isometric contractions (MVICs) of the wrist extensors. CUT training included cutaneous stimulation (2xRT for 3sec @ 50Hz) of the superficial radial (SR) nerve at the wrist only. Training for VOL+CUT included MVICs of the wrist extensors with simultaneous SR stimulation. Two pre-training and 1 post-training session assessed the relative increase in force output during MVICs for wrist flexion, wrist extension and handgrip strength. Simultaneous maximal voluntary muscle activation (EMGmax) was measured from the flexor and extensor carpi radialis (normalized to maximal evoked M-waves), as well as the biceps and triceps brachii muscles. Changes in efficacy in cutaneous reflex pathways were evaluated through stimulation of the SR and median (MED) nerves (3xRT for 5x1ms @ 300Hz)

during graded ipsilateral contractions of 5, 10, 25, and 50 % of EMGmax. Somatosensory evoked potentials were recorded at rest (3xRT for 1ms @ 300 Hz) via single pulse stimulation of the SR and MED nerves at the wrist. If unilateral cutaneous stimulation alters the strength gains in either the trained or untrained limb it will provide the first evidence of a cutaneous afferent contribution to the cross-education effect. This study will help refine a unifying model of unilateral strength training to include contributions from central motor output as well as afferent feedback.

Sci., Hlth. Sci. Univ. of Hokkaido, Tobetsu, Japan

Abstract: Cutaneous mechanoreceptors located in the limb can give rise to wide spread reflex actions even in the distant limb muscles. We previously reported that the cutaneous inputs from the contralateral foot could differentially modify the soleus H-reflex depending on the executed motor task. To date, however, it remains unclear how cutaneous inputs from discrete and remote limbs modulate the excitability of the spinal reflex during walking. The present study aimed to investigate how cutaneous inputs from the remote hand and foot could modify the H-reflex excitability in the ankle extensor muscle during standing and walking. Healthy volunteers were asked to walk on a treadmill at 4 km/h or to perform a weak tonic voluntary contraction of the

right soleus muscle during standing. The soleus H-reflex was elicited by electrical stimulation of the posterior tibial nerve at the right popliteal fossa. Conditioning non-noxious cutaneous nerve stimulation was applied to the superficial peroneal nerve at the left ankle (cSP), the superficial radial nerve at the right wrist (iSR), or the superficial radial nerve at the left wrist (cSR). The conditioning stimulation preceded the test stimulation to evoke the H-reflex by approximately 100–120 msec. The test stimulation, conditioning stimulation or a combination of the two was delivered during the early stance phase of the ipsilateral limb (~10% of gait cycle). During standing, the amplitude of the conditioned H-reflex increased in a non-specific manner (i.e., the conditioning effect was not dependent on the stimulated nerve). In contrast, a significant decrease in the amplitude of the conditioned H-reflex was observed during walking. Interestingly, the amount of decrease in the amplitude of the conditioned H-reflex was larger for cSP stimulation than for iSR or cSR stimulation. Conditioning cutaneous stimulation never changed the amplitude of the pre-stimulus background or ongoing EMG activity at a given latency (approximately 120-150 ms after the conditioning stimulation). These observations indicate that limb-dependent organization of the interlimb reflex transmission is specific to walking, but not to standing. Moreover, our findings strongly suggest that presynaptic mechanisms would play a crucial role in regulating the interlimb conditioning effect on the H-reflex.

Title: Changes in acoustic startle reflex in the upper trapezius during periods of low and high psychosocial stress

Authors: *R. J. MARKER, K. S. MALUF
Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: Introduction: An increase in upper trapezius muscle activity is common during periods of increased psychosocial stress, and may contribute to the development or persistence of chronic neck pain. The mechanisms of this increased activity, however, are relatively unknown. The reticular formation is associated with arousal levels of an individual, indicating that reticulospinal input to the upper trapezius may contribute to stress-induced muscle activity. The purpose of this study was to assess changes in reticulospinal input to the upper trapezius during periods of low and high psychosocial stress, as assessed with the acoustic startle reflex (ASR). Methods: Surface electromyography (EMG) was used to record the ASR from the non-dominate upper trapezius of healthy individuals. Participants were seated and instructed to perform a low-level shrug to provide a constant level of background muscle activity. A startling acoustic stimulus (SAS, 124 dB, 50 ms) was provided via headphones over a constant background sound intensity of 60 dB. In order to prevent habituation of the ASR, participants performed a simple reaction time task, with a non-startling tone as the imperative cue. In 30% of trials, the non-startling tone was replaced with the SAS. Increased psychosocial stress was achieved by providing participants with time demands and a monetary incentive, setting up camera surveillance, and introducing an unfamiliar, authoritative investigator. Percent of SAS trials producing an upper trapezius ASR, percent of ASRs resulting in inhibition of muscle activity, and length of silent period in inhibitory ASRs were calculated in low and high stress conditions. Results: The percent of SAS trials producing an ASR decreased from 70% to 48% during low and high stress, respectively. The percent of ASRs resulting in an inhibition of muscle activity, however, increased from 77% to 96%. Finally, the length of the silent periods present in inhibitory ASRs displayed minimal change (54 ms vs 46 ms, in low and high stress, respectively). Discussion: Reticulospinal input to the upper trapezius, assessed by ASR, appears to be primarily inhibitory. The reduction in ASRs produced during increased psychosocial stress may be one mechanism contributing to stress-induced muscle activity, while the increase in percent of inhibitory ASRs may be a compensatory mechanism, attempting to decrease excess muscle activity. Understanding these mechanism may assist in the treatment of individuals with chronic neck pain.

Title: Quantification of patellar tendon reflex response using an iPod wireless gyroscope application with experimentation conducted in Lhasa, Tibet and post-processing conducted in Flagstaff, Arizona through wireless Internet connectivity

Authors: *R. C. LEMOYNE[1,3], T. MASTROIANNI[2]
[1]Independent, Running Springs, CA; [2]Independent, Pittsburgh, PA; [3]Northern Arizona Univ., Flagstaff, AZ

Abstract: The patellar tendon reflex provides a foundational role in the standard neurological examination. The attributes of the reflex response can provide preliminary insight regarding the health of both the central and peripheral nervous systems. Traditional approaches to classifying the reflex response involve the application of an ordinal scale. Smartphones and portable media devices have been successfully tested and evaluated as wireless accelerometer platforms for reflex response quantification. The iPod is equipped with a gyroscope sensor capable of measuring rate of angular rotation. With a software application the iPod is capable of functioning as a wireless gyroscope platform. Trial data can be conveyed by wireless connectivity to the Internet through email enabling the experimentation and post-processing resources to be remotely located. The experimentation site was situated in Lhasa, Tibet; and the post-processing resources were located in Flagstaff, Arizona. The iPod wireless gyroscope application successfully demonstrates the capacity to quantify the features of the patellar tendon reflex response.

Title: Diversity of Purkinje cell morphology and physiology in the cerebellum of the adult zebrafish

Authors: *V. Z. HAN, J. P. WELSH
Ctr. for Integrative Brain Res., Seattle Children's, Seattle, WA

Abstract: The goal of this study was to explore the electrophysiological and morphological properties of Purkinje cells (PCs) in the zebrafish cerebellum. Sagittal cerebellar slices (~200 μm thick) were prepared from adult wild-type zebrafish (≥6 months old) of either sex. Whole-cell somatic patch recordings were performed in either voltage- or current-clamp mode under visual control, and recording pipettes were loaded with Neurobiotin to label the cells following physiological characterization. PCs were identified by having a soma in the PC layer and an axonal arbor that was restricted to the lower PC/upper granule cell layers where their synaptic targets, the eurydendroid cells, are located. An unexpected diversity in PC dendritic morphology was encountered that segregated into 3 groups. Group 1 (n=5) had dendritic arbors restricted to the inner molecular layer (ML); Group 2 (n=10) had a primary dendrite whose length ascended up to 30 μm through the inner ML before branching in the outer ML; Group 3 (n=11) had dendritic arbors that branched throughout the thickness of the ML, similar in that way to mammalian PCs. The spontaneous firing of zebrafish PCs was characterized by narrow (< 2 ms width) and broad (5-10 ms width) spikes, presumably of axonal and dendritic origin that were blocked by TTX and Cd^{2+}, respectively. The two spike types were co-expressed in some - but not all - PCs. Groups 1 and 3, sharing the trait of branched dendritic arbors near the soma, primarily showed both narrow and broad spikes (13 of 16 PCs) while Group 2, having only a single dendrite close to the soma, primarily showed only narrow spikes (9 of 10 PCs). Focal stimulation in the ML activated graded responses similar to parallel fiber responses (n=7), whereas stimulation in the upper granule cell layer evoked large all-or-none responses similar to climbing fiber responses (n=5). Both responses remained unchanged under the NMDA receptor blocker AP5, but disappeared under the AMPA receptor blocker CNQX. The study revealed that zebrafish PCs are morphologically and physiologically heterogeneous to an extent not seen in mammals, indicating that the functional circuitry of the zebrafish cerebellum may have unique integrative properties. **Support:** Seattle Children’s Research Institute

Title: Dicer knockout mice suggest critical role of micro-rna in cerebellar cell proliferation, organization, and migration

Authors: *E. ARNESON[1], T. MIGHELL[1], M. BOSCH[1], G. SOUKUP[2], C. BRADFIELD[2], A. SHIBATA[1]
[1]Biol., [2]Biomed. Sci., Creighton Univ., Omaha, NE

Abstract: MicroRNAs (miRNAs) are involved in a variety of essential cell mechanisms such as proliferation, differentiation, and apoptosis. Both *in vitro* and *in vivo* studies show that miRNAs are involved in essential processes controlling neural development. We hypothesize that miRNA expression is required for the proper postnatal differentiation, migration, and survival of granule cells in the cerebellum. To investigate miRNA function in cerebellar granule precursor cells (CGPCs), conditional Dicer knock-out (CKO) mice using the expression of Cre recombinase under the control of the cerebellar granule cell specific Atoh1 gene promoter were developed (Soukup et al., 2009). Characterization of the motor behaviors and cerebellar development in Atoh-1 CRE conditional Dicer knockout mice reveals a critical role for miRNAs in the differentiation, migration, survival, and function of CGPCs. Immunohistochemical studies show that the vermis, Crus I, and Crus II regions of the cerebellum are malformed in CKO mice. CGPC differentiation determined by Zic 2 and NeuN staining and Purkinje cell differentiation determined by Calbindin staining are disrupted in CKO mice as compared to wild type. Cell proliferation as determined by Ki-67 staining is reduced and aberrant and also reveals abnormal migration of CGPCs as compared to wild type. Disrupted proliferation of CGPCs may be linked to abnormal sonic hedgehog (SHH) signaling from Purkinje cells. SHH immunofluorescence suggests that this signaling pathway is disrupted in CKO mice. CKO mice also show elevated levels of GFAP and activated Caspase-3 suggesting increased astrogliogenesis and apoptosis following miRNA dysfunction. Western blot analysis confirmed decreased expression of NeuN (-87%) and Calbindin (-71%) and increased expression of GFAP (+146%) and activated Caspase-3 (+256%). Synaptic development may also be significantly affected and western blot analysis demonstrates that PSD-95 expression is decreased by 42% in CKO mice. MiRNA microarray analyses of CKO and wild type mice show significantly elevated levels of miR-293, miR-500, and miR-483, and significantly decreased levels of miR-208a, miR-125b, miR-214, miR-540, miR-33, and miR-878 ($p<0.05$). MiR-878 is of particular interest since it has not been implicated previously in cerebellar granule cell development. Further analysis is focused on investigating the relevance of the differential expression of these miRNAs. These findings support critical role for miRNA expression in CGPCs and provides a model system for investigating the mechanisms of miRNA regulation of cerebellar development and function.

Title: Ethanol disrupts transmissoin through the cerebellar cortex via GABAA and non-GABAA receptor-mediated mechanisms in C57BL/6J and DBA/2J mice

Authors: *J. KAPLAN[1], D. J. ROSSI[2]
[1]Behavioral Neurosci., Oregon Hlth. and Sci. Univ., Portland, OR; [2]Integrated Physiol. and Neurosci., Washington State Univ., Pullman, WA

Abstract: Purkinje cells are the sole integrators of afferent sensory information from the periphery to the cerebellum. Peripheral signals are conveyed to Purkinje cells by mossy fibers via granule cells. One mechanism by which ethanol is thought to impair cerebellar-dependent behavior is by enhancing $GABA_A$ receptor-mediated transmission to granule cells. However, we recently demonstrated that acute application of ethanol to cerebellar slices, on average, increased $GABA_A$ receptor-mediated transmission to granule cells in low ethanol consuming DBA/2J mice that are behaviorally sensitive to ethanol-induced ataxia, but reduced $GABA_A$-mediated transmission to granule cells of high ethanol consuming C57BL/6J mice that are insensitive to ethanol-induced ataxia. The impact of opposite ethanol responses on $GABA_A$ receptor-mediated transmission to granule cells on signal transmission through the cerebellar cortex is unknown, but it may represent a molecular mechanism that confers differential sensitivity to ethanol-induced cerebellar disruption. Using acutely prepared cerebellar slices and whole-cell current-

clamp electrophysiology, we examined the impact of ethanol on mossy-fiber evoked Purkinje cell excitatory post-synaptic potentials (eEPSPs) in these two strains of mice. Ethanol (31mM and 52mM) attenuated the amplitude of evoked EPSPs and Purkinje cell action potential output in both strains of mice, which persisted, but to a lesser extent, in the presence of the broad-spectrum $GABA_A$ antagonist, GABAzine. However, using this method, complex network activity made it impossible to isolate ethanol's impacts on evoked excitatory and inhibitory input to Purkinje cells, independently. Therefore, we used voltage-clamp procedures to isolate these effects. Our results indicate that both $GABA_A$ receptor-mediated and non-$GABA_A$ receptor-mediated mechanisms play important roles in ethanol's disruption of cerebellar processing and highlight the importance of multiple molecular interactions in mediating the overall impact of ethanol on Purkinje cell integration of afferent information.

Title: Loss of β_4 reduces the pacemaker frequency of cerebellar Purkinje neurons in an ataxic mouse model

Authors: *B. BENEDETTI, B. E. FLUCHER
Innsbruck Med. Univ., Innsbruck, Austria

Abstract: Mutations of all the major subunit components of the PQ-type calcium channel in cerebellum CaV2.1, β_4 and $\alpha2\delta$-2 cause ataxia and epilepsy in humans and mice. It has been shown that mouse mutants of CaV2.1 and $\alpha2\delta$-2 show reduced synaptic input, altered dendritic morphology and irregular pacemaker activity in the cerebellar Purkinje neurons. However, there is little information on the neuronal phenotype of the ataxic mutant of β_4 *(lethargic).* Although previous work on *lethargic* thalamus and heterologous systems suggests an important role of β_4

in synaptic release, up to date there are no studies on the physiology of β_4 in neuronal circuits controlling motor coordination. Here we addressed this problem by studying the electrical activity of Purkinje cells in acute cerebellar slices. Using cell-attached recordings we measured the pacemaker frequency in *lethargic* neurons. Compared to wildtype controls, a large number of *lethargic* Purkinje cells were electrically silent. In the remaining Purkinje cells the firing frequency was 38 ± 7 Hz, significantly sparser than in healthy controls where the firing frequency was 113 ± 18 Hz. Nevertheless, the pacemaker activity of *lethargic* Purkinje cells was fairly regular. To assess the relevance of β4 for synaptic release we measured the frequency and amplitude of excitatory and inhibitory synaptic currents in Purkinje neurons. Whole-cell recordings in healthy neurons revealed an age-related increase in the frequency of spontaneous excitatory and inhibitory synaptic input. This was equally observed in *lethargic* neurons. Furthermore, tonic GABAergic inhibition of the glutamatergic input was observed in both healthy and ataxic mice after postnatal day 12. Measurements of cell capacitance predicted no difference in the size of healthy and ataxic neurons. Accordingly, morphological analysis of reconstructed Purkinje cells revealed only small differences between the dendritic arborization of *lethargic* neurons and controls. In conclusion, the synaptic input and dendritic morphology of Purkinje cells are not altered in *lethargic* cerebellum, but the output is severely depressed. Thus, the loss of the β_4 subunit may be fully compensated in parallel fiber - Purkinje cell synapses but β_4 appears necessary for Purkinje cell intrinsic mechanisms of action potential generation.

Title: The molecular profile of ion channels in cultured cerebellar neurons from mouse

Authors: ***K. J. CURTICE**[1], L. S. LEAVITT[1], T. R. HARRIS[1], K. CHASE[2], R. W. TEICHERT[1], M. P. HORVATH[1], B. M. OLIVERA[1]

Abstract: The cerebellum is a region of the brain responsible for controlling the coordination and timing of motor activity. Neurons of the cerebellum have classically been defined using cell morphology, neural connectivity, and electrophysiological recordings. These studies have led to identification of distinct cell types within the cerebellum that include Purkinje, Golgi, granule, stellate, basket, and unipolar brush cells. Here we utilized calcium imaging to observe a mixed population of dissociated cerebellar neurons and, through the use of selective pharmacological tools, we defined the ion channel composition in individual neurons. We evaluated glutamate receptors, acetylcholine receptors, GABA receptors, and a variety of voltage gated ion channels. The resulting response profiles were then analyzed with a cluster analysis that revealed distinct neuronal classes and provided the frequency of each cell type. Cultured neurons from mouse cerebellum were dominated by small glutamatergic neurons responsive to N-methyl-D-aspartate (NMDA) that were consistent with granule cells. Additionally, larger cholinergic neurons were observed in lower frequency. Some of the large, cholinergic neurons were also responsive to α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and putatively corresponded to Purkinje cells. The spectrum of response phenotypes observed in our experiments suggests that neuronal diversity exists beyond the classic cell types of the cerebellum. Furthermore, this work elucidates novel cell-specific receptor and ion channel combinations that will be useful for defining the physiological role of individual cell-types of the cerebellum.

Title: Intrinsic and synaptic properties of identified nucleo-olivary cells of the deep cerebellar nuclei

Authors: *M. NAJAC, I. M. RAMAN
Dept. of Neurobio., Northwestern Univ., Evanston, IL

Abstract: Neurons in the inferior olive (IO) give rise to climbing fibers that make excitatory synapses onto Purkinje cells and modulate their parallel fiber inputs. Purkinje cells in turn inhibit diverse cell types in the cerebellar nuclei, including small GABAergic nucleo-olivary cells that project to the IO, thus making a tri-synaptic loop critical for motor learning. We retrogradely labeled nucleo-olivary cells by injecting choleratoxin B coupled to Alexa fluor 488 in the IO of P21 mice. Most labeled nucleo-olivary cells were found in the contralateral interpositus and lateral nuclei. Using patch-clamp recordings in acute slices from P25-P30 mice, we compared the intrinsic and synaptic properties of identified nucleo-olivary cells and large neurons, which project to premotor areas. Nucleo-olivary cells had input resistances of 1.43 ± 1.12 GΩ (n=40), higher than large cells (118 ± 109 MΩ, n=24), and capacitances of 6.3 ± 1.9 pF (n=40), smaller than large cells (34.3 ± 10.0, n=24). In response to depolarizing current steps, they fired spikes over a relatively narrow dynamic range, entering depolarization block at rates above 74 ± 11 Hz (n=7). In contrast, large cells fired at rates up to 400 Hz (n=7). GABAA R-mediated IPSCs in nucleo-olivary cells were evoked at 0 mV with local electrical stimulation, with NMDARs and AMPARs blocked. These IPSCs were small and slow (peak, 43 ± 23 pA, decay time constant 32.6 ± 19.1 ms, n=7) relative to large cells (502 ± 209 pA, 2.0 ± 0.6 ms, n=6). To test whether Purkinje cells contribute to evoked IPSCs, we repeated the experiment in mice expressing ChR2 in Purkinje cells. Light-evoked IPSCs in nucleo-olivary neurons had a similarly slow decay time constant (23.1 ± 16.9 pA, n=8) consistent with a dominant contribution of functional synapses from Purkinje cells. Previous work shows that a fast decay of IPSCs allows large cells to entrain to rapid synchronous inhibitory inputs. As nucleo-olivary cells IPSCs had slow kinetics, we tested how they responded to trains of electrical stimulation of increasing frequencies. Whereas in large cells, IPSCs decay fully between stimuli even at 100 Hz, in nucleo-olivary cells, stimuli from 20-100 Hz evoked large tonic currents resulting in summation of IPSCs (e.g. at 100 Hz, total IPSC11/peak IPSC1 = 1.68 ± 0.56 and tonic IPSC11/peak IPSC1 = 1.19 ± 0.59, n=7). These results suggest that nucleo-olivary cells will be sensitive to the frequency of their inhibitory inputs, unlike large cells, which are also sensitive to timing. These two types of

projection cells from the cerebellar nuclei may therefore process different parameters of Purkinje cell activity in ways that are related to their different roles in the circuit.

Title: Ionic mechanisms shaping DCN responses to pauses in PC background firing

Authors: *C. M. PEDROARENA
Hertie-Inst EKU-Tübingen, Tubingen, Germany

Abstract: Pauses or reductions in Purkinje cells background firing rate are observed during diverse movements and some forms of learned motor acts. Synchronization of these events are postulated as one of the signals that cerebellar cortex uses to modulate the activity of their target neurons in the deep cebellar nuclei (DCNs. The resulting excitation of DCNs is likely to reflect the interaction between the des-inhibition and the activation/deactivation of diverse membrane conductances. In this study we investigated the ionic mechanisms shaping the response of DCNs to pauses in PC background firing. For this purpose WCP recordings from DCNs in rodent cerebellar slices were performed. PC axons were activated using tungsten electrodes in the white matter and different temporal patterns of stimulation. Pharmacological tools were used to manipulate diverse membrane conductances. Our previous studies showed that T-type calcium channels are functional and mediate rebound responses in DCNs (Boehme & Pedroarena, 2011). Since there is evidence that tonic T-type currents may be active at usual membrane potentials, in a first series of experiments we tested how DCN responses to desinhibition were modified by the specific T-type channel blocker,TTA-P2. Our results showed that although TTA-P2 blocked rebound responses to hyperpolarizing pulses and short trains of IPSPs, the responses evoked by suppression of PC background firing were not affected the same procedures.

Title: Upregulation of mGluR1/5-modulated current in the deep cerebellar nuclei of male Gabrb3 mutant mice and its effect on cerebellar behavior

Authors: *A. TURNOWCHYK, K. J. PALARZ, I. M. RAMAN
Neurobio., Northwestern Univ., Evanston, IL

Abstract: The maternal allele of *Gabrb3*, which encodes 3 subunits of $GABA_A$Rs, is absent in Angelman syndrome, an autism spectrum disorder. Because *Gabrb3* is expressed in the cerebellar cortex, where it is expected to prolong IPSCs, we investigated the effect of loss of maternal *Gabrb3* (m-/p+) on cerebellar output in P17-24 mice. We made whole cell recordings from large projection neurons of the cerebellar nuclei (CbN) in brain slices from male mice and stimulated mossy fibers (MFs) and Purkinje (Pkj) axons (100 Hz, 200 ms, 36-37.5°C). With AMPARs and NMDARs blocked, PSCs consisted of $GABA_A$R-mediated IPSCs and a small tonic excitation mediated by mGluR1/5-modulated currents. The net outward PSC decayed incompletely between stimuli, producing a phasic (evoked) current that was unaltered in m-/p+ cells vs. +/+ controls, and a tonic (residual) current that was reduced in m-/p+ cells by ~50%. $GABA_A$R kinetics, however, were unchanged (single IPSC decay τ: +/+ 2.3 ± 0.1 ms; m-/p+ 2.5 ± 0.2 ms). The mGluR1/5 antagonist CPCCOEt did not affect +/+ PSCs but restored m-/p+ tonic current to +/+ levels. Thus, mGluR1/5-modulated current is upregulated in m-/p+ cells, counteracting tonic IPSCs. In current-clamped CbN cells, stimulation (100 Hz, 500 ms) suppressed spontaneous firing via IPSPs and elicited prolonged rebound firing, which is known to be facilitated by mGluR1/5 activation. In male mice, +/+ cells increased their firing rates by 59 ± 19% (post-stim rate / pre-stim rate), while in m-/p+ cells the increase almost doubled to 103 ± 19%. Consistent with enhanced mGluR1/5-modulated current in the mutants, CPCCOEt removed this difference (+/+ 53 ± 14%; m-/p+ 51 ± 10%). Unlike in males, rebound firing in +/+ and m-/p+ females did not differ (+/+ 79 ± 12%; m-/p+ 70 ± 24%). Pilot Western blots of mGluR1 normalized to actin in CbN from age-matched mice confirmed a sex difference in mGluR1 expression: +/+ females expressed relatively more mGluR1 than +/+ males, and only

males upregulated mGluR1 in m-/p+ mice (n=2, each group). To assay changes in motor learning, mice were tested on the accelerating rotarod. Male P22 +/+ mice remained on the rod for 46 ± 17 sec longer (days 5-7 vs. day 1). Similarly, m-/p+ male mice improved by 43 ± 12 sec. In contrast, while female +/+ mice improved by 71 ± 13 sec, female m-/p+ mice failed to learn, remaining on the rod for 8 ± 11 sec *less* at the end of training. These data support the idea that loss of *Gabrb3* reduces inhibition of Pkj cells, yielding more inhibition of the CbN. Increased mGluR1/5 activity in CbN cells of m-/p+ males, but not females, may compensate for the elevated inhibition, preventing deficits in rotarod learning.

Title: *In vivo* two-photon imaging of cortico-cerebellar mossy fiber synapses

Authors: *D. RYLKOVA, Z.-Y. YE, A. CRANK, D. L. LINDEN
Johns Hopkins Univ., BALTIMORE, MD

Abstract: Using a combination of two-photon imaging *in vivo* and in brain slices, we are characterizing the morphological and functional dynamics of basal pontine mossy fibers (mfs), which form the cortico-cerebellar circuit's input stage. To this end, we are labeling pontine mfs with dsRed-express, in conjunction with the genetically-encoded calcium indicators GCaMP3 or GCaMP6 by injecting AAVs into the basal pons. We then perform chronic *in vivo* two-photon imaging in unanesthetized adult rats through a cranial window over the cerebellar hemisphere. Dual labeling allows us to reconstruct multiple axons within a volume and subsequently characterize calcium signals in populations of terminals with reference to their parent axon. During *in vivo* calcium imaging, animals' behavior is recorded using a high speed camera. Spontaneous movements such as grooming are then analyzed offline. In addition to scoring movement onsets and offsets, we are also tracking the position of body regions, which allows us

to examine the relationship between activity and movement parameters in fine detail. Furthermore, sensory-evoked activity is tested in response to tactile, proprioceptive, auditory and visual stimuli. These experiments have allowed us to characterize cerebellar sensorimotor representations at the level of individual presynaptic terminals. While the activity of the majority of imaged axons was correlated with movement, these were interspersed with axons specifically active in response to tactile sensory stimuli. The activity of a third class of inputs was not correlated to either movement or the sensory stimuli tested. Surprisingly, we have observed that calcium transients are not simultaneously detectable at all terminals on an "active" axon. This does not appear to be a result of branch point failure because calcium transients can be detected in terminals distal to an inactive terminal. In general, the activity of terminals on the same axon is more highly correlated than those on different axons, and there is an inverse relationship between distance and correlated activity for all terminals. We have also reproduced this finding in brain slices, where we have observed that, for a given stimulation protocol, terminals sharing a parent axon do not all show Ca responses.

Title: Mossy fiber excitation of cerebellar nuclear cells preserves phase-locked spiking resulting from synchrony of Purkinje cells

Authors: *Y. WU, I. M. RAMAN
Dept. Neurobio., Northwestern Univ., Evanston, IL

Abstract: Neurons of the cerebellar nuclei (CbN) integrate inhibition from Purkinje (Pkj) cells of the cerebellar cortex and excitation from mossy fibers. Recent work showed that synchrony of Pkj simple spikes inhibits spontaneous firing by CbN cells during brief IPSPs, but permits short-latency spiking after IPSPs; this periodic inhibition/disinhibition lets CbN cells phase-lock their

firing to that of synchronized Pkj cells. Here, we investigated how synaptic excitation modulates CbN cell responses to inhibition. Whole-cell recordings were made from large projection CbN cells in P17-P23 mouse cerebellar slices in SR95531 to block endogenous inhibition at 34-37°C. EPSPs were electrically evoked by 200-ms trains of mossy fiber stimulation (90, 133, and 160 Hz) and IPSPs were generated by dynamic clamp, which mimicked either 40 Purkinje inputs each firing at 50 spikes/sec ("asynchronous") or 20 asynchronous inputs with 20 synchronized at 50 or 100 Hz ("50% synchrony"). Voltage-clamp recordings at -70 mV showed that the mean evoked mossy fiber EPSC was 367 ± 91 pA (decay constant 1.6 ± 0.3 ms) and depolarized the membrane potential by 5.1 ± 1.2 mV (n=8). During trains of stimuli, EPSCs depressed by 74.8% at 90 Hz and 80.6% at 160 Hz. In current clamp, CbN cells fired spontaneously at 116 ± 34 Hz (n = 5) or rested in depolarization block (n = 3). During asynchronous IPSPs, CbN firing was greatly reduced (4.6 ± 1.8 spikes/sec, measured in a 200-ms period). The number of spikes did not significantly increase when EPSP trains at 90 or 133 Hz were applied, but rose by 10.9 ± 4 spikes/sec when EPSPs were evoked at 160 Hz. Thus, CbN cells could not detect excitation even up to 133 Hz with a background of asynchronous IPSPs, indicative of effective shunting and a narrow dynamic range for encoding excitatory input. In contrast, with 50% synchronous IPSPs at 50 Hz (no EPSPs), the rate was 11.3 ± 2.2 spikes/sec. Consistent with phase-locking, plots of interspike interval histograms confirmed that most of these spikes fell in 4-ms bins around multiples of the interval between synchronized IPSPs. Against this background of 50% inhibitory synchrony, all frequencies of EPSPs significantly increased the total number of spikes (90 Hz: by 5.1 ± 2.1; 133 Hz: by 10.0 ± 2.4; 160 Hz: by 12.3 ± 4.3 spikes/sec). The fraction of ISIs that fell into bins around multiples of 20 ms (for synchrony at 50 Hz) or 10 ms (for synchrony at 100 Hz) was unchanged by excitation. The data suggest that excitation < ~160 Hz may be insufficient to drive CbN spiking against asychronous inhibition but may increase the spike probability upon disinhibition after synchronous IPSPs, while leaving the jitter on phase-locked spiking relatively unchanged.

Title: Optogenetic mapping of inhibitory circuit between Purkinje cells and cerebellar molecular layer interneurons

Authors: *J. KIM[1], G. J. AUGUSTINE[1,2]
[1]LKC Med. School-NTU, Singapore, Singapore; [2]Ctr. for Functional Connectomics, Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: Although anatomical studies have suggested that Purkinje cell axon collaterals form synaptic contacts with cerebellar molecular layer interneurons (MLI; J Neurosci. 9: 2141), the function of these putative connections has not been determined. Here, we investigated the functional properties and spatial organization of this circuit by using a high-speed optogenetic circuit mapping technique (PNAS 104: 8143). Using transgenic mice that selectively express channelrhodopsin-2 in Purkinje cells, we could photostimulate Purkinje cells via small spots of blue light (405 nm), while simultaneously recording resulting postsynaptic responses in MLI. By correlating the location of photostimulation with the presence of postsynaptic responses, we could map the spatial organization of the circuit between Purkinje cells and MLI. Photostimulation of Purkinje cells evoked monosynaptic, GABAA-mediated IPSPs that inhibited the firing of basket cells located in the inner third of the molecular layer. This connection was never observed in stellate cells and was relatively sparse, being observed in only 20% of MLI recordings even when many Purkinje cells were photostimulated. Unlike Purkinje cell-Purkinje cell connections, which are developmentally transient (Nature Neurosci. 12:463), Purkinje cell-MLI connections are functional in adults. The area of the presynaptic input field was similar in size to the optical footprint of individual Purkinje cells, suggesting 1:1 convergence between Purkinje cells and MLI. However, in a few cases, multiple Purkinje cell inputs were observed. The inhibitory inputs from Purkinje cells to MLI were up to 200 μm in width in the sagittal plane, except for rare cases of multiple connections whose range extended up to 300 μm. In coronal slices, Purkinje cells provided inhibitory inputs to MLI within 100 μm of the postsynaptic cell soma. Paired recordings were used to determine whether there are reciprocal inhibitory connections between Purkinje cells and MLI. In no case were mutually inhibitory pairs detected, suggesting that the inhibitory circuit between Purkinje cells and MLI is non-reciprocal. Therefore, inhibition of MLI by Purkinje cells will disinhibit neighboring Purkinje cells, which may help synchronize Purkinje cell activity. These novel features of the Purkinje cell-MLI inhibitory network are likely to be important for information processing within the cerebellum.

Title: A tale of two circuits - parallel processing in the rat cerebellum

Authors: *G. J. WOJACZYNSKI[1], J. P. CARD[2]
[2]Neurosci., [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Efferent projections from the cerebellar nuclei (CN) originate from two separate populations of projection neurons. Glutamatergic projection neurons send their axons to the red nucleus and thalamus (nucleo-premotor; NPM) while GABAergic neurons project to the inferior olive (nucleo-olivary; NO), completing the olivo-cortico -nucleo-olivary loop (OCNO). The OCNO circuit has been proposed to form a cell-by-cell-by-cell closed loop architecture, yet there is a lack of definitive anatomical data to this end. Furthermore, the degree to which Purkinje cell (PC) input is segregated to projection-specific populations of CN neurons has not been firmly established. We addressed these questions in adult male rats using combined viral transneuronal and classical tracing. Injection of a cocktail of the retrograde transneuronal tracer pseudorabies virus (PRV) and the beta fragment of cholera toxin (CTβ; a bidirectional monosynaptic tracer) into the inferior olive (IO) confirmed that OCNO loops are in fact closed, with CTβ labeled IO climbing fibers innervating the same PRV+ PCs from which they receive disynaptic input through the CN. Next, we tested the hypothesis that both pathways receive synaptic input from a common set of local interneurons and the same PCs. To test this hypothesis we injected two isogenic recombinants of PRV that express unique reporters (EGFP or mRFP) into the red nucleus (RN) and the IO, respectively. Retrograde transneuronal spread of virus to the CN and their presynaptic PC afferents was analyzed 48 hours later. We found contrary to our hypothesis that the majority of PCs innervate either the NPM or NO pathways; i.e., most of the PCs expressed only EGFP or mRFP. NPM and NO projecting PCs did not fall along zebrin II parasagittal bands and were intimately interdigitated with neighboring cells, producing alternating PCs expressing only one reporter of infection. Notably, retrograde spread of PRV from the RN and IO differentially infected neurons in distinct CN subfields. CN neurons synaptically linked to the two pathways were also observed. These results question the presumed equivalence of PC influence on NPM and NO projection neurons and place the CN at the core of cerebellar processing, integrating dynamic regulatory control of the IO via OCNO loops with excitatory output of the NPM projection.

Title: Striatal interneurons expressing calretinin in 6-OHDA-lesioned mice

Authors: *S. PETRYSZYN, D. GAGNON, J.-M. BEAULIEU, A. PARENT, M. PARENT
CRIUSMQ, Quebec, QC, Canada

Abstract: The striatum is the largest and major integrative component of the basal ganglia. It is composed of a large population of morphologically homogeneous projection neurons and a relatively small group of highly heterogeneous interneurons. The functional organization of the striatum is severely affected by the progressive degeneration of its dopaminergic afferent projections that characterizes Parkinson's disease. Despite their small number, interneurons are believed to play a crucial role in the integrative activity of the striatum. This study was designed to describe in details the regional distribution and morphological features of striatal interneurons expressing the calcium binding protein calretinin (CR) in normal condition and to investigate if these interneurons are involved in the reorganization of the striatal microcircuitry that occurs in Parkinson's disease. In order to do so, we examined and compared data gathered from normal mice and from mice that received a unilateral injection of 6-hydroxydopamine (6-OHDA). Immunostaining for CR revealed the presence of two morphological distinct types of CR striatal interneurons, which were designed as CR1 and CR2 and whose distribution and density were determined stereologically in normal, sham and 6-OHDA-injected mice. The CR1 cells abound in the rostral striatum. They had a small (9-12 μm), round and intensely fluorescent cell body that gave rise to one or two typically beaded processes. The CR2 cells were more uniformly distributed than the CR1 cells. They had a larger (15-20 μm) and less intensely fluorescent cell body that yielded 2-4 poorly branched dendrites. In 6-OHDA-lesioned mice, no major difference in the density of CR1 cells was detected between intact and 6-OHDA-lesioned striatum, or between sham and 6-OHDA-lesioned animals. However, the density of CR2 cells was decreased in 6-OHDA-injected mice compared to sham animals, and this diminution was significant on the lesioned side (43 %). Immunostaining for CR in BAC double transgenic mice expressing tdTomato protein under the control of dopamine D1 receptor promoter and GFP under the

control of D2 promoter showed that CR1 and CR2 cells were devoid of D1 or D2 receptors. The latter findings suggest that dopamine exerts its influence upon CR2 striatal interneurons indirectly, either by modulating the glutamatergic excitatory striatal projections of cortical or thalamic origin, or by stimulating the large cholinergic interneurons, which express dopamine receptors.

Title: Serotonin innervation of the striatum in a primate model of Parkinson's disease

Authors: ***D. GAGNON**[1], T. DIPAOLO[2], M. PARENT[1]
[1]CR-IUSMQ, Quebec, QC, Canada; [2]CR-CHU, Quebec, QC, Canada

Abstract: Parkinson's disease is characterized by the progressive loss of midbrain dopaminergic neurons that innervate the striatum. The administration of L-Dopa is the most effective pharmacotherapy for alleviating the motor symptoms of this neurodegenerative disease. However, the chronic use of this compound often produces adverse side effects, such as L-Dopa-induced dyskinesia. Unregulated release of dopamine by serotonin (5-HT) axons following L-Dopa administration is believed to be a major presynaptic determinant of dyskinesia expression. The present study was designed to characterize the reorganization of 5-HT striatal afferent projections following dopaminergic denervation in a primate model of Parkinson's disease. Our sample comprised eight cynomolgus monkeys (*Macaca fascicularis*): four that were rendered parkinsonian following systemic injections of the neurotoxin MPTP, and four others that served as controls. The state of the striatal 5-HT and dopamine innervation was evaluated by means of immunohistochemistry with antibodies raised against the 5-HT transporter (SERT) and tyrosine hydroxylase (TH), respectively. A detailed stereological investigation revealed a 51.2% increase in the number of 5-HT axon varicosities in the dorsolateral sector of the striatum of MPTP-intoxicated monkeys (0.62 ± 0.74 SERT+ axon varicosities/mm^3) compared to controls (0.41 ±

0.88 SERT+ varicosities/mm^3). This significant increase of the 5-HT striatal innervation was particularly obvious in the so-called sensorimotor territory of the striatum, where the dopamine denervation (TH-poor sector) was the most severe. A similar stereological approach applied to transverse sections of the dorsal raphe nucleus immunostained for tryptophan hydroxylase (TPH) indicated no significant difference in the density of TPH+ cell bodies between MPTP-injected monkeys and controls. Electron microscopic examination of the dorsolateral sector of the putamen showed that the SERT+ axon varicosities established about twice as many synaptic contacts in MPTP-injected monkeys (synaptic incidence of 46 ± 3 %) than in controls (20 ± 8 %). These findings demonstrate the highly plastic nature of the 5-HT striatal afferent projections, a feature that becomes particularly obvious in the absence of striatal dopamine, that is, in the parkinsonian state. Although the number of dorsal raphe 5-HT neurons remains relatively constant in parkinsonian monkeys, their ascending axonal projections undergo marked proliferative and synaptic adaptive changes that might play a significant role in the expression of L-Dopa-induced dyskinesia.

Title: The contribution of the dopamine system to selection of motor programs

Authors: *J. PÉREZ, A. KARDAMAKIS, B. ROBERTSON, S. GRILLNER
Dept. of Neurosci., Karolinska Inst., Stockholm, Sweden

Abstract: In the lamprey, as in mammals, dopamine plays a key role in movement control by modulating the excitability of projection neurons in the striatum. The direct "go" pathway

neurons express the dopamine D1 receptor and mediate a net facilitation of motor actions through an inhibition of the pallidal GABAergic output neurons (disinhibition), whereas the indirect "no go" pathway, acting through the D2 subtype, mediates motor suppression (Gerfen and Surmeier, 2011; Ericsson et al., 2013). The dopaminergic innervation of striatum derives from the nucleus of the posterior tuberculum, a region that shows striking similarities with the mammalian substantia nigra pars compacta (SNc). It receives pallial (cortex in mammals) input and shows the same connectivity with the other basal ganglia subnuclei observed in mammals. The SNc also receives input from the optic tectum as the evolutionary basis for salience/novelty detection (Pérez-Fernández et al., submitted to J. Comp. Neurol.). The importance of the dopaminergic innervation from the SNc is reflected in the fact that, when depleted, it gives rise to a marked hypokinesia, as in Parkinson's disease (Thompson et al., 2008). One striking feature is that the SNc in lamprey sends direct dopaminergic projections to different motor command centres, including the diencephalic and mesencephalic motor regions, and the output layer of the optic tectum. The SNc dopaminergic control of motor responses is thus likely to be more complex than generally assumed, and involve additional pathways to the widely studied striatal projection. Here, we explored how dopamine modulates motor responses in the optic tectum, the homologous region of the mammalian superior colliculus. In all vertebrates, including the lamprey, this region has similar features, with a laminated structure, controlling eye, orienting and evasive trunk movements. The dopamine fibers from the SNc innervate the inner motor output layer and *in situ* hybridization shows that tectal premotor cells express D1 and D2 receptors. Patch-clamp recordings of premotor cells show that dopamine differentially modulates their excitability, increasing the excitability of D1-expressing neurons and decreasing excitability of those expressing the D2 receptor. Our results indicate that dopamine directly modulates motor responses in premotor regions and, given the high degree of conservation of the basal ganglia, this previously unexplored mechanism is likely to also be present in higher vertebrates including mammals.

Title: The pedunculopontine nucleus: A precise anatomical and neurochemical description in human and non-human primates

Authors: *L. GOETZ[1,2], M.-J. WALLMAN[1], A. PARENT[1,2], M. PARENT[1,2]
[1]CRIUSMQ, Quebec, QC, Canada; [2]Univ. Laval, Quebec, QC, Canada

Abstract: Since the first identification of the pedunculopontine nucleus (PPN) in 1909 by Jacobsohn and its more detailed description in 1954 by Olszewski and Baxter, the delineation of tegmental structures and their terminologies, based on cytoarchitectural, connectivity and functional considerations, have been a source of confusion. It was then unsurprising that controversies regarding PPN anatomical localization were raised in the neurosurgical community when this nucleus became a new promising target for the treatment of freezing of gait in Parkinson disease by deep brain stimulation (DBS). Particularly worth noting is the marked variation encountered in the literature regarding the site of DBS electrode placement in the brainstem, indicating that a detailed anatomical description of the PPN is deeply needed. We used immunofluorescence with antibody against choline acetyltransferase (ChAT), combined to antibody against a vesicular glutamate transporter (Vglut2) and histochemistry for NADPH diaphorase, luxol fast blue and cresyl violet in order to provide a precise anatomical and neurochemical description of the PPN and its surrounding structures. Staining were made on post-mortem brain sections of human, cynomolgus and squirrel monkeys. Examination of axial and sagittal sections of brainstem revealed the presence of a dense cluster of ChAT+ neurons that corresponds to the PPN pars compacta lying at the pontomesencephalic junction along the rostral surface of the superior cerebellar peduncle. This neuronal cluster was surrounded by a more diffuse ChAT+ neuronal population corresponding to the PPN pars dissipata. Different types of ChAT+ neurons were described according to their morphology. Fusiform neurons had a long axis ranging from 36.5 to 54.2 μm (mean 44.3 μm). Triangular neurons were usually endowed with 3 primary dendrites and a cell body ranging from 16.5 to 63.8 μm in diameter (mean 31.7 μm). Ovoid neurons had a diameter ranging from 16.6 to 44.8 μm (mean 28.2 μm). Examination of doubly immunostained sections for ChAT and Vglut2 revealed that a large proportion of PPN neurons expressing ChAT, also contain the VGluT2, indicating a potential co-release of glutamate with acetylcholine by these neurons. Taking into account the different stereotaxic approaches used in DBS literature, we provided a set of coordinates corresponding to this brainstem structure in human. Our data obtained from post-mortem brain sections provide relevant anatomical basis to precisely localize and characterize the neurochemical content of PPN neurons and its surrounding structures in the perspective of anatomo-clinical study of the effect of PPN DBS.

Title: Serotonin innervation of the internal and external pallidum in a primate model of Parkinson's disease

Authors: *L. EID[1], D. GAGNON[1], C. WHISSEL[1], T. DIPAOLO[2], A. PARENT[1], M. PARENT[1]
[1]Psychiat & Neurosci Dept, Univ. Laval, Quebec City, QC, Canada; [2]Pharm., Univ. Laval, Quebec, QC, Canada

Abstract: The primate pallidum is divided into an internal (GPi) and an external (GPe) segment, both receiving a highly heterogeneous serotonin (5-HT) innervation arising mainly from the dorsal raphe nucleus. The main purpose of this light and electron microscopic study was to characterize neuroadaptive changes of 5-HT axons in the GPi and GPe following dopaminergic denervation in a primate model of Parkinson's disease. Eight cynomolgus monkeys (*Macaca fascicularis*) were used: 4 were rendered parkinsonian by systemic injections of the neurotoxin MPTP and 4 served as controls. The state of the pallidal 5-HT innervation was evaluated by means of immunohistochemistry with an antibody raised against the 5-HT transporter (SERT). In MPTP-intoxicated monkeys, unbiased quantification at the light microscopic level revealed a two-fold increase in the density of SERT+ axon varicosities in the GPi ($0.83 \pm 0.12 \times 10^6$ SERT+ axon varicosities/mm^3 vs. 0.43 ± 0.05) and the GPe (0.58 ± 0.10 vs. 0.32 ± 0.03). Overall, the GPi appeared more densely innervated by SERT+ axon varicosities than the GPe. This difference between GPi and GPe was exacerbated in MPTP monkeys. Electron microscopic analysis of both pallidal segments indicated that the morphological features of SERT+ axon varicosities were similar between MPTP and control monkeys. Compared to unlabeled profiles, only few SERT+ axon varicosities were seen to establish a synaptic contact in the GPi (synaptic incidence of $23 \pm 3\%$) and the GPe ($35 \pm 10\%$) of control monkeys. A slight decrease of the synaptic incidence for SERT+ axon varicosities was observed in the GPi ($15 \pm 4\%$ vs. $23 \pm 3\%$) and the GPe ($21 \pm 7\%$ vs. $35 \pm 10\%$) of MPTP monkeys, though such difference was not statistically significant when compared to controls. The few synaptic contacts established by SERT+ axon varicosities observed in the pallidum were of the symmetrical and asymmetrical types in equal proportions and targeted exclusively dendritic profiles. Our data indicate that dopaminergic lesion leads to an increase of the number of 5-HT axon varicosities in both pallidal segments. This reorganization

of 5-HT afferent projections may be involved in deregulated neuronal firing pattern of pallidal neurons noted in Parkinson's disease as well as in the expression of motor symptoms and L-Dopa-induced dyskinesia.

Title: Cholinergic neurons intrinsic to primate external pallidum

Authors: *A. PARENT, L. EID, M. PARENT
Psychiat. & Neurosci. Dept, Univ. Laval, Quebec City, QC, Canada

Abstract: The relationship between cholinergic neurons of the nucleus basalis of Meynert (NB) and neurons of the globus pallidus (GP) was studied in squirrel (*Saimiri sciureus*) and cynomolgus (*Macaca fascicularis*) monkeys by means of choline acetyltransferase (ChAT) immunohistochemistry. In both species, the large (40-50 μm) and multipolar ChAT+ cells of NB, which project to the cerebral cortex, form a densely packed neuronal population lying just beneath the GP. At various points along the rostrocaudal extent of NB, some ChAT+ neurons encroach significantly upon the GP dorsally. At anterior commissure levels, ChAT+ neurons morphologically similar to, and topographically continuous with those of NB surround the rostral pole of the internal segment of the GP (GPi). As the GPi enlarges caudally, the ChAT+ cells become gradually confined to the internal and external medullary laminae. These NB-like ChAT+ neurons remain largely segregated from pallidal neurons throughout the rostrocaudal extent of the GP. However, we noted, in both primate species, the presence of a distinct population of ChAT+ neurons closely intermingled with pallidal neurons in the external segment of the GP (GPe), but not in the GPi. Morphologically, the ChAT+ neurons that occur in GPe display numerous highly branched dendrites emerging from cell bodies that are smaller (25-30 μm) than those of neurons present in the NB and in its dorsal extensions in the medullary laminae. A quantitative stereological analysis of the GPe in squirrel monkeys yields an overall

density of 55 ± 6 ChAT+ neurons/mm^3 compared to 3 000 ± 127 pallidal neurons/mm^3, indicating that the cholinergic elements represent about 1.8% of the total GPe neuronal population. These ChAT+ GPe neurons are uniformly distributed along the rostrocaudal and mediolateral planes, but display a marked dorsoventral increasing gradient, with a density of 38 ± 3 neurons/mm^3 dorsally compared to 86 ± 6 neurons/mm^3 ventrally. Double immunofluorescence studies in cynomolgus monkeys show that, in contrast to all typical pallidal neurons, the ChAT+ GPe neurons are devoid of GAD. Furthermore, at variance with the corticopetal ChAT+ neurons of NB, which typically express the Nerve Growth Factor receptor (NGFr), none of the ChAT+ GPe neurons stain for NGFr. These findings demonstrate the existence of a unique population of cholinergic pallidal neurons that share more similarities with the striatal cholinergic interneurons than with the NB cholinergic projection neurons. We hypothesize that these elements act as a local source of acetylcholine and, as such, influence the activity of the GPe, as well as that of other closely interconnected basal ganglia nuclei.

Title: Similarities and differences in GABA and glutamate-mediated modulation of striatal dopamine release between mouse and guinea pig

Authors: *B. O'NEILL, J. C. PATEL, M. E. RICE
Neurosurg., New York Univ. Sch. of Med., New York, NY

Abstract: Hydrogen peroxide (H_2O_2) is an intra- and intercellular signaling molecule that can influence processes from embryonic development to cell death. Our previous work in guinea pig brain slices showed that H_2O_2 can also mediate rapid signaling by activation of ATP-sensitive K^+ (K_{ATP}) channels in the nigrostriatal dopamine (DA) pathway – a modulatory system that has critical roles in movement and motor learning. In guinea pig midbrain slices, endogenously

generated H_2O_2 in DA neurons activates channels that inhibit DA neuron firing. In guinea pig striatum, the source of H_2O_2 is not DA axons, but rather striatal medium spiny neurons (MSNs). Generation of H_2O_2 in MSNs requires evoked glutamate release, AMPA receptor (AMPAR) activation, and action potentials in MSNs. Diffusible H_2O_2 generated in MSNs activates K_{ATP} channels on DA axons, which inhibits striatal DA release. Thus, blocking AMPARs during local striatal stimulation decreases H_2O_2 generation and enhances DA release. Conversely, MSN excitability and consequent H_2O_2 generation are decreased by $GABA_A$ receptor ($GABA_AR$) activation, such that blocking $GABA_ARs$ leads to further H_2O_2-dependent suppression of DA release. Here, we report that modulation of striatal DA release by H_2O_2 is minimal in mice, compared to guinea pigs. We used fast scan cyclic voltammetry to monitor locally evoked extracellular DA concentration ($[DA]_o$) in dorsolateral striatum in *ex vivo* slices from adult male guinea pigs and mice. Similar to the results in guinea pigs, AMPAR antagonism enhanced evoked $[DA]_o$, whereas $GABA_AR$ antagonism suppressed evoked $[DA]_o$. In contrast to guinea pig, however, this regulation was not H_2O_2 dependent in the mouse, given that co-application of catalase (an H_2O_2 scavenging enzyme; 500 IU/mL) did not prevent DA release modulation by AMPAR or $GABA_AR$ antagonists. To test whether the lack of H_2O_2 dependence in mice might reflect the absence of axonal DA release regulation by K_{ATP} channels, we compared the effect of a K_{ATP} channel opener, diazoxide, in both species. A comparable suppression of evoked $[DA]_o$ in mouse and guinea pig striatum demonstrated the presence of K_{ATP} channels as potential targets of H_2O_2 in both species. Other factors could include species differences in H_2O_2 generation or metabolism. Surprisingly, despite the minimal role for inhibitory H_2O_2, the pattern of DA release regulation by glutamate and GABA appears to be conserved in mice and guinea pigs. Additionally, the similarity of DA release suppression by diazoxide in these species supports a species-independent role for K_{ATP} channels as regulators of DA neuronal function and DA transmission.

Title: Differential expression of cb1 receptor-dependent long-term depression at corticostriatal and thalamostriatal synapses

Authors: Y.-W. WU[1], J.-I. KIM[2], V. L. TAWFIK[3], G. SCHERRER[3], *J. B. DING[4]
[2]Dept. of Neurosurg., [3]Dept. of Anesthesiol., [1]Stanford Univ. Sch. of Med., Palo Alto, CA; [4]Neurosurg., Stanford Univ., Palo Alto, CA

Abstract: Striatal spiny projection neurons (SPNs) receive two principle excitatory inputs, from the cerebral cortex and the thalamus. A dominant form of synaptic plasticity expressed at these glutamatergic inputs onto SPNs is endocannabinoid-dependent long-term depression (eCB-LTD). However, whether eCB-LTD can be induced in all striatal SPNs is still debatable. Using region-specific Cre mouse lines combined with optogenetic tools, we achieved selective investigation of corticostriatal or thalamostriatal projections. We found that eCB-LTD induced by activation of group 1 metabotropic glutamate receptors (mGluR1s) is absent at thalamostriatal synapses, but is successfully induced at corticostriatal synapses, regardless of the expression of dopamine receptor types in the postsynaptic SPNs. This difference is attributable to differential expression of cannabinoid type-1 (CB1) receptors on corticostriatal and thalamostriatal presynaptic terminals. This study reveals that striatal eCB-LTD is input-specific rather than postsynaptic cell-type-specific and lays the groundwork for understanding cortico-thalamo-striatal synaptic plasticity and its relevance to motor learning.

Abstract: Cholinergic neurons within the striatum and basal forebrain express the vesicular glutamate transporter 3 (VGLUT3). In the striatum, VGLUT3 not only mediates the synaptic release of glutamate but also increases the loading of acetylcholine. VGLUT3 knockout (KO) animals were previously reported to have elevated locomotor activity during their waking cycle. It was hypothesized that loss of VGLUT3 in cholinergic interneurons caused an increase in dopamine signaling, leading to the hyperactivity. Interestingly, deletion of the vesicular acetylcholine transporter in the striatum does not alter locomotor activity, supporting a role for glutamate release in this defect. Here, we assess dopamine-related neurochemical and anatomical changes within the striatum of KO mice and we use our newly generated conditional VGLUT3 knockout mouse to determine whether striatal cholinergic interneurons are indeed the locus of the defect. Consistent with the altered locomotor behavior, we find that dopamine release, measured in striatal slices by fast scan cyclic voltammetry, is greater in the KO than in WT mice at night, but is equal in both genotypes during the day. We also find that the content of dopamine in striatal tissue is also elevated in KO mice at night, suggesting a mechanism of increased synthesis. Finally, we show that mice lacking VGLUT3 specifically in forebrain cholinergic neurons do not show hyperlocomotor activity, but do have behavioral impairments related to exploration and motivation.

Title: Dual recording of real-time dopamine release and presynaptic calcium transients reveals distinct properties of dopaminergic afferents in dorsal and ventral striatum

Authors: C. SGOBIO[1], H. CAI[1], *D. M. LOVINGER[2]
[1]Lab. of Neurogenetics, Natl. Inst. Aging, BETHESDA, MD; [2]Chief, Lab. Integrative Neurosci, Natl. Inst. Alcohol Abuse & Alcohol, ROCKVILLE, MD

Abstract: Calcium triggers dopamine release from presynaptic terminals of midbrain dopaminergic (mDA) neurons in the striatum. However, calcium transients within the mDA axon terminals are difficult to study and little is known about how they are regulated. Here we describe presynaptic calcium transient (PreCaT) measurements in striatal presynaptic elements of mDA neurons using brain slice photometry and expression of the genetically encoded calcium indicator (GECI) GCaMP3 expressed in transgenic mice. We have also combined these measurements with simultaneous fast-scan cyclic voltammetry (FSCV) to measure changes in extracellular DA. Electrical stimulation-induced PreCaTs appear to be less sensitive to activation of dopaminergic autoreceptors (D2Rs) or inhibition of the dopamine transporter (DAT) in comparison to DA transients produced by the same stimulation. This may suggest factors that regulate DA release downstream of effects on presynaptic calcium entry, but the well-known power relationship between intracellular calcium concentration and DA release may also account for these differences. Simultaneous measurement of PreCaTs and DA release induced by the same electrical stimulatus were also compared in dorso-lateral (Caudate-Putamen, DLS) versus ventral (Nucleus Accumbens, VS) striatal slices. Single pulse-induced PreCaTs and [DA] release are smaller in magnitude in NAc than in DLS, but stronger paired-pulse facilitation of PreCaTs was observed in VS in comparison to DLS. This difference in potentiation indicates that factors controlling presynaptic calcium levels and DA release are differentially controlled in the two striatal subregions, in a manner that cannot be simply ascribed to differential expression of proteins involved in negative feedback or uptake (D2R, DAT), or the presence of fewer fibers innervating the VS. Subregional differences in effects of calcium channel toxins, Gi/o receptor antagonists and cholinergic agonists and antagonists are also being examined. We will thus determine if these molecules play any roles in the subregional differences in mDA presynaptic function.

Title: Evidence against dopamine as a basal ganglia regulator of behavioral disengagement

Authors: *M. N. TERMINEL, T. MORENO, A. E. HERNANDEZ, J. RAMOS, E. CASTAÑEDA
Univ. of Texas At El Paso, El Paso, TX

Abstract: The Basal Ganglia circuitry, a fundamental motor system, has long been known to be compromised in Parkinson's disease. While it is well established that Parkinson's patients suffer from pronounced motor deficits, recent behavioral studies suggest that the function of the Basal Ganglia is disengagement of behavior, which allows transitions between voluntary and respondent movement. Interestingly, one study suggests that dopamine (DA) in the Basal Ganglia, specifically the nigrostriatal pathway, regulates engagement ("starting") and disengagement ("stopping") of movement in rats. Unfortunately, little is known about how DA modulates locomotion during disengagement. The objective of this study is to provide insight about the role of DA within the basal ganglia to produce locomotor behavior. Our central hypothesis states that DA in the nigrostriatal motor pathway, an intrinsic circuitry of the basal ganglia circuitry, is important for initiating and terminating movement. To test this hypothesis we trained rats to walk on a treadmill in a continuous (for a period of 1 hr) and discontinuous (during 1 hr, 30 sec on/15 sec off) fashion. During treadmill walking, *in vivo* intracerebral microdialysis sampling for DA and its metabolites (DOPAC, HVA) were collected at the neostriatum. Dialysate was subsequently assayed using high pressure liquid chromatography (HPLC) coupled with electrochemical detection. We initially predicted that DA utilization would be greater during discontinuous treadmill walking that involves repetitive engage/disengage behavior. Contrary to our hypothesis, we found that both continuous and discontinuous treadmill walking produced an increase in DA release to the same extent. There were similar significant increases in extracellular DA metabolites when rats engaged in locomotor activity across both conditions. Our discussion will consider potential explanations for the present findings and set the foundation for a number of new studies to investigate changes in functionally relevant DA release, in contrast to pharmacologically induced overflow, in questions related to Parkinson's disease and substance abuse disorder.

Title: Opioidergic control of striatal low threshold spiking interneurons (LTSIs)

Authors: R. ELGHABA[1], *J. BERWICK[3], E. BRACCI[2]
[1]Psychology, [2]Univ. of Sheffield, Sheffield, United Kingdom; [3]Dept Psychol, Univ. Sheffield, S. Yorkshire, United Kingdom

Abstract: The striatum is the largest nucleus and the main input structure of the basal ganglia. Low-threshold spike interneurons (LTSIs) are the only nitrergic neurons in the striatum and represent one of the tonically active neurons (TANs) in the striatum. While opioid receptors and their ligands encephalin and dynorphin play an important role in the striatum, their action on LTSIs has not been investigated. Using transgenic mice in which the NPY-expressing neurons are marked with green fluorescent protein (GFP), we investigated the effect of DAMGO (a μ receptor agonist), DPDPE (a δ recetor agonist) and (-)-U-50488 hydrochloride (a κ receptor agonist) on LTSIs activity. While DPDPE (1 μM) and (-)-U-50488 hydrochloride (20μM) produced hyperpolarizing effects in all LTSIs tested, DAMGO (1μM) produced hyperpolarizing effects in 80% of LTSIs and depolarizing effects in 20% of LTSIs tested when applied in control solution. We investigated the cause of this DAMGO-induce depolarization in a subpopulation of LTSIs. The dual effects of DAMGO persisted in the presence of tetrodotoxin (TTX), a sodium channel blocker. However, when GABAA, nicotinic & muscarinic receptors were additionally blocked, DAMGO effects on LTSIs were always hyperpolarizing. These finding suggest that μ-receptor agonists affect LTSIs both directly (exerting inhibitory effects) and indirectly, through presynaptic inhibition of GABA and acetylcholine release.

Title: Regionally distinct dopamine release dynamics between striosome and matrix compartments of the striatum

Authors: *A. G. SALINAS[1,2], M. I. DAVIS[1], K. T. BLACKWELL[2], D. M. LOVINGER[1], Y. MATEO[1]
[1]Natl. Inst. On Alcohol Abuse and Alcoholism, Rockville, MD; [2]The Krasnow Inst. for Advanced Study, George Mason Univ., Fairfax, VA

Abstract: The striatum is a basal ganglia brain region involved in a number of neurological processes including learning and action control. It is comprised of GABAergic medium spiny projection neurons (~90%) and an assortment of interneurons (~10%). The striatum receives glutamatergic inputs from several cortical and thalamic areas and dopaminergic innervation from the substantia nigra and ventral tegmental area. The striatum has also been classically characterized as having two major output pathways: the direct pathway, which consists of D1 dopamine receptor-enriched neurons projecting directly to the substantia nigra and internal segment of the globus pallidus, and the D2 dopamine receptor-enriched, indirect pathway, which projects sequentially to the external segment of the globus pallidus, the subthalamic nucleus, and the midbrain. The striatum has also been classified into striosome and matrix compartments, based on the differential expression of a number of proteins, including the mu opioid receptor and Nr4a1 (nuclear receptor subfamily 4, group A, member 1). A number of functional differences between the striosome and matrix compartments have been noted and are implicated in neurological disorders including Huntington's disease, Parkinson's disease, and drug addiction. Given the importance of dopamine signaling in all of these conditions and the differences between striosome and matrix compartments in models of these conditions, we hypothesized that dopamine release dynamics between striosome and proximal matrix compartments would differ. To address this hypothesis, we used mice expressing eGFP under the Nr4a1 promoter to identify striosomes and fast scan cyclic voltammetry to measure evoked dopamine release from striosome and matrix compartment pairs throughout the striatum. We found that evoked dopamine release in striosomes located in the dorsal striatum was reduced approximately 33% compared to the matrix compartment. We further found that in the ventral striatum, this pattern was reversed, such that, dopamine release in striosomes was approximately 46% greater than in the matrix compartment. We found no differences in dopamine clearance between striosome and matrix compartments or between striatal subregions. Further studies are

underway to determine possible mechanisms gating the altered dopamine release between striosome and matrix compartments and striatal subregions.

Title: Lisophosphatydilinosytol modulates GABA release in substantia nigra pars reticulata trough GPR55 receptor

Authors: ***R. SANCHEZ**[1], G. LOPEZ-RAMIREZ[1], F. PAZ-BERMUDEZ[1], M. RODRÍGUEZ-SÁNCHEZ[1], M. MUNOZ-ARENAS[2], B. FLORAN[1]

Abstract: The G protein-coupled receptor 55 (GPR55) has been proposed as a cannabinoid receptor and some authors suggest that Lisophosphatydilinosytol (LPI) can be its endogenous ligand. The mRNA for this receptor is high expressed in the Central Nervous System (CNS) in the cerebral cortex, cerebellum, hippocampus, thalamus and striatum. By immunohistochemistry we found GPR55 receptor expression in the striatum and subthalamic nucleus of rat, since both structures project to the SNr, we asked if GPR55 receptor can modulate GABA release. By western blot we found GPR55 expression in nigral synaptosomal fractions. LPI increases K+ evoked [3H]GABA release in a dose dependent fashion, this effect was prevented by the GPR55 selective antagonist CID16020046 [400 nM]. The increase of K+ stimulated [3H]GABA release is abolished by preincubation with EGTA 3 mM but not by thapsigargin 10 uM. This results suggest GPR55 receptor present in GABAergic terminal in the SNr modulate GABA release trough Ca++ extracellular mobilization, but not from intracellular compartments.

Title: Cannabinoids disrupt the cortical information transmission through the sensorimotor circuit of the basal ganglia

Authors: *T. MORERA-HERRERAS, I. BUSTINZA, A. GUTIERREZ, L. UGEDO
Pharmacol., Dept. Pharmacology. Univ. of the Basque Count, Leioa, Spain

Abstract: The CB1 cannabinoid receptor which is densely located in the basal ganglia is known to participate in the regulation of movement activity. The aim of this study was to determine the effect of cannabinoids (Δ^9-tetrahidrocannabinol (Δ^9-THC), and WIN 55,212-2) on spontaneous and cortically evoked activity in the substantia nigra pars reticulata (SNpr) by extracellular recording techniques in anaesthetized animals. Administration of Δ^9-THC (0.5 mg/kg, i.v.) stimulated (by 127 ± 14%) 6 of 11 SNpr recorded neurons, whereas it inhibited (by 73 ± 14%) the remaining 5 neurons. After Δ^9-THC the regularity of neuron activity was increased in all recorded neurons and the firing pattern changed toward a more bursting discharge. On the other hand, administration of WIN 55,212-2 (125-250 μg/kg, i,.v.) increased the firing rate of SNpr neurons (by 125 ± 7%, n=6) and the regularity of neuron activity, whereas did not modify the firing pattern. Previous administration of the cannabinoid receptor antagonist AM 251 (1 mg/kg, i.v.) completely blocked the effects induced by both agonists. Moreover, when AM 251 (1 mg/kg, i.v.) was administered alone also induced an increase (13 of 21 SNpr recorded neurons) or a decrease (remaining 8 neurons) in firing rate. After Δ^9-THC or WIN 55,212-2 administration, the inhibitory component of the cortically evoked response (activation of the direct striatonigral circuit) and the late excitatory response (activation of the indirect striato-pallido-subthalamo-nigral circuit) were decreased or completely lost. However, the early excitatory response (activation of the hyperdirect corticosubthalamic circuit) was not modified by cannabinoids administration. Previous administration of AM 251 (1 mg/kg, i.v.) completely blocked these effects without any modification of the cortically evoked responses. These results suggest that CB1 receptor activation modulates the sensorimotor transmission through the trans-

striatal pathways. This modulation may be relevant in the understanding of involvement of the cannabinoid system in motor control.

Center, Semel Institute, Dept. of Psychiat, Univ. of California Los Angeles, Los Angeles, CA; [4]Dept. of Radiology, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: Historically, the development of antipsychotic drugs has been based on the hypothesis that psychosis is related to increased dopaminergic tone. Although D2 dopamine receptor antagonists have been used to manage psychotic episodes, their efficacy is limited by motor side effects. Recent evidence, however, indicates that a D2-D3 partial agonist lacks these side effects, while retaining antipsychotic action (Caccia et al., 2013, Therap Clin Risk Man 9:319-328). We recently reported the ability of D2-like and D2 dopamine receptor selective compounds to attenuate the head twitch response (HTR) in DBA/2J mice (Rangel-Barajas et al., 2014, Neuropharmacology 83:18-27). Here, we studied the effect of the selective D3 dopamine receptor partial agonist WW-III-55 on HTR induced by the serotonin 5HT2A/2C receptor agonist 2,5-dimethoxy-4-iodoamphetamine (DOI), a hallucinogen used to screen for antipsychotic activity. Vehicle or WW-III-55 (6 mg/kg, ip) was administered 5 min before DOI (5 mg/kg ip) to FvB/NJ mice. DOI-induced HTR was monitored every 5 min for 30 min. Neuronal activity was recorded in primary motor cortex (M1) and dorsal striatum. We found that

WW-III-55 significantly inhibited DOI-induced HTR with a maximum efficacy of 50.2%. We also found a reversal of DOI-induced electrophysiological activity. In both M1 and dorsal striatum, DOI increased the rate and pattern of spike bursts and WW-III-55 reversed these effects. Our results suggest that selective activation of D3 dopamine receptors may represent a potential therapeutic target for psychiatric disorders.

Abstract: Activation of serotonin 5HT2a/2C receptors by 1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane (DOI) induces involuntary motor responses characterized by spontaneous head twitching. Given that corticostriatal pathway plays a critical role in motor output, we evaluate the activity of cortical pyramidal neurons (CPNs) in primary motor cortex (M1) and medium spiny neurons (MSN) in dorsal striatum for 30 min in freely behaving mice (FvB/N) following injection (ip) of 5mg/kg DOI. Our results show that DOI decreased firing rate in both CPNs and MSNs. Interestingly, although no changes in the burst rate of individual spike trains were recorded, the properties of spike bursts, such as the number of spikes per burst, burst duration, and burst surprise value, were significantly augmented in both CPNs and MSNs. After DOI-

induced corticostriatal neuronal changes were characterized, we evaluated the effect of the novel dopamine D3 receptor agonist, WC 44, on the number of head twitches and the observed changes in CPNs and MSNs activity. Pretreatment with 5 mg/kg WC 44, 5 minutes before DOI, significantly reduced the number of head twitches and reversed the changes in CPN and MSN activity induced by DOI. Collectively, our results implicate the D3 dopamine receptor as a possible target for the control of involuntary movements associated with various neuropathological conditions.

Title: Cholinergic mechanisms of DBS in entopeduncular nucleus

Authors: *F. LUO, T. CHOMIAK, Z. KISS
Dept. of Clin. Neuroscience, Univ. of Calgary, Hotchkiss Brain Inst., Calgary, AB, Canada

Abstract: Chronic, high frequency (>100 Hz) electrical stimulation, known as deep brain stimulation (DBS), of the internal segment of the globus pallidus (GPi) is a highly effective therapy for Parkinson disease and dystonia. However, how it works remains unknown. Several hypotheses about its mechanisms of action have been proposed, such as depolarization blockade, activation of inhibitory synapses, depletion of neurotransmitters, and/or disruption/alteration of network oscillations. To date, none of these hypotheses have discussed cholinergic mechanisms. Yet, cholinergics are ubiquitous in the basal ganglia and could play an important role in DBS therapeutic benefit. GPi is the major output nucleus of the basal ganglia and receives cholinergic inputs from the pedunculopontine tegmental nucleus in addition to its own local cholinergic interneurons. Here we investigated the cellular mechanisms of simulated DBS (sDBS) in entopeduncular nucleus (EP, rat equivalent of GPi) neurons using whole-cell patch clamp

recordings focusing on cholinergics. We found that sDBS applied inside the EP nucleus induced a prolonged afterdepolarization that was dependent on stimulation frequency, pulse duration, and current amplitude. The high frequencies (>100 Hz) and pulse widths (>0.15 ms) used clinically for dystonia DBS could reliably induce these afterdepolarizations which persisted under blockade of ionotropic glutamate (kynurenic acid, 2 mM), GABA (picrotoxin, 50 μM) and acetylcholine nicotinic (DHβE, 2 μM) receptors. However, this effect was blocked by atropine (2 μM, non-selective muscarinic antagonist) or TTX (0.5 μM). A 10 s intracellular current (100 pA) injection combined with activation of muscarinic receptors with non-selective agonist oxotremorine (10 μM), while under GABA (picrotoxin 100 μM) and glutamate blockade (2 mM kynurenic acid), was also able to mimic the effect of a 10 s sDBS train. Finally, the muscarinic-dependent afterdepolarizations were sensitive to either phospholipase C pathway or calcium-sensitive nonspecific cationic channels (CAN channels) blockade. Hence, these data suggest that muscarinic receptor activation during sDBS can lead to feedforward excitation through the opening of CAN channels. This study for the first time describes a cholinergic mechanism of sDBS in EP neurons that provides new insight into our understanding of the underlying mechanisms of clinical DBS in humans.

Abstract: Background: Current protocols or repetitive transcranial magnetic stimulation (rTMS) induce mixed facilitatory and inhibitory effects. More selective, quasi-monophasic high-frequency stimulators have now become available. We sought to investigate the impact of current direction and pulse width on intermittent theta burst stimulation (iTBS) effects on human motor cortex excitability. Also, we estimated strength-duration time constants from motor threshold and input-output (IO) curves for posterio-anterior (PA) and AP orientations. Methods: We stimulated the dominant hand representation of the motor cortex in 15 healthy subjects, using "unidirectional biphasic" pulses generated by a controllable TMS machine (cTMS-3, Rogue Resolutions Ltd., Cardiff, UK), connected to a standard figure-8 coil. iTBS was applied conventionally, using 20 sequences of 2 seconds iTBS (10 bursts at 5 Hz burst repetition frequency, each burst consisting of 3 pulses of 80 % AMT intensity repeated at 50 Hz frequency). In separate sessions pulses differing in current direction and shape were applied: a) PA dominant current direction in the brain, 75 μs (iTBS_PA75). b) AP current direction, 45 μs (iTBS_AP45). Before and for 30 minutes after iTBS, we monitored the modulation of motor evoked potential (MEP) amplitude from the dominant first dorsal interosseus using conventional, monophasic, suprathreshold pulses generated by a Magstim 2002 stimulator, inducing PA currents in the brain, at 0.2 Hz frequency. In an additional study on ten healthy subjects, we investigated the effect the two coil orientations with three different pulse widths (30, 60 and 120 μs) on the IO curve and the latency of the motor evoked potentials (MEPs). Results: iTBS_AP45 yielded a pronounced and slightly delayed inhibition of MEP amplitude in all but one subjects; the amount of inhibition was unrelated to the MEP latency differences. iTBS_PA75 had a variable and inconsistent effect that was in part related to the AP-LM latency difference, in that long latency differences were correlated with the induction of inhibition rather than facilitation. We found a longer time constant for AP than PA orientation. MEP latencies yielded an interaction between pulse width and orientation, due mainly to longer onset latencies following AP stimuli of short duration. Conclusions: Current direction influences the outcome of iTBS, with a preference for AP currents. PA and AP stimuli activate the axons of neurons with different time constants. Those activated by AP pulses excite corticospinal outputs with a longer latency than those activated by PA pulses. AP pulses of short duration recruit long latency inputs most selectively.

Title: Aerobic exercise modulates the cortical response to motor training

Authors: *A. M. SINGH, J. L. NEVA, W. R. STAINES
Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Aerobic exercise may modulate cortical excitability in primary motor cortical (M1) regions. Previous work from our lab indicates that acute exercise can decrease intracortical inhibition in M1 and also enhances the induction of early, long-term potentiation (LTP)-like plasticity. However, the effect on motor training has not been studied. In this study, we sought to determine the effect of acute aerobic exercise on an upper limb bimanual training task. It was hypothesized that a session of moderate-intensity aerobic exercise would facilitate cortical adaptations to bimanual training. Thirty young, healthy, right-handed participants were recruited and divided into three groups with the following experimental interventions: a) bimanual motor training alone; b) exercise alone; and c) exercise followed by bimanual motor training. The resting excitability of the extensor carpi radialis (ECR) muscle was measured at baseline and again immediately following the intervention. Single-pulse transcranial magnetic stimulation (TMS) was applied over the left M1 in order to map the boundaries of the cortical right ECR representation. After determining the resting motor threshold (RMT), the cortical map was obtained by sampling from sites in all directions from the motor hotspot in steps of 1 cm. Ten

single pulses at 110% of RMT were delivered at each site with an inter-stimulus interval of 3 s. The sites at which motor-evoked potentials (MEPs) were no longer observed were considered to be the boundaries of the representation. Sites with an average MEP amplitude greater than 30 μV were considered active. Following motor mapping, participants underwent one of the following interventions: a) 160 trials of a bimanual visuomotor training task; b) twenty minutes of stationary biking at 70% of age-predicted maximum heart rate; or c) both tasks, with the exercise bout immediately preceding the bimanual training. Immediately following each intervention, the TMS protocol was repeated to re-map the representation of the ECR muscle. Changes in excitability were quantified as either a change in the size of the ECR map as reflected by the number of active sites, a shift in the center of gravity of the map, or a difference in the average MEP amplitude within and across active sites. Preliminary analysis indicates that when training is preceded by exercise, this combination facilitates expansion of the motor cortical map to a greater extent than performing exercise or training alone. The current findings suggest that exercise may act to prime M1 for experience-dependent plasticity and can improve the effectiveness of subsequent motor training.

Title: Evaluating the role of the premotor cortex in early somatosensory processing using somatosensory evoked potentials (SEPs) and continuous theta burst stimulation (cTBS)

Authors: ***M. J. BROWN**, J. L. NEVA, A. M. SINGH, W. R. STAINES
Kinesiology, Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Frontal N30 somatosensory evoked potentials (SEPs), elicited by median nerve (MN) stimulation, are recorded maximally over the scalp from fronto-central electrodes. These frontal N30 SEPs represent early somatosensory input into non-primary motor areas rather than traditional primary sensory areas. There has been conflicting evidence from intracranial recordings and repetitive transcranial magnetic stimulation (rTMS) as to whether the

supplementary motor area (SMA), dorsal premotor cortex (PMd) or both are involved in the generation of frontal N30 SEPs. The purpose of the current study was to evaluate the role of the PMd in the generation of frontal N30 SEPs using continuous theta burst stimulation (cTBS). Frontal P20 and N30 SEPs were recorded from the FCz electrode position after MN stimulation to both left and right wrists. Changes in N30 peak and P20-N30 peak-to-peak amplitudes were compared at rest before to after (0, 15, 30 and 60 minutes) the application of cTBS to the right PMd (2.5 cm anterior to FDI motor hotspot in M1). Furthermore, previous research has suggested that variability in individual responses to cTBS in M1 may be predicted by the onset latencies of motor-evoked potential (MEP) with different coil orientations. Thus, MEP onset latencies were measured and compared in the current study when applying monophasic single pulse TMS to the M1 motor hotspot representation of the right FDI with anterior-posterior (AP), posterior-anterior (PA), lateral-medial (LM) and medial-lateral (ML) coil orientations. Preliminary group results did not reveal any significant modulation of frontal N30 peak or P20-N30 peak-to-peak amplitudes after cTBS to the right PMd. However, significant correlations were revealed between MEP latency difference (between AP-LM and AP-PA coil orientations) and the amount/direction of P20-N30 peak-to-peak amplitude change (elicited by left MN stimulation) after cTBS. These results demonstrated that a greater latency difference between MEPs elicited with AP-LM and AP-PA coil orientations was associated with increases in P20-N30 peak-to-peak amplitude while decreased latencies were associated with decreases in amplitudes. Based on these findings, individual variability in response (inhibition, excitation or no response) to PMd cTBS may be predicted by MEP onset latency differences with different coil orientations. Furthermore, although there is variability in the response after PMd cTBS, these results support that the PMd may be a contributor to the generation of frontal N30 SEPs.

Title: Changes in corticospinal excitability induced by paired associative transcranial alternating current stimulation

Authors: *E. MCNICKLE[1], R. G. CARSON[1,2]
[1]Trinity Col. Inst. of Neurosci., Trinity Col. Dublin, Dublin, Ireland; [2]Queen' Univ. Belfast, Belfast, United Kingdom

Abstract: Many types of non-invasive brain stimulation alter corticospinal excitability (CSE). Paired Associative Stimulation (PAS) attracts particular attention as its effects ostensibly adhere to Hebbian principles of neural plasticity. In prototypical form, a single electrical stimulus is directed to a peripheral nerve in close temporal contiguity with transcranial magnetic stimulation (TMS) delivered to the contralateral primary motor cortex (M1). Repeated pairing of the two discrete stimulus events (i.e. association) over an extended period either increases or decreases the excitability of corticospinal projections from M1, contingent on the interstimulus interval (ISI). We studied a novel form of associative stimulation, consisting of 500 ms trains of peripheral afferent stimulation paired with short bursts of high frequency (≥ 80 Hz) transcranial alternating current stimulation (tACS) over contralateral M1. Elevations in the excitability of corticospinal projections to the forearm were observed for a range of tACS frequency (80Hz, 140Hz and 250Hz) and current (1mA, 2mA and 3mA) parameters. tACS bursts of 1000ms duration generated larger increases in CSE than 250ms or 500ms bursts. The effects were more reliable than those brought about by PAS or transcranial direct current stimulation (tDCS). When paired with tACS, muscle tendon vibration induced greater elevations of CSE than electrical nerve stimulation. In demonstrating that associative effects are expressed when the timing of the peripheral and cortical events is not precisely circumscribed, these findings suggest that multiple cellular pathways may contribute to a LTP-type response. Their relative contributions will differ depending on the nature of the induction protocol that is used.

Title: Changes in neuronal responses induced by paired associative nerve stimulation

Authors: *B. HABEKOST, S. N. BAKER
Inst. of Neurosci., Newcastle Upon Tyne, United Kingdom

Abstract: Non-invasive methods have been developed to induce plastic changes in the sensorimotor cortex. These rely on stimulating pairs of afferent nerves. By associative stimulation of two afferent nerves, excitability changes in the motor cortex occur as indicated by studies reporting changes in motor evoked potentials (MEPs) elicited by transcranial magnetic stimulation (TMS). The repetitive stimulation of those nerves has a potential in rehabilitation and treatment of neurological disorders like stroke or spinal cord injury. Despite promising results and applications in human subjects using these methods, little is understood about the underlying basis for the changes which are seen. In the present study, we record from identified pyramidal tract neurons and unidentified cells in primary motor (M1) and somatosensory cortex (S1), in a single macaque monkey before and after one hour associative stimulation of the median and ulnar nerve. Cell discharge was recorded during selective independent movements of thumb and index finger, as well as in response to electrical stimulation of each nerve independently. Cells in M1 (and S1) showed increased and decreased firing rates in response to nerve stimulation after one hour of associative nerve stimulation. These findings suggest that the sensorimotor cortex undergoes plastic changes in response to associative nerve stimulation.

Title: Reliability of measures of motor cortical inhibition derived from transcranial magnetic stimulation

Authors: *A. VIRANI[1], D. RADKE[2], T. DAVIDSON[2], F. TREMBLAY[3]
[2]Human Kinetics, [3]Sch. of Rehab Sci., [1]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Neurophysiological properties of the motor system can be studied non-invasively using transcranial magnetic stimulation (TMS). The cortical silent period (CSP, Werhahn et al., 1999) and short afferent inhibition (SAI, Tokimura et al., 2000) are two common measures derived from TMS to probe the excitability of local inhibitory networks within the primary motor

cortex (M1). There is still relatively little information, however, regarding the reliability of these measures of cortical inhibition when repeated between sessions. In the present study, we examined the inter-session reliability of CSP and SAI measurements, as well as the inter-rater reliability of CSP measurements. The CSP and SAI were measured in two different sessions, 1 week apart, in healthy participants (n=10) using standardized procedures. For the CSP, suprathreshold TMS pulses (130%) were delivered while participants exerted a submaximal force (10-20% MVC) against a pinch dynamometer. For SAI, electrical pulses were delivered to the median nerve at the wrist (200 μs pulse, minimal twitch) at an interval of 20 ms before the TMS pulse (120%). SAI levels were expressed as % $MEP_{conditioned}/MEP_{unconditioned}$. Comparisons of SAI levels and CSP durations revealed good reliability between sessions, with intraclass coefficients of 0.72 and 0.74, respectively. In addition, comparisons of estimates of CSP duration from visual inspection derived from different examiners revealed very high inter-rater reliability (ICC = 0.996). In sum, both CSP and SAI proved to be reliable measures in young healthy adults when repeated between sessions at an interval of one week. In addition, our results concur with other studies (e.g., Kimberley et al. Neurosci Lett 464, 84-87, 2009) and confirm the high inter-rater reliability of CSP duration estimates derived from visual inspection.

Title: Hemispheric inhibition between motor cortices: A reliability study of TMS-derived measures of interhemispheric inhibition

Authors: *D. P. RADKE, A. VIRANI, T. DAVIDSON, F. TREMBLAY
Bruyère Res. Inst., Ottawa, ON, Canada

Abstract: The motor transcallosal pathway is thought to be critical both for bimanual motor coordination and for unimanual tasks. One way to assess *in vivo* the transcallosal connections between motor cortices is by means of transcranial magnetic stimulation (TMS). With this technique, two different measures of transcallosal inhibition (TCI) can be derived. The first one is based on double coil stimulation to examine inter-hemispheric inhibition (IHI) elicited either at short- (IHI_{10}) or long- interval (IHI_{40}). The second measure is obtained via supra-threshold

cortical stimulation during active contraction via the ipsilateral silent period (iSP). The present study examined the inter-session reliability of measures of TCI derived from double coil stimulation (IHI_{10}, IHI_{40}) and iSP in 10 healthy young participants. The IHI measures were obtained using two focal coils coupled with Magstim 200 (test stimuli 120% MT) and Rapid^2 (conditioning stimuli 120% MT) stimulators. The iSP was obtained by applying suprathreshold stimulation (130%) to the left motor cortex while participants exerted maximal effort with the left hand and light contraction with the right hand (target muscle: 1st dorsal interosseous). Reliability between sessions (1 wk interval) was assessed via the intraclass correlation coefficient (ICC) and Pearson's moment correlation (r). The inter-rater reliability of iSP analysis was also examined. The inter-session reliability of both IHI_{10} and IHI_{40} was found to be fair (ICC of 0.41 and 0.47, respectively), while the inter-session reliability of indices derived from visual inspection of iSP traces (latency onset and duration of TCI: LTI, DTI) were both found to have excellent reliability (ICC of 0.98 and 0.94, respectively). The inter-rater reliability of LTI and DTI indices from the iSP were also found to be highly reliable between examiners (ICC of 0.98 and 0.97, respectively). Finally, in line with Chen et al (2003), we also found high correlation ($p<0.01$, $r^2= 0.37$) between IHI_{40} and iSP duration (DTI), whereas such association was not found for IHI_{10}. Our results indicate that measures of TCI derived from iSP traces are more reliable than measures derived from variations in MEP amplitude using the double coil stimulation. In addition, our results confirm the close association between IHI seen at 40 ms interval and TCI measured via the iSP, as suggested by Chen et al. (J Neurophysiol 89, 1256-1264, 2003).

Title: Modulation of transcallosal inhibition in the motor cortex by transcranial direct current stimulation (tDCS)

Authors: *T. DAVIDSON[1,4], F. TREMBLAY[2,4], M. BOLIC[3]
[2]Sch. of Rehabil. Sci., [3]Sch. of Electrical Engin. and Computer Sci., [1]Univ. of Ottawa, Ottawa, ON, Canada; [4]Bruyère Res. Inst., Ottawa, ON, Canada

Abstract: Anodal tDCS of the primary motor cortex (M1) is known to lead to a lasting increase in corticospinal excitability, as evaluated using transcranial magnetic stimulation (TMS). However, there is still little information with regards to the effects of tDCS on TMS-derived measures of transcallosal inhibition. Here, we investigated the effects of a single session of anodal tDCS on both cortical excitability, as reflected in the facilitated motor evoked potential (facMEP) amplitude, and motor transcallosal inhibition, as measured with the ipsilateral silent period (iSP). Participants (young adults, n=12) underwent anodal tDCS (2 mA) over the left M1 for 20 minutes. Changes in MEP amplitude and iSP parameters were monitored before and at specific time intervals after tDCS. Following tDCS, a majority of participants exhibited the expected MEP facilitation (7/12, 76% increase), while the remaining tended to show depression (-31% decrease). In parallel, the duration of transcallosal inhibition (DTI) also increased in a majority of participants (7/12, 20% increase) after tDCS. Correlation between changes in MEP amplitude and in DTI post-tDCS revealed a trend for significance between the two (r=0.53, p=0.07). These results are in line with those of Lang et al (2004) and suggest that increase in corticospinal excitability induced by tDCS is accompanied by parallel changes in the excitability of the transcallosal connections from the stimulated M1 to the opposite MI. Our results also highlight the inherent variability of individual responses to plasticity inducing protocols by non-invasive brain stimulation techniques. We are currently investigating this issue using variations in MEP latency, as shown by Wiethoff and colleagues (Brain Stimul, 7, 2014).

Title: Hemispheric differences in modulation of corticospinal excitability associated with mental tasks

Authors: *L. FERRON, F. TREMBLAY
Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Observing others performing actions is a common way to learn new motor skills. Such ability appears to be linked with one's ability to mentally simulate actions. While mental simulation has been widely used in the context of athletic performance, the same approach has also been advocated in rehabilitation settings, where they target clinical populations with limb injuries or affected with chronic pain. Here, we investigated with transcranial magnetic stimulation (TMS) hemispheric differences in modulation of motor evoked potentials (MEPs) elicited in the context of mental tasks involving either speech production or hand rotations. We hypothesized that internal speech would lead to greater MEP facilitation in the left hemisphere (LH) owing to its major role of in language. Conversely, we anticipated that mental rotations involving hand laterality judgments would lead to larger MEP facilitation in the right hemisphere, given evidence of the right hemisphere role in kinesthesia (Goble & Brown, Neurosc & Biobehav Rev 32, 2008). Corticospinal excitability was tested (target muscle: 1st dorsal interosseus) with participants (n=16) seated in front of computer screen while they were asked to perform two mental tasks: 1) backward counting and 2) judging hand laterality. A third task wherein participants just watched an image of a "foot" was added as a "control". In all conditions, TMS (110% resting motor threshold) was delivered at a specific time delay based on prior assessment of performance in the hand laterality task (i.e., delay= half of the mean response time). Comparison of task-related variations in MEP log-amplitude reveals no significant hemispheric main effect or interaction, although MEPs tended to be larger in general in response to left TMS. A "task condition" effect was observed owing to the large MEP facilitation elicited during the mental counting task, which was significantly different ($p<0.003$) from either the control task or the hand rotation task. In fact, the latter task was associated with MEP depression, which almost reached significance ($p=0.056$) when compared to the control task. While no significant hemispheric asymmetry was found, our results point to larger task-related effect in the left vs. right hemisphere, especially in association with internal speech. Finding MEP depression with hand mental rotation suggests an active process which may be related to disengagement of

the distal hand representation in favor of more proximal muscles. We are currently investigating this issue.

Title: Effects of stress on motor map expression and behaviour

Authors: *K. A. SCULLION, A. KIM, M. GRAY, M. N. HILL, G. C. TESKEY
Hotchkiss Brain Inst., Univ. of Calgary, Calgary, AB, Canada

Abstract: Acute and chronic stress can have opposing effects within the CNS. Stress effects have been well documented in the limbic system but little attention has been given to the motor system. Previous research has demonstrated that acute stress increases glutamate receptors in the prefrontal cortex while chronic stress has the opposite effect. Consequently, glutamatergic transmission is altered during stress and this could result in changes in motor map expression. Motor maps are the topographical representation of movements and are derived by stimulating pools of pyramidal neurons in layer V of the neocortex using a technique called intracortical microstimulation (ICMS; Young et al., 2011). Motor maps can be considered an assay of brain excitability as the balance between cortical inhibition and excitation determines map expression. The quantity and type of neurotransmitters present in the neocortex also determines map expression. We examined the role of acute and repeated stress on the expression of cortical forelimb motor maps and behaviour. We tested three hypotheses 1) acute stress will decrease movement thresholds and increase motor map size 2) repeated stress will increase movement thresholds and decrease motor map size 3) repeated stress will impair the rat's ability to perform the single pellet skilled reaching task and will result in less motor map reorganization and expansion typically seen after skilled training. In experiments 1 to 3, the rats were stressed by

being placed on an elevated platform in a brightly lit room for 30 minutes each day. Blood samples were collected from the rats pre- and post- stress. All rats underwent high resolution intracortical microstimulation (ICMS) to map forelimb (digit, wrist, elbow, shoulder) and non-forelimb movement representation areas. For experiment 1, the rats were stressed and underwent ICMS on the same day. For experiment 2, the rats were stressed once daily for 5 consecutive days. On the last day of stress testing, ICMS was performed. For experiment 3, rats were trained on the single pellet skilled reaching task for 15 days. On the 16th day, the rats underwent stress testing once daily for the next 5 days. On the 5th day of stress testing, the skilled reaching performance of the rats was assessed and then ICMS was performed. Our preliminary results indicate that only repeated stress alters forelimb motor map expression. These results show that prolonged elevation of glucocorticoids play an inhibitory role on motor map expression. Outcomes of this investigation could lead to further understanding of how stress mediated effects can lead to motor system disorders.

Title: Changes of corticospinal tract after wearing prosthesis in serial bilateral below knee amputation

Authors: *S. KANG[1], D. KIM[1], K. SEO[1], J. KIM[2]
[1]Physical Med. & Rehabil., [2]Radiology, Chung-Ang Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: After amputation, brain has been known to be reorganized especially in motor primary cortex. We report a case of a patient whose corticospinal tract (CST) showed change after serially performed bilateral below knee (BK) amputation using diffusion tensor imaging (DTI). A 78 years old man visited orthopedics clinic complaining of right big toe's gangrene in 2011. In past medical history, he had diabetes mellitus for 10 years, and has had amputated 2nd toe of right foot since 2005. He also had below knee amputation on his left side since 2008 due to diabetic arterial stenosis. After BK amputation on his left side, he was able to walk

independently with his prosthesis. With his frequent pain and small multiple wounds, we assumed that he walked with the left prosthetic limb for supporting weight, not with right leg. He underwent right BK amputation in 2011, and transferred to rehabilitation department. DTI was performed before beginning gait training with new prosthesis for his right leg, and it showed larger number of fiber lines in right CST than left CST (Figure A). This result reflects that he walked with his left prosthetic limb more than right limb for supporting weight after left BK amputation in 2008. He had intensive rehabilitation program for 2 months, and discharged when he could walk with walker independently. He returned to his walk and he serially visited our clinic for 2 years, and he did not report any medical or surgical problems during this period. He was able to walk with bilateral cane without complication on his bilateral stump. A follow up DTI was performed at this point (2013), and it showed no definite difference in the numbers of fiber lines between both CST (Figure B). This result reflects that he has walked with bilateral prosthetic limb almost equally for supporting weight after right BK amputation in 2011. In conclusion, we found that side-to-side differences in corticospinal tract in unilateral below knee amputation were equalized after proper use of bilateral prosthesis in a patient with diabetic atherosclerosis.

Title: Influence of BDNF polymorphism on neurophysiology in human motor cortex

Authors: *R. CASH, K. UDUPA, R. CHEN
Toronto Western Res. Inst., Toronto, ON, Canada

Abstract: INTRODUCTION: The influence of genetic variation in the brain-derived neurotrophic factor gene (BDNF) on human cortical plasticity has recently attracted much interest, however careful studies of the effects on intracortical circuitry have been lacking. We investigated the influence of a common single nucleotide polymorphism (SNP) BDNF Val66Met on TMS measures of intracortical circuitry using carefully chosen parameters that are likely to tease out differences. METHODS: 18 participants were recruited, 9 Val homozygotes (aged 35 ± 2 years) and 9 Met allele carriers (aged 33 ± 4 years). The following circuits were investigated: GABAA receptor mediated short interval intracortical inhibition (SICI), GABAB receptor mediated long interval intracortical inhibition (LICI) and an excitatory circuit termed short interval intracortical facilitation (SICF). LICI was measured using 3 conditioning stimulus (CS) intensities: 90, 110 and 130% of resting motor threshold (RMT) and an interstimulus interval (ISI) of 150ms to avoid floor effects or saturation. SICI was measured at a CS intensity of 65% RMT & ISI 2ms, thus minimising contamination by excitatory circuitry. Test stimului (TS) evoking 1mV MEP were used for SICI and LICI. A SICF ISI curve was generated at 0.2ms intervals comprising the first I-wave peak and trough (1.1-2.3ms), using stimuli of equal intensity (110% RMT, Tokimura et al. 1996). As SICF peaks and troughs vary between individuals, maximal (max) and minimum (min) SICF was also computed across individuals. RESULTS: SICI was consistently stronger in Val/Val (23±3.5%) compared to Met allele carriers (57±11.3). LICI was stronger in Val/Val subjects at intensities of 110 and 130% RMT with no inhibition in either group at 90% RMT. SICF ISI curves differed strikingly between groups. SICF(max) was greater in Val/Val (1470±364 %) compared to Met carriers (555±133%), while there was little difference at SICF(min): 156±56% vs 100±12% of TS alone in Val/Val and Met groups. SICF TS amplitude (at 110% RMT) was equal between groups (~0.2mV). There were no differences between Val/Val and Met groups in RMT (49±4 and 49±4% MSO respectively) or the intensity required to generate 1mV peak-to-peak MEP amplitude (62±5 and 68±5% MSO respectively). DISCUSSION: We found stronger inhibition in GABAA and GABAB mediated circuitry, and stronger excitation in Val/Val homozygotes compared to Met allele carriers. As BDNF release is greater in Val/Val homozygotes, these results may be attributable to the role of BDNF in the development and maintenance of cortical circuitry, or its role in potentiating synaptic transmission, which contribute to BDNF's role in enhancing plasticity.

Title: Brief high intensity cycling enhances BDNF release and locomotor learning

Authors: *E. E. HELM, K. MATT, K. KIRSCHNER, D. REISMAN
Univ. of Delaware, Newark, DE

Abstract: Exercise, when coupled with a motor learning task, is believed to enhance neural plasticity and therefore promote improved learning post-stroke. Animal models have demonstrated exercise-induced neural plasticity through upregulation of proteins involved in synaptic plasticity, neural remodeling and learning particularly Brain Derived Neurotrophic Factor (BDNF). Literature concerning the role of BDNF in enhancement of motor learning in the human population is limited; however intensity of exercise has been shown to moderate the relationship between peripheral BDNF levels and cognitive learning. We theorize that high intensity exercise may also enhance motor learning. We hypothesize that a single 5 minute session of high intensity upper extremity cycling immediately prior to a locomotor learning task will elicit an up-regulation of peripheral BDNF levels and this upregulation will correlate with enhanced locomotor learning. In an ongoing study, 6 neurologically intact subjects have been randomly assigned to an Exercise+Learn or Learn only condition. Subjects participated in 2 sessions of split-belt treadmill walking on 2 consecutive days. On the first day subjects in both conditions walked on the split-belt treadmill at a 1:1 ratio for 2 minutes in order to assess baseline step asymmetry. Subjects then walked at a 3:1 speed ratio for 15 minutes. Both groups performed the identical motor learning task with the only difference between conditions that subjects in the Exercise+Learn condition performed a short bout of high intensity exercise on an upper body ergometer prior to split-belt walking. Cycling consisted of pedaling for 1 minute with high resistance immediately followed by 1 minute with low resistance to achieve 80% of subjects maximum heart rate. Subjects received a 1 minute rest and then repeated the cycling protocol. Subjects in the Learn Only group quietly rested for 5 minutes to account for time differences. On Day 2, longer term learning was assessed by having participants walk on the split belt treadmill in the same configuration as Day 1. Consistent with our hypothesis, initial results demonstrate that 5 minutes of high intensity exercise can increase serum BDNF levels relative to quiet rest. Additionally, the current trend indicates that those within the Exercise+Learn group demonstrate enhanced learning of the split belt learning task as assessed by improved step length symmetry. If the current trend is maintained with increased sample size, these results will directly impact the design and implementation of neurorehabilitation programs targeted toward facilitation of neuroplasticity.

Abstract: The noradrenergic system plays an important role in arousal, vigilance, response to stress and panic, as well as in motor learning. The cerebellum is an important region involved in the timing and plasticity underlying motor behaviors. Noradrenergic fibers, originating from the locus coeruleus, project to the cerebellum particularly innervating the Purkinje cell layer and the lower portion of molecular layer. Despite its undoubted presence in the cerebellum, the noradrenergic system in this brain region has received little attention. The goal of our study was to determine how the noradrenergic innervation of voluntarily active rats is altered relative to sedentary rats. In addition, we compared mild voluntary exercise on the running wheel (5

km/day) with excessive exercise (15 km/day), which is evoked by the stressful situation of food restriction. Previous studies have shown that excessive exercise on the running wheel exhibited by food restricted rats is maladaptive, in that it causes negative energy balance to the point of death, unless the food restriction is attenuated. To quantify the effect of exercise on the noradrenergic innervation, eight rats were singly housed in the presence of a running wheel starting P36 until P44 (EX group), while eight other rats were excessive exercise-induced (EEX group) by allowing voluntary wheel access and limiting food availability to 1 hr/day. In addition, eight other rats were singly housed without a wheel but with ad libitum food access (CON group) for the matching ages to obtain baseline values. We used the primary antibody dopamine-β-hydroxylase and subsequently visualized noradrenergic fibers and their varicosities with 3,3'-diaminobenzidine (DAB) as the immunolabel. We acquired image stacks of the DAB labeled noradrenergic fibers using a Photo Multiplier Tube (PMT) for digitization of the confocal microscope image. Next, using the Neurolucida Software (MBF Bioscience), we traced each noradrenergic fiber and added a marker demarcating each encountered varicosity. The inter-varicosity distances were 8.51μm for the CON group (N =8) and reduced to 7.79 μm for the EX group (N = 8) and also reduced to 7.45 μm for the EEX group (N =8). This difference across the groups suggests that voluntary wheel running during adolescence increases the amount of norepinephrine available for release in the molecular layer of the cerebellum.

Title: Frontal and cerebellar networks interact to determine potential for motor cortex plasticity

Authors: *J. L. MIRDAMADI, L. Y. SUZUKI, S. K. MEEHAN
Sch. of Kinesiology, Univ. of Michigan, Ann Arbor, MI

Abstract: Motor skill learning is driven by experience-dependent changes in multiple cortical and subcortical networks. During early learning, changes in the motor cortex (M1) are associated with increased attention, mediated by the dorsolateral prefrontal cortex (DLPFC), and feedback-corrections, mediated by the cerebellum. Increasing visual attention load attenuates the

facilitatory after-effect of intermittent theta burst stimulation (iTBS) through gating of somatosensory inputs to cortex, most likely through a DLFPC-thalamic network. However, both DLPFC and cerebellar-mediated networks can influence sensory processing, yet how these two networks interact to optimize learning is uncertain. Here, we used cerebellar TBS to assess whether cerebellar networks influencing sensory processing may interact with the attention sensory gating mechanism to determine potential for M1 plasticity. First, we hypothesized that in the absence of cerebellar iTBS, M1 plasticity would be attenuated by increase attentional demands, as previously shown. Second, we hypothesized that cerebellar TBS would inhibit thalamic projections to M1 and revert the effect of attention loads on subsequent M1 plasticity. M1 plasticity in the first dorsal interosseous was assessed using 2-second trains of TBS (3 pulses at 50 Hz, every 200 msec, 80% AMT) while participants engaged in a visual detection task requiring low or high loads of visual attention. Motor cortical excitability was assessed using single pulses of TMS (120% RMT). Five pulses were delivered 4 seconds apart prior to the TBS. 6 additional pulses were delivered every 4 seconds post-TBS, starting from 2 seconds after cessation of TBS. Trials were performed both before and after iTBS over the right posterior cerebellar cortex (20 two-second trains of TBS, 8 second inter-train interval). 15 trials were completed for each combination of attention load and cerebellar priming. Preliminary results (N=9) suggest that in the absence of cerebellar priming, MEP amplitude was facilitated after M1 TBS under low load, but unchanged after M1 TBS under high load, consistent with previous research. Following cerebellar iTBS, M1 TBS under low load failed to enhance MEP amplitude. In contrast, M1 TBS under high load enhanced MEP amplitude. These results suggest that both attention and error driven networks influence sensory input to the cortex. However, in circumstances where both serve to reduce excitability of M1, via the thalamus, a metaplastic response may be initiated that may be counterproductive to early motor skill learning. These results highlight the importance of controlling for attention when studying motor learning and plasticity.

Title: Short-term memory requirements decrease potential for plasticity in motor cortex

Authors: L. Y. SUZUKI, J. L. MIRDAMADI, M. SIERANT, *S. K. MEEHAN
Sch. of Kinesiology, Univ. of Michigan, Ann Arbor, MI

Abstract: Cognitive processes, such as attention and working memory are important determinants of motor learning. It has been proposed that increased loads of attention reduce motor cortical excitability through somatosensory gating. However, the impact of working memory upon motor cortical excitability has yet to be determined. The current study sought to determine the impact of increasing short-term memory loads upon recruitment of neuroplastic mechanisms that underlie skilled motor learning. It was hypothesized that increasing demands upon short-term memory would prevent theta burst stimulation (TBS) induced increases in motor evoked potential amplitude (MEP) when TBS was applied during the retention but not the acquisition phase of the Sternberg short-term memory (STM) task. Short-term memory requirements were manipulated by increasing the set size to be encoded and remembered from 2 digits to 6 digits. The memory set was presented for 2 seconds and was followed by a 2 second retention phase prior to the presentation of a single probe digit. TBS was either timed to coincide with the presentation of the digit set (encoding phase) or the two seconds following digit presentation but preceding presentation of the single digit probe (retention phase). TBS was delivered over the first dorsal interosseus (FDI) motor cortical hotspot (3 stimuli at 50 Hz, repeated every 0.2 seconds for 2 seconds total, 80% AMT). Motor cortical excitability was assessed using single pulses of TMS (120% RMT). Five pulses were delivered 2 seconds apart prior to the TBS. 10 additional pulses were delivered every 2 seconds post-TBS, starting from 2 seconds after cessation of TBS. 12 trials were completed for each combination of set size and STM task phase. Preliminary results show that for TBS delivered during the acquisition phase of the STM task the impact of set size differed across time. For a set size of 2 digits there is an initial facilitation for the first 6 seconds post-TBS followed by a return to pre-TBS amplitude. During high load there was no change during the first 10 seconds post-TBS, but a facilitation 12-20 seconds post-TBS. For the retention phase, there was no change in MEP amplitude compared to pre-TBS regardless of STM load. These results suggest that short-term memory may influence motor skill learning, in part, by directly influencing LTP- and/or LTD-like mechanisms in motor cortex. These effects appear to be dependent upon the extent to which information must be encoded and retained over short periods of time. There results may have important implications for developing instructions/feedback that may need to be held in short-term memory during rehabilitation interventions.

Title: Separate representations of the unimpaired and the impaired forelimbs in primary motor cortex following neonatal pyramidotomy in rats

Authors: *T. WEN[1], D. GUPTA[1], J. B. CARMEL[1,2]
[1]Burke Med. Res. Inst., White Plains, NY; [2]Neurol. and Pediatrics, Brain and Mind Res. Inst., New York, NY

Abstract: Background: After significant injury to one hemisphere in early development, the corticospinal tract from the uninjured hemisphere maintains connections to both sides of the spinal cord. During acquisition of motor skill, the uninjured hemisphere assumes control over both sides of the body. This comes at a cost; many movements of the impaired side are mirrored on the unimpaired side. We are interested in using brain stimulation to restore function to the impaired side. To understand how best to sculpt corticospinal circuits with electrical stimulation, we sought to determine how each forelimb is represented in the same motor cortex in the uninjured hemisphere. We hypothesized that each forelimb would have overlapping but distinct representations. Methods: We cut the corticospinal tract from one hemisphere at the level of the medulla oblongata in the postnatal-day 7 rat. Three months after pyramidotomy, we mapped motor responses of ipsilateral impaired and contralateral unimpaired forelimbs using intracortical microstimulation (ICMS) of forelimb motor cortex. Following ICMS, we injected the retrograde neural tracer fast blue into the spinal cord to map spinal connections on the ipsilateral impaired or the contralateral unimpaired side of the cervical spinal cord. Two weeks after injections, the fast blue-labeled corticospinal neurons were counted and the distribution reconstructed by mapping the counted neurons onto a 3-dimensional brain atlas. Results: During ICMS mapping, there were more sites that elicited contralateral than ipsilateral forelimb responses. Sites with low threshold contralateral responses tended to show ipsilateral responses as well. Thus, the representations were coextensive, but the contralateral map was larger and more robust. However, retrograde tracer experiments also showed important differences. Fewer neurons projected to the ipsilateral spinal cord than the contralateral, and these were more widely scattered throughout the motor cortex in the uninjured hemisphere. The contralateral representation, but not the ipsilateral representation, was clearly divided into two areas: the rostral forelimb motor area and the caudal forelimb motor area. Thus, the representation of the ipsilateral forelimb covers a larger area but is sparser that the contralateral. Conclusion: The

differences in the representation of each forelimb suggest a substrate for independent control that may be targeted for therapy.

Title: The effect of motor point associative stimulation and tDCS on manual dexterity and neurophysiology of the motor cortex

Authors: *N. HOSEINI, H. J. BLOCK
Indiana Univ., Bloomington, IN

Abstract: Manual dexterity, the ability to manipulate objects with the hands, is often impaired after stroke. Proprioception (position sense), which is critical for manual dexterity, is also frequently affected. Associative stimulation of motor points (MPAS) in hand muscles both modulates motor cortex excitability and improves manual dexterity (McDonnell & Ridding 2006). However, it is not known if the effect of this peripheral stimulation can be improved by central stimulation of sensorimotor cortex with transcranial direct current stimulation (tDCS). tDCS is a noninvasive brain stimulation technique in which a small electric current is passed through the head via two sponge electrodes. The current flow modulates cortical excitability in the target area in a polarity-specific way, resulting in measurable effects on behavior and neurophysiology. Here we investigated the effect of MPAS, with and without tDCS over sensorimotor cortex, on motor cortical neurophysiology, manual dexterity, and proprioceptive acuity in healthy adults. These measures were assessed pre and post-intervention with transcranial magnetic stimulation (TMS), the Purdue Pegboard Test, and an adaptive staircase method, respectively. Pilot data from 5 subjects supports the idea that MPAS increases motor cortex excitability. The TMS intensity needed to evoke a muscle twitch of 1mV amplitude pre-MPAS was compared with post-TMS. On average (±SE), muscle twitch amplitude increased by

0.55 ±0.35 mV after real MPAS, compared to only 0.03 ±0.20 mV after sham (asynchronous) MPAS. Preliminary results from 4 subjects who completed two experimental sessions each (MPAS with Sham tDCS vs. MPAS with excitatory (Anodal) tDCS) suggest that anodal tDCS may increase the effect of MPAS on motor cortex. After MPAS/Anodal tDCS, the slope of the TMS input/output curve increased 50 ± 25%, indicating greater recruitment of motor cortical neurons for a given TMS intensity, vs only 34 ± 21% after MPAS/Sham tDCS. Anodal tDCS may also increase the effect of MPAS on manual dexterity: average time to place 20 pegs in the Pegboard task decreased 1.67 ± 0.76 s after MPAS/Anodal tDCS, vs. only 0.78 ± 0.73 s after MPAS/Sham tDCS. While very preliminary, these results suggest the possibility that MPAS in combination with tDCS over sensorimotor cortex may be a stronger intervention than MPAS alone. Since proprioception is an integral part of manual dexterity, interventions that influence sensory as well as motor pathways may be more likely to improve manual dexterity in stroke patients. MPAS does so peripherally, while tDCS applied over sensorimotor cortex does so centrally. The combination may have benefits for sensorimotor function.

Title: Myelin water fraction imaging to evaluate white matter content changes after upper-limb training in a semi-immersive virtual reality environment

Authors: *B. LAKHANI[1], J. N. JACKSON[1], M. R. BORICH[2], A. L. MACKAY[1], L. A. BOYD[1]
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Emory Univ., Atlanta, GA

Abstract: Background: It is well accepted that the brain undergoes numerous structural and chemical changes when learning a novel motor skill. Neuroimaging studies that evaluate these changes have primarily focused on changes in grey matter of the central nervous system (CNS). However, data characterizing white matter, which consists of myelinated tracts that transfer signals across the CNS, has been limited. Multi-component T_2 relaxation imaging (MCRI) can

quantify the proportion of water trapped between lipid bilayers of myelin to provide an objective, validated marker of white matter myelin content (myelin water fraction or MWF). To date, there is no research that has attempted to longitudinally quantify changes in myelin content in response to motor skill learning. Therefore, the objective of the current study is to explore the relationship between changes in MWF and acquisition of a novel upper-limb motor task in healthy young adults. **Methods:** Fifteen, right hand dominant, healthy young adults (26 ± 4 years old; 8 female) underwent magnetic resonance imaging (MRI) prior to and within 24 hours of the last of ten sessions of upper-limb training in a semi-immersive virtual reality environment using the Microsoft Kinect© gaming system. The training was conducted over a four-week period and each training session consisted of five blocks of 200 skilled motor movements with the right arm used to control an avatar displayed in a 2-dimensional environment on a monitor. The goal was to intercept and release a moving target. Participants progressed in difficulty levels upon achieving at least an 80% success rate in two consecutive training blocks. Differences in MWF following training were assessed in a priori regions of interest (posterior limb of the internal capsule (PLIC), intraparietal sulcus (IPS), whole-brain normal appearing white matter (NAWM)). **Results:** There was a significant reduction in mean time to target interception (movement time) between the first and last training sessions (**Δ**=698ms). Preliminary results to date indicate that, following training, the % MWF change (post-pre) increased in the left IPS (**Δ**=7.08%;) but not in the right IPS (**Δ**=-1.40%), left PLIC (**Δ**=-1.93%), right PLIC (**Δ**=0.89%), NAWM (**Δ**=0.12%). **Conclusions:** Results from this study indicate that MWF in task-related regions of interest may be modifiable following practice of a skilled motor task in healthy young adults. The outcomes from this work may have important implications for neurological populations (e.g. stroke) that may benefit from therapeutic interventions that can selectively increase white matter myelin content in an effort to improve rehabilitation outcomes.

Title: Vagus nerve stimulation dependent enhancement of cortical plasticity requires cholinergic innervation of the cortex

Authors: *D. HULSEY[1], S. HAYS[1], N. KHODAPARAST[1], R. CASAVANT[2], A. RUIZ[1], P. DAS[1], E. NUTTING[1], X. CARRIER[1], M. IYENGAR[1], I. QUARESHI[1], S. SULTANA[1], R. RENNAKER, II[1], M. KILGARD[1]
[1]The Univ. of Texas At Dallas, Richardson, TX; [2]Microtransponder Inc., Austin, TX

Abstract: Primary motor cortex (M1) transiently reorganizes in response to motor skill learning. Pairing forelimb movements with Vagus Nerve Stimulation (VNS) drives enhanced and robust analogous plasticity within M1. These changes occur outside of the typical period for motor plasticity and are independent of new skill learning. The mechanism by which VNS enhances M1 plasticity is not well understood. Skill learning and the associated cortical plasticity is dependent on cholinergic innervation of the cortex. VNS may enhance plasticity by engaging neuromodulatory systems necessary for plasticity. We hypothesize that cholinergic innervation of M1 is necessary for motor plasticity associated with VNS pairing. To test this hypothesis, we trained female Sprague Dawley rats on a skilled lever pressing task emphasizing use of the proximal forelimb. After task acquisition, one group of rats received a lesion to the cholinergic neurons of the basal forebrain using 192-IgG-Saporin, while another group received a control injection. All subjects also received a VNS cuff implant during the surgery. After one week of recovery, all subjects receive VNS paired to successful task performances for five days. Intracortical microstimulation was performed to derive M1 maps of each group 24 hours after their final VNS paired session. Subjects with an intact cholinergic system show significant expansion of proximal forelimb representation over naïve animals within the cortex. Subjects without cholinergic innervation of the cortex show no difference in M1 organization when compared to naïve animals. We conclude that cholinergic innervation is necessary for the effects of VNS on motor plasticity.

Title: Amputation-related changes in inter-hemispheric interactions are reversible through transplantation of the human hand

Authors: *K. F. VALYEAR[1], B. A. PHILIP[1], C. L. KAUFMAN[2], J. E. KUTZ[2], S. H. FREY[1]
[1]Dept. of Psychological Sci., Univ. of Missouri, Columbia, MO; [2]Christine M. Kleinert Inst., Louisville, KY

Abstract: Use of the intact hand by unilateral amputees is associated with increased activity in both the contralateral (intact) and ipsilateral (former) sensorimotor hand territories. Ipsilateral responses are believed to reflect reductions in normal levels of inter-hemispheric inhibition maintained by activity-dependent, transcallosal, GABAergic pathways. Former amputees who have undergone hand transplantation provide a unique opportunity to address whether these activity-dependent reorganizational changes can be reversed. If so, then following regeneration of peripheral nerves, movements of the intact (non-transplanted) hand should exhibit the same pattern as healthy adults, primarily activating contra- but not ipsilateral sensorimotor cortex. Here, we used functional MRI to map cortical sensorimotor representations in patient DR, a right-hand dominant male who suffered traumatic amputation of his left hand proximal to the wrist in 1998 (age 23) and underwent hand transplantation 13 years later (age 36). Patient DR completed the same protocol 15 and 26 months post-transplant. At 15 months post-transplant, DR showed a pattern of activation similar to amputees: specifically, he activated both contra- and ipsilateral sensorimotor cortices when moving his intact hand. However, when tested at 26 months post-transplant, patient DR showed a pattern of activation similar to controls: specifically, he activated only contralateral (but not ipsilateral) sensorimotor cortex when moving his intact hand. Between 15 and 26 months post-transplant, DR exhibited substantial improvements in hand functions that reflect regeneration of peripheral sensory and motor nerves. These results are consistent with the hypothesis that amputation-related changes in the normal inhibitory balance between sensorimotor cortices can be reversed when afferent and efferent activity between hand and brain is restored. The fact that this was observed in a fully mature brain has potentially important implications for understanding the role of experience in recovery from injuries to the central and/or peripheral nervous systems.

Title: Anodal transcranial direct current stimulation (tDCS) enhances prolonged motor skill learning in chronic stroke patients

Authors: M. HAMOUDI[1], H. M. SCHAMBRA[2], L. G. COHEN[3], A. SCHOECHLIN-MARX[1], B. FRITSCH[1], *J. REIS[1]
[1]Dept. of Neurol., Univ. of Freiburg, Freiburg, Germany; [2]The Neurolog. Inst. of New York Columbia Univ. Med. Ctr., New York, NY; [3]Natl. Inst. of Neurolog. Disorders and Stroke, NIH, Bethesda, MD

Abstract: Background: Anodal tDCS applied over M1 can enhance motor skill learning in healthy subjects1. However, the effects of tDCS on specific temporal subcomponents of motor skill learning have not been investigated in stroke patients. Here we study the effects of anodal tDCS on acquisition (online effects), consolidation (offline effects) and long term retention of a visuomotor skill as well as general motor function in other tasks in the chronic phase after stroke. Methods: Thirty-six patients with chronic unilateral, first ever ischemic stroke and a mild to moderate hemiparesis (UEFMS ~ 58) participated. They practiced the sequential visual isometric pinch force task (SVIPT)1 for 5 consecutive days with their paretic hand while receiving either anodal tDCS (n=18) or sham tDCS (n=18) for 20 minutes over M1 of the affected hemisphere. Follow ups were performed at day 8, 29, 57, 85 and 113. A skill measure based on movement time and error rate was developed. The Jebsen Taylor hand function test (JTT) and the Grooved Pegboard Test (GPT) were performed to test for general enhancement of motor function. A control group (n=12 to date) performed the JTT and GPT only, without stimulation or training to measure improvements on these tasks due to repeated assessment. Results: In general, patients became more skilled in the task. There were significantly greater total skill gains with anodal tDCS compared to sham, mainly mediated through online effects. The skill advantage of the anodal tDCS group was due to significantly faster movement times compared to sham, achieved at similarly increasing accuracy. First results of the follow ups indicate that anodal tDCS did not

change the retention rate relative to sham, hence skill remained superior with anodal tDCS in the long term. The interim analysis of JTT and GPT data suggests that training also enhanced performance on other motor tasks, with anodal tDCS showing the greatest improvements. Only minor improvements were observed in the control group. Conclusions: Our preliminary results suggest that anodal tDCS combined with 5 days of motor training can facilitate motor skill learning in chronic stroke patients. Training itself was successful to induce general enhancements in motor function, a process that may be further enhanced by anodal tDCS. These findings could be directly transferable to neurorehabilitative treatments of stroke patients as a strategy to break behavioral ceiling effects. 1.Reis et al., PNAS 2009;106(5):1590-5.

Title: Motor skill learning in the acute phase of stroke: Does training-induced plasticity surpass spontaneous biological recovery?

Authors: P. PAPE, A. SCHÖCHLIN-MARX, *B. FRITSCH, J. REIS
Univ. of Freiburg/ Neurocenter, Freiburg, Germany

Abstract: Objective: Stroke is the leading cause of disability in adults. Here, we aimed to reveal mechanistic information about the pathology of motor skill learning in the acute phase after stroke that will contribute to the understanding of plasticity after brain injury. We characterized both the speed-accuracy-tradeoff (SAF) of a visuomotor task as well as motor skill learning in acute stroke patients with mild to moderate hemiparesis in comparison to age-matched healthy controls. Furthermore, we distinguished learning effects from of spontaneous biological recovery (SBR) in patients. Methods: In patients with acute, unilateral, first-ever ischemic stroke causing a moderate hemiparesis (no neglect, no apraxia, no aphasia) we measured the SAF on day 1 and day 5 after stroke. The change from the initial SAF (day 1) over the course of early spontaneous recovery (clinical treatment as usual, SAF retest on day 5, n=14) was compared to the SAF

change in patients receiving specific motor skill training on days 2-4 (n=10). A patient group tested on the SAF only once on day 5 (n=13) served as a second control for task repetition effects and SBR. Furthermore, SAF shift and motor skill learning were compared between the trained patients and a group of trained, healthy age-matched controls (n=12). Results: All patients showed similar initial impairment (UEFMS 56 ±2, NIHSS 5±1). Compared to the patient group without training (SBR), trained subjects showed a significantly greater shift in the SAF, i.e. lower target error rates at predefined speeds. This shift was distinguishable from SBR and task repetition effects. Compared to healthy controls, the initial SAF was shifted towards higher error rates in patients, but the training induced shift was similar. In accordance, patients had a significantly poorer baseline skill on the training task, but motor skill increased similarly in both groups and was preserved at a 1 month follow up. Nearly all trained patients had returned to maximum UEFMS at the 1 month follow-up. However, there was no further shift, i.e. improvement, in the SAF curve indicating a remaining skill deficit compared to healthy subjects. Conclusions: Our preliminary data suggest that motor learning ability in acute stroke patients is preserved. Motor skill changes as assessed by the shift of the SAF curve in trained patients seem to exceed the shift observed with spontaneous biological recovery. The findings emphasize the effectiveness of specific motor skill training during the first days of admission to a stroke unit to enhance fine motor function. 1.Reis et al., PNAS 2009;106(5):1590-5.

Title: Cortical and behavioral correlates of a conditioning protocol that combines action observation with peripheral electrical nerve stimulation

Authors: *A. BISIO[1], L. AVANZINO[1], N. GUEUGNEAU[1], T. POZZO[2], P. RUGGERI[1], M. BOVE[1]
[1]Univ. Genoa, Genova, Italy; [2]Italian Inst. of Technol., Genoa, Italy

Abstract: Action observation (AO) is known to affect the activity of the primary motor cortex (M1). However, the AO effects may vanish if motor practice is not concurrent or immediately follows it. This suggests that a prompt comparison between the visual and the somatosensory

representations of movement could be necessary to induce plasticity in M1. The aim of this study was to test whether action observation combined with a peripheral nerve electrical stimulation was able to evoke cortical plastic changes in the left M1. To do that we proposed a stimulation protocol (AO-PNS) where the observation of a video showing repetitive thumb-index tapping movements was combined with electrical stimuli delivered on the right peripheral median nerve, i.e., the nerve innervating the abductor pollicis brevis (APB) muscle (the target muscle of the video and electrical stimulation). In the first part of this work, left M1 excitability, measured by mean of transcranial magnetic stimulation (TMS-recruitment curve), was compared with that assessed after action observation (AO) and peripheral electrical median nerve stimulation (PNS) alone. Then, we tested the long-term effects of AO-PNS by recording MEP amplitudes in the APB muscle before (PRE), immediately after and 15, 30, and 45 minutes after the stimulation protocol. Finally, the effects of AO-PNS on the MEPs amplitudes of the right APB muscle were compared with those elicited in the adductor digiti minimi (ADM) muscle to assess the topographic specificity of the AO-PNS. Results showed that left M1 excitability increased only after AO-PNS whereas the effects of AO and PNS alone on M1 excitability vanished immediately after video observation. Notably, the increased M1 excitability was still present 45 minutes after the AO-PNS protocol administration and was specific for the stimulated muscle - APB. Thus, we showed that plasticity in M1 can be induced by the activation of the mirror neuron system but only in an associative context (e.g., afferent signals from periphery). Looking at these findings, one might speculate that M1 plasticity induced by AO-PNS could have a behavioral correspondence dealing with changes in motor behavior such as an increased efficiency in finger-tapping movements. For that reason, in the second part of the work, we are testing the motor performance of two groups of participants who performs a finger tapping movement before and after AO and AO-PNS. Following the results of the first part of the experiment, we predict that after AO-PNS the motor efficiency, in term of movement frequency measured 45 minutes after the conditioning protocol, will increased than after AO alone.

Title: Neuroplasticity within repetitive robotic arm training changes with age

Authors: *C. L. MASSIE[1], S. S. KANTAK[3], P. NARAYANAN[2], G. F. WITTENBERG[2]
[1]Physical Therapy and Rehabil. Sci., [2]Neurol., Univ. of Maryland Sch. of Med., Baltimore, MD; [3]Moss Rehabil. Res. Inst., Elkins Park, PA

Abstract: Use-dependent neuroplasticity is an important factor for stroke rehabilitation, yet the potential is considered to decrease with age. The objective of the study was to determine how age influences the degree of neuroplasticity during repetitive robotic arm training. Ten young and 14 older adults participated with mean ages of 26 and 66, respectively. Participants completed 480 movements in a robotic reaching intervention. Transcranial magnetic stimulation (TMS) was used as a neurophysiologic assessment before, during, and after the reaching training. Ten suprathreshold (120% of resting motor threshold) stimulations were delivered and motor evoked potentials (MEP) were recorded from the biceps, triceps, anterior deltoid, and posterior deltoid. The amplitude and direction of evoked movements were also recorded by the robot. Change scores from baseline were calculated and analyzed with an ANOVA (time by age). Biceps and anterior deltoid MEP were significantly different between age groups ($p < 0.05$), but not the triceps or posterior deltoid ($p>0.05$). There was a trend for a significant interaction for the amplitude of TMS evoked movements with the older adults generally having smaller percent changes over time compared to the increases in younger adults. The direction of evoked movement changes were similar across age groups. These results suggest that neuroplasticity is influenced, not limited, by age within an intervention and demonstrates the importance of understanding dosing implications within the potential use of robotic training in older adults.

Title: Short-term plasticity in human motor cortex is associated with changes in cerebral blood flow delivery

Authors: R. HERMOSILLO, K. FJELD, T. BURNETT, D. CHENG, F. COLINO, G. BINSTED, *P. VAN DONKELAAR
Hlth. and Exercise Sci., UBC - Okanagan, Kelowna, BC, Canada

Abstract: Our understanding of the neural correlates of sensorimotor plasticity has increased substantially over the past two decades. Previous studies examining this issue has typically used neural imaging to measure correlates of alterations in neuronal activity. However, it is unclear whether these alterations are associated with changes in cerebral blood flow delivery. Repetitive transcranial magnetic stimulation (rTMS) has been used widely to transiently disrupt function in the brain. Previous studies examining the effect of rTMS on the brain have shown both neuronal and behavioural disruptions. However, it is not currently known how neurons respond to the stimulation, and furthermore if the plastic changes are accompanied by changes in cerebral blood flow. In the present experiment, we probed this relation by quantifying how rTMS alters motor maps in the primary motor cortex, while simultaneously measuring cerebral blood flow in the middle cerebral artery using transcranial Doppler ultrasound. We sought to observe whether these motor changes were accompanied by a corresponding change in cerebral flow. Motor mapping was carried out prior to and after a 30 minute session of either 1Hz real rTMS or sham rTMS. After real TMS, cortical excitability increased compared to sham and this was associated with an alteration in blood flow. Interestingly, some sites within the motor map that were previously unresponsive became responsive after real TMS. This suggests that the short-term cortical changes due to rTMS induce changes in cerebral blood flow delivery.

Title: Physical training improves brain connectivity

Authors: *H. E. HULSHOFF POL[1], A. SVÁTKOVÁ[2], R. MANDL[1], T. SCHEEWE[1], R. KAHN[1], W. CAHN[1]

Abstract: There are indications that keeping your body fit is healthy for your brain. While learning a new skill causes structural changes in the brain, it is unclear whether continuous physical training of learned skills can improve structural brain connectivity. We measured connectivity of the brain before and after a six months interval on diffusion tensor images obtained at 3 Tesla MRI. Changes in connectivity over the interval were measured by the difference in the fractional anisotropy map at time 2 minus the map at time 1, as analyzed using family-wise corrected TBSS and by white matter fiber reconstructions based on FSL. A total of 81 young adult individuals participated, of which 48 were healthy and 33 had a diagnosis of schizophrenia. Individuals were assigned to either one of the two conditions, i.e., physical exercise or life-as-usual, balanced for diagnosis. Physical exercise involved supervised indoor trainings twice weekly, and included biking. With an estimated 1,3 bikes owned per person over four years of age, biking is a highly overlearned skill in the inhabitants of The Netherlands. We report that 6 months of regular physical exercise including bicycling significantly increases the integrity of motor-functioning related brain white matter fibers whereas life-as-usual leads to a decrease in fiber integrity, irrespective of diagnosis. Thus keeping the body fit through continuous physical stimulation improves the brains' wiring in health and disease. Indeed, brain connectivity improves from repeated physical exercise.

Title: Targeting the right dorsolateral prefrontal cortex with transcranial direct current stimulation during a concurrent implicit and explicit sequence task

Authors: *B. GREELEY[1], R. SEIDLER[1,2]
[1]Sch. of Kinesiology, Univ. of Michigan, Ann Arbor, MI; [2]Dept. of Psychology, Ann Arbor, MI

Abstract: There is an ongoing debate concerning whether implicit and explicit systems interact during motor learning. One line of behavioral and neuroimaging evidence suggests that implicit learning occurs independently of explicit knowledge (Song et al., 2005; Destrebecqz et al., 2005). However, another line of both behavioral and neuroimaging evidence suggests instead that implicit and explicit learning mechanisms interact (Boyd & Winstein, 2004; Aizenstein et al., 2004). Here, we attempt to elucidate the relationship between implicit and explicit learning by using transcranial direct current stimulation (tDCS), a non-invasive form of brain stimulation, while participants engage in a concurrent implicit and explicit sequence motor learning task. The prefrontal cortex is engaged during the cognitively demanding early stages of motor learning (Doyon & Benali., 2005). Anguera and colleagues (2009) found that the right dorsolateral prefrontal cortex (DLPFC) was involved in early learning, but not in late learning of visuomotor and spatial working memory tasks. The right DLPFC has also been shown to be involved in explicit learning paradigms (Destrebecqz et al., 2005; Fletcher et al., 2005; Hazeltine el al., 1997; Toni et al., 1998). In the current study, all participants will complete a concurrent implicit and explicit motor sequence learning task similar to that used by Aizenstein and colleagues (2007) and be placed in one of three tDCS groups. One group of participants is receiving tDCS targeting the right DLPFC, another group is receiving tDCS targeting the left DLPFC, and the third group is receiving sham tDCS. We anticipate that participants in the right DLPFC tDCS group will demonstrate a faster rate of learning early in the explicit, but not in the implicit sequence learning trials. Preliminary results demonstrate that the concurrent implicit and explicit sequence task results in simultaneous learning of implicit and explicit sequences. This study contributes to a greater understanding of motor learning and will help discriminate implicit and explicit motor learning systems.

Title: Immunolesions of melanopsin receptive neurons in the adult Pekin drake attenuates the hormonal reproductive axis

Authors: *G. S. FRALEY
Hope Col., HOLLAND, MI

Abstract: Several light sensitive receptors have been described in the avian brain that are thought to regulate the reproductive axis independently from the eyes and pineal gland. Recently, my lab has described the presence of three of these photoneuroendocrine systems in the Pekin duck: opsin, opsin 5, and melanopsin. I set out to test the hypothesis that melanopsin receptive neurons are necessary to maintain seasonal reproductive status in the Pekin drake. To accomplish this, 50-week-old Pekin drakes were housed in the aviary at Hope College under long day length (18 hrs lights on) conditions in floor pens (5 drakes per pen). To specifically lesion melanopsin-receptive neurons, drakes were anethestized (8 mg/kg Propofol, IV), given analgesics (2 mg/kg ketfen, SC) skin incised and a trephine hole drilled 10 mm caudal to bony orbits and 1 mm to the left of midline. A 33 gauge stainless steel needle attached to a Hamilton syringe was lowered stereotactically 3.5 mm ventral to dura into the lateral ventricle. Three microliters of an anti-melanopsin-saporin conjugate (MSAP, 100 ng/ul) was injected into the lateral ventricle (n = 10). Control drakes were injected with 3 ul of equimolar unconjugated anti-melanopsin and saporin (SAP, n = 10). The incision was closed with VetBond, and the drakes returned to the aviary after complete recovery from anesthesia. After 4 weeks, birds were euthanized (400 mg/kg FatalPlus, IP) and body weight measured, and brains, pituitaries, and testes collected and stored for analyses. MSAP-treated drakes had significantly ($p < 0.001$) reduced relative teste weights compared to SAP controls. qRT-PCR analyses (n = 5 per treatment) of anterior pituitary showed a significant reduction ($p < 0.001$) in both LH-beta and FSH mRNA's. Immunoctyochemical analyses (n = 5 per treatment) showed a significant reduction in melanopsin and GnRH-immunoreactivities. These data underscore the importance of the photoneuroendocrine system in maintaining the reproductive axis in seasonally breeding birds.

Title: Season- and steroid-dependent regulation of D2 dopamine receptor, kisspeptin, and neurokinin B in KNDy cells of the ovine arcuate nucleus

Authors: *P. W. WEEMS[1], R. L. GOODMAN[4], L. M. COOLEN[2], M. N. LEHMAN[3]
[1]Neurosci., [2]Physiol. & Biophysics, [3]Neurobio. & Anatom. Sci., Univ. of Mississippi Med. Ctr., Jackson, MS; [4]Dept. of Physiol., West Virginia Univ., Morgantown, WV

Abstract: Seasonal reproduction in sheep is a result of a dramatic increase in the ability of estradiol (E_2) to inhibit the pulsatile secretion of gonadotropin-releasing hormone (GnRH) during the non-breeding season (anestrus). Recent work suggests that a key intermediary in the negative feedback influence of E_2 is a neuronal subpopulation in the arcuate nucleus (ARC) that co-expresses kisspeptin (Kiss), neurokinin B (NKB), and dynorphin (termed KNDy neurons). The pathway responsible for E_2 negative feedback in anestrus includes dopaminergic projections from the retrochiasmatic area to the ARC. Dopamine released from these afferents binds to D2 dopamine receptors (D2R) on KNDy cells to decease Kiss release and thus inhibit GnRH pulses during anestrus. However, while ARC Kiss is reduced by E_2 during anestrus, the effects of E_2 on expression of NKB or receptors in these cells have not been examined. In the present study we examined the influence of season and E_2 on the regulation of D2R, Kiss and NKB in KNDy neurons of the ewe. Adult Suffolk ewes were ovariectomized (OVX) (n=16). Following surgery, half of the ewes (n=8) received a s.c. capsule containing E_2 (OVX+E). Brains were collected from OVX and OVX+E ewes perfused either during anestrus (May) or breeding season (November) (n= 4/season/group). Coronal sections through the middle ARC were processed for triple-label immunocytochemistry for D2R, Kiss and NKB, and the number of single- double- and triple-labeled neurons were counted in each animal. We found that OVX+E ewes had significantly lower numbers of D2R, Kiss, and NKB cells compared to OVX ewes, in both the breeding season and anestrus. Thus, E_2 inhibits D2R, Kiss, and NKB expression at both times of years. In addition, OVX+E animals showed a seasonal decrease in both Kiss and NKB during anestrus, but this did not alter the high degree of colocalization of these two peptides. The percentage of KNDy neurons containing D2R increased in OVX+E anestrous ewes, but this was due to the decrease in Kiss and NKB expression because the number of KNDy neurons containing D2R did not change seasonally. Thus, it appears that changes in D2R may not contribute to the increased ability of E_2 to inhibit GnRH pulses during anestrus. These results are consistent with the hypothesis that increased dopamine release during anestrus, rather than an increased response to dopamine, is responsible for inhibiting Kiss and NKB from KNDy

neurons. Thus, both of these stimulatory neuropeptides could play a role in seasonality in the ewe.

Title: The stimulatory effect of Neuromedin U on pulsatile LH secretion: Insights from a seasonal mammal

Authors: *P. GRACHEV, R. B. MCCOSH, J. A. LOPEZ, G. L. NESSELROD, M. VALENT, S. L. HARDY, J. M. CONNORS, S. M. HILEMAN, R. L. GOODMAN
Dept. of Physiol. and Pharmacol., West Virginia University, Sch. of Med., Morgantown, WV

Abstract: Central signaling mechanisms involving the activation of the neuromedin U receptors type 1 (NMU1R) and type 2 (NMU2R) by their endogenous ligands, neuromedins U (NMU) and S (NMS), have been shown to regulate LH secretion, the timing of puberty, appetite, food intake and energy expenditure. NMU, NMS and NMU1R and NMU2R are highly conserved through evolution; however previous studies have relied almost exclusively on rodent models. Although NMS is predominantly expressed within the suprachiasmatic nucleus of the hypothalamus (SCN), its role in photoperiod regulation of reproduction in seasonal mammals remains yet to be elucidated. As a first step in exploring this question, we treated anestrous ewes with NMU-8 (1 nmol, intracerebroventricularly), a synthetic peptide the sequence of each resembles the receptor-binding portion of both, endogenous sheep NMU and NMS, and subjected them to frequent blood sampling to determine the effect of hypothalamic NMU2R activation on pulsatile LH secretion. NMU-8 administration triggered single LH pulses and increased LH secretion (area under the curve) more than 3.5-fold ($P<0.05$) in the 48-min period following administration compared to vehicle (100 μl saline, intracerebroventricularly). These data demonstrate that acute activation of central NMU1R and/or NMU2R stimulates hypothalamic circuitry involved in GnRH pulse generation and provide the first insight into the roles of NMU/NMS in this species.

Title: Kappa opioid receptor is present within a majority of KNDy neurons in the ewe

Authors: ***C. F. WITTY**[1], P. W. WEEMS[2], R. L. GOODMAN[4], L. M. COOLEN[1,3], M. N. LEHMAN[3]
[1]Physiol. & Biophysics, [2]Grad. Program in Neurosci., [3]Neurobio. & Anatom. Sci., Univ. of Mississippi Med. Ctr., Jackson, MS; [4]Physiol. & Pharmacol., West Virginia Univ., Morgantown, WV

Abstract: Kisspeptin-Neurokinin B-Dynorphin (KNDy) cells of the arcuate nucleus (ARC) of the hypothalamus have been proposed as a critical component regulating pulsatile release of gonadotropin-releasing hormone (GnRH) neurons, including the negative feedback control of GnRH pulses by estradiol and progesterone. Current evidence in sheep and goats suggest that dynorphin released by KNDy cells acts as a “stop” signal for the pulse generator, and terminates each GnRH pulse by acting upon kappa opioid receptors (KOR). However, the precise localization of KOR, and whether they are present in KNDy cells in the sheep, is unknown. We first determined the distribution of KOR in the ovine hypothalamus using a KOR antibody whose specificity we confirmed by Western blot analyses and blocking peptide controls. Tissue sections from gonadal-intact ewes perfused during the luteal phase of the estrous cycle (n = 4) were processed for single-label immunoperoxidase detection and revealed KOR-positive cells in a number of hypothalamic regions, including the preoptic area (POA), the paraventricular nucleus (PVN), and the arcuate nucleus (ARC), areas which also contain KOR mRNA. In a second set of experiments, we determined whether KOR is co-expressed in KNDy cells in the ewe hypothalamus. Tissue sections from the same luteal-phase ewes (n = 4) were processed for dual-label immunofluorescent detection of KOR and neurokinin B (NKB). Confocal microscopic analyses showed a high degree of co-localization, with 94% of NKB cells containing KOR,

while 46% of KOR cells in the ARC were double-labeled for NKB. In conclusion, a large majority of KNDy cells in the sheep ARC co-localize KOR. In addition, there are also a sizable proportion of KOR-positive cells in the ARC which do not contain NKB, and hence represent a separate subpopulation from KNDy cells. We suggest that dynorphin may exert its inhibitory control of GnRH pulse frequency by binding to postsynaptic KOR either within KNDy cells (autoregulatory actions), or by actions upon adjacent non-KNDy ARC neurons, which, in turn, may project onto KNDy and/or GnRH neurons.

Title: Is dynorphin involved in the prepubertal suppression of LH secretion by estradiol in female sheep?

Authors: J. A. LOPEZ[1], L. J. MEADOWS[1], R. B. MCCOSH[1], *R. L. GOODMAN[2], S. M. HILEMAN[1]
[1]Physiol. and Pharmacol., [2]West Virginia Univ., MORGANTOWN, WV

Abstract: Neural mechanisms underlying the onset of puberty are not well understood. In sheep, this process involves an increase in GnRH release due to decreased sensitivity to estradiol (E2)-negative feedback. As GnRH neurons do not express the relevant estrogen receptors, this pathway must involve interneurons. Recent data suggests that neurons of the arcuate nucleus of the hypothalamus that coexpress kisspeptin (kiss), neurokinin B, and dynorphin (DYN), i.e. KNDy neurons, may play a critical role. Kiss and neurokinin B are stimulatory to GnRH, while DYN is inhibitory. Thus, we hypothesized that kiss expression would be positively associated, and DYN expression negatively associated, with LH secretion in prepubertal female sheep. Ewe lambs were randomly assigned to three groups: ovariectomized (OVX), OVX+E2, or left ovary-intact. Jugular blood samples were collected every 12 min for 4h to assess luteinizing hormone (LH) secretion. As expected, mean LH and LH pulse frequency were increased by ovariectomy

compared to either ovary-intact or OVX+E2 lambs. As hypothesized, numbers of kiss-immunopositive cells were increased by OVX compared to either ovary-intact or OVX+E2 lambs. Contrary to our hypothesis, very few DYN-immunopositive cells were found in any treatment group, even though they were readily evident in concurrently immunostained hypothalamic tissue collected from adult ewes in the luteal phase of their estrous cycle. This may be due to either reduced expression of DYN or high rates of DYN secretion during the prepubertal period. Further work will be necessary to distinguish between these two possibilities.

Title: Neuronal insulin signaling is not required for reproductive maturation or competency in mice

Authors: *M. C. EVANS, G. M. ANDERSON
Anat., Univ. of Otago, Dunedin, New Zealand

Abstract: Central insulin signaling plays a critical role in the metabolic control of fertility. Mice exhibiting insulin receptor (InsR) deletion from all neural progenitor cells (NIRKO mice) display hypothalamic hypogonadism and reduced fertility. However, the neuronal population(s) critically involved in mediating insulin's central effects on the neuroendocrine reproductive axis remain largely unidentified. To date, the targeted deletion of InsR's from any neuronal population tested has failed to recapitulate the reproductive impairments observed in the NIRKO mice. In an attempt to narrow down the critical insulin-responsive candidates, we used the Cre-loxP system to target the deletion of InsR's to GABAergic (InsR-lox/lox, Vgat-Cre+) or glutamatergic (InsR-lox/lox, Vglut2-Cre+) neurons and then compared multiple reproductive and metabolic parameters between the knockout (KO) and control (InsR-lox/lox) mice. Puberty onset, estrous cyclicity and adult fertility were not impaired in either the male or female GABAergic or glutamatergic InsR KO mice relative to littermate control mice, although female GABAergic

InsR KO mice exhibited increased body weight and adiposity. We then re-evaluated the widespread belief that neuronal insulin signaling is required for fertility by generating forebrain neuron InsR KO mice (InsR-lox/lox, CamKIIα-Cre+). These KO mice showed a complete lack of hypothalamic insulin responsiveness (phospho-AKT activation), and both the males and females displayed increased body weight and other metabolic impairments. Surprisingly, however, the male and female forebrain neuron InsR KO mice were fully fertile, with normal puberty onset, estrous cyclicity, and age of reproductive senescence. We conclude from these experiments that neuronal insulin signaling is not critically involved in the metabolic control of the neuroendocrine reproductive axis, but plays an important role in regulating metabolic function. It remains possible that insulin exerts a critical role through non-neuronal brain cells.

Title: Evidence for a repressive role of zinc finger genes in the hypothalamic control of primate puberty

Authors: J. M. CASTELLANO[1], V. MATAGNE[1], A. LOMNICZI[1], C. TORO[1], M. TENA-SEMPERE[2], T. M. PLANT[3], *S. R. OJEDA[1]
[1]Oregon Natl. Primate Ctr., BEAVERTON, OR; [2]Univ. of Cordoba, IMIBIC/HURS, Cordoba, Spain; [3]Ctr. for Res. in Reproductive Physiology, and Magee Womens Res. Institute, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract: Puberty in primates is triggered by reactivation of pulsatile hypothalamic GnRH release, considered to result from a concomitant loss of transsynaptic inhibition and increased transsynaptic and glial excitatory inputs to GnRH neurons. Emerging evidence suggests that a balance of permissive and repressive transcriptional controls, including epigenetic regulation, operating in cellular subsets upstream to GnRH play an important role in this process. However, the identity of the various factors involved and the underlying complexity of these regulatory mechanisms remain incompletely characterized. To gain insight into this issue we interrogated the medial basal hypothalamus (MBH) of agonadal male rhesus monkeys using Affymetrix DNA arrays. Cerebral cortex was used as a control. Our results revealed that hypothalamic expression of several genes encoding zinc finger proteins endowed with a Krüppel-associated box (KRAB domain) – known collectively as KRAB Zinc-finger (KZNF) genes – decreased during the juvenile-pubertal transition, coinciding with the pubertal increase in pulsatile GnRH as reflected by LH secretion. Half of the human KZNF genes are clustered within the long arm of chromosome 19 (q13.12-13.43). Quantitative PCR analysis of selected KZNF mRNAs transcribed from the q13 locus (KZNF566, KZNF573, KZNF264, KZNF542, and KZNF587) verified the array results. In addition, hypothalamic expression of two other Zinc-finger genes identified by genome-wide association studies of others as influencing either age of menarche (KZNF462, chromosome 9) or pediatric height (GATAD1, chromosome 7), also decreased at puberty. Although GATAD1 does not contain a KRAB domain, it is remarkable as it represses transcription via an epigenetic mechanism. It first "reads" H3K4me3, a histone mark associated with gene activation, and then forms a transcriptional co-repressor complex. Additional array and qPCR analyses showed that, with exception of KZNF573 and GATAD1, different KZNFs had decreased pubertal expression in intact female monkeys. One of these two (GATAD1) was therefore selected for mechanistic studies. GATAD1 inhibited the promoter activity of genes regulating puberty onset (KISS1, TAC3, EED, PENK and EAP-1), but required the presence of the H3K4me3 demethylase, JARID1A, to exert its repressive action. Overexpressing GATAD1 in the arcuate nucleus of immature rats delayed first ovulation and resulted in ovarian follicular atrophy, supporting the notion that GATAD1 association to transcriptionally active promoters in the MBH via a histone modifying complex may be a component of a repressive mechanism controlling the timing of primate puberty.

Title: The role of the posterodorsal medial amygdala in pubertal timing in female rats

Authors: ***M. HU**[1], X. LI[1], B. P. HANLEY[1], Y. LIN[1], L. POSTON[1], S. L. LIGHTMAN[2], K. T. O'BYRNE[1]
[1]Women's Health,School of Med., King's Col. London, London, United Kingdom; [2]Henry Wellcome Lab. for Integrative Neurosci. & Endocrinol., Univ. of Bristol, Bristol, United Kingdom

Abstract: Puberty is a developmental process initiated by maturation of the hypothalamic-pituitary-gonadal (HPG) axis. The central mechanisms underlying changes in pubertal timing as a consequence of metabolic status or stressful perturbations are not well understood. Obesity is the major risk factor for early onset of puberty, but there is emerging evidence that other factors are involved, amongst these are psychosocial stress. One key brain region is the amygdala, notable for its roles in controlling caloric intake and regulating stress and behavioural reactivity. Early research showed that amygdaloid lesions that included the medial nucleus advanced puberty in rats. More recently, it was shown that a critical site for lesion-induced hyperphagia and obesity in rats is the posterodorsal subnucleus of the medial amygdale (MePD), which may explain the altered pubertal timing by way of an earlier attainment of the critical body mass. It has also been reported that glutamatergic activity increases in the MePD during puberty without a corresponding GABAergic change, suggesting an overall activation of this site at the onset of puberty. The role of endogenous glutamatergic and GABAergic signalling in MePD in pubertal timing remains to be investigated. In the present study, we report that lesioning the MePD (postnatal day 20), using ibotenic acid, advances the onset of female puberty (vaginal opening and first estrus) and increases the rate of weight gain prior to puberty onset in rats receiving a normal diet. MePD lesioned rats fed with a 25% non-nutritional diet also showed a dramatic advancement of puberty, but without the increased rate of weight gain. In both dietary groups the MePD lesion resulted in an increase in socialization (social interaction) and a decrease in play fight (pinning behaviour). We have also shown that chronic infusion (via osmotic mini-pump starting on postnatal day 20) of the GABA receptor antagonist, bicuculline, into the MePD had the same effect as the MePD lesion on both pubertal timing and behaviour without the alteration of weight gain, while infusion of the glutamate receptor antagonist, amino-5-phosphonovaleric acid, had the opposite effect. In conclusion, our results suggest that the MePD alter the timing of puberty onset via a mechanism independent of change in body weight and food intake. Glutamate in this limbic brain area seems to have an advancing effect on puberty, whilst GABA has the opposite.

Title: The central role of substance p/nka in puberty onset and fertility

Authors: *V. M. NAVARRO, S. SIMAVLI, R. CARROLL, U. B. KAISER
Med., Brigham and Women's Hosp. / Harvard Med. Sch., Boston, MA

Abstract: Puberty is a very tightly regulated process that ultimately leads to the reactivation of GnRH pulsatility and attainment of reproductive function. Kiss1 neurons play a crucial role by stimulating GnRH neurons to induce puberty onset, however, the mechanisms determining the activation of Kiss1 neurons in this developmental process remain unknown. Kiss1 neurons are regulated by tachykinins neurokinin A (NKA), neurokinin B (NKB) and substance P (SP). NKB has been involved in the activation of Kiss1 neurons prepubertally and we have recently documented in mice that a) NKA and SP receptor agonists induce gonadotropin release in a kisspeptin dependent manner and b) advance puberty onset, and c) Tac1 mRNA (encoding NKA and SP) expression increases prior to puberty. Here, we extend these findings by characterizing

the reproductive phenotype of Tac1 null mice. Female Tac1-/- mice present delayed puberty onset compared to wild-type (WT) controls, as determined by the age of vaginal opening (VO). The day of first estrus and estrous cycle length was not significantly different among groups; however, Tac1-/- mice displayed a significantly longer time from the first estrus to the initiation of the estrous cyclicity. Moreover, in a fertility test, Tac1 null animals showed a significantly lower number of pups per litter compared to WT controls. Interestingly, male Tac1-/- mice did not show any significant difference in puberty onset (determined by the age of preputial separation). In summary, these findings support the role for substance P and NKA in the stimulation of kisspeptin and GnRH release prior to puberty onset and documents the required presence of these neuropeptides to attain full reproductive capabilities in female mice. Altogether, these data suggest that all three tachykinins may participate in the coordinated regulation of Kiss1 neurons.

Title: Increased luteinising hormone pulse frequency in a mouse model of polycystic ovarian syndrome

Authors: *M. PRESCOTT, C. J. MARSHALL, R. E. CAMPBELL
Physiol., Univ. of Otago, Dunedin, New Zealand

Abstract: Polycystic ovarian syndrome (PCOS) is characterized by hyperandrogenism, anovulation and cystic ovaries, and is currently the most common endocrine disorder among women of reproductive age worldwide. PCOS is associated with an increase in luteinising hormone (LH) pulse frequency, suggestive of increased gonadotropin-releasing hormone (GnRH) pulse frequency, hypothesized to result from impaired steroid hormone feedback. Prenatal androgen exposure (PNA) of mice on embryonic days 16-18 results in female offspring that present with a PCOS-like phenotype, including hyperandrogenism, disrupted estrous cyclicity and ovarian morphology, and infertility. However, it remains to be determined whether

pulsatile LH secretion is increased in this model. Until very recently, LH measurement has been limited to single samples in mice due to the large sample volume required. The development of a sensitive sandwich ELISA to measure LH in as little as 2µl of whole blood has enabled us to address for the first time whether PNA exposure in mice results in an increase in LH pulse frequency using repeated blood sampling. In order to assess LH pulsatility, vehicle and PNA treated mice were habituated for 4 weeks with daily handling and training with a cardboard tube prior to blood sampling. A 5µl tail blood sample was taken in 6 or 10 minute intervals for 2 hours, diluted in PBS-Tween and immediately frozen. LH levels were then determined by ELISA. LH pulses, identified by peak values greater than 3 standard deviations above baseline and shape, were detected in the majority of the mice sampled. Compared with prenatally vehicle-treated controls in diestrus (n=5), PNA-treated mice (n=6) had a significant increase in LH pulse frequency (1.6± 0.37 vs 3± 0.24/2hr, $p<0.05$), and a significantly reduced pulse interval (74± 11.2 vs 41± 5.4 min, $p<0.05$). Mean baseline LH, peak LH, LH pulse amplitude, and area under the curve was not different between groups. This increase in pulsatile LH in PNA-treated mice provides additional support for the utility of this murine model of PCOS and supports the hypothesis of impaired steroid hormone feedback of the GnRH/LH system in this common form of female infertility.

Title: Involvement of kndy neurons in luteinizing hormone surges induced by steroids

Authors: ***C. V. HELENA**[1], N. TOPORIKOVA[3], B. KALIL[4], A. M. STATHOPOULOS[2], J. A. ANSELMO-FRANCI[4], R. BERTRAM[2]
[1]Biol. Sci., [2]Florida State Univ., Tallahassee, FL; [3]Washington and Lee Univ., Lexington, VA; [4]Univ. of Sao Paulo, Ribeirao Preto, Brazil

Abstract: A subset of hypothalamic arcuate neurons that coexpress kisspeptin, neurokinin B and dynorphin (KNDy neurons) has been postulated to be critical for puberty onset and regulation of

luteinizing hormone (LH) secretion. A method for targeted ablation of KNDy neurons was recently developed using the molecular neurotoxin saporin conjugated to the selective NK3R agonist [MePhe7]Neurokinin B (Nk3-SAP). Ovariectomized rats were microinjected bilaterally into the arcuate nucleus with Blank-SAP or Nk3-SAP. One set of rats was transcardiacally perfused 1, 2 or 3 weeks after the injections and immunocytochemistry for kisspeptin was performed in the arcuate nucleus region. The number of KNDy neurons was significantly decreased after 1 week of the toxin injection, however maximal fiber ablation was only achieved 3 weeks after the microinjections. Another group of rats was treated with oil (OVO), estradiol (OVE) or estradiol plus progesterone (OVEP). One week later, rats had their jugular vein cannulated and blood samples were taken at 10am and hourly from 3 until 6pm. Selective ablation of KNDy neurons of OVO rats significantly reduced basal LH levels at all time points studied. Basal LH levels in OVE and OVEP animals did not differ between groups, yet KNDy ablation increased peak LH levels in the afternoon of OVE and OVEP rats. A third group of OVE animals was microinjected with norbinaltorphimine (nor-BNI), a kappa opioid receptor antagonist, directly into the anteroventral periventricular nucleus (AVPV) one hour before the expected LH surge. The blockage of dynorphin receptors intra-AVPV significantly increased the LH surge, similar to the effect of KNDy ablation in OVE rats. Our results suggest that KNDy neurons provide inhibition to AVPV kisspeptin neurons through dynorphin and thus regulate the size of the LH surge induced by estradiol or estradiol plus progesterone.

Title: Estrogen modulates the interaction of leptin and nitrergic system in the brain areas involved in the control of the reproductive function in females rats

Authors: *L. OLIVEIRA, B. DEL-BIANCO BORGES, C. R. FRANCI
Physiol., Ribeirão Preto Med. School, Univ. of São P, Ribeirão Preto, Brazil

Abstract: Leptin (a known mediator of the energy balance) and nitric oxide (NO) have been identified as mediators in the mechanisms to control the reproductive function. We aimed assess whether estrogen and food condition modulate a possible interaction between leptin and NO. Estrogen-primed and unprimed ovariectomized rats were subjected to the fasting for 48 hours before the experiment or normally fed. Two hours after saline (control) or leptin (3μg/1μl) intracerebroventricular (icv) microinjection, the animals were decapitated or transcardially perfused to remove the encephalon. We assessed neuronal NO synthase (nNOS) content (Western blotting) and nNOS gene expression (RT-PCR) in the medial preoptic area (MPOA) and medial basal hypothalamus (MBH); and nNOS/ phosphorylated-signal transducer and activator of transcription-3 (pSTAT3) co-expression (immunohistochemistry) in the MPOA and hypothalamic nuclei (arcuate - ARC; ventromedial - VMH; dorsal / ventral dorsomedial- dDMH / vDMH; premammilar ventral - PMV). The results were evaluated by multifactorial analysis of variance (ANOVA) followed by post- test of Duncan. Leptin and estrogen did not change the nNOS gene and protein expression in the MPOA and MBH in fed rats, but increased in fasted rats. In all of the areas studied, leptin increased pSTAT3 and the interaction estrogen / fasting increased the action of leptin. Moreover, the leptin increased the percentage of nNOS / pSTAT3 co-expression in the MPOA only in estrogen-primed fasted rats. This co-expression increased in other hypothalamic regions in estrogen-primed and unprimed rats. Leptin increased nNOS-immunereactive cells expression in the VMH, DMH and PMV of estrogen-primed rats. The results indicate that in the fasting state, the interaction leptin and estrogen modifies the nNOS gene and protein expression in the MPOA and MBH. The leptin, in the presence of estrogen, increases the expression of nNOS in areas related to the control of reproductive function, facilitating the activity of the hypothalamic-pituitary-gonadal (HPG) axis. Thus, when occurs the fall of leptin, how in the fasting state, the leptin replacement is effective to increase the expression of nitric oxide that activates the HPG axis, when in presence of estrogen. Estrogen modulates the nitrergic system, the leptin sensitivity and consequently the leptin action on the nitregic system in some hypothalamic areas. vDMH and PMV seem to be the more involved areas in this interaction.

Title: Biphasic influence of substance P on LH secretion in female rats

Authors: *S. Y. LI[1], M. H. HU[1], X. F. LI[1], B. KALIL[2,3], T. M. PLANT[2], K. T. O'BYRNE[1]
[1]Div. of Women's Health, Sch. of Med., King's Col. London, London, United Kingdom; [2]Dept. of Obstetrics, Gynecoloy and Reproductive Sciences, Sch. of Med., Univ. of Pittsburgh, and Magee-Womens Res. Inst., Pittsburgh, PA; [3]Dept. of Physiol., Univ. of Sao Paulo, Ribeirao Preto, Brazil

Abstract: The pulsatile release of gonadotrophin-releasing hormone (GnRH) which results in the intermittent release of luteinising hormone (LH) is a prerequisite for normal reproduction. However, the exact neuronal components of the GnRH pulse generator are still unknown. **KNDy** neurones which co-express the neuropeptides **K**isspeptin, **N**eurokinin B (NKB) and **Dy**norphin A (Dyn) in the hypothalamic arcuate nucleus (ARC) have been postulated to represent part of this neuronal construct. Kisspeptin exerts stimulatory effect and Dyn exerts inhibitory effect on the GnRH pulse generator. NKB acts on neurokinin-3 receptor (NK3R) to stimulate or inhibit LH secretion depending on the sex steroid milieu. Recently, substance P, a neuropeptide belonging to the same family as NKB but acting on NK1R, has been shown to be expressed within the KNDy neurones in human hypothalamus. Furthermore, central administration of substance P alters LH release, but with conflicting results; both stimulatory and inhibitory actions evident. We hypothesize that substance P may be a fourth player in regulating the GnRH pulse generator. To address this, ovariectomized (OVX) rats with or without 17β-estradiol replacement were used. Rats were chronically implanted with bilateral intra-ARC cannulae and cardiac catherters. Serial blood samples were automatically taken every 5 min for 6 h for measuring LH concentrations. We showed that intra-ARC administration of substance P dose-dependently suppressed pulsatile LH release in OVX rats. In contract, intra-ARC administration of substance P in OVX, 17β-estradiol-replacement rats (estradiol level: 38.1 ± 4.2 pg/ml) stimulated LH secretion followed by an inhibition. These data suggest that substance P is involved in the regulation of the GnRH pulse generator in female rats and its effects may be biphasic depending on circulating levels of estradiol.

Title: Effect of ovarian steroids in the response to oxytocin of anterior pituitary gonadotrophs from intact and ovariectomized female rats

Authors: *A. E. GONZALEZ-IGLESIAS[1], J. A. ARIAS-CRISTANCHO[2], P. A. FLETCHER[2], R. CRISTANCHO-GORDO[2], R. BERTRAM[2], J. TABAK[2]
[1]Biol. Sci., Florida State Univ., TALLAHASSEE, FL; [2]Mathematics, Florida State Univ., Tallahassee, FL

Abstract: The peptide oxytocin (OT) is secreted by hypothalamic neurons and exerts numerous actions related to reproduction. We and others have shown previously that administration of OT to proestrus rats advances the preovulatory prolactin (PRL) and luteinizing hormone (LH) surges. We have also found that perifused anterior pituitary lactotrophs from proestrus rats are more sensitive than those from diestrus to the stimulatory actions of OT on PRL release and intracellular Ca2+ (Ca2+i). Here we sought to evaluate whether similar differences to the action of OT on hormone release and Ca2+i response exist between diestrus and proestrus gonadotrophs. In addition, to determine the influence of ovarian steroids we compared OT-induced responses *in vitro* between cells from ovariectomized (OVX) rats, OVX rats receiving an implant of 17 β-estradiol (OVE) and OVE rats receiving progesterone implants (OVEP). OT stimulated the secretion of LH in a dose-dependent manner in gonadotrophs from diestrus and proestrus rats, but the latter exhibited greater responses and sensitivity. The half maximal effective concentration (EC50) of OT was 17.6 nM and 2.6 nM for diestrus and proestrus, respectively. Both OT-stimulated LH release and Ca2+i transients were stronger in gonadotrophs from steroid-treated OVX rats, which exhibited an increase in the fraction of cells responsive to OT. Taken together, these results show that ovarian steroids influence OT actions on gonadotrophs and suggest that the heightened responsiveness of LH releasing activity to OT on proestrus may be partially accounted for by direct effects at the pituitary.

Title: Deletion of estrogen receptor-α (ERα) from RFamide-related peptide-3 (RFRP-3) neurons disrupts the negative and positive feedback effects of estradiol on gonadotrophin secretion

Authors: *M. Z. RIZWAN, M. A. INGLIS, G. M. ANDERSON
Ctr. for Neuroendocrinology, Dept. of Anat., Univ. of Otago, Dunedin, New Zealand

Abstract: Fertility in humans and animals is driven by the pulsatile secretion of GnRH neurons in the hypothalamus. The negative and positive feedback effects of estradiol modulate it, but indirectly since GnRH neurons do not express ERα. RFRP-3, a neuropeptide produced by neurons with cell bodies distributed around the dorsomedial hypothalamus, has been postulated to act upstream of GnRH to modulate the feedback effects of estradiol, and to inhibit the surge of GnRH and gonadotrophins that triggers ovulation. Many RFRP-3 neurons express ERα, project to GnRH neurons and suppress their activity. In support of this, our group has demonstrated that RFRP-3 infusion suppresses the GnRH and gonadotrophin surge in rats (Anderson et al 2009, Endocrinology 150: 1834-40), and that hypothalamic RFRP-3 levels markedly decline just prior to the surge in this species (unpublished observation), presumably to permit its occurrence. To definitively determine the requirement of RFRP-3 for ovulation and fertility, we utilised a new Cre-loxP transgenic mouse model created by our group. RFRP-3-Cre mice were crossed with ERα floxed mice to produce mice with ERα deleted specifically from RFRP-3 neurons. These mice exhibit an advanced first estrus, and disordered subsequent estrous cycles. The aim of the current study was to investigate whether RFRP-3 neurons mediate estradiol negative and positive feedback in female mice. LH levels in diestrus RFRP-3-Cre-ERα knockout (RERKO) animals were approximately three-fold higher than the littermate controls ($p<0.05$, $n=5$). All mice were ovariectomised (OVX) for 7d before measurement of pulsatile LH secretion in frequently collected tail-tip whole blood samples. Chronic low-dose estradiol (E2)-filled capsules were then implanted sub-cutaneously to generate negative feedback. Mean and basal LH concentrations were suppressed to about 30% of OVX values by E2 treatment in control mice ($p<0.05$), although pulse frequency (2-3 pulses/2h) was unaffected. In RERKO mice, however, all pulse parameters remained at OVX levels. When treated with estradiol benzoate to induce a positive feedback response, the RERKO mice showed no evidence of an LH surge ($p<0.05$ vs control peak surge values). It is possible that the latter effect represents a secondary response to impaired

negative feedback prior to the surge. These results highlight the importance of RFRP-3 neurons as key players in the hypothalamic control of fertility via estradiol.

Title: Sex differences in medium spiny neuron electrophysiological properties in pre-pubertal rat dorsal striatum

Authors: D. M. DORRIS, J. CAO, *J. MEITZEN
Biol. Sci., North Carolina State Univ., Raleigh, NC

Abstract: Neural sex differences are traditionally associated with areas of the brain directly involved with reproduction in adult, post-pubertal animals. There is growing acknowledgement that sex differences can exist in other brain regions and developmental periods as well. However, the pervasiveness of neural sex differences is still largely unexplored, especially in the pre-pubertal period widely used for electrophysiological recordings. Here we test the hypothesis that passive and active medium spiny neuron (MSN) electrophysiological properties in pre-pubertal rat dorsal striatum (caudate/putamen) differ by sex. This neuron type and brain region was chosen given its prominence and the known sex differences in adult striatum and relevant behaviors/pathologies. We recorded 30 MSNs from males and 31 MSNs from females using whole-cell current clamp technique in Sprague Dawley (CD) rat brain slices. We analyzed electrophysiological properties according to Meitzen et al., 2009. We found that: 1) the slope of the evoked firing rate to current injection curve was increased in MSNs recorded from females compared to males. Likewise, the initial action potential firing rate was increased in MSNs recorded from females compared to males. 2) Action potential afterhyperpolarization peak was decreased and threshold hyperpolarized in MSNs recorded from females compared to males. 3) No sex differences in passive electrophysiological properties were detected. These findings

indicate that MSN excitability is increased in females compared to males, providing a mechanism that may contribute to generating sex differences in striatal-mediated behavior and pathologies. Broadly, these findings demonstrate that sex differences in neuron electrophysiological properties can exist pre-puberty in brain regions not directly related to reproduction.

Title: Sex hormones and sex chromosomes separately influence brain structure of intact mice as seen by MRI

Authors: *C. CORRE[1], M. FRIEDEL[2], D. A. VOUSDEN[2], A. METCALF[2], S. SPRING[2], L. R. QIU[1], M. R. PALMERT[1], J. P. LERCH[2]
[1]Div. of Endocrinol., [2]Mouse Imaging Ctr. and Program in Neurosci. and Mental Hlth., The Hosp. For Sick Children, Toronto, ON, Canada

Abstract: Males and females exhibit dimorphisms in brain structure and function. To determine the basis for these sex dimorphisms, we investigated the influences of sex hormones and sex chromosomes on brain structure and function in mice. We used the Four Core Genotype (4CG) mice, which can generate both male and female mice with XX or XY sex chromosome complement, allowing decoupling of effects of sex chromosomes from those of the hormonal milieu. In order to determine the influences of sex hormones and sex chromosomes in a normal context, we used intact mice, characterized their endocrine function, and found that during the course of our study males and females displayed physiological levels of sex hormones regardless of chromosome complement. To assess differences in cognitive function, mice were trained on a radial arm maze, and to examine whole brain structure, high resolution ex-vivo MRI was performed. As reported for other cognitive tests, maze training demonstrated strict hormone-dependency with no apparent influence of sex chromosomes on spatial learning and memory. The influence of sex chromosomes on brain structure has been thought of as small in comparison

to that of sex hormones. However, voxel-wise and volumetric analyses of MRI data uncovered influence of chromosomes in several areas. Of 30 regions that displayed variation among the 4CG mice, 15 were exclusively hormone-dependent and 13 were exclusively chromosome-dependent. Only two brain regions displayed structural variation that associated with both chromosomes and hormones, and the combined effects were additive rather than interacting. The structural variation we observed overlapped with previously identified dimorphisms, and also highlighted differences in areas that are less well documented, such as the pons, medulla, cerebral peduncle, fornix, and internal capsule.Understanding the influences of chromosomes and hormones on brain structure and function is important for understanding sex differences, an endeavor that has implications for understanding gender biases observed in the prevalence of psychiatric disorders.

Title: BDNF immunolabeling in SNB motoneurons and levels in target musculature are not dependent on estrogens during postnatal development

Authors: *L. M. RUDOLPH, D. R. SENGELAUB
Indiana Univ., Bloomington, IN

Abstract: The lumbar spinal cord of rats contains the sexually dimorphic, steroid-sensitive motoneurons of the spinal nucleus of the bulbocavernosus (SNB). In males, these motoneurons innervate the perineal muscles bulbocavernosus (BC) and levator ani (LA) that control penile reflexes. We have previously demonstrated that testosterone interacts with brain-derived neurotrophic factor (BDNF) to regulate SNB dendritic morphology in adulthood. For example, after castration of adult males, SNB dendrites undergo significant atrophy, BDNF

immunolabeling decreases in SNB motoneuron somata, and BDNF levels increase in the BC muscle. Blockade of BDNF prevents castration-induced dendritic atrophy, indicating a regulatory role for BDNF. Furthermore, the castration-induced dendritic atrophy and changes in BDNF in SNB motoneurons and target muscles can be reversed by androgen treatment, suggesting that androgens mediate BDNF action to maintain SNB dendritic morphology in adulthood. Developing SNB dendrites are also dependent on gonadal steroids, and require estradiol to support dendritic growth. Early castration prevents SNB dendrite growth, and treatment of castrates with estradiol fully supports SNB dendrite growth during the early postnatal period. This estrogenic support is mediated by the expression of estrogen receptor α in the target musculature through postnatal day (P) 21. In the present study, we assessed if estrogens could mediate BDNF in SNB motoneurons and their target muscle, potentially providing a mechanism for regulating SNB dendrite growth. Male rats were castrated on P7 and left untreated or were given an estradiol implant (0.1 mg) either at the BC muscle or in the interscapular region. Another group of males was castrated on P7 and received a blank implant at the BC muscle; an additional group of gonadally intact males was left untreated. At P21, BDNF was assessed in SNB motoneurons by immunohistochemistry (AB1779, Millipore, Temecula, CA) and muscle BDNF levels were assessed by ELISA (CYT306, Millipore). BDNF immunolabeling in SNB motoneurons did not change in response to castration or estradiol treatment. As observed in adulthood, castration resulted in a significant increase (45%) in BDNF in the BC muscle, and thus may be involved in the failure of SNB dendrites to grow after early castration. However, estradiol treatment or the presence of a blank implant had no effect on the castration-induced increase in muscle BDNF. These data suggest that while BDNF may be involved in SNB dendritic development, the failure of estrogen treatment to alter muscle BDNF levels indicates that estrogen-dependent SNB dendrite growth is not mediated by BDNF.

Title: Sex differences of blood in DNA methylation

Authors: *M. INOSHITA[1], S. NUMATA[1], M. KINOSHITA[1], A. TAJIMA[2], I. IMOTO[2], T. OHMORI[1]
[1]The Univ. of Tokushima, Tokushima, Japan; [2]Human Genet., Inst. of Hlth. Biosciences, The Univ. of Tokushima Grad. Sch., Tokushima, Japan

Abstract: Object- : DNA methylation, which is the addition of a methyl group to the cytosine in a CpG dinucleotide, plays an important role in disease as well as in normal development. Accumulating evidence indicates that sex is one of the major influences over DNA methylation. However, only a few genome-wide methylome studies investigating sex differences have been reported, and little is known about sex-biased DNA methylation on autosomes. The aim of the present study was to investigate sex-biased DNA methylation on the autosomes in human blood. Methods- : We performed a genome-wide DNA methylation profiling of the peripheral leukocytes from non-psychiatric controls (N=94; 50 males and 44 females) using Infinium HumanMethylation450 BeadChips, and we examined sex differences in DNA methylation using multiple linear regression analysis with an adjustment for the covariates that we had identified in a surrogate variables analysis. The final data set included 398,753 CpG sites. All subjects were of unrelated Japanese origin, and they signed written, informed consent forms that were approved by the institutional ethics committee of the University of Tokushima Graduate School for participating in this study. Results- : We identified significant sex differences in DNA methylation at 471 autosomal CpG loci at 5-% Bonferroni correction. Some of these loci also showed the same sex-biased DNA methylation patterns in a recent human post-mortem brain study by Xu and colleagues (2013). Conclusion- : We identified differential DNA methylation between males and females in blood at numerous CpG loci on autosomes. This finding suggests that DNA methylation may be responsible for the sexual dimorphism of blood in particular genes, and will shed light on the molecular mechanism of sex differences.

Title: Gestational and trans-generational effects of Bisphenol-A on vasopressin immunoreactive AVP

Authors: *J. GOLDSBY, J. T. WOLSTENHOLME, E. F. RISSMAN
Univ. of Virginia Sch. of Med., Charlottesville, VA

Abstract: Bisphenol-A is an endocrine disrupting compound used to make resins and plastics. It is found in many commonly used items such as food can linings, plastic bottles, and thermal receipts. Exposure to BPA during development alters steroid hormone function, which in turn affects brain organization and sexual differentiation. We fed female C57BL/6J mice phytoestrogen-free diets that did not (control) or did contain BPA (5mg/kg of diet). Females were mated and when pups were born they were all fostered to dams on control diets to limit BPA exposure to gestation in the first generation. Pairs from the same diet lineages were bred to the third generation with no further BPA exposure. Adult brains from the first (F1) and third (F3) generations were collected, acrolein fixed, then stained for AVP. Three sexually dimorphic regions, the lateral septum (LS), the bed nucleus of the striate terminalis (BNST), and the medial posterodorsal amygdala (MePD) were analyzed and quantified for size of stained area and intensity of staining. In the first generation (n=3 per group) the expected sex difference was noted in the LS, males had more intense AVP immunoreactivity than females. An interaction between diet and sex was found in the BNST whereas the males exposed in gestation to BPA had more intense immunoreactivity than all other groups. In the F3 mice (n=5-6 per group) the expected sex difference in area stained was noted in the LS, and the intensity of the immunoreactivity was affected in this regions by diet (controls > BPA lineages). The same diet effect on intensity was found in the BNST. In the MePD sex differences (males>females) were found for both immunoreactive area and the staining intensity. These pilot data show the some of the expected sex differences in AVP immunoreactivity in both F1 and F3 braind. Moreover, BPA lineage animals (F3) have less AVP present in normally AVP-expressing cells when compared with control animals. Thus, we can conclude that exposure to a low dose of BPA during gestation has a transgenerational effect on production and/or release of AVP in the brain, suggesting a transgenerational effect on brain neuropeptide dynamics. Title: Deciphering roles for CB1 versus CB2 endocannabinoid receptors in development of the amygdala

Authors: *K. J. ARGUE, M. M. MCCARTHY
Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The amygdala is a collection of nuclei that are critical for social and emotional behaviors, parameters that differ in males and females and are altered across a broad spectrum of psychiatric disorders. In rats, adolescent males display higher levels of social play behavior compared to females, and previous studies from our group showed that treatment of female rats with the non-specific endocannabinoid agonist WIN-55,212 (WIN) between postnatal days 0-3 (PN0-3) increases the frequency of adolescent play behavior to the level observed in males (PNAS 107; 2010). The differences in play behavior correlate to a sex difference in BrdU+ cells in the developing medial amygdala in which females have more newly born cells compared to males at PN4, and treatment with WIN reduces the number of new cells in females to those observed in males. The endocannabinoid system includes two major receptor types, CB1, which modulates synaptic function through inhibition of neurotransmitter release, and CB2, which is typically associated with the immune system and inflammatory cells. Given their distinct expression patterns, CB1 and CB2 are not thought to work together. In order to more completely understand the role of CB receptors in sexual differentiation of the amygdala and social play, we administered highly selective agonists for each receptor to male and female rat pups from PN0-3. To our surprise, specific agonism of either CB1 or CB2 alone was not sufficient to increase adolescent female social play behavior (ANOVA $p < 0.05$), however combined treatment with specific CB1 and CB2 agonists recapitulates the effect observed with WIN such that dual-agonist treated females exhibited male-like levels of social play (ANOVA $p > 0.05$). Due to the association of CB2 with the immune system, it has been traditionally considered a peripheral endocannabinoid receptor that is not abundant in the healthy brain. Here we show *in situ* hybridization and immunohistochemical evidence that CB2 is abundantly expressed in the developing amygdala and that expression appears to decrease with increasing age. Additionally, we are pursuing an extensive analysis of the role of the endocannabinoid system in mediating sex specific proliferation and differentiation via stereological analysis of astrocyte, inhibitory neuronal, and excitatory neuronal proliferation in the developing amgydala. These studies provide insight into the role of the endocannabinoid system in sexual differentiation of the brain and aid in a more complete understating of the relative contributions of the endocannabinoid receptors in brain development

Title: Endocannabinoid-induced phagocytosis in the developing amygdala mediates a sex difference in cell genesis

Authors: *J. W. VANRYZIN[1,2], M. M. MCCARTHY[3,4]
[2]Program in Neurosci., [3]Dept. of Pharmacol., [4]Dept. of Physiol., [1]Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: The mechanisms underlying the establishment of sex differences in the developing brain are still largely unknown, but recent evidence suggests an increasing role for non-neuronal cells in this process. Microglia, the resident immune cells of the brain, act in a variety of roles outside of their capacity to survey and respond to insult. In development, microglia are involved in synaptic pruning, tissue homeostasis, and the support and regulation of neuronal precursor populations both through signaling and targeted phagocytosis of viable cells- termed 'phagoptosis'. To further support this, we implicated microglia as an integral component of brain sexual differentiation in the preoptic area, suggesting an important signaling capacity of these cells in organizing sex-specific brain structure and behavior (Lenz et al. J Neurosci 33(7). 2013). Additionally, we reported a sex difference in cell proliferation in the developing rat medial amygdala (MeA) that was mediated by endocannabinoids, with females having higher rates of cell proliferation than males. These differences in cell proliferation correlated to behavioral changes, as female treatment with the CB1/2 agonist WIN55,212-2 exhibited masculinized juvenile social play behavior (Krebs-Kraft et al. PNAS 107(47), 2010). Further investigation revealed a surprising new role for microglia phagoptosis in mediating the number of newborn cells with effects specific to the postnatal MeA. Males displayed twice as many Iba1+ microglia exhibiting a phagocytic morphology as compared to females. These microglia contained one or more processes that ended in a phagocytic cup, but otherwise exhibited thick or ramified processes. Furthermore, exogenous CB1 receptor agonist treatment increased the number of phagocytic microglia in females to levels observed in males. Treatment with the tetracycline

derivative minocycline, an inhibitor of microglial activation, increased male BrdU+ cell counts to female levels, but did not alter the number of female BrdU+ cells. We found that every microglia exhibiting a phagocytic morphology was also DAPI+, a marker for DNA, within the phagocytic cup; thus, we sought to characterize the specific cell types targeted by the microglia. BrdU colocalized to the phagocytic cup, in addition to inhibitory interneuron markers calbindin and nNos. This work was supported by RO1 MH52716-018 to MMM.

Title: Sexual dimorphism in the expression of pituitary specific genes during rat development

Authors: *I. BJELOBABA, K. MAREK, S. S. STOJILKOVIC
Section on Cell. Signaling, Natl. Inst. of Child Hlth. and Human Develop., Bethesda, MD

Abstract: The developmental increase in GnRH release in hypophyseal portal blood accounts for gradual establishment of hypothalamic-pituitary-gonadal axes in mammalian females and males. Released GnRH reaches pituitary gonadotrophs wherein it facilitates the expression of a gene for its own receptor, Gnrhr, and genes coding for gonadotropin subunits Cga, Lhb, and Fshb. Our experiments with developing rats revealed a progressive and comparable increase in the pituitary Gnrhr expression in females and males, reaching the peak in expression at 4 and 5 weeks of age, respectively, followed by a significant decline during peripubertal period. In males, there was a strong correlation between pituitary Gnrhr vs. Lhb, Fshb, and Cga expression, reflecting similar developmental pattern of gene expression. However, in female pituitaries Lhb, Fshb, and Cga expression did not correlate well with Gnrhr expression, the lack of correlation was not related to variations in gene expression during estrous cycle in postpubertal females, and the level of expression was lower than in males. The expression of Spp1, another gonadotroph specific gene (encoding osteopontin), was also significantly higher in male pituitaries, but correlated well with Gnrhr expression in both males and females. The sexual dimorphism in the expression of gonadotroph-specific genes was established during juvenile period, in parallel with the sexual dimorphism in the expression of a lactotroph specific gene Prl, which was ten fold higher in females than males. These data indicate that the synchronized activity of gonadotroph-

specific genes during development in males reflects a dominant role of GnRHR, whereas in female gonadotrophs GnRHR-controlled gene expression is substantially modified by other factors.

Title: Sex difference and laterality in the number of astrocytes in the adult posterodorsal aspect of the medial amygdala of mice

Authors: *D. R. PFAU[1], N. J. HOBBS[2], S. M. BREEDLOVE[2], C. L. JORDAN[2]
[1]Neurosci., Michigan State Univ., Lansing, MI; [2]Neurosci. Program, Michigan State Univ., East Lansing, MI

Abstract: In rodents, pheromonal signals play a key role in the expression of stereotypical and sex-specific adult sexual behaviors. Vital to the detection and integration of such chemical signals is the posterodorsal aspect of the medial amygdala (MePD) which receives input from sensory pathways transducing pheromonal signals. In adult rats, the MePD is sexually dimorphic, as males have a larger MePD volume than females. The MePD in male rats also contains more and larger neurons than females. Interacting with these sex differences are laterality differences, with X MePD being larger than X MePD but only in males. Astrocytes in the rat MePD are also sexually dimorphic and lateralized, with sex differences in astrocyte number and complexity, but unique to only one side or the other. For example, males have more MePD astrocytes than females on the right side, and more complex astrocytes than females in the left MePD. Furthermore, masculinization of MePD astrocytes depends on functional androgen receptors, since the morphology of MePD astrocytes in XY rats deficient in functional ARs is completely feminized. Here we investigated whether the MePD in adult C57Bl/6J mice is also

sexually dimorphic in its volume and astrocyte morphology. Astrocytes were visualized with an antibody directed against glial fibrillary acidic protein (GFAP). MePD volume in adult male C57 mice is larger and contains more astrocytes than in females. Moreover, the total number of astrocytes is lateralized with their being more in the left hemisphere in females only, so there is a sex difference favoring males only on the right side. Given the sex difference in MePD volume, we also asked whether the density of astrocytes depended on either sex or hemisphere and found that no such differences. Neither did we find a sex difference or laterality in the complexity of astrocytes in mice, contrary to findings in rats. Overall these data show that the MePD is sexually dimorphic in mice, underscoring its possible role in detecting pheromonal signals important for the development and expression of sex-specific social-sexual behaviors.

Title: Aggressive behavior in progesterone receptor knockout (PRKO) mice

Authors: *D. LALITSASIVIMOL, C. K. WAGNER
Psychology, Univ. At Albany, Albany, NY

Abstract: The display of sexually dimorphic behaviors, such as aggression, in adulthood is directed by the differential exposure of males and females to steroid hormones during critical developmental windows. The medial preoptic nucleus (MPN) is sexually differentiated by hormones during development and is important for the display of intermale aggression in adult male rodents. During perinatal development, differential exposure to the testosterone metabolite, estradiol, induces a significant sex difference in progesterone receptor (PR) expression in the MPN, suggesting that PR plays an important role in the sexual differentiation of the MPN and MPN-mediated behaviors. The present study examined intermale aggressive behavior in adult male PR knockout (PRKO) and wildtype (WT) mice using the resident intruder paradigm. PRKO and WT adult males were castrated and implanted with a silastic capsule containing testosterone

propionate (TP) to clamp circulating testosterone levels. PRKO males demonstrated significantly lower levels of aggression compared to WT males. PRKO males exhibited significantly longer latencies to attack ($p<0.05$) and a significantly reduced attack frequency compared to WT males. Ongoing experiments test the hypothesis that whether PR expression during neonatal life is required for the masculinization of aggressive behavior by testosterone. Neonatal female PRKO and WT mice were exposed to TP or oil vehicle from postnatal days 1-7 and in adulthood were ovariectomized, implanted with TP capsules, and tested for the display of male-typical aggressive behavior in response to an intruder. Results to date suggest that the expression of PR is essential for the normal display of intermale aggression in mice.

Title: Serotonin promotes feminization of sexually dimorphic nuclei in a cell phenotype-specific manner

Authors: *A. M. MADDEN, N. E. SHTEYNBERG, A. A. BARTLETT, A. T. PAUL, S. L. ZUP
Psychology, Univ. of Massachusetts Boston, Boston, MA

Abstract: Testosterone and its metabolites are known to masculinize the brain during a critical perinatal window. Evidence of this can be seen in the relative size of sexually dimorphic brain areas, including the sexually dimorphic nucleus of the hypothalamus (SDN; larger in males), and the anteroventral periventricular nucleus (AVPV; larger in females). Interestingly, serotonin (5HT) also seems to play a role in the development of these nuclei, as both chronic administration of a general serotonin agonist (5-methoxytryptamine; 5MT) given across perinatal development and more acute administration of a 5HT2A/2C-specific agonist (-DOI) given across the second week of life have been shown to feminize these structures in males. Therefore, 5HT2A/2C receptor activation over the second week of life may drive the feminizing effect of serotonin, although that has yet to be shown conclusively. Thus, we injected male and female Sprague-Dawley rat pups with saline, 5MT, or ketanserin (a 5HT2A/2C antagonist; KET) over the second week of life from postnatal day (PND) 8 to PND16. This allowed us to both examine

the importance of (1) the proposed critical window, and (2) the necessity of 2A/2C activation for this effect. On PND18, the brains were collected and processed for calbindin or tyrosine hydroxylase immunostaining and thionin counterstain. The volume of the calbindin+ SDN was found to be larger in males than in females, regardless of treatment (ANOVA; $p<.001$). A similar pattern was found in the calbindin+ cell count and soma size, with males having more and larger calbindin+ cells than females (ANOVA; $p<.001$, and $p<.005$, respectively). Preliminary results from the AVPV suggest that the effect of 5HT on nucleus size may depend on cellular phenotype, as an interaction was observed between sex and drug in this nucleus (ANOVA; $p<.05$). This study highlights the importance of considering cellular phenotype within sexually dimorphic structures, as activation of 5HT2A/2C receptors has been shown to be sufficient for feminization of overall nucleus size in the SDN and AVPV, while the present data suggests that they may not be necessary for development of the specific sex differences in calbindin+ SDN or TH+ AVPV cell number.

Title: Sex differences in the distribution of Calbindin-D28K immunoreactive cells in wildtype and progesterone receptor knock-out (PRKO) mice in adulthood

Authors: B. GROTH[1], D. LALITSASIVIMOL[2], *C. K. WAGNER[3]
[2]Psychology, [1]Univ. At Albany, Albany, NY; [3]Univ. Albany, ALBANY, NY

Abstract: Steroid hormones activate nuclear receptors, which as transcription factors can exert powerful influences on fundamental processes of neural development. There is a dramatic sex difference in the expression of progesterone receptor (PR) within the rodent medial preoptic nucleus (MPN) during perinatal life, suggesting that PR is important for the sexual differentiation of this region. The distribution of calbindin-D28 is sexually dimorphic within the MPN of mice (Gilmore et al., 2012) and can be used as a marker of sexual differentiation. The

present study examined the number and distribution of calbindin immunoreactive (CALB-ir) cells in the MPN of adult male and female PR knockout (PRKO) or wildtype (WT) mice. Results demonstrate a significant effect of sex and genotype with females having a significantly fewer CALB-ir cells compared to males and PRKO mice having significantly fewer CALB-ir cells than WT mice. In addition, there are significant differences in the distribution of CALB-ir cells within the MPN. In WT males there is a distinct clustering of CALB-ir cells that is essentially absent in PRKO males with a more dispersed and medial distribution of CALB-ir cells in PRKO males. These results suggest that the expression of PR is critical for the sexual differentiation of the MPN and that the absence of PR activity may alter the normal neural circuitry of this behaviorally important region.

Title: Effects of exposure to bisphenol A (BPA) during development on progesterone receptor expression in the medial preoptic nucleus of female rats

Authors: A. PHILLIPS[1], K. STRYKER[1], *P. Q. MENNELLA[2], C. K. WAGNER[1]
[1]Psychology, Univ. at Albany, Albany, NY; [2]Neurosci., Bay Path Col., Longmeadow, MA

Abstract: The expression of progesterone receptor (PR) within the medial preoptic nucleus (MPN) of rodents during perinatal life is highly dependent on the aromatization of testosterone to estradiol in males (Quadros et al 2002). Perinatal females, in the relative absence of gonadal steroid hormones, express extremely low levels of PR in the MPN. PR expression is virtually abolished in neonatal male rats castrated on the day of birth, male rats administered an aromatase inhibitor or in estrogen receptor alpha knockout mice. Conversely, PR expression is induced to levels similar to that of males in neonatal female rats given testosterone or estradiol. In this regard, PR expression within the MPN of neonatal male and female rats serves as a sensitive bioassay for exposure to compounds that exert estrogenic activity and/or disrupt endogenous estrogen action. The present study examined the estrogenic effects of the plastics contaminant,

bisphenol A (BPA) on the fetal and neonatal brain. In Experiment 1, neonatal male and female rats were injected with BPA (5mg/kg) or vehicle On P2-4 and the estrogen receptor antagonist ICI 182,780 (1.5mg/kg) or vehicle on P1-4 and tissue was collected on P5. In Experiment 2, pregnant mothers were administered BPA (10 or 50mg/kg) or vehicle orally by ingestion of a BPA-laced vanilla wafers from gestation day E12-E22 and tissue was collected on the day of birth. Preliminary evidence from both studies suggests that neonatal or maternal exposure to BPA increases the expression of PR in the MPN of females, consistent with the idea that BPA exposure can exert estrogenic-like effects in developing MPN and may alter the sexual differentiation of brain and behavior.

Title: Age-related impairments in the dynamic regulation of active microglia by astrocytes

Authors: *D. M. NORDEN[1], P. J. TROJANOWSKI[1], F. R. WALKER[2], J. P. GODBOUT[1]
[1]The Ohio State Univ., Columbus, OH; [2]Univ. of Newcastle, Newcastle, Australia

Abstract: Systemic infection is associated with an increased frequency of behavioral complications in the elderly. In aged rodents, acute activation of the innate immune system causes an exaggerated neuroinflammatory response that is associated with the development of neurobehavioral complications. Our studies have shown that while the anti-inflammatory cytokine IL-10 is highly expressed in the aged brain, microglial activation is prolonged. Recently we showed that astrocytes of adult mice express the IL-10 receptor (IL-10R) and that IL-10 re-directs active astrocytes to produce TGFb, which in turn, attenuates the activation of microglia. Therefore, the purpose of this study was to investigate the degree to which these key cytokine interactions between glia are impaired in the aged brain following systemic immune challenge. First, the morphology and gene expression of astrocytes was determined in the brain of adult (2-3mo) and aged (18-20 mo) BALB/c mice. In the hippocampus of aged mice, there was increased

expression of the astrocyte inflammatory markers vimentin and GFAP. Moreover, there was evidence of significant remodeling and cytoskeletal re-organization of aged astrocytes in the hippocampus. For instance, aged astrocytes had a global enlargement of the GFAP cytoskeleton without a concomitant increase in branch length, indicating that aging provokes significant cytoskeletal hypertrophy. This was also reflected in increased GFAP labeling intensity. There was no evidence of age-related changes in the number of astrocytes. These data suggest that astrocytes have an early stage pathological profile with age. Moreover, astrocytes from aged mice had reduced surface IL-10R expression compared to adults. Next, to investigate the degree to which these changes influence immune regulation, adult and aged mice were injected with LPS and astrocyte and microglial populations were sorted and collected during the resolution phase following LPS (24h). NanoString gene array of these specific populations indicated that astrocytes from adult mice had an mRNA expression profile associated with increased IL-10 signaling including increased IL-10R and TGFb expression. Astrocytes from aged mice, however, failed to upregulate either IL-10R or TGFb mRNA. This lack of regulation by TGFb was associated with decreased TGFb signaling and exaggerated expression of pro-inflammatory mediators in aged microglia. In summary we interpret these data to indicate that astrocytes have an important role in regulating microglia via TGFb signaling and that an impaired IL-10 response in aged astrocytes contributes to age-related deficits in the regulation of active microglia.

Title: The effects of surgery and morphine treatment on neuroinflammation and cognitive decline in aged rats

Authors: *R. M. BARRIENTOS, V. M. THOMPSON, M. M. KITT, L. R. WATKINS, S. F. MAIER
Dept. of Psychology & Neurosci., Univ. Colorado Boulder, BOULDER, CO

Abstract: Opioids, such as morphine, induce potent analgesia and are the gold standard for the treatment of acute and chronic pain. However, opioids also activate glia, inducing proinflammatory cytokine and chemokine production within the brain. Aging potentiates neuroinflammatory responses to a peripheral challenge, due in large part to sensitized microglia, and this potentiation is especially prominent in the hippocampus. Furthermore, this exaggerated proinflammatory response is causally associated with robust memory impairments. We have previously shown that aged rats that have undergone an abdominal surgery exhibit persistent neuroinflammation in the hippocampus, with striking deficits in the formation of new memories occurring during this neuroinflammatory period. Aged patients who undergo surgery are often treated with morphine for several days to manage post-operative pain. In this study we explore the possibility that the duration of the proinflammatory response following surgery, and the accompanying memory deficit will be further extended in aged rats by morphine treatment. Preliminary data show that rats that have undergone surgery and have received daily morphine injections exhibit a potentiated neuroinflammatory response in the hippocampus compared to rats exposed to either surgery or morphine alone.

Title: Absence of mast cells disrupts grooming behavior in mice: Involvement of dopaminergic and histaminergic systems

Authors: *M. I. SOLLOZO DUPONT, F. GUZMAN-MEJÍA, C. GONZÁLEZ-ESPINOSA, C. LÓPEZ-RUBALCAVA
Ctr. de Investigación y de Estudios Avanzados del IPN (CINVESTAV-IPN), Mexico, Mexico

Abstract: Evidence show that brain mast cells degranulation induces the release of many neuro-active mediators, some of which are involved in behavioural and physiological components of anxiety. Considering that the analysis of grooming microstructure is a useful measure of anxiety

in rodents, this study was designed to determine the potential influence of mast cells on grooming phenotypes, focusing on the dopaminergic system. Mast cells deficient mice (KitWsh/Wsh), congenitally normal mice C57BL/6J (wild-type, WT) and KitWsh/Wsh intraperitoneally reconstituted with WT mast cells were used. In addition, because brain mast cells contribute to the neural pool of histamine and there are several studies revealing histaminergic modulation of emotional behaviors in rodents, we analyzed the effects of histamine microinjections on grooming in KitWsh/Wsh and WT mice. Results showed that KitWsh/Wsh mice had a greater number of grooming patterns and an increased percentage of incorrect transitions in comparison to WT and reconstituted mice. Increased levels of dopamine in striatum were also observed in KitWsh/Wsh. By contrast, DOPAC/DA and HVA/DA were decreased in KitWsh/Wsh in comparison with the other two strains. While KitWsh/Wsh exhibited a strong positive correlation between dopamine levels and incorrect transitions, the correlation was notably negative in WT and KitWsh/Wsh reconstituted mice. When histamine was injected to KitWsh/Wsh, a reduction in the percentage of incorrect transitions in KitWsh/Wsh compared with controls (KitWsh/Wsh administered with saline solution) occurred after the administration of 2.5 and 5.0 μg of histamine. The percentage of incorrect transitions observed in animals administered with both doses of histamine was similar to the value registered by the WT group. In conclusion, our data implicate brain mast cells in the modulation of grooming and provide evidence that these cells are contributing in the regulation of the dopaminergic system. Our results also confirm that mast cell deficiency could alter brain histamine content, with the subsequent impact on behaviour.

Title: Acute but not chronic social stress activates microglia in the prefrontal cortex of CX3CR1-GFP reporter mice

Authors: *M. L. LEHMANN, R. B. SCHEINERT, M. E. DEAN, H. A. COOPER, M. HERKENHAM
Natl. Inst. of Mental Hlth., NIH, BETHESDA, MD

Abstract: Microglia are the innate immune cells in the brain parenchyma and are functionally and morphologically dynamic. Activation (by infection, trauma, or cell impairment) rapidly alters microglia_they retract their processes, produce inflammatory molecules, and can cause pathology. Recent studies have argued that psychosocial stress activates microglia in select brain areas. Data on the effects of psychosocial stress on microglial activation status have been inconsistent. Here we examined the effects of acute and chronic stress on microglial density and phenotype in specific stress-responsive regions of brain using CX3CR1-GFP reporter mice that display strong GFP reporting confined to microglia. We first mapped changes in microglial cell density following acute and chronic stress exposure. Mice were exposed to either two (acute) or fourteen (chronic) days of social defeat stress. Mice were then phenotyped for social behaviors, perfused, and brains examined for changes in microglia number and proliferation. We also isolated microglia from brains and used fluorescence-activated cell sorting of the cell-surface markers CD11b, CD45, and CD68 to determine activation status. Lastly, an *ex vivo* approach was used to address whether acute or chronic stress alters the responses of microglia to pro-inflammatory stimuli. C57BL6/J mice were exposed to acute or chronic stress, and microglia in the prefrontal cortex were isolated and challenged with LPS to probe for stress-modified pro-inflammatory cytokine production. Both acute and chronic stressed mice showed reduced social and hedonic behaviors indicative of depressive-like phenotype. The amount of anhedonic behavioral change was stress-duration dependent. Acute but not chronic stress increased microglia density and proliferation in stress-responsive brain regions, including the medial prefrontal cortex. Acute stress also enhanced expression of CD11b on microglia taken from the prefrontal cortex. Lastly, when stimulated with LPS, peritoneal macrophages from mice exposed to acute stress expressed higher levels of pro-inflammatory cytokines than those from mice exposed to chronic stress or unstressed home cage mice. The data showed that stress had a biphasic effect on microglial activation. Acute stress increased the density, proliferation, and activation of microglia within the prefrontal cortex. After 14 days of stress exposure, microglia appear to have adapted_both the density and levels of activation were comparable to non-stressed mice. The mechanisms and consequences of such microglial adaptation are currently under investigation.

Title: Minocycline treatment blocks LPS-induced impairment in context discrimination memory retrieval

Authors: *J. CZERNIAWSKI, J. F. GUZOWSKI
Neurobio. & Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Neuroinflammation is implicated in cognitive deficits associated with disease, aging, and trauma. During an immune challenge, there is an increase in cytokine levels in the CNS, which can impair certain forms of learning. Recently, we demonstrated that systemic administration of the bacterial endotoxin lipopolysaccharide (LPS) results in elevated mRNA expression of the proinflammatory cytokines IL-1β, TNF-α, and IL-6 in the rat brain and produces a robust impairment in context discrimination memory retrieval. Furthermore, using the Arc/Homer catFISH immediately-early gene imaging method, we observed greater overlap in neuronal ensembles activated in dorsal hippocampus during each context presentation in LPS-treated rats compared to controls, consistent with the notion of impaired pattern separation. These data provide support for a direct link between cytokine mediated changes at the neural circuit activity level with cognitive impairment at the behavioral level. Because these cytokines are produced in the brain by microglia, the present study aimed to determine if blocking microglia with minocycline, a semi-synthetic tetracycline antibiotic, could block the LPS-induced neuroinflammation and cognitive deficits. Young adult male Sprague Dawley rats were trained in context discrimination conditioning (CDC), in which they were placed into 2 similar behavioral chambers (A and A') daily for 3 min each. One of the environments (A) was paired with a brief, mild footshock (0.5 mA, 1s). Upon reaching discrimination criterion, each subject received an intraperitoneal (i.p.) injection of minocycline (50 mg/kg) or saline after the last day of training and a second dose the next day. Thirty minutes after the second dose of minocycline or saline, LPS (150 μg/kg, i.p.) or saline was administered and subjects were tested 6 h later in each of the contexts. Preliminary findings indicate that minocycline treatment blocks the impaired context discrimination memory retrieval and elevated expression of IL-1β in dorsal hippocampus observed in LPS-treated rats. Findings from this study will help provide a direct causal link between cytokine expression in the brain and the observed cognitive and neural circuit activity deficits. Furthermore, because minocycline can readily cross the blood-brain

barrier, it is valuable to determine the mechanistic effects of it in the brain as a putative treatment for human patients with impairments in cognitive function resulting from neuroinflammation.

Title: Churg-Strauss syndrome following vaccination against 2010 influenza A (H1N1): A case report

Authors: *H. M. FU
Med. 5th Floor, Dept. of Neurology,, Kaohsiung City, Taiwan

Abstract: Churg-Strauss syndrome (CSS) is a systemic disorder characterized by asthma, transient pulmonary infiltrates, hypereosinophilia, and systemic vasculitis. This is a rare syndrome of unknown etiology, and several inducing factors such as inhaled allergens, infections, vaccinations, and drugs have been reported. Here we present a 55-year-old female who developed signs and symptoms of this syndrome after receiving H1N1 vaccination with good recovery after steroid treatment.

Title: Sex differences in neonatal immune function and potential implications for developmental delays in learning

Authors: J. I. CAULFIELD, L. S. TERASAKI, *J. M. SCHWARZ
Psychology, Univ. of Delaware, Newark, DE

Abstract: Microglia are the resident immune cells of the brain. Under baseline conditions in the adult brain, microglia express low levels of immune molecules (cytokines and chemokines), they survey the microenvironment, and they interact with surrounding neurons and astrocytes via thin, long processes. Microglia are thus intricately involved in neural and cognitive function. Microglia respond to infection, insult, or injury, with a rapid change in morphology and a robust increase in the production of cytokines and chemokines in order to re-establish homeostasis in the brain. Neurons exhibit a marked sensitivity to the inflammatory signals produced by microglia and if left unchecked, these stimuli can cause neuronal dysfunction, cognitive dysfunction, or even neuronal death. Microglial activation is associated with multiple neurodevelopmental disorders that also have known or suspected immune etiologies, including autism, ADHD, schizophrenia, and cerebral palsy. Notably, all of these disorders exhibit a strong sex bias in males. We recently discovered a striking sex difference, that males have significantly more microglia in the developing hippocampus, cortex and amygdala than females on postnatal day 4 (Schwarz et al. J. Neurochem., 2011). Given these rodent data and the well-known human epidemiological data, we hypothesize that neonatal males may be more vulnerable to an immune challenge than neonatal females, which may have significant consequences neural and cognitive development. To test this hypothesis, we first treated male and female rat pups with a mild Escherichia coli (E.coli) infection on P4 and examined both the peripheral and neuroimmune responses to the infection. We found a significant interaction of sex and infection in the expression of multiple cytokines and neurotropic factors that were dependent upon brain region (hippocampus vs. cerebellum). In contrast, we saw a significant effect of infection on the peripheral immune response that was not dependent upon sex. This suggests that sex-specific effects of neonatal immune activation are particular to the brain and the brain region examined. In a second experiment, we allowed a similar cohort of rat pups to grow till postnatal day 21 at which point we measured anxiety behaviors. We found that neonatally-infected males were significantly more anxious than control males and neonatally-infected or control females (Sex X Infection Interaction: $F_{1,29} = 4.04$; $p < 0.05$), similar to previous reports. On-going experiments will determine the impact of sex and neonatal immune activation on juvenile immune function and the onset of hippocampal-dependent learning that occurs around this young age.

Title: Interleukin 1 receptor signaling and fadrozole regulate anxiety behaviors in mice

Authors: *K. A. DUNCAN[1], A. FEIGHERY[2], J. JOSIMOVICH[2], J. ORR[2], K. BLACKSHEAR[2], C. J. SALDANHA[4], K. S. HOLLOWAY[3]

Abstract: Activation of the immune response through proinflammatory cytokines influences a range of physiological and behavioral responses. These responses include fever, inflammation, reduced locomotor activity, sleep disorders, and interestingly diminished social interactions. Specifically neuroinflammation, mediated by Interleukin 1 (IL-1β), elicits changes within the CNS that are implicated in emotional disorders such as depression and anxiety. In the present study, we investigated the role of the IL-1 signaling pathway in anxiety-like behaviors. We then tested the effect of decreased estrogen on anxiety-like behaviors. Previous data has shown that estrogen-mediated neuroprotection is through a decrease in inflammation, thus we hypothesized that decreased circulating estrogens by the use of aromatase inhibition would alter anxiety-like behaviors. Adult male mice (IL-1 receptor knockouts (IL-1R KO) and wild type C57BL/6) were tested for measures of both sickness and anxiety-like behaviors two hours following an injection of LPS or vehicle. IL-1R KO mice differ in their anxiety response prior to treatment. This effect is further exacerbated following LPS treatment and immune system activation. For studies examining the role of aromatase inhibition and anxiety-like behaviors, Fadrozole was given at the same time as the LPS injection. Interestingly, Fadrozole decreased anxiety behaviors in all mice, but the effect was greater in wild-type versus IL-1R KOs. These data suggest that IL-1 signaling is associated with anxiety-like behaviors and steroid hormone levels can ameliorate this effect.

Title: Microglia possess a circadian clock that controls inflammatory responses independent of glucocorticoids

Authors: *L. K. FONKEN, M. G. FRANK, M. M. KITT, L. R. WATKINS, S. F. MAIER
Univ. of Colorado Boulder, Boulder, CO

Abstract: The circadian system regulates many physiological functions including inflammatory responses. For example, mortality following administration of lipopolysaccharide (LPS) varies depending on the time of immunostimulation in mammals. The effects of more subtle challenges on the immune system and cellular changes underlying circadian differences in inflammatory responses are not well understood. Thus, we investigated whether a sub-septic dose of LPS injected in the light or dark phase would differentially affect rats' sickness responses, and whether these differences were related to circadian oscillations in microglia. Adult male Sprague-Dawley rats were injected with 100ug/kg of LPS during either the middle of the light or dark phase. Rats injected during the light phase displayed elevated sickness behaviors and hippocampal cytokine production compared to rats injected during the dark phase. Because microglia are the primary immune cell of the CNS we next sought to determine whether microglia demonstrate circadian regulation of inflammatory factors. Hippocampal microglia isolated from adult rats rhythmically expressed inflammatory factors and circadian clock genes. There were robust rhythms of TNFα and IL1β mRNA expression in hippocampal microglia, with peak cytokine gene expression occurring during the middle of the light phase. Moreover, microglia isolated during the light phase were more reactive to immune stimulation; *ex vivo* treatment with LPS resulted in an exaggerated cytokine response in microglia isolated during the light phase. Finally, we explored whether glucocorticoids mediate circadian responses in microglial. Time of day differences in clock and inflammatory gene expression persisted in microglia isolated from adrenalectomized rats. However, treating microglia with corticosterone *ex vivo* induced Per1 expression. Therefore, circadian clock gene expression in microglia appears to be entrained by, but oscillate independent of, glucocorticoids. Taken together, these findings demonstrate that microglia possess a circadian clock that influence inflammatory responses.

These results indicate time of day is an important factor to consider when planning surgeries or immunotherapies.

Title: Social Influences on Neuroinflammation after Ischemia

Authors: *M. M. GAUDIER-DIAZ, N. ZHANG, M. ZHOU, A. C. DEVRIES
Neurosci., The Ohio State Univ., Columbus, OH

Abstract: Social support is associated with improved cardiovascular and cerebrovascular health in humans. Likewise, affiliative social interactions reduce neuronal damage after both experimental stroke and cardiac arrest in rodents. The goal of this project is to determine whether the brains of socially isolated mice are "primed" to respond to cerebral ischemia in a way that increases neuronal damage. The overarching hypothesis is that socially isolated mice mount a greater pro-inflammatory response to cerebral ischemia than socially housed mice, which in turn leads to increased neuronal death. To test this hypothesis, male mice were housed in pairs with an ovariectomized female (n=20) or individually (n=20) for 7 days prior to the induction of 8 minutes of cardiac arrest followed by CPR (CA/CPR). Following resuscitation, the mice were returned to their original housing conditions. Twenty-four hours later, IL-1β was significantly elevated in the hippocampus of socially isolated CA/CPR mice relative to pair housed mice. In a second experiment, *in vitro* oxygen glucose deprivation (OGD) was used to determine whether a trajectory for increased neuroinflammation among socially isolated mice is already established at the time of the ischemic injury. The brains of male pair housed (n=8) or socially isolated mice (n=8) were collected and sectioned into eight slices, 4 of which were exposed to an OGD solution containing (in Mm) 125 NaCl, 25 NaHCO3, 1.25 NaH2PO4, 3.5 KCl, 2 CaCl2 and 1 MgCl2, bubbled with 95%N2/5%CO2, and 4 of which were exposed to control condition for 15 minutes. To determine whether there is a housing-induced difference in the pro-inflammatory response to OGD, tissue was collected for qPCR of pro-inflammatory cytokines after 120 min (n=8/group) of *in vitro* reperfusion. There was a significant increase in TNF-α and IL-6 mRNA

expression in the OGD sections relative to the control sections, but no significant effect of housing. Additional later time points are currently under investigation. In summary, *in vivo* CA/CPR data demonstrate that the brains of socially isolated mice are more susceptible to ischemia-induced damage than brains from pair housed mice; nevertheless, *in vitro* data does not support priming of the pro-inflammatory cytokine response during OGD as a likely mechanism.

Title: Dynamics of TLRs and chemokine expression in the regulation of inflammatory immune cells migration into the CNS: A potential mechanism for neuropathogenesis in drug abuse/HIV model with secondary infection

Authors: *R. DUTTA, S. ROY
Univ. of Minnesota, Minneapolis, MN

Abstract: Accelerated neuropathological complications were reported in human immunodeficiency virus (HIV) infected patients with opioid (morphine) abuse and/or addiction. Even though in HIV infected opioid dependent individuals, the neurological damages are more pronounced in the presence of secondary opportunistic infection, the mechanism associated with this clinical condition is poorly understood. In this study we demonstrate that systemic co-infection with S. pneumoniae may be the contributing factor in the increased prevalence of HIV associated neurocognitive disorder (HAND) among opioid dependent population. Flow cytometry and adoptive transfer experiments demonstrates differential leukocyte migration

(CD3+, F4/80+ and Ly6C+ cells) with specific chemokine expression into the CNS of mice treated with morphine in combination with HIV-1 Tat and/or S. pneumoniae. Dissemination of S. pneumoniae to CNS takes place through the 'Torjan Horse' model using F4/80+ and Ly6C+ monocyte subpopulation as transporter across blood brain barrier. Trafficking of immune cells is mediated through CNS chemokine production which facilitates chemokine receptor-dependent accumulation of leukocytes at the sites of infection. We observed significant induction of CCL5 following HIV-1 Tat treatment, however infection with S. pneumoniae led to preferential induction of CXCL12. Morphine potentiated both Tat HIV-1 and S. pneumoniae mediated chemokine induction. Our pervious published data demonstrate that morphine treatment potentiate Toll like receptors (TLR) expression in microglia. Therefore, the role of TLR in chemokine ligands induction was further investigated. Our present data showed a significant role of TLR2 in CD3+CCR5+ migration and however activation of both, TLR2 and 4 was necessary for the migration of monocyte subtypes with chemokine receptors (CCR5 and CXCR4). Our present study, in addition to the previous one, emphasizes the contribution of systemic infection as a potential neuroinflammatory mediator responsible for exacerbated HAND in opioid drug abusers.

Title: Kynurenine metabolism mediates inflammation-induced cognitive dysfunction and impulsivity

Authors: *J. C. O'CONNOR[1], J. M. HEISLER[1], J. MORALES[1], D. A. CRUZ[2], P. M. THOMPSON[2]
[1]Pharmacol., [2]Psychiatry, UTHSCSA, San Antonio, TX

Abstract: The dorsolateral prefrontal cortex (dlPFC) is the critical brain region that regulates working memory, cognitive flexibility, planning and impulse control (i.e. executive function). Imaging and postmortem studies suggest that dlPFC dysfunction is a core neurobiological feature of many neurodevelopmental and neuropsychiatric diseases. While the molecular mechanisms underlying dlPFC dysfunction remain poorly understood, proinflammatory activation of the kynurenine pathway(KP) has been identified as a putative pathogenic factor. Here, we demonstrate that proinflammatory cytokine transcripts were increased in the dlPFC of subjects with mood disorders compared to matched controls, and both tumor necrosis factor(TNF)-α and microglia upregulation are strongly associated with motor impulsivity and cognitive inflexibility. Metabolism of tryptophan along the kynurenine pathway was also increased in subjects with mood disorders and associated with dlPFC dysfunction. In mice, we subsequently determined that endotoxin-induced inflammation increases microglial activation and kynurenine metabolism within the medial prefrontal cortex (mPFC), which is the functionally analogous region to human dlPFC, and impairs PFC-dependent cognitive flexibility and motor impulsivity. Mice lacking indoleamine 2,3-dioxygenase, the rate limiting enzyme of the KP, are protected cognitive impairment. Together, these data identify the KP as a key factor in the neuropathology of mood disorders and as a novel therapeutic target.

Title: Hippocampal neuroinflammation and cognitive decline as a consequence of acute myocardial ischemia-reperfusion

Authors: *B. JOHNSTON[1], K. E. EVONUK[1], M. E. YOUNG[2], T. M. DESILVA[1]
[1]Dept. of Physical Med. and Rehabil., Univ. of Alabama At Birmingham, Birmingham, AL; [2]Div. of Cardiovasc. Diseases, Dept. of Med., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: An emerging literature has demonstrated the need to further understand the impact of cardiovascular disease (CVD) on cognitive decline. Human studies have documented lesions in brain regions critical to learning and memory, and a correlation between impaired cognitive function and adverse cardiac events. To better understand the mechanisms of CVD-related cognitive decline, and propose therapeutic strategies to ameliorate cognitive decline in this rapidly expanding patient population, it is essential to validate animal models that recapitulate the neuropathology in these phenotypes. We utilized two murine models of ischemia-reperfusion (I/R), an open- and closed-chest model. For the open-chest model, the left anterior descending (LAD) coronary artery of 20 week old C57BL/6 male mice were ligated for 30 minutes followed by reperfusion. An occluding device was implanted in the closed-chest model without immediate ligation. One week later, the LAD was occluded for 30 minutes followed by reperfusion. Seventy-two hours post-surgery the hippocampus was assessed for reactive glia. Using stereological methods, every 10th serial section of the CA1, CA3, and dentate gyrus subfields of the hippocampus from bregma -1.06 mm to bregma -3.64 mm were counted to determine GFAP and Iba-1 positive cell estimates. Activated astrocytes and microglia in all subfields of the hippocampus in both I/R models were increased relative to sham controls. To investigate how vascular permeability may change in response to I/R, mice received tail-vein injections of FITC-dextran and TRIC-albumin 72 hours post-I/R. An increase in fluorescent intensity for both markers was observed in the hippocampus of mice subjected to I/R. Consistent with an increase in activated glia and vascular permeability within the hippocampus a deficit in hippocampal-dependent learning was observed. Contextual fear-conditioning demonstrated a decrease in freezing behavior in mice 2 months post I/R relative to sham. These data suggest that following a cardiac-ischemic event, rapid inflammatory responses in the hippocampus contribute to subsequent impairment in hippocampal-dependent learning and memory.

Title: Cerebral expression of IFN-α reduces weight gain with low plasma leptin in mice

Authors: *J. WANG, Y. DAI
Dept Pharmacol, Univ. Missouri-Kansas City, KANSAS CITY, MO

Abstract: Interferon-alpha (IFN-α) is an innate immune mediator. It is permeable to the blood-brain barrier, and peripheral IFN-α can act at the central nervous system. Chronic treatment of IFN-α has been shown to result in neuropsychiatric complications. To determine the impact of long-term IFN-α stimulation in the brain, astrocyte-targeted IFN-α transgenic (GFAP-IFNα) mice with C57BL/6J background was generated by backcross-breeding. Selective expression of IFN-α transgene in the brain is confirmed as stimulation of prototypic IFN-stimulated genes is found exclusively in the brain, but not in peripheral tissues. Body weight monitoring reveals a profound difference in the body weight trajectory between adult wildtype and transgenic mice. Compared with controls, the body weight gain is significantly reduced in the transgenic mice after 6 months of age. Such reduction is progressive, and the weight gap between the two groups of mice becomes greater, from 9.7% at 6 months of age to 31.7% at 12 months of age. Measurement of blood glucose indicates a low glucose level in transgenic mice (119.7 ± 6.1) compared with the controls (150.6 ± 10.8) ($p < 0.02$). However, feeding behavior tests show unchanged food or water intake between the two groups. ELISA reveals a remarkable decrease in plasma leptin concentration in mice with IFN-α expression ($p < 0.001$). Western blots show a significant increase in STAT1 expression and activation in the brain regions confirming IFN-α-triggered JAK/STAT signaling. Nevertheless, cerebral expression and activation of the molecules implicated in leptin signaling such as STAT3, Akt, Erk1/2 remains unchanged between GFAP-IFNα and control mice. In conclusion, our findings demonstrate that chronic exposure of the brain to antiviral cytokine IFN-α would decrease body weight gain, and such effect may be mediated by dysregulated leptin signaling.

Title: Effect of cold shock on neural function and behavior

Authors: *H. M. CHARLES, K. A. KILLIAN
Biol., Miami Univ., Oxford, OH

Abstract: During its lifetime, an animal can be exposed to varying environmental temperatures, and large fluctuations in temperature can influence survival. Even if survival is not directly comprised, exposure to temperature extremes could have lasting impacts on an animal's physiology and behavior. At low temperatures, many insects enter a state of immobility called chill coma from which an insect can recover. Our goal was to characterize the long-term effects of a single cold shock on the behavior, neural function and immune function of male *Acheta domesticus* crickets. Crickets, 9-12 days in age past the adult molt, were placed into individual conical tubes submerged in an alcohol bath at 0C for 6 hr. After removal to 20°C, cold-shocked males took approximately 2.5 hr to recover and right themselves. To examine the effects of the shock on general neural function, a set of age-matched cold-shocked (CS, n=24) and non-cold-shocked control (NCS, n=24) males were given a series of mechanical touches 24 hr after shock. CS males produced significantly fewer jumps in response to such stimulation (p=0.005). We also assessed long term effects on agonistic behavior. Seven days after shock, a pair of age- and weight-matched CS and NCS males was placed in an arena separated by a barrier. After 15 min, the barrier was lifted and each fight scored. All pairs fought and fights reached a level of aggression similar to that previously observed for fights between control males. However, CS males were more likely to become subordinate (67%, n=21 pairs) in such trials. We examined the effects of a cold-shock on immune function since a previous study in our lab suggested a direct link between immune function and aggression. CS males had significantly lower hemolymph activity of the enzyme phenoloxidase (PO) 7 days after shock. PO converts DOPA into melanin during the insect encapsulation response; PO activity in each blood sample was thus measured as change in absorbance per min. CS males exhibited a significantly lower total blood PO activity relative to NCS males (n=8 both groups; CS: 2.15 Δ absorbance/min; NCS: 7.52 Δ absorbance/min; p<0.0001). We also examined direct effects of a cold shock on the brain by injecting CS and NCS males with BrdU 48 hr after shock. We observed a 10-fold greater number of BrdU+ cells directly below the neural lamella on the brain surface of CS males (n=5) *vs*. NCS

males (*n*=5). We hypothesize these are perineurial glia proliferating in response to the shock; we are currently performing experiments testing this idea. Our results thus support that exposure to a single cold shock can have lasting impacts on brain function, immune function and behavior.

Title: Mold exposure alters adult new neuron migration in the mouse hippocampus

Authors: *A. LOPEZ[1], K. PAGE[1,2], E. NORMAND[3], B. SHAUKAT[1], N. ADAMS[3], K. LIN[3], L. BICKERTON[3], C. F. HARDING[2,3], C. L. PYTTE[1,2]

Abstract: Exposure to environmental mold is a growing concern for individuals living or working in water-damaged buildings. In addition to a suite of somatic effects, mold exposure is also associated with cognitive impairments. Alarmingly, neurologists cannot differentiate between cognitive deficits in patients exposed to mold and those with mild traumatic brain injury. Prior research in our lab has found that mold exposure leads to a decrease in hippocampal-dependent memory in a contextual fear task. We have also demonstrated that mold exposure leads to a significant decrease in hippocampal new neuron survival assessed in mature (~35-day old) neurons. Moreover, numbers of mature new neurons were negatively correlated with numbers of cells expressing the inflammatory interleukin-1 beta (IL-1β). Here we further characterize the effects of mold on hippocampal neurogenesis. To determine whether mold inhalation specifically targets the survival of mature neurons, we quantified numbers of younger

hippocampal neurons (<30 days old) expressing doublecortin (DCX) in mice treated with mold. New neurons are primarily incorporated into the granular layer of the dentate gyrus; however, in damaged brains, ectopic neuron incorporation is seen, particularly in the hilar region. Therefore, we also assessed the relative numbers of mature new neurons seen in the granular layer and hilus. C57BL/6 mice were given intranasal instillations of 1) intact Stachybotrys spores (IN), 2) extracted Stachybotrys spores that had toxins removed and proteins denatured leaving skeletal elements (EX), or 3) saline vehicle (VEH). Mice were treated 3x per week for 6 weeks. We injected mice with bromodeoxyuridine (BrdU) 31-37 days and 3 hours before sacrifice. Immunohistochemistry was used to visualize cells expressing BrdU and the neuronal marker Hu. We also labeled cells expressing doublecortin and the inflammatory marker, IL-1β. We found that numbers of mature new neurons were negatively correlated with IL-1β, whereas numbers of young neurons were positively correlated with IL-1β. This suggests that inflammatory effects of mold exposure decrease new neuron survival specifically in older neurons (by age 31-37). Increased numbers of young DCX-expressing neurons may reflect compensation for cell death of older cohorts. In addition, mice exposed to mold spores had fewer new neurons in the granular layer and greater numbers of new neurons in the hilus than vehicle controls. These findings suggest that impaired hippocampal-dependent learning may also be associated with aberrant new neuron migration in addition to decreased new neuron numbers.

Title: Environmental mold exposure leads to spatial memory deficits

Authors: *D. LIAO[1], C. HARDING[1,2], R. PERSAUD[1], K. LIN[1], K. PAGE[2,3], C. L. PYTTE[2,3]
[1]Psychology, Hunter College, CUNY, New York, NY; [2]Behavioral & Cognitive Neurosci. Doctoral Program, Grad. Center, CUNY, New York, NY; [3]Psychology, Queens College, CUNY, New York, NY

Abstract: An estimated 40% of American buildings contain mold. Exposure to environmental mold can cause motor impairments, chronic fatigue, and cognitive deficits. To our knowledge, no animal research has been published examining how mold causes these problems. We developed a mouse model to determine the physiological mechanisms behind these neurobehavioral issues. Adult male C57BL/6 mice were given intranasal instillations (3X/week) of 1) intact, toxic *Stachybotrys* spores (IN), 2) extracted *Stachybotrys* spores with their toxins removed and proteins denatured (EX), or 3) the saline vehicle. Our basic hypothesis is that mold inhalation activates an innate immune response, leading to brain inflammation and consequent behavioral impairment. Because innate immune activation specifically impairs hippocampal function, we examined the effects of mold exposure on performance in the Morris water maze using a two-day protocol that compared the mouse's ability to find the nonvisible platform after four visible training trials 24hr previously. As predicted, mold exposure caused significant deficits in spatial memory. After 4.5-5.5 weeks treatment, EX mice performed significantly worse in finding the hidden platform compared to VEH or IN mice. EX mice showed the greatest deviation from their performances during visible training trials. They took significantly longer to reach the hidden platform and used longer paths. Performance in locating the visible platform predicted performance in locating the hidden platform for VEH mice. The same was not true for the spore-treated groups. Greater durations/path lengths and inconsistent performance suggest memory impairment in EX and IN mice. Performance on the water maze was inversely correlated with numbers of interleukin-1β (IL-1β)-immunoreactive cells in hippocampal CA1 (r^2 = -0.56, p = 0.01). This relationship was stronger for the spore-treated groups, consistent with spatial memory impairment resulting from brain inflammation due to mold treatment. Spatial memory deficits on both the last training trial (r^2 = 0.52, p = 0.004) and the first testing trial (r^2 = 0.59, $p < 0.001$) also correlated positively with weight gain during the first three weeks of treatment. Once again, this relationship is stronger for the spore-treated mice. This was not surprising since energy reserves modulate immune responses. It is unclear why treatment with spore skeletons (EX) caused greater impairment than treatment with intact, toxic spores (IN). Clearly, the spore skeleton is sufficient to elicit adverse cognitive effects. These findings are consistent with brain inflammation as a cause of neurobehavioral dysfunction.

Title: Mold-induced changes in microglial morphology: A method for quantifying dimensions

Authors: *K. PAGE[1,2], M. NAGAI[3], T. DESAI[4], C. F. HARDING[1,3], C. L. PYTTE[1,2]
[1]Psychology, Grad. Center, CUNY, New York, NY; [2]Psychology, Queens College, CUNY, Flushing, NY; [3]Psychology, [4]Anthrop., Hunter College, CUNY, New York, NY

Abstract: Histologically, microglia are frequently divided into two phenotypes: ramified and amoeboid. However, this classification is clearly limiting and much debate surrounds where the dividing point for the two categories should be. I propose to assess microglial phenotypes along a continuum. This method was used to analyze microglial morphology in the dorsomedial granular dentate gyrus of mice exposed to intact toxic mold spores, spore skeletons, or control vehicle. IBA-1-expressing cells were traced with closed area contours using NeuroLucida software (MBF). These contours provide valuable information about the cell such as area, roundness and distance to the nearest cell. Across all animals, increased numbers of microglia were correlated with larger microglial cell bodies ($p=0.03$). Numbers of IL-1β-expressing cells were also correlated with larger microglia ($p=0.04$). Together, these findings indicate that brains with higher numbers of microglia also had larger, more inflamed, microglia. We also assessed microglia distribution by comparing the number of cells per area with average distance between cells. In the control condition, cell density was positively correlated with cell distance, suggesting microglia were evenly distributed throughout the granular layer of the dentate gyrus. However, following mold exposure there was no correlation between cell density and cell distance. We believe this is represents a change in microglial territoriality following mold-exposure. To determine if different measures of microglial phenotypes predicted outcomes in a

hippocampal-dependent memory task, values of morphological measures were correlated with behavioral measures from the same animals. Increased numbers of microglia and larger microglia both were correlated with decreased memory in a contextual fear task 24 hours post training ($p=0.049$, $p=0.046$). Taken together, these data suggest this method of quantifying soma size of microglial cells can provide useful information pertaining to the activation state of the cells. Furthermore, morphological measurements can be useful to help identify specific characteristics of microglia corresponding to neurological and behavioral measures in an effort to better understand what phenotypic changes relate to experimental outcomes.

Title: Developmental programming of body weight, neuroinflammation, and behavior by western diets

Authors: *M. G. WILEY[1], J. L. BOLTON[2], L. A. SIMMONS[3], B. RYAN[2], S. TRUONG[2], S. D. BILBO[2]
[2]Psychology and Neurosci., [1]Duke Univ., Durham, NC; [3]Duke Univ. Sch. of Nursing, Durham, NC

Abstract: Obesity is now a multigenerational epidemic. Alarmingly, maternal obesity during gestation/lactation can "program" offspring long-term for increased obesity themselves, along with increased vulnerability to mood disorders. Emerging evidence suggests that this programming by perinatal diet is propagated via inflammatory mechanisms, specifically linked to two components that are enriched in a "Western diet": saturated fatty acids and branched-chain amino acids (BCAAs). We have previously shown that maternal high-fat diet (HFD) can "prime" microglia, the primary immune cells of the brain, and result in elevated levels of

proinflammatory cytokines within the hippocampus of adult offspring, in conjunction with increased anxiety. BCAAs are known to compete with tryptophan transport across the blood-brain barrier, thus resulting in decreased serotonin production and increased anxiety. In the current study, we tested the hypothesis that the HFD and BCAA dietary components would synergize to result in exacerbated brain and behavioral consequences in offspring. We placed female mice on one of 4 diets: 1) high-fat diet (HFD), 2) low-fat diet (LFD), 3) HFD supplemented with BCAA (HFD+BCAA), or 4) LFD supplemented with BCAA (LFD+BCAA) for 6 weeks prior to breeding, resulting in the following weight pattern: HFD+BCAA > HFD = LFD+BCAA > LFD. HFD+BCAA dams had pups with significantly lower birth weights, and qPCR analysis of offspring brains at postnatal day (P)1 revealed that HFD and HFD+BCAA pups had decreased expression of microglial markers (e.g., Iba-1, CD11b), suggesting that microglial colonization and maturation may be delayed or altered in these groups. At weaning (P28), HFD pups weighed more than LFD, whereas both BCAA groups weighed significantly less. Despite placement on a LFD at weaning, HFD and HFD+BCAA offspring showed signs of increased anxiety- and depressive-like behavior as adults. Analyses are currently ongoing to determine whether microglia are primed long-term by these perinatal diets, as well as whether peripheral infiltrating macrophages play a role in the neuroinflammation of the adult offspring (as has been observed in other models), and what, if any, are the consequences for the serotonergic system. In sum, perinatal diet, particularly HFD, can program body weight, microglial development, and behavior of offspring into adulthood.

Title: Inflammation-induced fatigue: Exploring neurobiological mechanisms and potential treatments

Authors: *D. BONSALL[1], H. KIM[1], A. M. PETRONZIO[1], P. C. MOLYNEUX[1], T. E. SCAMMELL[2], M. E. HARRINGTON[1]
[1]Smith Col., Northampton, MA; [2]Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: The induction of fatigue is a common response of an animal to systemic challenge by pathogens. This response is in part mediated through action of the pro-inflammatory cytokine interleukin-1 beta (IL-1). We have characterized a dose of peripherally-administered IL-1 that can reduce wheel-running and general locomotor activity in middle-aged (6-12 mo) C57Bl/6 mice, without induction of other signs of sickness, such as fever, muscle ache or anhedonia (as measured with abdominal temperature probes, pre-treatment with the analgesic buprenorphine and through sucrose preference respectively). Here we report our studies of the effects of IL-1 on two possible candidate pathways implicated in fatigue, the orexin-containing neurons of the lateral hypothalamus and the circadian rhythmic neurons in the suprachiasmatic nucleus (SCN), as well as the impact of several possible pharmacological treatments. Prior research has shown that LPS- and chemotherapy-induced reductions in general locomotor activity were associated with fewer Fos-positive orexin neurons and could be reversed by i.c.v. administered orexin (1,2). Here we first replicated prior work showing reduced wheel use in orexin-/- mice. We further demonstrate reduced wheel-running activity (normalized to baseline) following i.p. administration of 400ng IL-1 in middle-aged male and female orexin-/- mice, equivalent to the response seen in wild-type controls. This suggests that orexin is not necessary for IL-1-induced reductions in wheel-running. Given that patients with fatigue show dampened daily cortisol rhythms and disruptions in sleep-wake cycles, we hypothesized fatigue may be associated with deficits in circadian output from the SCN. We used mPer2luc/+ mice (3) to show altered SCN responses to shifted light-dark cycles following chronic administration of IL-1. Our results suggest that following IL-1 administration, the SCN's ability to drive coordinated output rhythms may be impaired. Given that the availability and success of therapeutic treatments for fatigue is currently limited, we examine the effectiveness of three potential clinical treatments in our animal model of fatigue. These include the stimulants modafinil and methylphenidate as well as the histamine H3 inverse agonist/antagonist pitolisant. We demonstrate the varying success of different potential treatments in restoring locomotor activity following IL-1 administration. These studies will allow us to determine possible neural pathways through which IL-1 induces fatigue. 1.Grossberg et al., J Nsci (2011) 31:11376-86. 2. Title: Chronic T. gondii infection in the Nurr1-null heterozygous mice exacerbates elevated open field activity and disrupts sensorimotor gaiting

Authors: *J. B. EELLS[1], A. VARELA-STOKES[2], S. X. GUO-ROSS[2], E. KUMMARI[2], H. M. SMITH[2], E. COX[2], D. S. LINDSAY[3]
[2]Basic Sci., [1]Mississippi St Univ., Mississippi State, MS; [3]Dept. of Biomed. Sci. & Pathobiology, Virginia Technol., Blacksburg, VA

Abstract: Infection with *Toxoplasma gondii* is common in humans (approximately 30% of the global population) and is a significant risk factor for schizophrenia. Since prevalence of *T. gondii* infection is far greater than prevalence of schizophrenia (around 0.5-1%), genetic risk factors are likely also necessary to contribute to schizophrenia. To test this concept in an animal model, Nurr1-null heterozygous (+/-) mice and wild-type (+/+) mice were evaluated using an emergence test, activity in an open field and in a novel object, response to bobcat urine and prepulse inhibition of the acoustic startle response (PPI) prior to and 6 weeks after infection with *T. gondii*. In the emergence test, *T. gondii* infection significantly decreased the amount of time spent in the cylinder. *Toxoplasma gondii* infection elevated open field activity in the female +/- mice, but not the female +/+ mice, and in both the male +/+ and +/- mice, but with a significantly greater effect in the male +/- mice. Additionally, *T. gondii* infection disrupted PPI only in the male +/- mice. The +/+ female mice showed a significant aversion to bobcat urine which was lost after infection with *T. gondii*. Antibody titers to *T. gondii* were a critical variable associated with changes in open field activity, with a significant increase in activity at low and medium antibody levels but no effect at high antibody levels. These data are the first to show disrupted sensorimotor gating with *T. gondii* infection and demonstrate that the Nurr1 +/- genotype predisposes mice to *T. gondii* induced alterations in dopamine-related behaviors that are correlated with symptoms of schizophrenia. We propose that these alterations in murine behavior are due to further exacerbation of the altered dopamine neurotransmission and identification of mechanisms driving those alterations will help to elucidate how *T. gondii* infection contributes to the development of schizophrenia.

Title: The effect of interleukin 1-beta (IL-1β) on memory reconsolidation is mediated by a reduction in glutamate release, calcium influx and AMPA phosphorylation. Modulation by alpha-melanocyte-stimulating hormone (α-MSH)

Authors: *I. MACHADO[1], P. GONZALEZ[1], A. VILCAES[2], M. LASAGA[3], T. SCIMONELLI[1]
[1]IFEC-CONICET Facultad De Ciencias Químicas- UNC, Córdoba, Argentina; [2]CIQUIBIC-CONICET, Dept. de Química Biológica. Facultad de Ciencias Químicas. UNC, Córdoba, Argentina; [3]Inst. de Investigaciones Biomédicas INBIOMED UBA-CONICET, Facultad de Medicina, Buenos Aires, Argentina, Buenos Aires, Argentina

Abstract: The immune system is an important modulator of learning, memory and neural plasticity. Interleukin 1β (IL-1β), a pro-inflammatory cytokine, significantly affects several cognitive processes. Previous studies of our group have demonstrated that the intrahippocampal administration of IL-1β impairs reconsolidation of contextual fear memory. This effect was reversed by the melanocortin alpha-melanocyte-stimulating hormone (α-MSH). The mechanisms underlying the effect of IL-1β on memory reconsolidation have not been established yet. Our results demonstrate that IL-1β produced a significant decrease in the glutamate release from dorsal hippocampus synaptosomes after reactivation of the fear memory. Examination of the cytosolic Ca2+ using Fluo-3AM revealed that the inhibition of glutamate release could be attributed to a reduction in voltage-dependent Ca2+ influx. Also, western blot analysis demonstrated that IL-1β reduced the phosphorylation of GluR1 AMPA subunit. The intrahippocampal administration of α-MSH can modulate these effects. Our results establish a possible mechanism involved in the detrimental effect of IL-1β on memory reconsolidation and also that α-MSH may exert a beneficial modulatory role in preventing IL-1β effects.

Title: IL-1 receptor antagonism in the basolateral amygdala reduces binge-like ethanol intake of C57BL/6J mice

Authors: *S. A. MARSHALL[1,2,3], J. A. RINKER[4,3], J. D. CASACHAHUA[4], D. T. LYSLE[4], T. E. THIELE[4,3]
[2]SPIRE Fellow, [3]Bowles Ctr. for Alcohol Studies, [4]Behavioral Neurosci., [1]Univ. of North Carolina, Chapel Hill, NC

Abstract: The transition from experimental binge alcohol consumption to ethanol abuse and dependence is thought to be a result of neuroplastic changes that fundamentally alter both biological and behavioral functions. The ability of chronic alcohol exposure to alter the neuroimmune system has recently come to the forefront. Maladaptations within the neuroimmune system have been shown to underlie addictive-like behaviors in other drugs of abuse including opioids. Moreover, problems within the neuroimmune system are associated with several alcoholism comorbidities such as depression and pain dysregulation. It has previously been established that excessive ethanol consumption alters the neuroimmune system of human alcoholics, but the implications of these changes, particularly a shift in the cytokine profile, have yet to be determined. Our lab has recently found that following the “drinking in the dark” (DID) paradigm, there are increases in IL-1β mRNA and immunoreactivity in the

basolateral amygdala (BlA). The current study furthers this research by measuring ethanol consumption following antagonism of the IL-1 receptor in the BlA. Male C57BL/6J, underwent stereotaxic bilateral cannulae placement into the BlA and were given a week of recovery before DID procedures. Each DID trial, mice were allowed two hours of access to 20% ethanol beginning for three days, however, on the fourth day, or test day, mice were given four hours of ethanol access. Animals underwent DID procedures twice, receiving either IL-1 receptor antagonist (IL-1Ra) or saline on the test day in a 2 x 2, Latin-square design. Tail blood samples were collected at the end of each test session for blood ethanol concentration (BEC) determination. Following all testing, animals were perfused to ensure accurate cannulae implantation. T-tests were used to determine if IL-1R antagonism had a significant effect on consumption and BECs. IL-1Ra reduced ethanol consumption by 57%, reducing average consumption from 4.3g/kg to 2.5g/kg. The reduced consumption attributed to IL-1Ra manipulation also resulted in reduced BECs (Saline = 87.5±9.9; IL-1Ra = 46.0± 7.6). These data align with other findings that anti-inflammatory agents such as ibudilast and minocycline can reduce ethanol self-administration; however, this study indicates a specific role of IL-1β and IL-1 receptor signaling in the BlA in alcohol consumption. The actions of IL-1Rathat lead to reduced consumption still warrant investigation; however, this data suggest that manipulating the neuroimmune system remains a viable target for alcohol use disorder therapeutics. (Support by NIH grants AA022048, AA013573, AA015148, AA011605 & NIGMS GM000678).

Title: Meningeal sinuses: Key site for T cells in regulating brain function?

Authors: *A. LOUVEAU[1,2], S. GADANI[1], N. DERECKI[1], T. HARRIS[1], J. KIPNIS[1]
[1]Ctr. For Brain Immunol. and Glia, Charlottesville, VA; [2]Neurosci., Ctr. for Brain Immunol. and Glia, Charlottesville, VA

Abstract: Meningeal sinuses: key site for T cells in regulating brain function ? Antoine Louveau, Sachin Gadani, Noel Derecki, Tajie Harris, and Jonathan Kipnis. Recent studies have enlightened the role of T lymphocytes in learning and memory and more precisely the pro-cognitive effect of accumulation of IL-4 secreting CD4 T cells in the meninges. However, the specific localization of T cells within the meningeal space and the signal that drives them into the meninges under physiological condition remains poorly understood. Using confocal microscopy of brain slices and dura/arachnoid whole mount, we were able to show that the vast majority of T cells reside in the close vicinity to or even within the brain sinuses located in the dura matter. T cells were also found in other meningeal compartments, such as dura, arachnoid, pia and choroid plexus, but at a much lower density. Interestingly, after a cognitive task, we measured a specific increase of T cells density within the sinuses but not in the other areas of the meninges suggesting that the sinuses are the major site for T cell function in the meninges. Immunostaining and *in vivo* injection of fluorescent CD45 antibody indicated an abluminal localization of the T cells suggesting that the sinus might be a gate for T cell trafficking into the meninges. Moreover, qPCR analysis of whole meninges and choroid plexus from naive and trained mice showed specific increase of CCL5, CCL8 and CXCL9 in the meninges after cognitive task performance, suggesting a chemokine-induced recruitment of T cells during cognitive task. Overall, this study will allow the development of new tools to study the structurally and functionally poorly understood brain sinuses and decipher the path of T cell entry into the meninges under physiological conditions. Understanding the physiological paths, may shed a new light on etiology of neuroinflammatory conditions, such as Multiple Sclerosis.

Title: Chronic fatigue syndrome from vagus nerve infection: A psychoneuroimmunological hypothesis

Authors: *M. B. VANELZAKKER[1,2]
[1]Dept Psychol, Tufts Univ., MEDFORD, MA; [2]Psychiatric Neurosci., Massachusetts Gen. Hosp., Boston, MA

Abstract: Chronic fatigue syndrome (CFS) is an often-debilitating condition of unknown origin. There is a general consensus among CFS researchers that the symptoms seem to reflect an ongoing immune response, perhaps due to viral infection. Thus, most CFS research has focused upon trying to uncover that putative immune system dysfunction or specific pathogenic agent. However, no single causative agent has been found. Here, I describe a new hypothesis for the etiology of CFS: infection of the vagus nerve. When immune cells of otherwise healthy individuals detect any peripheral infection, they release proinflammatory cytokines. Chemoreceptors of the sensory vagus nerve detect these localized proinflammatory cytokines, and send a signal to the brain to initiate sickness behavior. Sickness behavior is an involuntary response that includes fatigue, fever, myalgia, depression, and other symptoms that overlap with CFS. The vagus nerve infection hypothesis of CFS contends that CFS symptoms are a pathologically exaggerated version of normal sickness behavior that can occur when sensory vagal ganglia or paraganglia are themselves infected with any virus or bacteria. Drawing upon relevant findings from the neuropathic pain literature, I explain how pathogen-activated glial cells can bombard the sensory vagus nerve with proinflammatory cytokines and other neuroexcitatory substances, initiating an exaggerated and intractable sickness behavior signal. According to this hypothesis, any pathogenic infection of the vagus nerve can cause CFS, which resolves the ongoing controversy about finding a single pathogen. The vagus nerve infection hypothesis offers testable hypotheses for researchers, animal models, and specific treatment strategies.

Title: The gut microbiota as an important intercurrent variable in behavioral research

Authors: A. C. ERICSSON, D. J. DAVIS, C. L. FRANKLIN, *C. E. HAGAN
Dept. of Vet. Pathobiology, Univ. of Missouri, Columbia, MO

Abstract: The NIH has highlighted concern about the reproducibility of research, particularly preclinical research using animal models. Our group has established that there is significant variability in enteric microbial ecology among different vendors and genetic backgrounds of mice. Given that host-microbe interactions are gaining recognition as important factors shaping neurodevelopment, brain function, and behavior, we hypothesized that the gut microbiota could be a source of variability that could compromise reproducibility in studies of brain function and behavior. To test this hypothesis, we used a multi-dimensional experimental approach involving microbiota transfers, next-generation sequencing, cell culture, behavioral testing, and measures of peripheral immune function. Specifically, we sought to determine how two different vendor-specific microbial communities affect brain function and behavior when transferred into genetically identical mice. Our results suggest that a more complex microbiota confers enhanced stress resilience and reduced anxiety. This conclusion is based on measurements of behavior, serum cytokines, serum corticosterone, and cytokine production by splenocytes, microglia, and astrocytes. These results underscore the need to consider the gut microbiota as an important intercurrent variable in behavioral research.

Title: Neurotoxic kynurenine metabolism mediates inflammation induced behavioral despair in mice

Authors: *J. M. PARROTT[1,2], L. REDUS[1], J. C. O'CONNOR[1,2]
[1]Pharmacol., Univ. of Texas Hlth. Sci. Ctr. At San Antonio, San Antonio, TX; [2]Ctr. for Biomed. Neurosci., San Antonio, TX

Abstract: Mounting evidence indicates that the kynurenine pathway of tryptophan metabolism plays an important role in mediating the behavioral effects of inflammation, which has implications for a number of neuropsychiatric disease populations. Both human and rodent studies have demonstrated that increased kynurenine metabolism is associated with depressive symptoms or preclinical depressive-like correlates, and inhibition of the rate limiting kynurenine pathway enzyme, indoleamine 2,3 dioxygenase, prevents the development of most inflammation-induced depressive-like behaviors. However, the kynurenine pathway consists of two functionally distinct metabolic branches with either excitatory or inhibitory effects on glutamatergic neurotransmission. To determine if inflammation results in an excitatory imbalance in kynurenine metabolism, wild type (WT), heterozygous or homozygous kynurenine 3-monooxygenase (KMO) deficient mice were treated with either lipopolysaccharide (LPS, 0.5mg/kg) or saline. KMO is the rate limiting enzyme for the subsequent generation of excitatory and potentially neurotoxic metabolites, and following peripheral immune challenge with LPS, pro-inflammatory cytokine and KP enzyme expression, including KMO, was up-regulated in the brains of WT mice in a time-dependent manner. Consistent with previous reports, a robust depressive-like phenotype was observed in WT mice 24h post-LPS. However, KMO deficient mice were specifically protected from LPS-induced behavioral despair measured in the tail suspension test, not anhedonia (sucrose preference) or anxiety-like behaviors (open field test). Metabolite analysis confirmed that KMO-dependent kynurenine metabolism was increased in the brains of LPS-challenged WT mice, and KMO deficient mice failed to exhibit any metabolic activity along this branch. Finally, mice lacking the hydroxyanthranilic acid dioxygenase (HAAO) gene, which is responsible for producing the final excitatory kynurenine metabolite (quinolinic acid), were challenged with LPS. Similar to KMO deficient mice, LPS did not induce depressive-like behavior in these mice as assessed in the tail suspension test. Together these results suggest that excitatory kynurenine metabolites are important mediators of inflammation induced behavioral despair.

Title: Mast cells in the neonatal brain: Sex differences, biochemical mediators and early life programming of social and anxiety behavior

Authors: *K. M. LENZ, A. GALAN
Psychology, The Ohio State Univ., Columbus, OH

Abstract: Innate immune cells in the brain regulate many processes that are necessary to normal neurodevelopment, including cell genesis, cell death, synaptogenesis and synaptic pruning. Another such process is brain sexual differentiation. We have previously characterized major sex differences in the number and activation profile of innate immune cells in the developing rodent preoptic area, including microglia and mast cells. Both ameboid microglia and mast cells are twice as numerous in neonatal male rats than in females (Lenz et al., 2013, J Neurosci). In the preoptic area, activation of both microglia and mast cells contributes to sex differences in the number of dendritic spine synapses and resultant masculinization of adult reproductive behavior (Lenz et al., 2013). A majority of mast cells are located within the hippocampal parenchyma as well as in the pia mater between the hippocampus, thalamus, and amygdala during development. We have recently found a similar sex difference in both mast cells and microglia in the developing hippocampus, with males having approximately twice as many ameboid microglia and mast cells as females on postnatal day (PN) 4 (quantified using Stereoinvestigator). We have begun to assess the crosstalk between microglia and mast cells during brain development and the consequences of this crosstalk for neuronal and behavioral development. Pharmacological activation of mast cells using Compound 48/80 (administered icv) during the first four postnatal days produced a male-typical activated microglial morphology in the female hippocampus, which was assessed on Iba1-stained tissue using computer-based morphometry software (Neurolucida). Neonatal stimulation of mast cell activation in females also led to an increased number of newly-born BRDU-positive cells in the hippocampus on PN4, which is a masculinized phenotype. Mast cell activation early in life also programs behaviors that depend upon the brain regions in which mast cells are found, including juvenile social play and anxiety behaviors, and males are more affected than females. Currently, we are assessing whether mast cell activation produces resultant changes in brain levels of mast cell derived mediators, including serotonin, histamine, proteases and inflammatory cytokines. Since mast cells are the main cellular mediator of the allergic response, we are testing whether allergic challenge of maternal dams during pregnancy leads to activation of mast cells in the fetal brain and resultant changes in the development of socioaffective behaviors. Together, these data show that mast cells play a crucial role in normal development of brain and behavior.

Title: Diet-induced obesity prevents spatial learning deficits following bacterial endotoxin exposure

Authors: *S. SETTI[1], A. LITTLEFIELD[2], C. DIAZ[2], A. JONES[2], S. JOHNSON[2], R. A. KOHMAN[2]
[2]Psychology, [1]UNC Wilmington, Wilmington, NC

Abstract: Diet-induced obesity (DIO) is associated with altered immune function. Activation of the immune system induces a series of behavioral changes, collectively known as sickness behavior, as well as impairs cognitive function. Prior research has shown that DIO can exaggerate and prolong the behavioral response to an immune challenge (Pohl et al, 2013), but whether DIO alters the learning deficits associated with inflammation is unknown. The current study examined whether DIO would influence the development of cognitive deficits following an immune challenge with the endotoxin, lipopolysaccharide (LPS). Adult female C57BL/6J mice were free-fed either a high-fat diet (HFD; 60% fat) or a control diet (CD; 10% fat) for a total of 5 months. After 4 months, mice were systemically injected with either LPS or saline, and 4 hours later tested for spatial-learning in the Morris water maze (MWM). One month later, mice received the same treatment (i.e., LPS or saline) they received prior to the MWM task. Four hours after treatment, brain, adipose, and spleen samples were collected. Behavioral data show that LPS administration impaired spatial learning in the CD mice, but diet-induced obese mice failed to develop cognitive deficits. Data collection is still in progress to determine whether the lack of a behavioral response in the DIO mice reflects a modified inflammatory response. Preliminary results show that hippocampal expression of the proinflammatory cytokines interleukin-1β and interleukin-6 did not significantly differ between the DIO and CD mice basally or following LPS administration. However, DIO mice failed to show an LPS-induced increase in expression of CD74, a molecule involved in trafficking major histocompatibility complex II (MHCII) proteins, in the hippocampus. Currently, our data indicate that DIO prevents the development of cognitive deficits following an immune challenge and may modify aspects of the neuroinflammatory response.

Title: A comparative analysis of GSK3β serine 9 and serine 389 inhibitory phosphorylation following acute challenge, variate stress, or voluntary exercise

Authors: *B. D. HARE[1], T. M. THORNTON[2], M. RINCON[2], D. M. JAWORSKI[3], W. A. FALLS[1]
[1]Psychological Sci., Univ. of Vermont, Burlington, VT; [2]Immunobiology Program, [3]Neurolog. Sci., Univ. of Vermont Col. of Med., Burlington, VT

Abstract: Glycogen synthase kinase 3β (GSK3β) is a constitutively active protein kinase expressed throughout the central nervous system. Inhibition of GSK3β has been a therapeutic target for stress related disorders since its inhibition by lithium was discovered. GSK3β inhibition via increased phosphorylation at its N-terminus, serine 9 (S9), is associated with reduced depression-like behaviors. Similarly, GSK3β-S9 phosphorylation is increased by exercise, a behavior associated with reduced anxiety. GSK3β inhibition at its C-terminus, serine 389 (S389), by p38 MAPK was recently demonstrated by the Rincon laboratory. Strikingly, GSK3β S389-mediated inhibition is independent of S9 phosphorylation. To date, the role of GSK3β S389 phosphorylation in depression- and anxiety-like behaviors has not been examined. Acute forced swim and fluoxetine administration replicated previously reported GSK3β S9 phosphorylation effects but failed to modulate GSK3β S389 phosphorylation, demonstrating the independence of S389- and S9-mediated GSK3β inhibition. GSK3β phosphorylation was next examined following 14 days of variate stress or 14 days of exercise, both of which are metabolic challenges that induce hypothalamic pituitary adrenal axis activation, but are associated with different behavioral outcomes, increased and decreased anxiety respectively. Variate stress was associated with elevated GSK3β S389 phosphorylation in the hippocampus, amygdala and bed nucleus of the stria terminalis (BSNT). GSK3β S9 phosphorylation was increased in the BNST, and decreased in the amygdala following both exercise and variate stress exposure. Our findings suggest that S9 and S389 phosphorylation of GSK3β are differentially modulated by variate stress and voluntary exercise. Notably, changes in GSK3β S389 phosphorylation were most evident in the variate stress group suggesting that metabolic challenge alone is not sufficient to produce changes in S389 phosphorylation. Analysis of upstream regulators of GSK3β

phosphorylation is ongoing, as is analysis of the association of GSK3β with DNA damage following variate stress or voluntary exercise.

Title: How the stress-induced protein DRR1 modulates actin dynamics

Authors: *A. KRETZSCHMAR[1], J.-P. SCHÜLKE[1], M. MASANA[3,2], M. B. MÜLLER[3,2], A. R. BAUSCH[4], T. REIN[1]
[1]Project Group Rein, [2]Project Group Müller, Max Planck Inst. of Psychiatry, München, Germany; [3]Dept. of Psychiatry and Psychotherapy & Focus Program Translational Neurosci., Johannes Gutenberg Univ. Med. Ctr., Mainz, Germany; [4]Lehrstuhl für Biophysik E27, Technische Univ. München, Garching, Germany

Abstract: Being previously known as a potential tumor suppressor, DRR1 was recently characterized as a direct link between stress, actin dynamics and cognition at our institute. It was shown to localize to actin-rich cellular structures and primarily to synapses in neurons. While it decreases neurite outgrowth and reduces LTP magnitude and spine density, mice with viral DRR1-overexpression show enhanced cognitive performance (Schmidt et al., 2011). These findings suggest a protective function of DRR1 counteracting adverse stress effects. Its relevance becomes evident as failing of stress coping imposes an increased risk for depression, anxiety or post-traumatic stress disorder. Currently, we are dissecting the molecular mechanism, cellular and synaptic function of this intriguing protein with *in vitro* and *ex vivo* studies. It exerts a three-fold effect on actin dynamics by bundling filaments, inhibiting their elongation but also enhancing nucleation of new filaments. As the most prominent cytoskeletal component at the synapse, actin is a major player in many processes impacting on synaptic transmission like synaptic shape, neurotransmitter vesicle release and postsynaptic receptor distribution. However, up to now, a profound mechanistic understanding of the pathway from stress to neuronal reorganization and cognitive performance remains elusive. Assuming that the mechanism of DRR1 is not only significant for coping with chronic stress but also during tumor development

and progression, elucidating DRR1's mechanism of action could contribute to several physiologically relevant processes.

Title: Stress-mediated signaling by the Gs-coupled GPCR PAC1 at the adrenomedullary synapse: Role of a novel camp sensor, NCS/Rapgef2

Authors: *A. C. EMERY[1], N. STROTH[1,2], T. MUSTAFA[1], L. E. EIDEN[1]
[1]Section on Mol. Neurosci., NIMH, Bethesda, MD; [2]Translational Neuropharm., Karolinska Institutet, Stockholm, Sweden

Abstract: The neuropeptide PACAP is released at the adrenomedullary synapse, during stress, to mediate epinephrine secretion from, and promote catecholamine biosynthesis in, chromaffin cells (Stroth et al. *Endocrinology* **154**: 330, 2013). PACAP signaling also mediates stimulus-transcription coupling for additional bioactive peptides and proteins whose expression is up-regulated during the stress response (Ait-Ali et al., *Cell Mol. Neurobiol.* **30**: 1441, 2010). We now identify the neuroprotective peptide stanniocalcin 1 (Stc1) as up-regulated in wild-type, but not PACAP-deficient mouse adrenal gland after restraint stress, and characterize its regulation by PACAP via a novel cAMP-dependent pathway in primary bovine chromaffin cells (BCCs) in culture. Stc1 mRNA is increased ~3-fold within one hr following acute restraint stress in C57Bl/6N mice, and this increase is maintained across 6 hr of restraint and reversed upon cessation of restraint. PACAP-deficient mice exhibit wild-type basal expression levels, but no significant increase in Stc1 mRNA expression, following 6 hr of restraint. In primary BCC cultures, treatment with PACAP causes up-regulation of Stc1 gene expression mimicked by treatment with 8-CPT-cAMP, a cell-permeable cAMP analog. A novel cAMP sensor, the

neuritogenic cAMP sensor (NCS) has been identified as the protein product of the Rapgef2 gene (Emery and Eiden, *FASEB J.* **26**: 3199, 2012; Emery et al. *Sci. Sig*., **6**: ra51, 2013), and cAMP elevation causes activation of both NCS/Rapgef2, linked exclusively to ERK phosphorylation, and PKA, linked exclusively to CREB phosphorylation in the NS-1 pheochromocytoma cell line (Emery et al., *J. Biol. Chem*., **289**: 10126, 2014). Likewise, in primary BCCs (which like mouse chromaffin cells express the PAC1 receptor), either 8-CPT-cAMP or PACAP cause both CREB and ERK phosphorylation. Stimulation of ERK phosphorylation and up-regulation of Stc1 mRNA levels initiated by PACAP, forskolin, or 8-Br-cAMP are concomitantly blocked by inhibition of MEK with U0126 in BCCs. Additional cAMP-responsive genes in BCCs, including those encoding galanin (GAL) and vasoactive intestinal polypeptide (VIP) conform to this pharmacological response pattern. On the other hand, multiple transcripts, such as that encoding substance P (Tac1), show PACAP-dependent induction that is blocked by H89, indicating PKA-CREB-dependent regulation. We conclude that the stress transmitter PACAP activates both NCS/Rapgef2 and PKA via cAMP elevation, leading to ERK and CREB phosphorylation and activation of two sets of cAMP response genes encoding proteins with distinct functions, in chromaffin cells.

Title: The omega-3 polyunsaturated fatty acid docosahexaenoic acid (DHA) as a novel strategy for stress-related psychiatric disorders: reversal of corticosterone-induced changes in cortical neurons

Authors: *M. PUSCEDDU[1,2], Y. M. NOLAN[3], H. F. GREEN[4], P. KELLY[5], T. G. DINAN[2,1], J. F. CRYAN*[3,1]
[1]Alimentary Pharmabiotic Ctr., [2]Psychiatry, [3]Anat. & Neurosci., Univ. Col. Cork, Cork, Ireland; [4]Clin. Neurosci., Karolinska Inst., Stockholm, Sweden; [5]Moorepark Food Res. Ctr., TEAGASC, Cork, Ireland

Abstract: Chronic exposure to stress can exert long-lasting changes on the brain increasing vulnerability to mental illness. Corticosterone (CORT) is the main rodent stress hormone that has been shown to exert negative effects on neuronal morphology and viability across a number of brain regions. Understanding the molecular and cellular basis of susceptibility and resilience to stress may open up novel therapeutic strategies for disorders such as depression and anxiety. Growing evidence suggests that omega-3 polyunsaturated fatty acids (PUFAs) may have a beneficial effect on health including mental health. Indeed, being constituents of the cellular membrane, they might play a critical role in the development and function of the central nervous system. However, the ability of PUFAs to abrogate the stress-induced toxic effects on neurons has not been well investigated. To this end, we studied the protective effect of the omega-3 PUFA docosahexaenoic acid (DHA), against CORT-induced cellular changes in a mixed cortical primary culture. We first characterized the effect of CORT (75, 100, 150, 200uM) at different time points (24, 48, 72 hours) in a mixed cortical primary culture over 10 days *in vitro* (DIV), prepared from rats at postnatal day 1-2. Cells were then pretreated with DHA (3, 6uM) at 2DIV. CORT (72 hours) induced a dose-dependent reduction in cellular viability as assessed by MTT. Moreover, we demonstrated that CORT (200uM - 72 hours) decreased the percentage composition of neurons whilst increasing the percentage of astrocytes as assessed by B-III tubulin and GFAP immunostaining, respectively. In contrast, DHA (6uM but not 3uM) attenuated CORT (200uM)-induced cell death (72 hours). This translated into a capacity for DHA to prevent neuronal death as well as astrocytes overgrowth following chronic exposure to CORT. Furthermore, DHA (6uM) reversed CORT-induced neuronal apoptosis as assessed by TUNEL, and attenuated CORT-induced reductions in BDNF and CREB mRNA expression. Finally, DHA inhibited CORT-induced down-regulation of GR expression on b-III tubulin-positive neurons. In conclusion, this work supports the view that DHA may be beneficial to ameliorate stress-related cellular changes in the brain and may be a beneficial strategy for stress-related psychiatric disorders.

Title: The role of tyrosine hydroxylase-2 producing neurons of zebrafish in stress response

Authors: S. SEMENOVA, Y.-C. CHEN, *P. A. PANULA
Univy Helsinki, U Helsinki, Finland

Abstract: The tyrosine hydroxylase (TH) gene is duplicated in zebrafish, and tyrosine hydroxylase 1 (TH1) is more closely related to mammalian THs than TH2. The largest groups of th2-expressing cells are found in the hypothalamus of zebrafish. Expression of the th2 gene is affected by social stress and adverse environmental conditions in adult and larval fish. Otherwise, little is known on the function of TH2-producing neurons and the regulation of their activity. We generated antibodies targeting zebrafish TH2 to study the morphology, projections and contacts of TH2 neurons. The antibodies were produced in hens (IgY) and rabbits injected with a GST-tagged N-terminal fragment of TH2. These antibodies also labeled TH1-producing cells, revealing the whole population of dopaminergic neurons in the zebrafish brain. Western blotting of adult zebrafish brain samples with rabbit or hen antibodies revealed both TH1 and TH2 protein bands, and affinity purification of the serum/IgY did not eliminate immunoglobulins reacting with TH1. TH2-producing cells, identified by labeling with the new TH2 antiserum only and not with a specific TH1 antiserum, comprised all neuron groups which express th2 mRNA. They received contacts from histaminergic and orexinergic neurons. None of the TH2-producing cells were immunopositive for serotonin. The first cells containing TH2 but not TH1 were detected in the larval zebrafish hypothalamus around 84 hours postfertilization. Immunoreactivity of TH2 cells with the new antiserum was abolished by morpholino oligonucleotide knockdown of th2 expression. Expression mapping of the immediate early gene c-fos combined with immunostaining for TH2 was used to characterize the response of zebrafish neurons to various types of stimuli. Handling stress induced c-fos expression in dopaminergic cells of the posterior tuberculum of larval fish. Changes in the ionic strength or pH of the environment, as well as addition of ammonium salts to the incubation medium, induced strong c-fos expression in the hypothalamus, including its caudal part where the TH2 cells are found. Neurons in the nuclei of lateral and posterior recess of the hypothalamus were activated by handling and antagonistic social interaction in adult fish. However, few of the c-fos expressing

cells were immunopositive for TH2. Therefore, TH2 cells of zebrafish are probably involved in long-term adaptive response to stress rather than in immediate brain reactions to stimuli.

Title: Activation of noradrenergic neurons in the locus coeruleus by different stress paradigms

Authors: *I. R. DOS SANTOS[1], N. PESTANA-OLIVEIRA[2], J. A. ANSELMO-FRANCI[3], C. M. LEITE[3]
[1]Ctr. Universitário Barão De Mauá, Ribeirão Preto, Brazil; [2]Physiol., Sch. of Med. of Ribeirao Preto, Ribeirao Preto, Brazil; [3]Morphology, Physiol. and Basic Pathology, Dent. Sch. of Ribeirao Preto, Ribeirao Preto, Brazil

Abstract: Acute stress can elicit endocrine, sympathetic and behavioral changes which allow the body to avoid sudden changes in the mechanisms that maintain the homeostasis. The stress response involves changes in the activation of noradrenergic (NE) system, primarily in the locus coeruleus (LC) neurons, increasing noradrenaline release in many stress-responsive brain regions and thereby mediating the feed forward drive to hypothalamic-pituitary-adrenal system responses to stress. Ovarian steroids may modulate stress response by acting on the LC. Since it is known that the stress response depends on the stress paradigm, stress magnitude, and the level of circulating plasma estradiol and that LC is activated by some of acutely stressful stimuli, but not by others, this study aimed to evaluate whether different acute stress paradigms applied on the morning of proestrus, when the estradiol levels are already high, could differentially activate the NE neurons of LC. At 10:00 h, proestrus female rats were submitted to one of the four stress paradigms: 1) restraint, 2) exposure to a cat, 3) uterine cervix stimulation or 4) all types of stress applied together. The rats were perfused 90 minutes after the beginning of stress section. The brains were removed and sections containing the LC were submitted to immunohistochemistry to

access tyrosine hydroxylase (TH) and c-Fos immunoreactive (-ir) neurons. Restraint stress, cervical stimulation and the association of all stress paradigms induced a similar increase in the number of Fos/TH-ir neurons in the LC; however this increase was not observed in the group exposed to the predator. These results suggest that the LC NE system plays an important role in mediating stress responses induced by restraint, uterine cervix stimulation and the association of all stress paradigms, but it seems not to participate in response to predator exposure. Interestingly, the association of all stress paradigms was not able to amplify the activation of LC neurons, suggesting that LC neurons are maximally activated after the exposure to one kind of stress and the association of all stress cannot overcome this response.

Title: Post transcriptional regulation of adrenal TH gene expression contributes to the maladaptive responses triggered by insulin-induced recurrent hypoglycemia

Authors: *B. B. NANKOVA[1], N. KIRTOK[2], O. CHAN[3], C. STERLING[4], A. TANK[4], E. F. LAGAMMA[5]
[1]Pediatrics & Biochem & Mol Biol, New York Med. Col., Valhalla, NY; [2]Pediatrics, New York Med. Col. and Maria Fareri Childrens Hosp., Valhalla, NY; [3]Intrnl. Medicine, Endocrinol., Yale Sch. of Med., New Haven, CT; [4]Pharmacol. and Physiol., Univ. of Rochester Med. Ctr.,

Rochester, NY; [5]Pediatrics, Biochem. and Mol. Biol., New York Med. Col. and Regional Neonatal Center, Maria Fareri Childrens Hosp., Valhalla, NY

Abstract: Acute metabolic stress (insulin-induced hypoglycemia) triggers a counter-regulatory response during which release of catecholamines (epinephrine), activation of tyrosine hydroxylase (TH) enzyme and compensatory biosynthesis of catecholamines occur in the adrenal medulla. However, recurrent hypoglycemia (RH) in humans (consequence of the tight glycemic control in individuals with type 1 diabetes) and in animal models compromise the physiological and behavioral defenses against subsequent glucoprivation episode, including progressive loss of circulating epinephrine response. The molecular mechanisms underlying this maladaptive response to repeated stress are largely unknown. We hypothesized that the impaired epinephrine release following RH reflects altered regulation of adrenal catecholamine biosynthesis. To test this hypothesis we compared the effect of single daily and twice-daily episodes of insulin - induced RH on adrenal epinephrine release and production (as evidenced by altered TH gene transcription, steady state TH mRNA levels, Ser40-phosphorylated- and total TH enzyme molecules) in normal SD rats. Antecedent treatments were: once daily saline (1xSal); once daily insulin (1xRH); twice daily saline (2xSal) and twice daily insulin (2xRH) for 3 days. Counter-regulatory hormonal responses were monitored during hypoglycemic-hyperinsulinemic clamp on day 4 for all experimental groups. To analyze changes in TH gene expression in dissected adrenal medulla, sets of animals from each experimental group were sacrificed on day 4 before (at 0 time point), during the clamp (at 30 and 60 min) or after 3 hrs recovery period (time point for maximal TH mRNA induction). The counter regulatory responses, relative TH transcription and TH mRNA levels and Ser40-TH phosphorylation (marker for enzyme activation) were induced to a similar extent in 1xSal, 2xSal and 1xRH groups. The observed defective epinephrine release in 2xRH (reported before by others for this animal model of hypoglycemia-associated autonomic failure, HAAF) was associated with reduced more than 40% abundance of TH mRNA and transient Ser40-phosphorylation of TH. Accumulation of total TH protein was observed only following the recovery period in 1xRH animals. Thus, adrenal TH gene expression is subjected to differential regulation depending on the metabolic stress paradigm. Our results suggest that novel posttranscriptional mechanisms controlling TH mRNA and activated TH enzyme turnover contribute to the impaired epinephrine responses and may provide new therapeutic targets to prevent HAAF.

Title: Role of dexras1 and stress in triggering of type 2 diabetes mellitus

Authors: *A. THAPLIYAL[1], R. VERMA[1], M. THAPLIYAL[2], P. ANTHWAL[1], T. KAPOOR[1], P. SEMWAL[1]
[1]Graphic Era Univ., Dehradun, India; [2]Pt. LMS Govt. PG Autonomous College, Rishikesh, Rishikesh, India

Abstract: Data from various sources project India to become, slowly, the "diabetes capital of world" as the number of diabetics is increasing steadily. In a sharp contrast, the number of patients of younger age groups, between the ages of 30 to 45, has increased tremendously. It has been generally observed that the lower age limit for diagnosis of diabetes in India is well into 30's. In case of type 2 diabetes mellitus, a healthy individual, after a certain time gap suddenly shows symptoms. This transition of a healthy to a diabetic individual should occur due to some molecular event. We carried out investigations to check our hypothesis that does dexras1, a monomeric G-protein, along with stress have any role in the triggering of type 2 diabetes. The basis of our hypothesis was that it is well known that Dexras1 is localized within pancreatic β-cells. It has been demonstrated that Dexras1 modulates insulin secretion in pancreatic β-cells and involves protein kinase A, protein kinase C, and ERK1/2 pathways. Today's lifestyle creates many stress conditions and stress up-regulates corticosteroid levels and this in turn influences. Our in-vitro data suggests that exposure of insulin secreting cell line to corticosteroid hormone (and dexamethasone) increases dexras1 expression. If the dexras1 expression increases is for a longer time period and continuous, it creates an imbalance of calcium ions inside the cells. This imbalance is sensed by the cells and somehow triggers slow cell death as dexras1 can interfere in calcium homeostasis. Further investigations into the molecular details are ongoing but our data suggests that under in-vitro conditions, long exposure to stress might be the trigger point for type 2 diabetes mellitus which is mediated by calcium imbalance and the exposure time is of great relevance. This finding will have profound effect on prevention of onset of diabetes mellitus at earlier age and suggests that lifestyle, especially stressful conditions might have a major role in triggering of type 2 diabetes mellitus and hence the brain connection is the most important factor.

Title: Temporal course of the serotonergic system of the medial amygdala in male rats subjected to restraint stress

Authors: *M. R. GONZALEZ LOPEZ[1], N. L. GARCÍA-SALDÍVAR[1], R. DOMÍNGUEZ[2], S. E. CRUZ-MORALES[1]
[1]UNAM FES-Iztacala, Tlalnepantla, Mexico; [2]UNAM FES-Zaragoza, Iztapalapa, Mexico

Abstract: The amygdala is involved in the coordination of behavioral, autonomic and endocrine responses to stress and receives serotonergic innervations from the dorsal raphe. The medial nucleus of the amygdala has been involved with the stress response, especially with psychological stressors. Restraint stress (R) increase the 5-HT levels in the central amygdale, but not in medial amygdale nucleus. It is known that 5- HT may be an important mediator in the response to inescapable stress. The aim of present study was to evaluate in male rats the effect of exposure 60 minutes of restraint in serotonergic system of the medial amydala nucleus evaluated 0, 1, 24, 48 or 72 hr after restraint. Male Wistar rats (250-270 g) , were assigned to 6 independent groups: an unstressed control group (C) and five groups subjected to R during 60 min , and sacrificed at different times after the R: 0 , 1, 24 , 48 or 72 hr. Samples of the medial amygdala nucleus were taken to measure [5 - HIAA] and 5- HT by HPLC. The serotonergic activity was calculated as [5-HIAA]/ [5-HT]. Significant differences were observed in [5 -HT], 1 and 24 hr after R the concentration were similar to C group, a significant increase was detected after 48 and 72 hr, and no changes were detected at time 0 because the sensitivity was below of the method. For the [5 -HIAA] groups at time 0 and 24 hr showed low concentrations compared to C group, and a tendency to recovery was observed in 48 and 72 hr. Serotonergic activity decreased at time 0, increased at time 1, and a recovery was clear since 24 hr, no significant differences were observed at 48 and 72 hrs compared with C group. The results show that at time 0 the [5-HT] and [5 -HIAA] is low, this effect may be explained to the inhibition of neurotransmitter synthesis induced by R. Previously we reported that in the medial raphe nucleus the exposure to 15 min of restraint, to the elevated plus maze and to elevated T-maze decreased [5HIAA]. Some authors have observed increases in [5HT] in the central nucleus of the amygdala , with no effect in the medial nucleus in studies conducted in the dark phase, however these studies were realized at different times during the day. The forced swim stress increases

serotonergic activity in amygdale at time 0, but not assess of serotonergic activity was done beyond 24 hr. We conclude that the serotonergic system in the medial amygdala is very sensitive to the restraint effects and inhibits the synthesis 5HTand that recovery of serotonergic systems is time dependent.

Title: Prenatal protein malnutrition in adult rats under stress results in increased activation of inhibitory interneurons in the anterior cingulate and medial prefrontal cortex

Authors: *X. WANG[1], A. C. AMARAL[2], F. MORTAZAVI[2], J. A. MCGAUGHY[3], D. J. MOKLER[4], J. R. GALLER[5], R. J. RUSHMORE[2], D. L. ROSENE[2]

Abstract: Exposure to prenatal protein malnutrition (PPM) increases the risk of a number of neuropsychiatric disorders that are associated with inhibitory processes, including depression, schizophrenia and attention deficits in humans. Previous studies using a rat model of PPM and c-Fos as a marker of neuronal activation have found that neurons in anterior cingulate cortex (ACC) and medial prefrontal cortices (mPFC) respond excessively to restraint stress. Surprisingly, parallel studies in this same model using 2-deoxyglucose as a marker of metabolic activity show that ACC and mPFC in resting state are hypo-active. While there are several possible explanations for these differential observations, one possibility is that the c-Fos positive neurons might be largely GABAergic and hence damping down overall activity of the ACC and mPFC. In this study, subjects were P90 Long-Evans male rats born from mothers that were fed isocaloric diets containing either 25% protein (control) or 6% protein (malnourished), cross-fostered at birth to control mothers and maintained on normal laboratory chow after weaning and

throughout adulthood. We replicated the restraint stress paradigm but used double-label immunohistochemistry to identify c-Fos positive neurons, combined with parvalbumin to identify inhibitory interneurons. Numbers of single and double-labeled neurons in the ACC and mPFC were quantified with unbiased stereology. Statistical analysis demonstrated that there was no effect of PPM on the total number of neurons or on the number of parvalbumin neurons in either stressed or unstressed subjects. However, PPM rats showed a significant increase in the number of c-Fos positive neurons as well as in the number of inhibitory parvalbumin positive neurons double labeled with c-Fos within the stress condition. The total numbers of c-Fos positive neurons or the total numbers of double-labeled neurons in unstressed subjects were not different in the two nutrition groups. This suggests that PPM altered the excitability of these inhibitory interneurons either directly or by altering their connectivity. [Supported by: R01-MH074811]

Title: Tonic and phasic endocannabinoid heterosynaptic modulation in hypothalamic magnocellular neuroendocrine cells

Authors: S. DI, I. R. POPESCU, *J. G. TASKER
Tulane Univ., New Orleans, LA

Abstract: Recent evidence suggests that different endocannabinoids (eCBs) may be responsible for the effects of tonic and evoked eCB release at some synapses. Thus, activity-dependent eCB effects are often dependent on 2-arachidonoylglycerol (2-AG) synthesis and tonic CB1 receptor activation is mediated by anandamide (AEA) at some GABA synapses in hippocampal slice

cultures. Here, we tested for the differential dependence on 2-AG of evoked vs. tonic eCB actions at GABA synapses onto magnocellular neurons using whole-cell patch clamp recording recordings in acute brain slices. We tested for the 2-AG dependence of both depolarization- and glucocorticoid-induced suppression of GABA release in vasopressin (VP) and oxytocin (OT) neurons recorded in slices from dehydrated rats, in which reduced astrocytic coverage of neuronal membranes allows eCBs to spill over from glutamate synapses onto GABA synapses. Bath application of tetrahydrolipstatin (THL), a diacylglycerol lipase antagonist that blocks 2-AG synthesis, blocked both the depolarization- and glucocorticoid-induced suppression of GABA release in both VP and OT neurons, suggesting that evoked eCB actions are mediated by on-demand 2-AG synthesis in these cells. We next tested for the dependence of tonic CB1 receptor activation on 2-AG synthesis. Unlike the evoked eCB actions, tonic CB1 receptor activation was insensitive to changes in glial coverage and to blockade of 2-AG synthesis, suggesting that it was mediated by constitutive AEA release. Thus, AEA is released tonically at GABA synapses and is insensitive to glial buffering, while 2-AG is released phasically in an activity-dependent manner and its access to GABA synapses is regulated by astrocytes.

Title: Fluorescent visualization of central osmosensitive areas activated by acute osmotic stimulation in c-fos-eGFP transgenic rats

Authors: *Y. UETA, T. ARITOMI, K. SHOGUCHI, T. MATSUURA, M. YOSHIMURA, T. ISHIKURA, T. MARUYAMA, H. HASHIMOTO
Univ. Occupat, Environml Hlth, Japan, Kitakyushu, Japan

Abstract: We have generated transgenic rats that express the c-fos and eGFP fusion gene after adequate stimuli. In the present study we examined the effects of acute osmotic stimulation on the induction of the expression of the c-fos and eGFP fusion gene in the forebrain and brainstem of the transgenic rats. The expression of the c-fos and eGFP fusion gene was observed by fluorescent microscopy for eGFP fluorescence and immunohisotochemistry for Fos protein.

Ninety min after intraperitoneal administration of hypertonic saline in c-fos-eGFP transgenic rats, GFP fluorescence was appeared markedly in the circumventricular organs such as organum vasculosum of the lamina terminalis, median preoptic area and subfornical organ that are known to be osmosensitive areas, the paraventricular and supraoptic nuclei, and the area postrema and the nucleus of the solitary tract in the brainstem. The immunostaining for Fos protein was almost merged with GFP fluorescence induced by acute osmotic stimulation. The c-fos-eGFP transgenic rats are powerful tool to study neuronal circuits in the central nervous system after adequate stimuli.

Title: Inhibition in the lateral septum increases sucrose overeating in rats with a history of repeated food restriction and stress

Authors: *A. MITRA, C. LENGLOS, J. CALVEZ, G. GUEVREMONT, E. TIMOFEEVA
Dept. of Neurosci. and Psychiatry, Ctr. Res. Inst. Cardiol. and Pneumology Quebec (IUCPQ), Quebec, QC, Canada

Abstract: Introduction: The Lateral septum (LS) is interconnected to the limbic, hypothalamic and reward centers of the brain to regulate coordinated behaviors such as stress response, feeding behavior and motivational states. LS lesion escalates sweet taste preference. Neuronal activity in LS is enhanced by stress and attenuated by access to sucrose. Stress responses elicit essential behavioral and physiological changes to ensure survival but chronic stress may become maladaptive. Role and mechanisms by which the LS regulate chronic stress-induced changes in dietary preference are largely unknown. Methods: We subjected rats to chronic food restriction with intermittent access to sucrose and weekly foot shock stress session to evaluate the ingestive

behavior along with molecular and electrophysiological effects on LS. Microinjections of GABA-B receptor agonist in LS were performed to see its effect on sucrose intake. Results: Treatment leads to increased consumption of sucrose with enhanced lick numbers, lick-cluster number and its duration. It also amplified GAD-67 mRNA expression, decreased firing rate of LS neurons, consequently reducing c-fos mRNA expression in the LS. Additionally, baclofen-induced LS inhibition increased sucrose intake and decreased anorectic stress effects. Conclusion: Food restriction and chronic stress induced LS inhibition leads to compulsivity and increased incentive value of palatable food, eventually switching rats to a stable sucrose-seeking and -consuming phenotype. This shifted preference towards high palatable food to counteract stress effects comes at a cost of maladaptive feeding behavior that could lead to harmful metabolic consequences including diet-induced obesity.

Title: Clonidine alters the response to chronic stress: Effect on neuron number and seizure susceptibility

Authors: *E. W. H. MU, K. BORGES, N. A. LAVIDIS
Sch. of Biomed. Sci., Univ. of Queensland, Brisbane, Australia

Abstract: Central noradrenaline plays a key role in modulating the stress response in the amygdala, however the role of α2-adrenoceptors following chronic stress has not been well-characterized. This study firstly examined the effects of chronic stress on seizure susceptibility and neuron morphology in the basolateral amygdala (BLA) and central amygdala (CeA). Secondly, by using α2-adrenoceptor agonist clonidine and antagonist idazoxan, the role of α2-adrenoceptor in these changes was determined. Four-week old male Wistar rats were divided into 6 groups (n=8 per group), 3 control and 3 stressed groups. Each group received daily subcutaneous injections (1mL/kg) of vehicle (0.9% saline), idazoxan (1mg/kg), or clonidine

(1mg/kg). Stressed groups were restrained for 4 hours daily post-injection. Following 21 days of treatment, rats were subcutaneously injected with pentylenetetrazol (PTZ, 70mg/kg) to induce seizures. Seizure behaviors including number of myoclonic twitches and latency to twitches were recorded. Once forelimb clonus was exhibited, rats were culled with pentobarbital and perfusion fixed with 4% paraformaldehyde. Brains were sectioned coronally and Nissl-stained. Unbiased stereological analysis of pyramidal neurons and glial cells in the BLA and CeA was completed. In saline-treated rats, stress increased pyramidal neuron number in the BLA by 25 ± 2% ($p<0.05$), while pyramidal neuron number decreased in the CeA by 50 ± 5% ($p<0.05$) compared to control. Clonidine further increased BLA pyramidal neuron number during stress by 38 ± 3% ($p<0.05$), while restoring pyramidal neuron number to control in the CeA. No significant change was observed in glia cell morphology. In the PTZ seizure model, stress had no significant effect on seizure behaviors. Chronic clonidine increased latency to first myoclonic twitch in control and stressed rats by 46-49% compared to saline-treated rats ($p <0.01$). Latency to clonic seizure increased in control clonidine rats by 60 ± 16% compared to saline-treated rats ($p<0.01$). There was no significant change in latency for clonidine-treated stressed rats. No significant difference was observed in seizure behavior or neuron counts in idazoxan groups. In summary, chronic stress changed pyramidal neuron number in the BLA and the CeA. Clonidine counteracts this stress response in the CeA, but not in the BLA. Chronic stress affected the physiological response to chronic clonidine treatment, alleviating its seizure protective effect. Interfering with α2-adrenoceptor activity long term can change synaptic transmission by remodeling neural circuitry and can cause morphological and behavioral changes.

Title: Effect of acute stress on GSK3 α and β activity in a menopause model in rats

Authors: *M. A. HERNANDEZ[1], C. LOPEZ-RUVALCABA[2], E. ESTRADA-CAMARENA[3]
[1]TLALPAN, Inst. NACIONAL DE PSIQUIATRIA RAMON DE LA FUEN, MEXICO CITY, Mexico; [2]CENTRO DE INVESTIGACION Y DE ESTUDIOS AVANZADOS DEL IPN, Mexico city, Mexico; [3]INSTITUTO NACIONAL DE PSIQUIATRIA RAMON DE LA FUENTE MUÑIZ, MEXICO CITY, Mexico

Abstract: The reduction of ovaric estrogens levels and the chronic stress exposition, are two factors that could promote depressive like behaviours in rodents. Hormonal changes are associated with reduction of active PI3k and Akt kinases, which are in turn modulators of Glycogen synthase kinase-3 beta activity (GSK3β). Recent studies showed that neurodegeneration and cell death are events associated with the rise of both GSK3β expression and GSK3β activity in the hippocampus of ovariectomized rats (OVX). Because of the administration of 17-β estradiol and antidepressant drugs promote the reduction of GSK3β levels in different brain regions (prefrontal cortex, hippocampus and striatum) of OVX animals, we suggest that acute stress and the reduction of estrogens induced by ovariectomy, could attenuate the PI3K/Akt survival pathway. The increase of the phosphorylated-inactive GSK3β may provide a valuable pharmacological tool to produce neuroprotective and antidepressant actions in animal models of menopause. However, the response of GSK3α to acute stress remains unknown. The aim of this study was analyze the effect of the acute stress on the GSK3α and GSK3β activation in the hippocampus and dorsal raphe nucleus of OVX Wistar rats. Female Wistar rats (250-300 g) were assigned in two groups: OVX and SHAM (non ovariectomized). Both SHAM and OVX groups were also subdivided into control (without stress) and experimental groups, according to the following acute stress treatments induced by forced swimming test (FST): a unique five (5 min) or fifteen min test (15 min), and an initial 15 min pre-test followed 24 hours later by a 5 min test. Animals were sacrified by decapitation 30 min after FST. Hippocampus (HC) and dorsal raphe nucleus (DRN) were collected in order to analyze by Western blot the expression of phosphorylated and active-non phosphorylated isoforms of GSK3 (GSK3α and GSK3β). Results showed that OVX reduced the phosphorylation of GSK3α and GSK3β in HC compared to SHAM group ($p<0.05$). OVX plus FST at 5 min, decreased the phospho- GSK3α levels in HC and DRN regions ($p<0.05$) but not GSK3β. FST is an acute stressor that could attenuate the GSK3α phosphorylation but not in GSK3β.

Title: The expression of the oxytocin-monomeric red fluorescent protein 1 fusion gene in the hypothalamus and spinal cord after acute nociceptive stimulation in transgenic rats

Authors: *T. MATSUURA, M. KAWASAKI, Y. MOTOJIMA, H. SUZUKI, M. YOSHIMURA, J.-I. OHKUBO, T. MARUYAMA, H. HASHIMOTO, H. OHNISHI, A. SAKAI, Y. UETA
Univ. of Occup. and Envrn. Health, Japan, Kitakyuusyuu-city/fukuoka-Ken, Japan

Abstract: Our scientific understanding of the chief roles of the neurohypophysial hormone oxytocin (OXT) is to stimulate milk ejection and uterine contraction. OXT is also involved in several physiological and pathological social functions such as feeding, social recognition, anxiety and stress responses. On the other hand, several lines of evidence have suggested that OXT plays an important role in pain modulation. Previous studies showed that a population of parvocellular OXTergic neurons of the paraventricular nucleus (PVN) projects their axons to the spinal cord. However, little is known about the neuronal spinal networks responsible for OXT effects. In the rat spinal cord, OXT binding sites as well as OXT receptor expression are located in the dorsal root ganglion, laminaeI-II, intermediolateral and intermediomedial gray mater, lamina X, and in the parasympathetic regions. In the present study, we assessed the effects of acute nociceptive stimulation on OXT- monomeric red fluorescent protein 1 (mRFP1) expression in the hypothalamus, posterior pituitary (PP) and spinal cord, and examined the role which OXT plays in acute nociceptive effects. The transgenic rat that expresses the OXT and mRFP1 fusion gene used here previously showed to be a powerful tool to visualize OXT dynamics after adequate stimuli. To examine the effects of acute nociceptive stimulation on OXT-mRFP1 expression, OXT-mRFP1 transgenic rats were subcutaneously injected with formalin at the bilateral hindpaws. We revealed that there was a significant increase in OXT-mRFP1 fluorescent intensity in the parvocellular and magnocellular divisions of the PVN and supraoptic nucleus of the hypothalamus. We have assessed whether increased hypothalamic OXT may be associated with the spinal pathway of the acute pain by influencing mechanical nociceptive threshold.

Title: Dopamine D3 receptor contributes to the adult behavior deficits induced by repeated stressful experiences during preadolescence

Authors: J. H. SEO, *E. V. KUZHIKANDATHIL
Pharmacol. & Physiol., Rutgers -New Jersey Med. Sch., NEWARK, NJ

Abstract: The transition from adolescence to adulthood is associated with many behavioral changes. In humans and rodents repeated or chronic stress during preadolescence has long-lasting effects and results in development of behavioral disorders, such as depression, anxiety and substance abuse, in adults. While it has been shown that chronic or repetitive stress during postnatal development increases the likelihood of developing depression and anxiety-related disorders as adults, the underlying molecular mechanisms are not well understood. Here we investigated the role of the dopaminergic system, in particular the dopamine D3 receptor, in mediating the long-lasting effect of repeated stress during preadolescence. To assess the role of D3 receptors, we used the drd3-EGFP reporter mice that express the enhanced green fluorescent protein in cells that express endogenous D3 receptors. Male drd3-EGFP reporter mice, subjected to a 5-day, 2-hour per day repeated restraint stress during the preadolescence period (P35 to P40) exhibited depression and anxiety-related behaviors as adults (>P90). The mice stressed during preadolescence exhibited a decrease in number of center zone entry in an Open Field test compared to non-stressed animals. The stressed animals also showed significantly lower latency to immobility and increased total immobility time in Forced Swim test. More importantly, systemic administration of, 10 mg/kg SB-277011-A, a D3 receptor-selective antagonist, ten minutes before each of the repeated restraint stress episodes, prevents the development of depression and anxiety-related behaviors as adults. The behavior data also correlated with changes in D3 receptor expression and signaling function in specific brain regions in adult mice that were subjected to stress during preadolescence. The expression and function of the D3 receptor was downregulated in adult mice that were subjected to stress during preadolescence. Our results suggest that dopamine D3 receptor and its signaling pathways play an important role in mediating the long-lasting effect of repeated stress experienced during preadolescence.

Title: A “multiple hit” model of affective disorders in rats selectively bred for differences in emotional reactivity

Authors: *C. AYDIN, K. FROHMADER, A. MEDINA, S. J. WATSON, Jr, H. AKIL
molecular and behavioral neuroscience institute, Universty of Michigan, Ann Arbor, MI

Abstract: In humans, certain temperamental characteristics can predict the propensity for mood disorders and substance abuse. One such personality trait, novelty-seeking behavior, is modeled in rats by identifying outbred rats as high (HR) versus low (LR) responders based on their locomotor reactivity to the mild stress of a novel environment. Compared to LRs, HRs display lower anxiety- and depression-like behaviors and higher vulnerability for drug seeking behavior. To ascertain the genetic and developmental underpinnings of these phenotypes, our laboratory has employed a selective breeding strategy to amplify and segregate these naturally occurring differences generating two lines, the bred HR (bHR) and bred LR (bLRs) rats. We have shown that these lines exhibit stable, predictable and profound differences in multiple facets of affective behavior suggesting a pervasive difference in emotionality. Here we ask how environmental interventions might interact with the genetic and epigenetic differences that bHRs and bLRs exhibit to alter affective behavior: Would the combination of genetic vulnerability and environmental “hits” alter the adult phenotypes to produce either a greater propensity for depressive behavior or addictive behavior? This series of studies focused on the impact of chronic stress exposure during adolescence, a time where environmental changes can have a great impact in the human population. This manipulation is followed by additional stressors in adulthood. We ask: Do “multiple hits”_genetic vulnerability, adolescent stress and adult stress, alter either depression-like behavior or vulnerability to substance abuse? We will report on the behavioral consequences of the multiple hit model using a battery of tests including social

interaction, sucrose preference and cocaine sensitization. We will also describe some of the neural correlates of these interventions. In particular, we will focus on the Fibroblast Growth Factor (FGF) system, given that this system is basally different in the bred lines and is critical both during development and in adulthood in modulating affective and addictive behaviors.

Title: Early-Life effortful control buffers the relationship between rumination and internalizing in adolescents: Behavioral and neural evidence

Authors: *C. WESTBROOK[1], C. BURGHY[2], D. BUSSAN[2], M. J. ESSEX[2], R. J. DAVIDSON[2]
[1]Univ. of Wisconsin - Madison, MADISON, ; [2]Univ. of Wisconsin - Madison, MADISON, WI

Abstract: Effortful control in childhood and brooding rumination in adolescence have both been demonstrated to have effects on the development of internalizing psychopathology. However, it's unknown whether these two variables interact to predict internalizing. Using data from 136 participants in a longitudinal study, we investigated whether childhood effortful control moderated the effects of early-adolescent brooding on the development of internalizing symptomatology in late adolescence. Additionally, we used fMRI during an implicit emotion regulation task to examine whether the interaction between brooding and effortful control affected neural responding to negative images. We found that childhood effortful control moderated the relationship between early-adolescent brooding and late-adolescent internalizing, and this relationship remained significant when controlling for concurrent brooding and prior internalizing. This interaction corresponded to increased activity in parahippocampal gyrus

during negative images, and activity in this region correlated with decreased internalizing symptomatology. This cluster of activation also demonstrated functional connectivity to other brain areas involved in emotional responding and memory, such as hippocampus and amygdala. Our results provide evidence for a moderating role of childhood effortful control on adolescent brooding rumination, and suggest a possible neural mechanism of this effect in the context of emotion regulation.

Title: Differential gene expression of components of the hypothalamic-pituitary adrenal axis signalling in juvenile and adult mice

Authors: *A. SADLER, S. J. BAILEY
Dept. of Pharm. and Pharmacol., Univ. of Bath, Bath, United Kingdom

Abstract: Stressful life events are known to correlate with an increase in the risk of depression in humans. In depressed adults, there is overactivity of the hypothalamic-pituitary-adrenal (HPA) axis in up to 50% of patients, who show both an increase in cortisol levels as well as reduced negative feedback inhibition. Conversely, this increase in cortisol is not always reported in adolescent depression (Kaufman et al. 2001. Biol. Psychiat. 49(12): 980-1001). Reduced expression of glucocorticoid receptor (GR) and mineralocorticoid receptor (MR) in the hypothalamus of depressed adults has been reported (Pariante and Lightman, 2008, Trends Neurosci. 31(9) 464-468). Similar reductions in GR and MR expression have been shown in mice following chronic stress. In both cases this reduced expression corresponds with impaired negative feedback inhibition of the HPA axis seen by non-suppression of glucocorticoid release in the dexamethasone suppression test. However, less is known about the expression of key components of HPA signalling in juvenile mice and whether this changes in response to stress. Here, we have determined gene expression patterns of components of HPA signalling in adult (9-10 weeks old) and juvenile (4-5 weeks old) BALB/cAnNCrl mice (Charles River, UK) both at baseline and following a repeated stress procedure. Expression of GR, MR, CRH, CRHR1, CHRH2, AVP and V1b were determined in the hypothalamus, hippocampus, prefrontal cortex and pituitary gland of both adult and juvenile mice using quantitative RT-PCR. Blood samples were taken from the tail vein at baseline and following stress, and neuroendocrine function was determined using ELISAs. In control, non-stressed animals, juvenile mice showed increased AVP expression, and decreased CRHR1 expression, in the hypothalamus, compared with adult mice. These data suggest there may be differences in HPA function between adult and juvenile mice that may have repercussions for stress-responsiveness and the development of depression-like behaviours.

Title: Effects of adolescent social play deprivation on responses to social stress and dendritic morphology in the ventral medial prefrontal cortex

Authors: C. A. BURLESON, R. W. PEDERSON, S. SEDDIGHI, *M. A. COOPER
Dept. of Psychology, Univ. of Tennessee, Knoxville, TN

Abstract: Social play is an important feature of animal development as the deprivation of social play leads to altered dendritic morphology in the prefrontal cortex as well as deficits in social and non-social behavior, including inappropriate responses to intraspecific aggression and increases in anxiety-like behavior. Although neural activity in the prefrontal cortex controls coping with stress, it is unknown whether play deprivation affects responses to social stress in adulthood. We used a model of social defeat in Syrian hamsters, called conditioned defeat, to investigate whether social play deprivation leads to impaired dendritic morphology in the ventral medial prefrontal cortex and increased defeat-induced social avoidance. Male hamsters were weaned at post-natal day 21 (P21) and either housed with peers in groups of 3-4 or housed with their mother. At P42, play-deprived animals were reintroduced to peer groups. At P70, animals received 3, 5 minute social defeats in the home cage of a larger resident aggressor or control animals were placed in the empty home cages of resident aggressors. The next day, animals were tested for conditioned defeat in a 5 minute social interaction test with a non-aggressive intruder and then immediately tested for social avoidance of a familiar resident aggressor in a Y-maze. Then brains were collected for Golgi-Cox staining and analysis of dendritic length and dendritic bifurcations in select brain regions. Preliminary data indicate that social defeat produces robust social avoidance compared to non-defeated controls. Analyses of the effects of social play deprivation on conditioned defeat and dendritic morphology in the infralimbic cortex are in progress. This study will address whether social play functions to organize the ventral medial prefrontal cortex to facilitate appropriate responses to social stress in adulthood.

Title: Different patterns of neuronal activity in adolescent compared to adult females exposed to repeated social stress

Authors: S. LUZ[1], H. SCHWARZBACH[2], G. KELLY[1], R. VALENTINO[3], *S. BHATNAGAR[4]
[1]Dept Anesthesiol., Children's Hosp Philadelphia, PHILADELPHIA, PA; [2]Univ. Pennsylvania, PHILADELPHIA, PA; [3]Dept Anesthesiol., Univ. Pennsylvania Sch. of Medicine, Children's Hosp Philadelphia, PHILADELPHIA, PA; [4]Dept Anesthesiol., Univ. Pennsylvania, Children's Hosp Philadelphia, PHILADELPHIA, PA

Abstract: Although social stress has adverse consequences for physical and mental health throughout life, its impact may be particularly relevant during adolescence, a time of substantial growth and reorganization of brain circuits. Furthermore, social stress is particularly relevant to adolescent females because their primary source of stress is their social relationships. Our previous work indicates that repeated social stress produces a different behavioral impact in adolescent compared to adult female rats. We sought to determine whether social stress during adolescence activates neural circuits underlying defensive behaviors differently in adolescence compared to adulthood in female rats. Adolescent (ages d28-35) or adult (d70-77) Sprague Dawley female rats were exposed to social stress by placement in the cage of a lactating female. Initial investigation was followed one of the following: supine defeat, five attacks on the intruder rat by the resident rat, or 15 min of resisting defeat, at which point a wire partition was used to separate the two rats. The intruder rat remained in this cage for the remainder of 30 min before returning to her home cage. This was repeated for 7 days and intruder rats were sacrificed 60 min after the 7th defeat. We examined neural activity as assessed by the presence of the Fos protein in the medial amygdala, a region important in mediating defensive behaviors, and the paraventricular thalamus, a region important in adaptation to repeated stress. We used cluster analysis to identify sub-populations of rats that are defeated rapidly (short latency) and rats that resist being defeated that exhibit long latencies to defeat. In adult male rats, short latency rats cope passively and exhibit indices of vulnerability to stress whereas long latency rats cope more actively and exhibit resilience. Preliminary data indicate that defeat resulted in increased numbers of Fos-expressing cells in the medial amygdala and a trend to increased numbers in stressed adult females compared to stressed adolescent females. The increased activation in the adult compared to adolescent stress group was due primarily to adult rats that exhibited rapid defeat (short latency). In the paraventricular thalamus, there were no effects of stress in either adolescence or adulthood when subgroups were combined. However, in adolescent rats exhibiting longer latencies to be defeated, the number of Fos-stained cells was significantly lower compared to short latency adolescent rats. These results indicate that activation of neural structures important for defensive behaviors in females is age dependent and determined by coping strategies

Title: Effect of early-life enriched environment treatment on depression-like behavior in mice lacking BDNF expression through promoter IV

Authors: S. JHA[1,2], *K. SAKATA[1]
[1]Pharmacol, Univ. Tennessee, Memphis, TN; [2]Dept of Biol. Sci., IISER Bhopal, Bhopal, India

Abstract: Promoter IV-driven expression of brain derived neurotrophic factor (BDNF), a major neuronal growth factor, is implicated in the pathophysiology of major depression. We previously reported that mice lacking expression of BDNF through promoter IV (knockin IV: BDNF-KIV mice, Sakata et al., PNAS, 106, 5942-5947, 2009) exhibit depression-like phenotypes (Sakata et al., Genes Brains and Behavior, 9, 712-721, 2010). We further demonstrated that 3 weeks of enriched environment treatment (EET) normalized the defective phenotypes caused by BDNF promoter IV deficiency_depression-like behavior and decreased BDNF levels_ in young-adult (2-5 month old) mice (Jha et al., Translational Psychiatry, e40, 2011). The effects of EET over the life span, particularly during early life, remain unknown. Since early-life development involves dynamic and long-lasting epigenetic processes, we hypothesized that EET provided during early-life development would have maximal antidepressive effects that would endure into later life due to enhanced and long-lasting expression changes in BDNF. Here, as a first step to test this hypothesis, we addressed the effects of early-life EET on depression-like behavior and BDNF protein levels. Mice were raised with or without EET since birth (postnatal 0: P0). Their depression-like behavior was measured by the tail suspension test (TST) and open field test (OFT) at 2 months of age (P60). EET since birth reduced depression-like behavior at P60 in BDNF-KIV mice, as indicated by reduced immobility in the TST and increased explorative activity in the OFT. We further examined if the antidepressive effects of early-life EET endure after 1 month of discontinuance of EET. BDNF-KIV mice raised with EET until P60 and then transferred to standard cages until P90 showed a sustained decrease in immobility in the TST and a trend towards an increase in explorative locomotor activity in the OFT. These results suggest that the antidepressive behavioral effects of early-life EET can endure after discontinuance of the treatment. ELISA measurements confirmed that early-life EET increased BDNF protein levels in the hippocampus and prefrontal cortex (the depression related brain regions) of KIV mice at P60. The induction of BDNF was greater for EET provided in early life than in adulthood. We are

currently investigating whether these BDNF increases endure after discontinuance of EET. In conclusion, early-life EET produces lasting antidepressive behavioral effects and robust induction in BDNF levels, suggesting its usefulness as a potent and lasting prevention/treatment against depression.

Title: Effects of chronic fluoxetine and paroxetine treatment on affective behavior in male and female adolescent rats

Authors: *Z. R. HARMONY, S. E. EATON, M. J. STONE, L. VANSA, C. A. CRAWFORD
Dept. of Psychology, California State University, San Bernardino, San Bernardino, CA

Abstract: Selective serotonin reuptake inhibitors (SSRIs) are the most commonly prescribed class of antidepressant drugs, largely because of their effectiveness and favorable side-effect profiles. Unfortunately, the use of SSRIs in pediatric populations is limited due to reduced efficacy and their tendency to induce suicidal ideation in adolescents. While the cause of this reduced efficacy is unknown we previously found that repeatedly treating adolescent rats with fluoxetine (FLX) or paroxetine (PAX) affects affective behaviors when measured 24 h after 10 consecutive days of drug treatment. Specifically, both SSRIs decreased time spent in the open arms of an elevated plus maze (EPM) and time spent in the light compartment of a light/dark box but did not alter sucrose preference. Thus the purpose of the present study was to determine if increasing the time of treatment would alter these SSRI-induced changes in affective behavior. To this end, male and female Sprague-Dawley rats were injected with PAX (2.5, 5, or 10 mg/kg, ip), FLX (5 or 10 mg/kg, ip), or vehicle for 30 consecutive days starting on postnatal day (PD) 30. Rats were assessed for depressive-like behavior using a sucrose preference test and anxiety-like behavior using both EPM and light-dark box procedures. Behavioral testing began 24 h after the last drug treatment (i.e., on PD 60) in all rats. Sucrose preference and behavior in the light/dark box were measured on PD 60 and behavior on the elevated plus maze was assessed 48 hr later. Total sucrose intake and sucrose preference were found to significantly decrease in rats receiving FLX (10 mg/kg). In addition, male rats ingested more sucrose than female rats

regardless of drug treatment. Interestingly, neither SSRI produced anxiety-like behavior after the 30 day treatment. These data suggest that chronic treatment during the adolescent period with PAX and FLX does not enhance anxiety-like behavior. However, the chronic treatment used in the present investigation produced an anhedonic effect not seen with the 10-day drug administration procedure.

Title: Age and sex differences in serum cytokine levels following exposure to a bacterial endotoxin

Authors: *J. ROOKE[1], D. KOLMOGOROVA[1], R. WENG[2], L. KANE[1], J. LIANG[2], N. ISMAIL[1]
[1]Psychology, [2]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Exposure to stressors can have long lasting consequences, both on the brain and behaviour, especially during critical periods of development. Puberty is a period of sexual maturation where the brain is undergoing important reorganization and developmental processes. Previous research has shown that an injection of the bacterial endotoxin, lipopolysaccharide (LPS), can cause pubertal mice to be less receptive to hormonal treatments in adulthood compared to adults who were injected with LPS. This study looked at if there were age- or sex-specific differences in serum cytokine levels following exposure to this endotoxin to investigate if differences in immune response could be a contributing factor to later alterations in brain and behaviour. We hypothesized that pubertal mice would show greater serum cytokine concentration levels than adults. Additionally, we anticipated females would show higher levels than males, due to previous research noting females' acute reactions to immune challenges. Six week and ten week old male and female CD-1 mice were injected with either saline or LPS, and then euthanized for trunk blood collection. These samples were analyzed with a multiplex

Luminex immunoassay to determine serum concentrations of TNFα, IL-10, IL-12(p70), IL-1β, and IFNγ. Results showed that there are significant sex differences in cytokine concentrations for TNFα, IL-10, IL-12(p70), and IFNγ, where females had higher concentrations than males for all except TNFα, where males had higher concentrations than females.

Title: Differential activation of microglia in the mouse brain following an immune challenge may contribute to vulnerability to stressors during puberty

Authors: ***M. K. HOLDER**, J. D. BLAUSTEIN
Univ. of Massachusetts, Amherst, Amherst, MA

Abstract: The peak age of onset for diseases of mental health is during puberty, with extremely stressful or traumatic experiences during this period contributing to an increased risk for affective disorders. In female mice, the experience of a single injection of the bacterial endotoxin, lipopolysaccharide (LPS), during pubertal development alters the behavioral response to estradiol in adulthood as demonstrated by perturbations of estradiol's anxiolytic and anti-depressive properties. Microglia, the primary type of immunocompetent cell within the brain, contribute to brain development and respond to stressors with dramatic and long-lasting morphological and functional changes. Recently, we have begun to investigate the role that microglial cells may play in mediating the alteration in hormone response that results from pubertal stressors. We have previously demonstrated that microglia display a more hyper-ramified, or activated, phenotype in the hippocampus, amygdala and hypothalamus during the pubertal period, as compared with adulthood. These data suggest that microglia have an increased sensitivity to stressors during the pubertal period as compared to adulthood. Here, we examined the activation of microglia following administration of LPS to pubertal (6wk) and adult (8 wks) female mice using immunohistochemistry for ionized calcium binding adaptor

molecule 1 (Iba1), which is constitutively expressed in microglia, in areas implicated in anxiety and depression. In all brain regions examined, LPS treatment increased Iba1-immunoreactivity (ir). In the hippocampus, the age of animal was without effect on the increase in Iba1-ir following LPS exposure. However, in the amygdala and hypothalamus, we observed more Iba1-ir following LPS treatment in 6 week-old mice, compared to 8 week-old mice. These data suggest that the differential activation of microglia during the pubertal period may underlie the alteration in hormone-responsive affective behaviors in adulthood. Title: Prefrontal-limbic change in dopamine turnover by acupuncture in maternally separated rat pups

Authors: *S.-T. KIM, D. KIM, H. JEON
Div. of Meridian and Structural Med., Pusan Natl. Univ., Mulgeum-Eup, Yangsan-si,gyeongsangnam-Do, Korea, Republic of

Abstract: The present study investigated the possible role of acupuncture in alleviating depression-like behavioral changes and examined changes in the levels of serotonin (5-HT), dopamine (DA), and their metabolites in the hippocampus (HP) and prefrontal cortex (PFC) of maternally separated rat pups. On postnatal day 15, rat pups were maternally separated and received acupuncture stimulation at acupoint HT7 or ST36 once a day for 7 days. Then, on postnatal day 21, a tail suspension test was performed, and the HP and PFC were harvested. Levels of 5-HT, 5-hydroxyindole-3-acetic acid (5-HIAA), DA, and 3,4-dihydroxyphenylacetic acid (DOPAC) in the tissue were then measured by high-performance liquid chromatography

analysis. The total duration of immobility in maternally separated rat pups increased after maternal separation, and this increase was alleviated by acupuncture stimulation at HT7. The 5-HIAA/5-HT ratio and the levels of 5-HT and 5-HIAA were not significantly changed, but those of DA and the DOPAC/DA ratio were significantly lower after maternal separation. The maternal separation-induced reduction of the DOPAC/DA ratio significantly improved after acupuncture stimulation at HT7.

Title: The presence of the mother alters the valence of cues associated with painful stimuli and regulates changes in gene expression in the amygdala of infant rats

Authors: *G. A. BARR[1,2], R. M. SULLIVAN[3,4,5]
[1]Anesthesiol. and CCM, Children's Hosp. of Philadelphia, PHILADELPHIA, PA; [2]Anesthesiol. and CCM, Perelman Sch. of Medicine, Univ. of Pennsylvania, Philadelphia, PA; [3]Adolescent Psychiatry, New York Univ. Sch. of Med., New York, NY; [4]Emotional Brain Inst., Nathan Kline Institute, New York Univ., New York, NY; [5]Neurosci. Inst., New York Univ., New York, NY

Abstract: In human infants, maternal contact reduces the pain and stress associated with noxious procedures. Simlarly, in animal models the presence of the dam while the infant is exposed to painful or stressful stimuli reduces the stress response and aversiveness of the noxious stimuli (Sullivan et al., 2000; Wiednemayer et al., 2005). Paradoxically, one might expect that cues

associated with infant pain are avoided, but these cues are powerfully attractive to the infant when the mother is present during pain and only aversive when she is not. Activation of amygdala by shock at this age occurs in the absence of the mother and is necessary for the aversion learning. In the presence of the mother, however, the amygdala is quiescent. The mechanisms underlying the dampening of pain by the mother, and which induce the change in valence, are not known. We explored the complex mechanisms that mediate the infant response to a mild noxious stimulus (shock) with or without the dam by assaying changes in gene expression (Affymetrix microarrays) in the amygdala in 12 day old rat pups shocked when the mother present or absent. Methods are as described previously (Barr et al., 2009; Sarro et al., 2013). Raw array data from the "pain" condition (shock vs no shock) and the "Mom present" condition (shock with/without the anesthetized dam) were preprocessed using standard methods and Rank Products analysis was used for assessing differential expression [corrected probabilities (pfp) <.01]. These results were then used for functional analyses. There were several hundred genes whose expression was altered in the pain condition and fewer than 100 in the mother present condition. Of the latter genes, about two-thirds overlapped with the pain treatment group and about one-third were unique to the mother present condition. Multiple functional classes were altered by each condition; changes included genes related to forebrain development, axon guidance, cyclic nucleotides and G-protein coupled receptor signaling. These functional groups differed for genes unique to the pain condition, unique to the mother condition, or that were shared between the two experimental conditions. Thus, the presence of the mother alters the valence of stimuli (odors) associated with noxious stimulation from aversion to preference, reduces the magnitude of induced changes in gene expression, and modifies the functional consequences of those gene expression changes.

Title: Changes in sleep architecture in response to remote pre-conditioning and ischemic stroke: Impact of Bmal1

Authors: *A. J. BRAGER, T. YANG, J. EHLEN, R. MELLER, K. PAUL
Neurobio., Morehouse Sch. of Med., Atlanta, GA

Abstract: Whole-body knockdown of Bmal1 is with an increase in total daily sleep amounts. Here, we investigate the impact of whole-body knockdown of Bmal1 on ischemic and sleep regulatory pathways. Male wild-type (WT) and Bmal1 knockout (KO) mice received EEG/EMG tether implants for a multi-step experiment. After a 24 h EEG/EMG recording, mild (or sham) ischemia was induced by tourniquet of the left hindlimb across two 10 minute intervals separated by 10 minutes of release (n=6/genotype and treatment). This procedure, also known as pre-conditioning, was followed by a 72 h EEG/EMG recording. Afterwards, harmful ischemia was induced by occlusion of the middle cerebral artery (MCAO) for 1 h and was followed by another 72 h EEG/EMG recording. Infarct volume was determined from a tetrazolium chloride (TTC) stain performed on 0.5 mm-thick coronal brain sections. At baseline, Bmal1 KOs had 9.5+2.2% more daily sleep (NREM and REM) and more sleep-wake fragmentation vs. WTs ($p<0.01$, both). Daily sleep amounts remained unchanged from baseline levels in Bmal1 KOs exposed to mild (0.6+7.2%, from baseline; $p>0.05$) and harmful ischemia (5.2+9.3%, from baseline; $p>0.05$) whereas daily sleep amounts increased by 33.1+11.3% from baseline levels in WTs exposed to mild ischemia ($p=0.02$) and by 32.0+17.7% from baseline levels in WTs exposed to harmful ischemia ($p=0.03$). Total infarct volume in the forebrain (+1.6 to 0.6 from bregma) was larger in pre-conditioned vs. sham animals (32.5+6.9% vs. 12.6+3.6%; $p=0.02$). There was a 50% mortality rate in pre-conditioned Bmal1 KOs vs. 20% in pre-conditioned WTs that was due to microhemorrhaging in the forebrain. This study suggests that Bmal1 is necessary for changes in daily sleep amounts in response to mild and harmful ischemia and modulates the extent of survival induced by harmful ischemia.

Title: Increased mRNA expression and putative release of neuropeptide S after sleep deprivation in rat

Authors: *C. ADORI[1], S. BARDE[1], S. VAS[2], R. K. REINSCHEID[3], G. BAGDY[2], T. HÖKFELT[1]
[1]Karolinska Inst. Dept. of Neurosci., Stockholm, Sweden; [2]Semmelweis University, Dept. of Pharmacodynamics, Budapest, Hungary; [3]Univ. of California, Dept. of Pharmaceut. Sci., Irvine, CA

Abstract: The 20 amino acid 'neuropeptide S' (NPS) is expressed by limited number of neurons in the brainstem. The NPS receptor (NPSR) is, however, widely expressed in the rodent brain. The unique behavioral response of animals after NPS administration, namely the simultaneous anxiolytic and arousal promoting effects make the NPS-NPSR system an interesting potential drug target in mood related- and sleep disorders. Here we applied the single platform-on-water sleep deprivation on Wistar rats and examined the role of NPS in the regulation of sleep and arousal with anatomical methods. Brains were analyzed after 72 hours of sleep deprivation and a subsequent 3-hour rebound sleep. NPS and NPSR1 expression was detected by quantitative *in situ* hybridization. NPS immunoreactivity (IR) was visualized by immunohistochemistry and was quantified by densitometry. Potential targets of NPS-IR fibers were examined by double-labeling and confocal microscopy, with special attention on brain regions/nuclei known to be involved in sleep regulation. NPS-level was determined by radioimmunoassay. The highest expression of NPS was found in the peri-coerulear region and in a cell cluster laterally to the external part of lateral parabrachial nucleus (LPN) and dorsolaterally to the Kölliker-Fuse nucleus (KF cluster). A moderate expression level was detected in the LPN and around the fourth ventricle. Moderate-dense innervations of NPS-IR fibers was found in several brain areas known to be involved in sleep/arousal regulation, including the preoptic area, dorsomedial nucleus and perifornical area in the hypothalamus; PVN in the thalamus; TMN and vlPAG. NPS-IR nerve terminals had frequent close contacts with GABAergic/galaninergic neurons in the VLPO area and TH-IR neurons in several dopaminergic nuclei. The NPS expression was significantly increased in the peri-coerulear cluster but not in the LPN or KF clusters after the deprivation. There was no such a significant increase in case of the large pot (stress control) animals. The expression level in the peri-coerulear cluster returned close to control levels after the 3-hour rebound sleep. The NPS-IR fiber density was significantly decreased after the sleep deprivation in the preoptic area and a parallel increase of NPS-level was found in the same region. The expression of NPSR1, however, did not alter significantly in the preoptic area or in the rhomboid thalamic nucleus. Our

results suggest a differential response of NPS expressing neuron clusters after sleep deprivation and emphasize the role of the peri-coerulear cluster in the modulation of arousal. The results also emphasize the importance of preoptic area in NPS action on sleep.

Abstract: Introduction: State-dependent activity of brainstem catecholaminergic (CA) neurons has been suggested to mediate sleep-related hypotonia of upper airway muscles in Obstructive Sleep Apnea patients. We hypothesized that A1/C1 neurons contribute to CA-mediated excitation of the genioglossus (GG) muscle, a major dilator of the upper airway. To test this hypothesis, we employed a pharmacogenetic approach comprising designer receptors exclusively activated by designer drugs (DREADD) to delineate the effects of acute inhibition of A1/C1 neurons on GG muscle activity during natural sleep-wake states. Methods: We used transgenic mice in which Cre recombinase is expressed in CA neurons under the dopamine beta-hydroxylaze (DBH-cre) promoter. The DREADD channel construct was packaged into an AAV vector (EF1a-DIO-hM4Di-mCherry-AAV10; hM4Di-AAV) and bilateral injections (50 nl) of hM4Di-AAV were placed into the A1/C1 cell groups in n=4 mice. One week after injections of

hM4Di-AAV, mice were implanted with electrodes for recording the cortical electroencephalogram (EEG) and neck and GG electromyograms (EMGs). Four weeks after hM4Di-AAV injections the animals were habituated to the recording chamber for two consecutive days. Following chamber habituation all animals received injections of saline or the hM4Di ligand, CNO (0.3 mg/kg; IP) at 12:00 PM. The recordings were analyzed from 10:00 AM to 5:00 PM. Sleep-wake behaviour of the animals was scored in 10 s-long epochs as wake (W), non-rapid-eye-movement (NREM) or rapid-eye-movement (REM) sleep and GG/neck EMGs were quantified separately for each state. Results: State duration and mean amplitudes of neck/GG EMGs were analyzed within 1 hour periods just before and 2.5 hours after the saline/CNO injections and compared using two-way repeated measures ANOVA. GG activity could be fully analyzed in n=3 animals. In these animals, inhibition of A1/C1 neurons decreased GG activity ($F_{2,1,1}=17.7$; $p=0.052$) but was without effect on neck muscle activity ($F_{2,1,1}=3.12$; $p=0.22$) during NREM sleep. There was no significant effect on durations of W, NREM or REM sleep (n=4). Conclusions: Our results suggest that A1/C1 neurons have excitatory effect on GG muscle activity and that they contribute to the maintenance of GG tone during NREM sleep. These studies, for the first time, implicate medullary A1/C1 neurons in the regulation of GG activity in behaving animals.

Title: Suppression of cortical activation from both gamma band auditory stimulation and hypercarbia-induced arousals from sleep by optogenetic inhibition of basal forebrain parvalbumin-containing GABA neurons

Authors: *R. W. MCCARLEY, S. THANKACHAN, J. W. CORDEIRA, T. KIM, J. M. MCNALLY, J. T. MCKENNA, R. BASHEER, R. E. STRECKER, R. E. BROWN

Abstract: INTRODUCTION. We hypothesized that basal forebrain (BF) parvalbumin GABA (pvGABA) neurons form a key final common pathway for cortical activation from both sensory and visceral stimuli. We used the 40 Hz auditory steady state response (ASSR) as sensory stimuli and measured the resulting activation of cortical gamma band oscillations (GBO, ~40 Hz). Visceral stimuli were hypercarbia (10% CO2), to model obstructive sleep apnea and its cortical activation and arousal from sleep. **METHODS.** For optogenetic inhibition, we bilaterally injected a viral vector with the proton pump ArchT and a green fluorescent protein marker (AAV-FLEX-ArchT-GFP) into the BF of parvalbumin-Cre mice (n=12), and histologically verified transduction. Inhibition was induced by 532 nM bilateral laser illumination preceding and during the 500 ms ASSR and 30 sec hypercarbia stimuli and was compared with no illumination in the same animal. **RESULTS.** Projections of BF pvGABA neurons to frontal cortex was confirmed by GFP-labeled fiber tracing. **Auditory Stimuli**. In each of 8 successfully transduced mice ArchT inhibition during wakefulness of BF PV cells attenuated ASSR-elicited GBO (binomial pbackground). **Hypercarbia.** With bilateral ArchT BF PV inhibition, NREM EEG arousal latencies with hypercarbia in 5 mice were significantly increased (6.5±0.8s without ArchT, 13.1±1.7s with ArchT, paired t-test, p=0.002), an increase of 101.5%. Additionally, under control conditions, arousals occurred at a mean ambient CO2 level of 6.3±0.6%, but when bilateral ArchT BF PV inhibition was applied, the CO2 level for arousal was significantly increased to 8.2±0.8% (paired t-test, p=0.025). **CONCLUSION.** Inhibition of BF pvGABA neurons confirms their key role in cortical activation from both sensory (auditory) and visceral (respiratory) stimuli.

Title: Macrophages are required for normal recovery sleep after sleep loss

Authors: C. AMES[1], *E. SZENTIRMAI[2]
[2]WWAMI Med. Educ. Program, [1]Washington State Univ., Spokane, WA

Abstract: We have previously shown that brown adipose tissue (BAT) heat production is a sleep-inducing signal and sleep loss increases the thermogenic activity of BAT. Recovery sleep after sleep loss is attenuated in BAT deficient, UCP-1 knockout (KO) mice. BAT is activated by norepinephrine (NE) released from postganglionic sympathetic neurons and from a recently recognized macrophage population, the alternatively activated (M2) macrophages. The heat-producing capacity of BAT is severely impaired in the absence of M2 macrophages. We hypothesized that intact macrophage function is also required for recovery sleep after sleep loss as well as for normal sleep responses to cold challenge. Male C57BL/6 mice (n = 15) were instrumented for sleep and body temperature recordings. After 10 days of recovery, baseline sleep and temperature were measured for two days. On the experimental day, the control group (n = 7) received intraperitoneal (ip) injections of isotonic saline and the experimental group (n = 8) was injected with clodronate-containing liposomes in a dose of 0.2 ml/mouse to elicit systemic macrophage depletion. All injections were performed 5-10 minutes before dark onset. Sleep-wake activity and body temperature were measured to determine the acute effects of macrophage depletion as well as its effect on recovery sleep after sleep deprivation. Forty-two h after clodronate administration, mice were sleep deprived by gentle handling during the last 6 h of the light phase. In a separate experiment, the effect of macrophage depletion on cold exposure-induced sleep changes were tested. Starting from dark onset, environmental temperature was reduced to 10oC for 24h. Sleep-wake activity, body temperature and motor activity were recorded for 24 hours after each manipulation. Macrophage depletion elicited an immediate robust increase in non-rapid-eye movement sleep (NREMS) and decrease in rapid-eye movement sleep (REMS). NREMS increased by 110 ± 38.9 min and REMS decreased by 30 ± 6.8 min across 24 h after clodronate treatment. NREMS intensity was suppressed during the initial 12 h after injection. Sleep deprivation elicited rebound increases in NREMS, REMS and SWA in both groups of mice, however, the increases were significantly, ~ 50% smaller in the macrophage-depleted mice. In response to cold exposure, macrophage-depleted mice lost significantly more NREMS and REMS than control mice. Present findings support the hypothesis that intact M2 macrophage function in BAT is required for compensatory sleep after sleep loss and cold-tolerance.

Title: Early signs of activation in the chick embryo cholinergic system

Authors: *A. CHAN, M. POMPEIANO
McGill Univ., Montreal, QC, Canada

Abstract: The dorsal pontine tegmentum (DPT) contains cholinergic neurons that are mostly active during waking and rapid eye movement (REM) sleep, and in adult mammals these regulate cortical excitability by activating cholinergic neurons of the basal forebrain (BF) (Jones 2008; Brown et al. 2013). In birds (chickens), well-developed cholinergic neurons are present by the second half of embryonic development (von Bartheld and Bothwell 1992), and a REM-sleep-like EEG pattern can be recorded a few days before hatching (Martinez-Gonzalez et al. 2012). Extended waking-like states only appear at or after hatching, but can be transiently induced in late-stage embryos (Balaban et al. 2012). To examine whether cholinergic neurons may regulate either the development of REM sleep in chick embryos or the emergence of waking-like states, we studied the developmental expression of cFos (a marker of neuronal activation) in cholinergic neurons of the BF and DPT. Fertilized eggs were incubated using standard conditions (37.5°C, 55-60% relative humidity). Embryos (in ovo) and hatchlings were anesthetized (isoflurane) and intracardially perfused with fixative. Brains were frozen and cut at a cryostat. Immunofluorescence double-labelling experiments were conducted by incubating brain sections of the BF and the DPT with primary anti-choline acetyltransferase (Millipore) and anti-cFos antibodies (Santa Cruz Biotechnology) overnight and then with secondary fluorescent antibodies. Activation of BF cholinergic neurons (as determined from cFos expression) were first detectable at E16, decreased at E20 and increased again at P1,with a developmental pattern similar to what was previously seen in orexin neurons (Pompeiano et al. 2013). Activation of DPT cholinergic neurons were first detected at E18, reached a peak in pipped (air-breathing) embryos, and declined to basal levels in awake hatchlings. cFos expression was also seen in non-cholinergic cells in both the BF and DPT cholinergic areas. These results suggest that BF cholinergic neurons may be involved in the development of waking-like states in chick embryos, while DPT cholinergic neurons may be involved in the emergence of sleep-like states in the final few days before hatching. Surprisingly, DPT cholinergic neurons seem to play a less substantial role in

supporting waking in chickens than in mammals. Ongoing experiments are increasing the time window and sample sizes of these observations. Further work is also necessary to better characterize the neurotransmitter phenotypes of the active non-cholinergic neurons in both the BF and the DPT, which may also contribute to the development of sleep and waking regulation.

Title: Dopamine d2 receptor plays a key role in sleep and circadian activity

Authors: *I. MERCADO, P. SABANDAL, K.-A. HAN
Univ. of Texas At El Paso, El Paso, TX

Abstract: Sleep is critical in maintaining body homeostasis and its disruption affects many physiological and behavioral processes. Furthermore, abnormal sleep patterns are typically observed in people with neuropsychiatric disorders such as autism, attention deficit hyperactivity disorder (ADHD), depression, and schizophrenia. Interestingly, those disorders are associated with anomalous dopamine systems. Dopamine is a major neuromodulator in humans and other species including flies and is involved in reward, movement control, cognition and sleep regulation. The goal of our study is to investigate the mechanism by which dopamine regulates sleep and circadian activity. In this study, we focus on D2 receptor in *Drosophila* melanogaster. Sleep and circadian activity of D2 mutant and the flies with overexpressed D2 were measured with the *Drosophila* Activity Monitor (DAM) system. Immunohistochemical studies were also performed on the dissected brain to visualize dopamine receptor expression. We have found that the flies with hypomorphic mutation in dD2R (D2 dopamine receptor) or overexpressed dD2R in the mushroom bodies, a brain structure critical for learning and memory, had morphological and behavioral phenotypes. We are currently analyzing the phenotypes in detail and investigating

how different factors such as sexual dimorphism and social isolation or interaction affect the morphological and circadian phenotypes in wild type and dD2R mutants.

Title: Melanin-concentrating hormone neurons in the chick embryo: ontogeny and signs of prenatal activation

Authors: *M. POMPEIANO[1], A. YIP[1], J. BIRD[1], K. E. GODDEN[1], B. S. SEOK[1], D. MARTINEZ-GONZALEZ[2]
[1]Dept. Psychology, McGill University-Dept Psychology, Montreal, QC, Canada; [2]Sleep and Flight Group, Max Planck Inst. for Ornithology - Seewiesen, Starnberg, Germany

Abstract: Melanin-concentrating hormone (MCH) neurons are found in the dorsal and lateral hypothalamus in rodents and birds. They send diffuse projections throughout the brain that regulate a variety of physiological and behavioral functions, including rapid eye movement (REM) sleep, during which they are most active. The developmental expression of MCH has been studied in rodents, but no information is available for birds. In order to better understand the possible role(s) of MCH neurons in the developing avian brain, we studied MCH expression in chick embryos of different ages and 1 day old chicks. Since a REM-sleep-like EEG pattern can be recorded from chick embryos a few days before hatching (Martinez-Gonzalez et al. 2012), we wondered whether MCH neurons may regulate REM sleep in chick embryos. Therefore, we studied the developmental expression of cFos (a marker of neuronal activation) in MCH neurons. Fertilized eggs were incubated at 37.5°C, 55-60% relative humidity. Embryos (in ovo) and hatchlings were anesthetized (isoflurane) and intracardially perfused with fixative. Cryostat-cut sections were exposed to the primary anti-proMCH antibody (Santa Cruz Biotechnology), a secondary biotinylated antibody and the ABC system with DAB as a chromogen. Double-labelled slides were incubated with primary anti-proMCH and anti-cFos antibodies (Santa Cruz Biotechnology) and then with secondary fluorescent antibodies. A substantial number of lightly-

labeled MCH neurons were first reliably seen at embryonic day (E) 10 in the posterior hypothalamus. The number of labeled neurons and the intensity of staining strongly increased by E12 and older ages. MCH neurons were generally seen in a medial, periventricular location (as in other, non-mammalian vertebrates) at more anterior and dorsal levels. At more posterior levels, they extended from the hypothalamic periventricular organ laterally into the lateral hypothalamic area (as in mammals), medial mammillary nucleus and retromammillary area. cFos expression was virtually absent in MCH neurons at E12, was present at a low level at E16 (~5%), reached a peak at E20 (~20%), and was present at decreased levels in awake 1-day-posthatching chicks. These results suggest that the distribution of MCH neurons in chickens is more complex than previously described, and intermediate between that of other non-mammalian vertebrates and mammals. The presence of a substantial proportion of active MCH neurons towards the end of embryonic development suggests that these neurons may play a functional role in sleep development. We propose that MCH neurons could be involved in the emergence of REM sleep in chick embryos.

Title: Brown adipose tissue plays a central role in sleep responses to systemic inflammation

Authors: *L. KAPAS, E. SZENTIRMAI
WWAMI Med. Educ. Program, Washington State University, Spokane, Spokane, WA

Abstract: Introduction Our previous work identified brown adipose tissue (BAT) as a source of peripheral sleep-inducing signals (1). Pharmacological activation of BAT enhances sleep while sleep loss results in the thermogenic activation of the organ. The heat-producing property of BAT is conferred by the tissue-specific presence of uncoupling protein 1 (UCP-1). Recovery sleep after sleep loss is attenuated in UCP-1 knockout (KO) mice as well as in mice with the sensory denervation of BAT. Since BAT plays a central role in regulating metabolism and sleep and systemic inflammation greatly affects sleep, metabolism and the function of adipose tissue, we hypothesized that sleep responses to inflammation are mediated by BAT-derived signals. To

test this, we determined the effects of systemic inflammation on sleep and body temperature in UCP-1 KO and WT mice. Intraperitoneal (ip) injections of lipopolysaccharide (LPS) and tumor necrosis factor-α (TNFα) were used as a model for acute, systemic inflammation. Methods Male WT and UCP-1 KO mice (n = 7, each) were instrumented for sleep and body temperature recordings. The animals were kept at 30 C, on a 12:12 h light-dark cycle. At dark onset, mice were injected ip with saline on the control day and with 0.3 or 1 µg TNFα or 100 µg/kg LPS on the experimental day. Sleep, body temperature and motor activity was recorded for 24 h after each treatment. Results In WT mice, NREMS increased by 85% after LPS injection for 12 h. Administration of TNFα lead to dose-dependent increases in NREMS . All these sleep responses were completely abolished in UCP-1 KO animals. LPS and 1 µg TNFα elicited biphasic changes in body temperature; after an initial hypothermia, temperature increased for ~12 h in WT mice. In KOs, the hypothermic phases were abolished but increases in body temperature were not affected. Both LPS and TNFα suppressed motor activity. There were no significant differences in the activity responses of WT and UCP-1 KO mice. Conclusions Present results indicate that BAT plays an essential role in generating sleep responses that accompany systemic inflammatory conditions. The febrile responses, however, are independent of the thermogenic activity of BAT. References 1. Szentirmai É and Kapás L, Eur J Neurosci, 2014, 39:984-998.

Title: Homeostatic sleep need is mediated by adenosine via a glial-neuronal circuit

Authors: *T. E. BJORNESS[1], A. SUZUKI[2], N. DALE[3], G. METTLACH[2], J. A. BIBB[2], M. YANAGISAWA[2], A. FIENBERG[4], R. W. GREENE[2]
[1]Psychiatry, Univ. of Texas, Southwestern Med. Ctr., DALLAS, TX; [2]Univ. of Texas Southwestern, Dallas, TX; [3]Univ. of Warwick, Coventry, United Kingdom; [4]Intra-Cellular Therapies, New York, NY

Abstract: Sleep need progressively increases with prolonged waking and dissipates following consequent sleep. Sleep need is most often assessed by measuring slow wave activity (SWA, 0.5-4.5 Hz) power within the EEG; SWA power is considered the best indicator of sleep need because of its strong correlation with previous waking duration. Additionally, sleep becomes more consolidated with increased sleep need. Here we show a novel indicator of sleep need, the time constant of SWA decay within a sleep episode, can be employed together with rebound SWA and sleep consolidation to demonstrate that a neuronal-glial circuit mediated by adenosine regulates sleep need. We determined the effect of adenosine modulation on the three parameters of sleep need under baseline and sleep deprivation conditions in adult, male wildtype and genetically modified mice. Sleep/waking activity was measured using EEG and EMG electrodes. SWA power was assess by a Fast Fourier Transform, the time constant of SWA decay was determined by fitting the normalized and averaged SWA decay with a single phase exponential, and sleep consolidation was measured using a cumulative distribution of episode length. Baseline (undisturbed) activity was recorded for 24-48 h, followed by 48 h of a 6 h sleep deprivation (SD) plus recovery cycle in which waking was enforced using a slowly moving treadmill for 4 h followed by 2 h of treadmill off for recovery (chronic SD; 8x 6 h cycles of sleep deprivation plus recovery) or for acute SD: 4 h SD (for 7 consecutive days) or 6 h SD (for 4 consecutive days). Following chronic SD, control groups showed increased SWA power, increased (slowed) time constant of SWA decay during SWS, and increased sleep consolidation compared with baseline conditions. Furthermore, the time constant of SWA decay progressively increased from baseline to acute 4 h SD to acute 6 h SD to chronic SD. In mice lacking neuronal adenosine A1 receptors, which do not show rebound SWA following sleep deprivation as previously reported by this lab, sleep was fragmented and there was a lack of SWA decay during sleep under baseline conditions. Using an inducible, tamoxifen-based conditional knockdown, adenosine kinase was conditionally knocked down in glial cells. Adenosine kinase converts ATP+adenosine into ADP+AMP and is expressed primarily in glial cells in adult animals. The adenosine kinase knockdown mutants showed increased SWA power, slowed SWA decay during SWS (with a time constant similar to that of control mice following chronic sleep deprivation), and increased sleep consolidation compared to controls under baseline conditions with further increases in SWA power and sleep consolidation following chronic SD.

Title: Selective activation of cholinergic basal forebrain neurons induces immediate sleep-wake transitions

Authors: *Y. HAN[1], Y.-F. SHI[1], W. XI[1], R. ZHOU[1], Z.-B. TAN[1], H. WANG[1], X.-M. LI[1], Z. CHEN[1], G. FENG[2], M. LUO[3], Z.-L. HUANG[4], S. DUAN[1], Y.-Q. YU[1]
[1]Zhejiang Univ. Sch. of Med., Zhejiang, China; [2]McGovern Inst., Cambridge, MA; [3]Natl. Inst. of Biol. Sci., Beijing, China; [4]Shanghai Med. Col., Shanghai, China

Abstract: The basal forebrain (BF) plays a crucial role in cortical activation. However, the exact role of cholinergic BF (ch-BF) neurons in the sleep-wake cycle remains unclear.We demonstrated that photostimulation of ch-BF neurons genetically targeted with channelrhodopsin 2 (ChR2) was sufficient to induce an immediate transition to waking or rapid eye movement (REM) sleep from slow-wave sleep (SWS).Light stimulation was most likely to induce behavioral arousal during SWS,but not during REM sleep,a result in contrast to the previously reported photostimulation of noradrenergic or hypocretin neurons that induces wake transitions from both SWS and REM sleep.Furthermore,the ratio of light-induced transitions from SWS to wakefulness or to REM sleep did not significantly differ from that of natural transitions,suggesting that activation of ch-BF neurons facilitates the transition from SWS but does not change the direction of the transition. Excitation of ch-BF neurons during wakefulness or REM sleep sustained the cortical activation.Stimulation of these neurons for 1 hr induced a delayed increase in the duration of wakefulness in the subsequent inactive period.Our results suggest that activation of ch-BF neurons alone is sufficient to suppress SWS and promote wakefulness and REM sleep.

Title: Nigrostriatal dopamine acting on globus pallidus regulates sleep

Authors: M. H. QIU[1], Q. L. YAO[2], R. VETRIVELAN[2], M. C. CHEN[2], *J. LU[2]
[1]State key Lab. of Med. Neurobio. and Dept. of Neurobio., Sch. of Basic Med. Science, Fudan Univ., Shanghai, China; [2]Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: Cell body lesions of the globus pallidus externa (GPe) of the basal ganglia (BG) produce a profound sleep loss (~45%) in rats, suggesting that GPe neurons promote sleep. As GPe neuronal activity is enhanced by dopamine (DA) from the substantia nigra pars compacta (SNc), by acting on D2 receptors in the striatopallidal neurons, we hypothesized that SNc DA via the GPe promotes sleep. To test this hypothesis, we selectively destroyed the DA afferents to the dorsal striatum (caudoputamen, CPu) using 6-hydroxydopamine (6-OHDA) and examined changes in sleep-wake profiles in rats. Rats with 80-90% loss of DA terminals in the CPu displayed a significant 33.7% increase in wakefulness. This increase significantly correlated with the extent of SNc DA neuron loss. Furthermore, these animals also exhibited sleep-wake fragmentation and reduced diurnal variability in sleep-wake cycle. We then photostimulated SNc DA terminals in the CPu to build up local DA levels and found that 20Hz stimulation during 9-10 PM increased total sleep by 69% and a tendency of increase in NREM sleep EEG delta power in 1-3Hz range. We finally examined sleep effects of directly exciting GPe neurons with optogenetics stimulation. Similar to SNc DA terminal stimulation, 20Hz stimulation of the GPe from 9 to 10 PM increased total sleep by 66% and significantly increased EEG delta power in the 0.5-3Hz range. These findings elucidate a novel circuit for DA control of sleep, and help to make clear the mechanisms of abnormal sleep seen in BG disorders such as Parkinson's disease, Huntington's disease and obsessive-compulsive disorder.

Title: The role of GABAergic neurons of the central amygdala in emotion-triggered cataplexy

Authors: *C. E. MAHONEY[1,3], L. VONG[2], B. B. LOWELL[4,2], T. SCAMMELL[1,5]
[1]Neurol., [2]Dept. of Med., Beth Israel Deaconess Med. Ctr., Boston, MA; [3]Dept. of Med. Sci., [5]Dept. of Neurol., [4]Harvard Med. Sch., Boston, MA

Abstract: Narcolepsy is a common sleep disorder characterized by chronic sleepiness and cataplexy – sudden muscle weakness triggered by strong, usually positive, emotions. We recently found that lesions of the amygdala reduce cataplexy, and that GABAergic neurons of the central amygdala (CeA) target brainstem regions known to suppress muscle atonia. We hypothesize that GABAergic neurons of the CeA are a major inhibitory output of the CeA that may promote emotion-triggered cataplexy. To test the role of the CeA GABAergic neurons in cataplexy, we used Designer Receptors Exclusively Activated by Designer Drugs (DREADD) technology in orexin knock out x vGAT-Cre mice (OXKO x vGAT-Cre). The M3 DREADD receptor is an engineered muscarinic receptors that depolarizes neurons in response to clozapine-N-oxide (CNO) but not to acetylcholine. We injected an adeno-associated viral vector coding for Cre-dependent DREADD (AAV8-hsyn-hM3-mCherry; 20nL) into the CeA of OXKO x vGAT-Cre mice and implanted EEG/EMG electrodes. Vehicle (Saline) or CNO (0.3mg/kg, ip) was injected just before lights off in one of three conditions, with no stimulus or with chocolate (Hershey's chocolate) or running wheel (RW) access. EEG/EMG and infrared video were acquired for 48hours after injection. The EEG/EMG traces were digitally filtered and scored using SleepSign. Mice were perfused and brains were sectioned and processed for mCherry immunohistochemistry to assess injection sites. Analysis of the EEG/EMG traces adhered to a consensus definition of cataplexy (Scammell et. al. (2009) *Sleep*). CNO increased the amount of cataplexy for the first 3 hours after dosing (bilateral and unilateral AAV injections; CNO 10.3$\pm$1.7% vs. Saline 5.9$\pm$1.6% $p<0.05$). CNO produced no additional increase in cataplexy in the presence of chocolate (CNO 13.2$\pm$1.9% vs. Saline 9.9$\pm$1.2% $p>0.05$) or running-wheels

(CNO 9.9±1.3% vs. Saline 8.3±1.0% p>0.05). The effect of CNO on cataplexy may be limited in the presence of these motivating stimuli due to the recruitment of a common network. These results demonstrate that GABAergic CeA neurons are sufficient to trigger cataplexy. These findings should improve our understanding of the neurobiology of positive emotions and motor control, and ultimately, this should lead to better therapies for cataplexy.

Title: Cortical nNOS/NK1 neurons are regulated by cholinergic inputs

Authors: *R. H. WILLIAMS, J. VAZQUEZ-DEROSE, A. NGUYEN, T. S. KILDUFF
SRI Intl., Menlo Park, CA

Abstract: Cortical GABAergic interneurons shown to co-express neuronal nitric oxide synthase (nNOS) and the neurokinin-1 (NK1) receptor are activated during sleep (Dittrich et al., 2012, Front. Neural Cir). These neurons have been proposed to play a role in sleep homeostasis (Gerashchenko et al., 2008, PNAS)as the proportion of this population expressing cFOS correlates with homeostatic sleep drive (Morairty et al 2013, PNAS). As these cells appear to "sense" sleep need, we investigated whether cholinergic inputs affect the electrophysiological properties of cortical nNOS/NK1 neurons. We prepared coronal mouse brain slices (250µm thick) for whole-cell patch-clamp recording in both voltage clamp and current clamp modes. After a brief application of the fluorescent NK1 agonist tetramethylrhodamine (TMR), cortical nNOS/NK1 neurons were readily identifiable. Following a 60min wash-out period to eliminate any residual TMR-mediated response, carbachol (CCh, a cholinergic mimetic) was applied. All cells tested responded to CCh (50µM; n=34). CCh had biphasic effects: an initial membrane hyperpolarization (-2.24±0.57mV, n=6) and outward current (+3.74±0.66pA, n=12) was followed by a large membrane depolarization (+9.18±1.87mV, n=8) and inward current (-5.59±2.22pA, n=12). In addition, CCh predominantly increased spontaneous excitatory postsynaptic currents (sEPSCs; +805.8±62.68%, n=15). In the presence of tetrodotoxin (TTX),

both outward (+3.18±0.74pA, n=9), and inward (-11.96±1.88pA, n=15) currents remained, indicating responses mediated by postsynaptic receptors. We tested whether the excitatory response mediated by CCh was attributable to activation of the Gq-coupled muscarinic type 1 receptors (M1R). Application of CCh in the presence of the M1R antagonist VU0235535 (5μM) reduced the membrane depolarization by 47.9±16.9% and inward current by 32.0±17.7% in 3/5 cells tested. The 2 remaining cells showed no change in their excitatory response but an increase in the outward current (+5.76±2.11pA, n=2). In contrast to sEPSCs, CCh decreased miniature EPSCs (mEPSCs) by -45.6±2.2% (n=6). The presence of VU0235535 did little to alter the reduction in mEPSCs seen following CCh application (after vs baseline: -53.1±2.8%, n=4), suggesting that M1Rs are largely postsynaptic. In summary, CCh has a network effect on excitability within the cortex, as both presynaptic and postsynaptic effects result in an oscillating pattern of nNOS/NK1 neuron excitability. When all inputs are blocked, the predominant response is excitation. We are currently attempting to determine the source of cholinergic inputs to cortical nNOS/NK1 neurons.

Title: Cytotoxic chemotherapy increases NREM and REM sleep with concurrent sleep fragmentation

Authors: *J. C. BORNIGER, M. M. GAUDIER-DIAZ, N. ZHANG, R. J. NELSON, A. C. DEVRIES
Neurosci., The Ohio State Univ. Wexner Med. Ctr., Columbus, OH

Abstract: Chronic fatigue and sleep disruption are among the most common complaints of cancer patients undergoing chemotherapy and are primary reasons for discontinuing treatment. Indeed, hypnotics are the most frequently prescribed drugs to combat chemotherapy-related side effects. Because of the complex interactions among cancer, treatment regimens, and life-history

traits, investigations into a causal link between chemotherapy and sleep disruption have been sparse. To investigate how chemotherapy acutely influences sleep, we ovariectomized adult (8-9 wks) female c57bl/6 mice and implanted wireless biotelemetry units. We subsequently collected EEG/EMG biopotentials over the course of 3 days pre- and post-injection (at ZT 7; 14:10 light/dark cycle) of 18 mg/kg doxorubicin and 180 mg/kg cyclophosphamide in saline vehicle or vehicle alone. Because previous research has implicated cytokine signaling in sleep disruption and chronic fatigue, we predicted that IV administration of cyclophosphamide + doxorubicin would disrupt sleep and increase central pro-inflammatory cytokine expression in brain areas known to govern vigilance states (i.e., hypothalamus and brainstem). The results largely support these predictions; a single chemotherapy injection dramatically increased NREM and REM sleep during subsequent active (dark) phases and this induced sleep was fragmented and of low quality. Mice displayed marked increases in low theta (5-7Hz) to high theta (7-10 Hz) ratios following chemotherapy treatment, indicating elevated sleep propensity (i.e., fatigue). The effect was strongest on the first night following injection, but mice displayed disrupted sleep for the entire post-injection recording time (3 days). qPCR analysis revealed that sleep disruptions were accompanied by increased IL-6, but not TNF-α or IL-1β, mRNA expression in the hypothalamus, but not the brainstem. Vigilance state timing was not influenced by treatment, potentially indicating that chemotherapy administered at this time alters sleep homeostasis without altering circadian output. Our study is the first to provide a causal link between chemotherapy and acute sleep disruption, and our data support previous research implicating hypothalamic inflammation in sleep disruption.

Title: Role of thalamic reticular nucleus in sleep spindle generation: An optogenetic investigation in the mouse with implications for schizophrenia

Authors: *S. THANKACHAN, J. M. MCNALLY, R. E. STRECKER, J. T. MCKENNA, R. E. BROWN, R. W. MCCARLEY
Psychiatry, VA Boston Healthcare Syst. & Harvard Med. Sch., Brockton, MA

Abstract: Alterations in human cortical sleep spindles have been recently identified as a reliable biological EEG marker of schizophrenia (Sz). Human sleep spindles (12 - 16 Hz EEG oscillations) are thought to originate in the thalamic reticular nucleus (TRN), a structure composed primarily of inhibitory GABAergic neurons containing the calcium binding protein parvalbumin (PV). The interaction of rhythmically bursting PV TRN neurons and thalamocortical (TC) relay neurons initiates spindle oscillations during NREM sleep, and these oscillations are postulated to be self-maintained by reciprocal interactions between cortical, TC relay, and TRN neurons, although the role of specific TRN neurotransmitter phenotypes in spindle generation is not clear. We hypothesized that direct, selective stimulation of PV TRN neurons would promote spindle activity, and inhibition would produce attenuated spindle activity, consistent with evidence of reduced PV expression and abnormal spindle activity in both animal models and clinical studies of SZ. To investigate for the first time, the specific role of PV-positive TRN neurons, we performed optogenetic experiments in mice expressing Cre recombinase in PV neurons (PV Cre mice). In our first experiment to test the role of PV neurons in spindle control, adeno-associated virus-ChR2 was first bilaterally injected into TRN in the PV Cre mouse to specifically transduce PV neurons of TRN, and blue laser-light (473nm) was then applied three weeks later for optogenetic excitation. Optogenetic excitation was tested (n = 5 mice) at varying frequencies (2-60 Hz). This produced the largest cortical EEG response at ~10 Hz, suggesting activation of an intrinsic oscillator tuned to the mouse spindle frequency (10-12 Hz). 10 Hz excitation elicited both a significant increase of cortical EEG power at the stimulation frequency, and regularly produced a cortical EEG spindle. In addition, 5 hrs of optogenetic stimulation at 10Hz (1 sec/min) led to a consistent increase in NREM sleep (n=2) compared to control experiments (no stimulation). Our experiments show that PV-positive TRN neurons have the ability to facilitate cortical spindles and NREM sleep. Ultimately, an increased knowledge of the pathophysiology of spindle deficits may provide potential pharmacological targets for treatment of spindle deficits such as those seen in schizophrenia.

Title: Chronic administration of glycine modify sleep pattern and metabolic parameters in rats

Authors: *A. JIMENEZ-ANGUIANO[1], J. C. RODRIGUEZ-AGUILAR[1], I. JASSO-VILLAGOMEZ[2], G. BLANCAS-FLORES[2], F. J. ALARCON-AGUILAR[2], J. VELAZQUEZ-MOCTEZUMA[1]

Abstract: Sleep is one of the physiological needs which is characterized by a reduction in awareness level and specific metabolic activities. Various neurotransmitters regulate sleep, including the glycine (Gly), which has a facilitating effect in humans, improving quality and reducing daytime sleepiness. Gly also is an effective adjuvant in the treatment and prevention of type 2 diabetes mellitus (T2DM), preventing cell injury by inhibiting the synthesis of proinflammatory cytokines. To determine the effect of chronic administration of Gly on various metabolic parameters and sleep pattern, we used 10 male rats (250-300 g), quantifying the levels of: cholesterol, triglycerides, uric acid, glucose, and various proteins in liver. Subsequently, electrodes were implanted for conventional sleep recordings and grouped under the following conditions: Control, normal water consumed (n=5) and water with Gly (10 g/1000 ml) for 30 days (n=5). Every week we realized polysomnographic recordings. At the end, they were again quantified metabolic parameters. Gly administration during the first week increased slow wave sleep II in relation to the control group, decreasing REM sleep. In the last three weeks, the Gly caused a gradual decrease in REM sleep at the expense of an increase in wakefulness. In the metabolic parameters, the chronic administration of Gly showed a trend to decrease glucose levels and increase levels of various transaminases. From the obtain results we suggest a dual effect of Gly on sleep-dependent on the time administration and possible effective adjunct in the treatment and prevention of various clinical manifestations of DM2.

Title: Optogenetic activation of cholinergic neurons in the LDT increases REM sleep

Authors: *C. J. VAN DORT[1,3], J. KENNY[1,3], D. ZACHS[2,3], R. GOLDBLUM[4], M. WILSON[3], E. BROWN[2,3]

Abstract: Rapid eye movement (REM) sleep is tightly regulated, yet the mechanisms that control REM sleep remain incompletely understood. Early pharmacological and unit recording studies suggested that acetylcholine was important for REM sleep regulation. For example, injection of cholinergic drugs into the dorsal mesopontine tegmentum reliably induced a state very similar to natural REM sleep in cats. Unit recordings from the cholinergic areas of the mesopontine tegmentum revealed cells that were active during wakefulness and REM sleep as well as neurons active only during REM sleep. Electrical stimulation of the laterodorsal tegmentum (LDT) in cat increased the percentage of time spent in REM sleep and activation of the pedunculopontine tegmentum (PPT) in rat induced wakefulness and REM sleep. In cat, lesions of the PPT and LDT do disrupt REM sleep but lesions in rodents have had little effect on REM sleep or increased REM sleep. Additionally, c-fos studies have found very few cholinergic cells activated under high REM sleep conditions leading to alternative theories of REM sleep regulation where cholinergic neurons do not play a key role. Therefore, we aimed to determine the role of cholinergic neurons in the LDT on REM sleep regulation using optogenetics. Adult male ChAT-ChR2+ transgenic mice (n=5) and wildtype littermates (n=5) were implanted with bilateral fiber optics aimed for the PPT and EEG and EMG electrodes. Experiments were conducted in the morning with 4 conditions in randomized order, baseline sleep and 3 stimulations (5ms pulses at 5Hz) of varying duration 60, 80, or 180 s. EEG, EMG, and video were recorded and used to score sleep. After completion of the experiments, mice were perfused and identification of the fibers above the LDT was confirmed. Optogenetic activation of cholinergic neurons in the LDT during NREM sleep increased REM sleep from 2 s in ChAT-ChR2- mice to 4.5 s in ChAT-ChR2+ mice for 60 s stimulations, from 2.7 to 8.1 s for 80 s stimulations, and from 12.4 to 22.7 s in 180 s stimulations. The probability of REM sleep

increased over the time course of the stimulation. The increase in REM occurred by increasing the number of REM sleep episodes but not REM sleep episode duration. The induced REM sleep state was electrophysiologically similar to natural REM sleep by power spectra analysis. Inferences were made by constructing 95% Bootstrap confidence intervals where differences are considered significant if the confidence intervals between groups do not overlap. These findings suggest that LDT cholinergic neurons are key modulators of REM sleep onset but not REM sleep maintenance.

Title: Pharmacogenetic activation of cholinergic, glutamatergic and GABAergic neurons in the PPT and their roles in sleep/wake behavior

Authors: *D. KROEGER, L. L. FERRARI, L. J. AGOSTINELLI, E. ARRIGONI, T. E. SCAMMELL
BIDMC / Harvard Univ., Boston, MA

Abstract: A variety of studies on different species have suggested that the pedunculopontine tegmental (PPT) region in the brainstem is a key site for the regulation of sleep/wake states - specifically REM sleep regulation. However, lesion studies, electrical stimulation, or local infusions of either GABA, glutamate or carbachol into the PPT region cannot determine which of the intermingled neurons in this region is responsible for the observed effect. We chose a genetically targeted approach to selectively and separately activate PPT neurons expressing acetylcholine, glutamate or GABA using excitatory Designer-Receptors-Activated-Exclusively-by-Designer-Drugs (DREADDs). Using three different cre mouse lines (Chat-cre, vGlut2-cre and vGat-cre mice), we transfected neurons in the PPT region with a viral vector coding for DREADD M3 receptors tagged with fluorescent mCherry. Two weeks later, we administered i.p. clozapine-N-oxide (CNO) or vehicle during the light and dark periods. Activation of DREADD-

expressing cholinergic neurons 2.5 hours after lights-on reduced EEG delta amplitude during NREM sleep by over 27% for a 3 h period with rebound delta sleep for the subsequent 6 h. CNO activation of vGlut2 neurons in the PPT potently induced wakefulness for 5-8h with animals showing the normal range of behaviors such as nesting, feeding, grooming, wheel running, etc. In contrast, activation of vGat neurons had little effect on sleep/wake behavior. We conclude that each neurochemical type of PPT neuron plays a distinct role in modulating sleep/wake states.

Title: Optogenetic interrogation reveals a causal role for VTA dopamine neurons in the regulation of sleep and wakefulness

Authors: *A. D. EBAN-ROTHSCHILD, W. J. GIARDINO, L. DE LECEA
Psychiatry and Behavioral sciences, Stanford Univ., Palo Alto, CA

Abstract: Dopamine (DA) neurons play a central role in many wake-related processes including motivation, reward, and learning. While these functions are associated with heightened arousal, the role of DA neurons in generating and maintaining arousal is largely unknown. In some psychiatric disorders, such as Schizophrenia and substance abuse, there are alterations in DA transmission as well as in arousal and sleep-wake architecture. Studies using knock-out animals and pharmacological manipulations further suggest that DA signaling participates in the

regulation of sleep and wakefulness. Nevertheless, previous studies lacked the spatial and temporal resolutions that are relevant for studying natural sleep/wake events. To decipher the precise role of DA in sleep-wake regulation, we combined optogenetic tools with EEG and EMG recordings in mice. We examined the causal role of DA neuronal activity in the ventral tegmental area (VTA) on cortical activation and sleep-wake dynamics. We focused on DA neurons in the VTA since they send widespread projections throughout the brain, making them particularly suitable for regulating sleep-wake states. To selectively target VTA-DA neurons, we stereotactically injected a Cre-recombinase-dependent adeno-associated virus (AAV) expressing channelrhodopsin 2 (ChR2) into the VTA of mice expressing Cre under the control of the tyrosine hydroxylase (TH) promoter (TH:Cre). As a control, we transduced TH:Cre littermate mice with a Cre-dependent AAV expressing only the fluorescent protein (eYFP). We also implanted the mice with a custom-made EEG-EMG device and a fiber optic cannula. We assessed the effect of optogenetic stimulation (at 1 and 25 Hz) of DA cell bodies and principle projections during the inactive phase on sleep-wake transitions, sleep-wake architecture and EEG power spectra. Our findings show that phasic activation (at 25 Hz) of VTA-DA neurons reliably produced immediate sleep-to-wake transitions and a decrease in slow-wave activity in ChR2 animals, but not in eYFP control mice. These effects were not dependent on sleep pressure. We also found that semi-chronic photostimulation of VTA-DA neurons induced long-term wakefulness. Our results demonstrate a causal role for VTA-DA neurons in promoting wakefulness and identify this neuronal population as a key node in the sleep-wake circuitry.

Title: Regulation of sleep by Neuropeptide Y in zebrafish larvae

Authors: *C. SINGH, C. N. CHIU, V. SAPIN, D. A. PROBER
Div. of Biol., Caltech, Pasadena, CA

Abstract: More than 40 million Americans are affected by chronic sleep disorders costing the nation $100 billion annually. Despite the impact of sleep disorders, the mechanisms that regulate sleep remain poorly understood. Zebrafish is emerging as a powerful model system to study genetic and neural mechanisms that regulate sleep. It offers the advantages of having simple yet conserved neuronal circuits, optical transparency during larval stages and sleep and arousal behaviors that can be monitored using high throughput assays. Neuropeptide Y (NPY) is a 36-amino-acid peptide that is widely distributed in the brain and peripheral sympathetic nervous system. Studies from rodents and humans have shown multiple effects of NPY on sleep ranging from inducing sleep to increasing wakefulness. These discrepancies in the observed effects of NPY may be due to the complex neuronal systems and experimental methods used. We have tested the effects of genetic perturbation of NPY on sleep-wake behaviors in 4-7 days old zebrafish larvae. Overexpression of NPY using a heat shock inducible promoter decreased locomotor activity and increased sleep. To further characterize the NPY neural circuit that mediates this effect, we generated a transgenic line expressing citrine in NPY neurons. We found that NPY is expressed in discreet nuclei in the telencephalon, hypothalamus, tegmentum of the mesencephalon, olfactory pit, rhombencephalon and retina. The optical transparency of zebrafish larvae allows imaging of the entire NPY neural circuit and will aid in investigating interactions between NPY neurons and other sleep-wake regulatory regions. The use of a simple diurnal model system has the potential to clarify the role of NPY in regulating vertebrate sleep/wake states.

Title: Glutamate release in the cortex of the inferior colliculus is correlated with phasic motor activity in sleep

Authors: T. KODAMA[1], K.-C. HSIEH[2], J. M. SIEGEL[3], *Y.-Y. LAI[4]
[1]Tokyo Metropolitan Inst. For Neurosci., Tokyo, Japan; [2]VAGLAHS Sepulveda, North Hills, CA; [3]VAGLAHS Sepulveda/UCLA, North Hills, CA; [4]Psychiatry, UCLA/VAGLAHS Sepulveda, NORTH HILLS, CA

Abstract: The external cortex of the inferior colliculus (ICX) receives afferent projections not only from the auditory pathway, but also from somatic sensory structures including the dorsal column nuclei. The majority of the somatic sensory projections are from the hindlimb (Aitkin et al., 1978). It has been postulated that the ICX plays a role in the integration of auditory and sensory-motor activities. Periodic leg movements (PLMs) have been observed in slow wave sleep in rats with either AMPA or NMDA infusion into the ICX (Hsieh et al., 2013). The PLMs in sleep induced by glutamate agonists infused into the ICX resemble the key behavioral symptom of Willis-Ekbom disease (WED or restless legs syndrome). In this study, we examined whether glutamate release in the ICX correlated with motor activity in sleep in the chronic rat using *in vivo* microdialysis and HPLC analysis techniques. Normal rats and humans show low levels of sleep PLMs. Sprague-Dawley rats weighing 250-500g were implanted with EEGs, nuchal and hindlimb EMGs, and a guide cannula aimed at the ICX. The animals were individually housed in sound-proof chambers with 12-12 light-dark cycles. A microdialysis probe (CMA/11) was inserted into the ICX 12 hours before the start of the experiment. On the day of the experiment, artificial cerebrospinal fluid at a flow rate of 2 µl/min was infused through the probe from ZT2 to ZT11. Twenty microliters of dialysate was collected every 10 min from ZT4 to ZT11. The next day, ICX-glutamate agonist infusion was also performed in all rats after dialysates collection. A total of 96 dialysates was collected from 3 rats, where ICX infusion of glutamate induced PLMs. We found that glutamate levels in the ICX are positively correlated with hindlimb phasic motor activity ($R=0.391$, $p<0.001$) in sleep. A small but significant correlation was also found between glutamate levels in the ICX and neck muscle activity in sleep ($R=0.22$, $p<0.05$). Histological examination showed that all dialysates were collected from the ICX. Conclusion: Glutamate levels in the ICX strongly correlate with hindlimb phasic motor activity in sleep in the normal rat. This correlation may account for the pathological PLM phenomenon seen in rats infused with AMPA or NMDA into the ICX. Abnormal release of glutamate, from peripheral sensory inputs, into the ICX may regulate the pathogenesis of WED.

Title: Orexin receptor antagonists promote both non-rem and rem sleep similar to physiological sleep onset in pre-clinical species

Authors: ***S. V. FOX**[1], P. L. TANNENBAUM[2], A. L. GOTTER[3], S. L. GARSON[3], A. T. SAVITZ[2], J. STEVENS[2], S. D. KUDUK[4], P. J. COLEMAN[4], C. J. WINROW[3], J. J. RENGER[3]
[1]Neurosci., Merck & Co., Inc., WEST POINT, PA; [2]Pharmacol., [3]Neurosci. Biol., [4]Chem., Merck & Co., Inc., West Point, PA

Abstract: INTRODUCTION: Orexin receptor antagonists provide a novel treatment for insomnia by reducing wakefulness and enabling sleep. In clinical trials, dual orexin receptor 1/2 antagonists (DORAs) decrease latency to persistent sleep and promote sleep maintenance in insomnia patients while promoting both non-REM (NREM) and REM sleep. Since insomnia patients exhibit reduced NREM and REM sleep, increasing both NREM and REM is important. Assessing structurally distinct DORAs and selective OX2 receptor antagonists (SORAs) in pre-clinical species is a translatable method for evaluating insomnia therapeutics. Sleep architecture and qEEG effects of DORAs, SORAs and GABAA receptor modulators were compared to that of natural sleep in rats, dogs and monkeys. METHODS: Wireless bio-physiological devices in rats, dogs and monkeys assessed electroencephalogram, electromyogram, electrooculogram (dog & monkey) and locomotor activity 24hr/day in multi-day crossover studies. Sleep architecture parameters were compared between vehicle treatment during the inactive period and novel DORA, SORA or GABAA receptor modulator treatment during the active period (insomnia model). A series of structurally distinct compounds were evaluated. RESULTS: In baseline recordings, both NREM and REM sleep were significantly increased at sleep onset in rats, dogs and monkeys. All compounds promoted NREM sleep when dosed in the active phase, however unlike GABA-A modulators, DORAs and SORAs also increased REM similar to that of baseline sleep onset; there were no generalizable characteristic NREM/REM differences between DORA and SORA sleep. By comparison, benzodiazepine and non-benzodiazepines significantly reduced REM sleep and disrupted qEEG spectral power relative to baseline sleep. CONCLUSION: In nonclinical studies both DORAs and SORAs increase NREM and REM sleep across preclinical species. Given that insomnia patients exhibit decreases in both NREM and REM sleep, therapeutics which restore NREM and REM sleep may be appropriate, and further clinical evaluations would be informative.

Title: Trib2-immunization induces hypocretin/orexin changes

Authors: S. TANAKA, Y. HONDA, K. HONDA, M. HONDA, M. WATANABE, *T. KODAMA
Dept Physiological Psychology, Tokyo Metropol Inst. Med. Sci., Setagaya, Tokyo, Japan

Abstract: Introduction: Autoimmune process is suggested to be involved in narcolepsy. Recent findings showed that 16-26% of narcolepsy patients were positive for anti-TRIB2 antibody and icv administration of IgG purified from sera of narcolepsy patients positive for anti-TRIB2 autoantibody caused marked hypocretin (also called as orexin) producing cell loss. We investigated pathophysiological roles of anti-TRIB2 antibody against hypocretin cells using TRIB2-immunized rats and hypocretin-ataxin3 transgenic mice, which show gradual denature of hypocretin cells. Method: Female Sprague Dawley rats were given every other week the subcutaneous injection of one of the following antigens; keyhole limpet hemocyanin(KLH), KLH conjugated-TRIB2 peptide, or saline. Sera, cerebrospinal fluid(CSF), and hypothalamic tissues were collected to investigate the change of anti-TRIB2 titers, hypocretin contents, mRNA expressions, and histologically determined hypocretin cell counts. The sera from hypocretin-ataxin3 transgenic mice were also used to examine whether anti-TRIB2 antibody increases in the sera during the denature of hypocretin producing cells. Results and Discussion: All the TRIB2-immunized rats, but none of KLH or saline-immunized rats were positive for anti-TRIB2 antibody. TRIB2 antibody titers were slightly increased in CSF of TRIB2-immunized rats (compared with CSF of intact rats). Both chronic TRIB2 and KLH-immunization reduced the hypocretin mRNA synthesis in hypothalamic tissue and hypocretin content in CSF. However, no differences were found in hypothalamic hypocretin contents, hypocretin cell number, and the levels of pro-melanin-concentrating hormone mRNA between TRIB2 and KLH immunized rats. There were no significant correlations between anti-TRIB2 antibody index and above mentioned parameters. Some hypothalamic hypocretin cells were positive for rat IgG in TRIB2-immunized rats. The sera from hypocretin-ataxin3 mice over 24 week-old showed positive reactions against TRIB2 antigen. Our results show that immunization caused the decrease of hypocretin mRNA and CSF hypocretin content regardless of the presence or absence of TRIB2 antigen, suggesting the general immune activation has the effect on the function of hypocretin neurons. Since no change in hypocretin cell number was found even in the immunized-rats showing high titer of anti-TRIB2 antibody in CSF, we assume that factors other than anti-TRIB2 antibody play a part in the loss of hypocretin-producig cells observed in narcolepsy.

Title: Optogenetic dissection of the neural circuitry underlying hypercapnia induced-arousals

Authors: *S. KAUR, D. KROEGER, P. FULLER, C. SAPER
Neurol., Beth Israel Deaconess Med. Ctr. and Harvard M, Boston, MA

Abstract: We have previously reported that glutamatergic signaling from the external lateral parabrachial subnucleus (PBel) regulates cortical arousals to hypercapnia. Anterograde projection patterns of the PBel suggest that these arousals may be mediated through forebrain structures such as the lateral hypothalamic area (LH), central nucleus of the amygdala (CEA), or basal forebrain (BF). However, the specific functions of these pathways in hypercapnic arousals remain unclear. To model cyclic hypercapnia as seen during sleep apnea, we investigated repeated EEG arousals to 10% CO2 given for 30s every 300s (RCA). We used optogenetic inhibition of glutamatergic neurons in the PBel area in one experiment and inhibition of the fiber terminals from PBel projecting to CEA in another, to investigate the role of this projection in regulating hypercapnic arousals. In Vglut2-Cre mice, we injected the PBel area on one side of the brain with Cre dependent adeno-associated virus (AAV) containing archaerhodopsin T (AAV-ArchT) and AAV containing diphtheria toxin subunit A (DTA) on the other side (EXP-1). In a separate set of Vglut2-Cre mice, we injected AAV-ArchT in the PBel area bilaterally and lesioned the CEA on one side using 30nl of 5% ibotenate (IBO)(EXP-2). Both cohorts of mice were also instrumented for sleep recording and implanted with a glass fiber targeting the PBel injected with ArchT in EXP-1 or targeting the CEA on the side contralateral to the IBO lesion in EXP-2. We compared the cortical arousals to RCA in these two cohorts, with and without the 593nm laser light to hyperpolarize the PBel or its terminal field in the CEA. The 60s of laser stimulation started 20s before the onset of 10% CO2 and lasted for 10s after the stimulus. Mice showed normal responses to CO2 (arousal latency: 10±2s) at baseline (with no laser), and they aroused within 30s on every trial (0% failure to arouse). When the 593nm laser light was applied to the PBel injected with ArchT in EXP-1, the mean latency of the response to CO2 increased to 38±10s and in three mice with accurate placement of injection and fiber on one side and deletion of PBel neurons on other, animals failed to arouse in 38% of the trials. In EXP-2, laser illumination of PBel terminals in the CEA containing ArchT (n=2) also delayed arousal to CO2 (arousal latency- 36±0.5s) compared to baseline (16±2s), and animals failed to arouse to CO2 on 26% of trials (compared to 0% with no laser). These results suggest that PBel projections to CEA mediate cortical EEG arousals to hypercapnia. CEA may mediate such arousals via projections to the BF and LH, which then project to the cerebral cortex. However, the roles of PBel projections to LH and BF need further investigation.

Title: Modifying sleep continuity with transcranial direct current stimulation

Authors: ***F. JAHN**[1], S. ZITTEL[1], L. KRONE[1], P. SELHAUSEN[1], L. FRASE[1], H. PIOSCZYK[1], B. FEIGE[1], D. RIEMANN[1], M. NITSCHE[2], C. NISSEN[1]
[1]Univ. Med. Ctr., Freiburg, Germany; [2]Univ. Med. Ctr., Göttingen, Germany

Abstract: Objective The tDCS (transcranial direct current stimulation) has proven to induce local changes in cortical activity and the local frontal cortex areas are substantially involved in the top-down sleep regulation. It therefore seems logically consistent that excitability dependent sleep parameters can be modified by tDCS. The underlying hypothesis was that periodical bilateral prefrontal anodal stimulation leads to a boost in cerebral excitability and arousals and disturbs sleep continuity whereas cathodal stimulation in the same region causes the reverse effect. Furthermore, it is evident that sleep contributes to the long-term consolidation of new memories. In addition to the sleep parameters, we observed how tDCS provoked modifications affect the declarative and the procedural memory. Methods In our randomized controlled study, we examined 18 healthy subjects (7 men, aged 40-65 years) for a total of 5 nights each in a sleep laboratory. After one night of adaption and one baseline night, the individuals were stimulated with tDCS immediately prior to polysomnographically monitored sleep. The stimulation protocol was composed of anodal-activating, cathodal-deactivating and placebo stimulation in a counterbalanced order. Each intervention was separated by an interval of 7 days. We performed the stimulation with 2mA current strength for 2x 9 minutes (cathodal) respectively 13 minutes (anodal) and an interstimulus interval of 20 minutes. Previous studies have shown that this protocol induces long-lasting aftereffects lasting up to several hours after the stimulation. Before undergoing the stimulation protocol, the subjects had to do one declarative and one procedural memory task. These were then repeated the next morning. We examined how diverse sleep parameters and memory consolidation changed according to the different stimulation conditions. Results The analysis of our data indicated significant polarity dependent effects of the stimulation. In essence, we observed important diminutions in total sleep time (27.6 minutes on

average) and sleep efficiency (5.6 percent on average) in the anodal condition (activation) compared to the cathodal (deactivation) condition. In contrast, we did not find any significant differences between the conditions concerning the memory tasks. Conclusion The results of this study provide a proof-of-concept that the change of prefrontal cortical activity has strong effects on regulatory circuits affecting sleep continuity. These results might be substantial for a better understanding of sleep regulation and for the development of new treatments for patients with sleep disturbances.

Title: Modulating sleep in a human model for cortical hyperarousal by transcranial direct current stimulation

Authors: *P. SELHAUSEN[1], S. ZITTEL[1], F. JAHN[1], L. KRONE[1], L. FRASE[1], H. PIOSCZYK[1], B. FEIGE[1], M. NITSCHE[2], D. RIEMANN[1], C. NISSEN[1]
[1]Univ. Med. Ctr., Freiburg, Germany; [2]Univ. Med. Sch., Goettingen, Germany

Abstract: Objective The regulation of sleep onset and maintenance is a complex process. Several regulatory brain circuits have been identified, including prefrontal corticothalamic feedback loops. Dysfunctions in one or more of those circuits might lead to an insomnia spectrum disorder. The ‘hyperarousal model of insomnia’ postulates an increased state of arousal leading to a disturbance of sleep onset and continuity. This arousal has been demonstrated to go along with an increased cerebral metabolism and accelerated rhythms in electroencephalography. In accordance with the ‘hyperarousal model of insomnia’ patients with primary insomnia (PI) can be seen as a human model for cortical hyperarousal. Transcranial direct current stimulation (tDCS) has been shown to be able to modify excitability in the prefrontal cortex and to modulate resting-state activity. The aim of this study is to answer the question whether modifying the cortical excitability in the prefrontal cortex via bilateral tDCS in patients with PI as a human model for cortical hyperarousal leads to a change in sleep parameters. The hypothesis is that

prefrontal anodal stimulation leads to an increase in excitability and arousal thereby disturbing sleep continuity whereas cathodal stimulation over the same region might improve the patients' disturbed sleep. **Methods** 19 patients with PI (13 females, aged 20-61 yrs) are being included. After an adaptation night, each subject undergoes a baseline polysomnography and three experimental sleep laboratory nights with a tDCS protocol immediately prior to polysomnographically monitored sleep. Three different conditions, anodal, cathodal and sham stimulation, are being applied in a counterbalanced order. **Results** A first analysis of our pilot data of N=6 subjects has not shown significant differences in our main outcome parameters sleep latency, total sleep time or sleep efficiency between the three different stimulation-conditions. The explorative data analysis revealed a significant effect in the rapid eye movement (REM) sleep-density. This has shown to be significantly denser after cathodal stimulation compared to anodal or sham stimulation. **Conclusion** The lack of significant results in our main outcome parameters so far might be a problem of low statistical power (N=6). Another possible explanation is that the hyperarousal overlies the modulating effects of tDCS. However, the significant effect in REM sleep-density shows that modulation of sleep by tDCS might be possible even in the state of cortical hyperarousal. The study will be completed in May 2014. At the annual meeting in November, a full analysis of the data of N=19 subjects will be presented.

Title: Modulation of sleep by transcranial direct current stimulation as an area-specific effect

Authors: *L. KRONE[1], S. ZITTEL[1], P. SELHAUSEN[1], F. JAHN[1], L. FRASE[1], H. PIOSCZYK[1], B. FEIGE[1], M. NITSCHE[2], D. RIEMANN[1], C. NISSEN[1]
[1]Univ. Med. Ctr., Freiburg, Germany; [2]Clin. Neurophysiol., Univ. Med. Sch., Goettingen, Germany

Abstract: Objective Corticothalamic feedback loops are supposed to be substantially involved in the initiation and maintenance of non-rapid eye movement (NREM) sleep, representing a 'top-

down' pathway of sleep regulation, which interacts with the 'bottom-up' pathway of the brainstem arousal system. In a pilot study, periodical application of transcranial direct current stimulation (tDCS) to prefrontal cortical areas resulted in a difference of 27.6 minutes total sleep time ($p < 0.01$) when anodal (activating) stimulation was compared to cathodal (deactivating) stimulation. In this study we investigated whether the effect of tDCS on sleep regulation is location-specific for stimulation of the prefrontal cortex. **Methods** We applied the standardized stimulation protocol (2mA, 2 x 9 min. cathodal, 2 x 13 min. anodal) to the parietal cortex of 10 healthy subjects in a randomized crossover design and compared the results to our initial group, which had undergone prefrontal stimulation. **Results** In contrast to prefrontal stimulation, parietal stimulation did not yield any significant effects. **Conclusion** This result strongly supports the hypothesis that sleep-modifying effects of tDCS are based on a modulation of specific corticothalamic feedback loops between the prefrontal cortex and thalamus. **Figure 1: Modulation of corticothalamic sleep regulation by transcranial direct current stimulation** [A] During NREM sleep prefrontal areas promote the functional disconnection of thalamus and cortex. Reticular thalamic (RE) neurons are activated and suppress transduction of information in thalamocortical (TC) neurons. [B] Anodal (activating) transcranial direct current stimulation of prefrontal areas disturbs physiological sleep regulation and enhances cortical activation via TC neurons.

Title: Orexin projections control locus coeruleus activity

Authors: *L. FERRARI, D. PARK, L. J. AGOSTINELLI, T. E. SCAMMELL, E. ARRIGONI
Neurol., Beth Israel Deaconess Med. Ctr. - Harvard Med. Sch., Boston, MA

Abstract: The orexin neurons play an essential role in driving arousal and maintaining normal wakefulness. Lack of orexin neurotransmission results in narcolepsy, with excessive sleepiness, frequent transitions between wakefulness and sleep, and episodes of cataplexy. Orexin neurons innervate and excite all the major arousal centers including the locus coeruleus (LC) neurons. Orexin neurons produce orexin-A and B, glutamate and dynorphin but the dynamics of their release are still unclear. We used channelrhodopsin-2 (ChR2)-assisted-circuit-mapping (CRACM) in *in vitro* brain slices to examine the input from orexin neurons to the LC. To express ChR2 in orexin neurons, we used an adeno-associated viral (AAV) vector coding for cre-dependent ChR2-YFP (AAV-Flex-ChR2(H134R)-YFP) in Dyn-ires-cre mice. We microinjected the AAV-ChR2-YFP into the perifornical region where the only neurons expressing dynorphin are the orexin population. Four to six weeks after these injections, we recorded LC neurons in whole-cell configuration. We identified LC neurons based on their anatomical location and electrophysiological fingerprint. We stimulated ChR2-expressing axons and terminals using 5-ms pulses of blue-light (473 nm). Photostimulation of orexin terminals evoked short latency (6.84 ± 0.6 ms) excitatory postsynaptic currents (EPSCs) in noradrenergic LC neurons. These photo-evoked EPSCs were abolished by DNQX, indicating that they were mediated by postsynaptic AMPA receptors. Photostimulation with a 10 sec train (10Hz) of 5 ms pulses, rapidly depressed the photoevoked EPSCs and was accompanied by a slow inward current compatible with orexin signaling. The frequency of asynchronous EPSCs was increased during and after the photostimulation train, indicating short-term synaptic facilitation. These results suggest that the orexin neurons directly activate the LC neurons through the release of glutamate, and in addition, orexin peptides can elevate LC excitability by increasing heterosynaptic glutamatergic afferent input to the LC neurons. These responses may provide a synergistic mechanism through which orexin neurons act upon the LC to promote wakefulness and improve cognitive performance.

Title: Pumilio regulates the sleep homeostatic response to chronic sleep deprivation in *Drosophila* melanogaster

Authors: *L. DE JESUS[1], N. RODRIGUEZ[2], C. PACHECO[2], J. ORTEGA[2], H. RODRIGUEZ[2], G. DIAZ[2], F. RIVERA[2], M. REYES[2], E. RIVERA[2], J. ALEMAN-RIOS[2], A. AVALOS[2], J. L. AGOSTO-RIVERA[2]
[1]Biol., Univ. of Puerto Rico, San Juan, Puerto Rico; [2]Univ. of Puerto Rico, Rio Piedras, Puerto Rico

Abstract: *Drosophila melanogaster* has been extensively used as a model system for sleep studies. Although much is known about the circadian regulation of sleep, the mechanisms underlying sleep homeostasis and its relationship with the circadian system remains largely unknown. Previously, our lab has generated data indicating that during chronic sleep deprivation, *Drosophila* exhibits a progressive increase in sleep over time, despite the continuous presence of a sleep depriving stimulus. RNAi knockdown of the neuronal homeostasis gene *pumilio*, using the timeless-Gal 4 driver, resulted in a reduction of the sleep recovery rate. Conversely, *pumilio* overexpression increases the sleep recovery rate. Furthermore, the sleep rebound normally observed after deprivation is abolished by *pumilio* knockdown. These findings suggest that *pumilio* is involved in promoting sleep drive. Given the role of *pumilio* in cellular homeostasis processes, our data suggests that mechanisms of cellular homeostasis in the circadian system, are linked to sleep homeostasis.

Title: Discovery of a neuropeptide signaling pathway that regulates sleep/wake behavior in zebrafish

Authors: *C. N. CHIU[1], J. RIHEL[2], E. A. MOSSER[1], D. A. LEE[1], C. SINGH[1], S. CHAKRAVARTHY[1], A. F. SCHIER[3], D. A. PROBER[1]
[1]Caltech, Pasadena, CA; [2]Univ. Col. London, London, United Kingdom; [3]Harvard, Cambridge, MA

Abstract: The discovery of the neuropeptide hypocretin's role in sleep and sleep disorders was a major breakthrough in sleep research. This finding underscored the potential advances that can be made by using genetics to discover new regulators of sleep. However, few molecular regulators of sleep have been discovered since. To identify genes that regulate vertebrate sleep, we performed a genetic overexpression screen using a high-throughput larval zebrafish locomotor activity assay. We found that overexpression of neuromedin U (NMU) dramatically increased locomotor activity and decreased sleep during both the day and night. To identify the signaling pathways that mediate this phenotype, we mutated the zebrafish orthologs of the two mammalian NMU receptors. We found that NMUR2, which is primarily expressed in the central nervous system, and not NMUR1, which is predominantly expressed peripherally, is required for NMU-induced arousal. We also found that inhibiting NMUR2 using a small molecule antagonist disrupts sleep/wake architecture by causing fragmented waking and frequent transitions to sleep. Previous studies hypothesized that NMU promotes behaviors associated with stress via the hypothalamic-pituitary-adrenal (HPA) axis, which is initiated by hypothalamic corticotropin-releasing hormone (CRH) signaling and ultimately stimulates adrenal production of glucocorticoids. We found that the NMU overexpression phenotype persists in zebrafish glucocorticoid receptor mutant larvae, suggesting that the HPA axis does not mediate NMU-induced arousal. Instead, we found that NMU overexpressions activates crh-expressing neurons in the rostral brainstem. These cells may be analogous to mammalian brainstem CRH populations in the locus coeruleus (LC) and pedunculopontine tegmental nucleus (PPT) which play an important role in sleep/wake regulation. Taken together, our data identify a role for NMU in regulating sleep/wake behaviors and suggest that the relevant effectors are arousal systems in the brainstem rather than classical HPA axis in the periphery.

Title: The effects of combined lithium and ethanol treatment on the behavioral circadian activity rhythm

Authors: *J. A. SEGGIO, K. CARLSON, N. NASCIMENTO, D. AMARAL, D. PYNE, G. NASH
Biol. Sci., Bridgewater State Univ., Bridgewater, MA

Abstract: Lithium has been traditionally used to treat Bipolar disorder among other psychiatric disorders that have been linked to disruptions in the circadian rhythm. Numerous studies have shown that lithium treatment produces period lengthening and amplifies expression of per2. Conversely, ethanol drinking has been shown to produce period shortening and reductions in per2 expression. In addition, ethanol drinking also blunts the phase-shifting effects of light pulses. Thus, this investigation aims to uncover the effects of combined ethanol and lithium treatment on the period and phase of the circadian rhythm. All B6 mice were placed into DD for 3-weeks with water only; after the initial 3-weeks, mice were given one of four drinking solutions: water, 10 mM LiCL, 10%-ethanol, or a combination of lithium and ethanol, and were allowed additional 3-weeks in DD. In addition, light pulses at ZT 15 and ZT 21 were conducted to determine if lithium can prevent ethanol's blunting of photic phase responses. As expected, lithium significantly increased the period, while alcohol produced a small but non-significant decrease in the period. When combined ethanol/lithium solution was given, it produced similar free-running periods to control mice. Additionally, ethanol produced reductions in photic phase shifting, but when lithium was given with ethanol, the combined effect produced phase shifts similar to water controls. The combined lithium/ethanol group drank significantly less fluid than the lithium, ethanol, and water groups, indicating that lithium treatment can be used as a mechanism for decreased ethanol intake, and thus, reducing the effects of both drugs on the circadian clock. These results may also indicate that lithium and ethanol may be affecting the same clock mechanisms and having opposite effects.

Title: Rapid eye movement sleep induction and maintenance by gabaergic neurons in the ventral medulla

Authors: ***F. WEBER**[1], S. CHUNG[1], M. XU[1], Y. DAN[1,2]
[1]Dept. of Mol. and Cell Biol., UC Berkeley, Berkeley, CA; [2]Howard Hughes Med. Inst., Berkeley, CA

Abstract: Rapid eye movement (REM) sleep is characterized by activation of the cortical and hippocampal electroencephalogram (EEG) and concomitant muscle atonia. Here, we demonstrate the role of the ventral medulla GABAergic neurons in inducing and maintaining REM sleep. To test how the activity of these neurons influences sleep, we recorded the EEG and nuchal electromyogram (EMG) in freely moving mice, while optogenetically activating the ventral medulla. Optogenetic stimulation of GABAergic neurons in the ventral medulla during Non-REM sleep reliably induces REM sleep and strongly increases the duration of REM sleep periods. Using optetrodes (tetrodes coupled to an optical fiber) we recorded GABAergic medullary neurons in freely moving mice. Most GABAergic neurons exhibited highest firing rates during REM sleep. Finally, to unravel regions providing input to the REM-inducing GABAergic neurons in the ventral medulla, we applied a monosynaptically restricted, trans-synaptic rabies virus tool. Our experiments combining optogenetics and electrophysiology in freely moving mice provide strong evidence that GABAergic neurons in the ventral medulla are causally involved in the induction and maintenance of REM sleep.

Title: Gabaergic parafacial zone neurons are necessary for the expression of normal slow-wave-sleep

Authors: *C. ANACLET, L. FERRARI, E. ARRIGONI, P. FULLER
BIDMC Harvard, BOSTON, MA

Abstract: We have previously reported that acute and selective activation of GABAergic parafacial zone (PZ) neurons is sufficient to produce slow wave sleep (SWS) and cortical slow wave activity (SWA), independent of the time of day. Using optogenetic-based mapping we have further established the presence of a functional synaptic PZ◊parabrachial nucleus◊basal forebrain◊cortex pathway through which GABAergic PZ neurons can potently drive SWS and modulate the cortical EEG. It however remains unclear if GABAergic PZ neurons are necessary for the expression of normal SWS and cortical SWA or, rather, are functionally redundant to the forebrain sleep-promoting ventrolateral preoptic nucleus (VLPO). To investigate whether GABAergic PZ neurons are necessary for the expression of normal SWS and cortical SWA, we placed small bilateral injections of an adeno-associated viral (AAV) vector containing a cre-enabled inhibitory receptor system [hM4Di-AAV10] into the PZ of Vgat-IRES-cre mice. Ligand (CNO, 0.3mg/kg, IP), but not vehicle, injections at ZT3 - a time of high sleep drive in the mouse - produced a significant increase in wake in mice expressing inhibitory hM4Di receptor in PZ GABAergic neurons. The waking response, observed during acute and selective inhibition of PZ GABAergic neurons, is the opposite of what we observed following acute activation of GABAergic PZ neurons. CNO injections were without effect on the waking cortical EEG power spectrum. These results recapitulate the effects produced by genetic-driven PZ lesions in mice and provide convincing evidence that GABAergic PZ neurons are necessary for the expression of normal SWS amounts in behaving mice and are not functionally redundant in their sleep-promoting properties to forebrain VLPO neurons. Title: The sleep promoting effect of DORA-12 is sex dependent in rats

Authors: *J. A. MONG, D. M. CUSMANO
Univ. Maryland, Sch. Med., BALTIMORE, MD

Abstract: Sleep disruptions are more commonly reported in women and typically coincide with periods of hormonal fluctuation. We have previously shown in rats that estradiol (E2) suppresses sleep in females and that sex differences in sleep are due to activational effects of E2 on sexually differentiated circuitry. Masculinization of the brain renders sleep behavior in males and masculinized females insensitive to the suppressive effects of E2. We have identified the median preoptic nucleus (MnPN) as a key site of E2 action. The MnPN is a sleep-promoting region that sends inhibitory projections to arousal nuclei like the lateral hypothalamus (LH). E2 reduces the activation of sleep-associated MnPN neuron and antagonism of estrogen receptors within the MnPN attenuates the E2-mediated suppression of sleep. Orexinergic neurons in the LH are regulated by MnPN activity and orexin is a key neuropeptide involved in arousal. Prepro-orexin mRNA expression is sexually dimorphic in the hypothalamus; females have higher levels compared to males. Circulating levels of gonadal steroids also modulate expression of orexin and its receptors. Thus, we hypothesize that orexin is the mediator of E2's suppressive effects on sleep. To test, we administered a dual orexin receptor antagonist (DORA-12, gift from Merck) in the presence or absence of E2. If orexin mediates E2's suppression of sleep, then we predict that antagonism of orexin receptors will attenuate E2's effect. Additionally, due to the sex difference in prepro-orexin mRNA and steroidal modulation of receptor expression, we predict that sleep promotion by DORA-12 will be sex and E2 dependent. Gonadectomized female and intact male rats were randomly assigned to DORA-12 or vehicle (VEH) groups. DORA-12 (30mg/kg) or VEH was given orally prior to lights out (ZT12) each day. Females received an oil injection and then two doses (5µg and 10µg) of E2 benzoate 24hrs apart at ZT21, while males received only oil injections. In females, DORA-12 significantly reduced wake and promoted sleep, but it did not block the suppression of total sleep by E2. The percent change in each vigilance state induced by E2 is not significantly different between VEH and DORA-12 treated females. DORA-12's sleep-promoting effect in females is greater than in males. In males, DORA-12 significantly suppressed wake 3-4hr post-administration. Wake suppression in females was steady across the 12hr dark phase following DORA-12 administration. Sex differences in sleep circuitry and/or drug metabolism may contribute to increased sleep promotion in females. We are

currently exploring this hypothesis by testing the metabolism of DORA-12 in males and oil/E2 treated females.

Title: Real-time sensing of glutamate in the basolateral amygdala (BLA) in the rat brain across sleep-wake states

Authors: *L. D. SANFORD[1], M. H. KIM[2], L. L. WELLMAN[1], H. YOON[2]
[1]Div. of Anat, Dept of Pathol & Anat, Eastern Virginia Med. Sch., NORFOLK, VA; [2]Engin. Dept., Norfolk State Univ., Norfolk, VA

Abstract: Evolving research demonstrates that the BLA can be a significant modulator of sleep and that it regulates the association between fear behavior, fear memories and sleep. Eighty percent or more of the neurons in BLA are phenotypically glutamatergic and, not surprisingly, glutamate has been a focus in studies of the amygdala and its role in the acquisition and storage of fear memory as well as in regulating sleep. As part of an effort to understand the role of BLA in regulating sleep, we used biosensors to examine glutamate release during spontaneous sleep and wakefulness. Four rats were implanted with cannula aimed into BLA and with telemetry transmitters to allow assessment of arousal state and allowed to recover. For recording, a glutamate biosensor (Pinnacle Technology, #7011) was slowly inserted into the pre-implanted cannula. These are glutamate oxidase (GluOx)-coated biosensors that allow virtual real-time detection of changes in extracellular glutamate levels. The biosensor was calibrated prior to insertion and after recording using glutamate and ascorbic acid in temperature controlled PBS. After a minimum of two hours to allow the signal to stabilize, recordings were made concurrently with spontaneous changes in sleep and wakefulness. All glutamate recordings were

made with a CH Instruments 760D potentiostat connected to the biosensor via a custom cable and PlasticsOne commutator to allow the rats free movement. The amplitude variation of measured currents across changes in arousal and sleep ranged between 0.04 nA to 0.07 nA for wakefulness, non-rapid eye movement sleep (NREM) and rapid eye movement sleep (REM), which corresponds to 51 nM ~ 89 nM concentration changes relative to the pre-calibration data. There was a clear association between changes in glutamate level in the BLA and changes in EEG associated with wake and sleep stages based on current increases during wakefulness and REM relative to levels in NREM. Thus, this work demonstrates changes in extracellular glutamate activity that are linked to changes in arousal states. Future work will be required to determine whether these changes are important for initiating changes in sleep and wakefulness.

Title: Analyzing sleep/wake architecture in mice with progressive orexin/hypocretin cell loss

Authors: A. F. BRANCH[1], W. NAVIDI[1], S. TABUCHI[2], A. YAMANAKA[2], T. E. SCAMMELL[3], *C. DINIZ BEHN[1]
[1]Dept. of Applied Math and Statistics, Colorado Sch. of Mines, Golden, CO; [2]Res. Inst. of Envrn. Med., Nagoya Univ., Nagoya, Japan; [3]Dept. of Neurol., Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: The orexin (also known as hypocretin) neurons are important for consolidating sleep/wake behavior, and loss of these cells is associated with the sleep disorder narcolepsy. The recent development of a rodent model utilizing the controlled expression of diphtheria toxin A in orexin neurons provides an opportunity to assess changes in sleep/wake architecture during progressive orexin neurodegeneration over the course of weeks. Disrupted sleep/wake architecture has been reported in these animals; however, the specifics of this disruption have not

been described. We analyzed scored sleep/wake data in these mice to quantify the changes in sleep/wake architecture associated with orexin cell loss and to investigate the implication of these changes for orexin function. Survival analysis of bouts of wake, rapid eye movement (REM) sleep, and non-REM (NREM) sleep durations showed a dose-dependent progression to the narcolepsy phenotype with putative orexin cell loss. Analysis of the hazard rates for wake bouts suggests a role for orexin in sustaining long periods of wakefulness. However, for wake bouts less than ~1.5 min, the hazard rate was lower in animals with orexin neurodegeneration, indicating that orexin may not contribute to sustaining brief wake bouts. For NREM sleep bouts, the hazard rate was consistently higher in animals with orexin neurodegeneration. In addition, progressive orexin cell loss was associated with dose-dependent attenuation in several measures of light/dark differences, thus supporting a role for orexin neurons in relaying circadian modulation of sleep/wake behavior.

Title: Selective tracing of descending basal forebrain projections

Authors: ***L. J. AGOSTINELLI**[1], T. E. SCAMMELL[2,3]
[2]Neurol., [1]Beth Israel Deaconess Med. Ctr., Boston, MA; [3]Harvard Med. Sch., Boston, MA

Abstract: Neurons of the basal forebrain (BF) project to the cortex to promote cortical activation and behavioral arousal, and this ascending pathway has been heavily studied. However, the BF also innervates many subcortical regions. Additionally, the BF is neurochemically heterogenous, and conventional tracing methods have limited our ability to map neurochemically specific projections. To further characterize and map these descending projections, we used conditional anterograde tracing of BF neurons producing acetylcholine, GABA, or glutamate to examine BF projections to subcortical regions. Using mice that express Cre recombinase selectively in GABA (vGAT-Cre), glutamate (vGlutT2-Cre), or acetylcholine (ChAT-Cre) neurons, we

microinjected the BF with an adeno-associated viral vector (AAV) coding for a Cre-dependent red fluorescent protein (mCherry). To examine how projections varied across the BF, we targeted several parts of the BF, including the substantia innominata, diagonal band, etc. Four weeks later, we double immunolabeled sections for mCherry and ChAT, vGlutT2 or vGAT and mapped the innervation of specific descending targets. This method produced robust and selective anterograde labeling in GABA, glutamate, or ACh BF neurons. *In situ* hybridization and immunolabeling confirmed that mCherry expression was limited to the correct cell types. GABAergic and glutamatergic BF neurons robustly innervated many similar targets such as the medial amygdala, lateral hypothalamus, supramammillary area, parasubthalamic nucleus, ventral tegmental area, substantia nigra pars compacta, dorsal and median raphe, lateral periaqueductal gray, and midbrain reticular formation. The lateral habenula was exclusively and intensely innervated by glutamatergic BF neurons, while the central medial amydgala was exclusively innervated by the GABAergic BF neurons. Cholinergic BF neurons heavily innervated the basolateral amygdala, but otherwise their descending projections were more limited than the GABAergic and glutamatergic projections. In addition, more caudal regions of the BF such as the substantia innominata had stronger descending projections than more rostral parts of the BF. These descending projections from the BF may play important roles in regulating and coordinating the activity of arousal networks.

Title: Distribution of terminals originating in pontine noradrenergic A6 (locus coeruleus), A7 and subcoeruleus neurons in the medullary viscerosensory nucleus of the solitary tract and hypoglossal motor nucleus

Authors: *L. KUBIN, K. BENINCASA HERR, C. D. HESKETH, D. V. VOLGIN, G. L. MANN
Dept. of Animal Biol., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Pontine noradrenergic neurons (PNN) have widespread and divergent projections and characteristically high activity during wakefulness, reduced activity during slow-wave sleep and no activity during rapid eye movement sleep. Although PPN aggregate into distinct groups, these features suggest that all PNN belong to one system whose purpose is to modulate activity throughout the CNS in a state-dependent manner. However, noradrenergic terminal density varies greatly among different brain regions, and retrograde tracing studies indicate that different groups of PNN project to different targets, suggesting some heterogeneity. We previously reported that the hypoglossal motor nucleus (XII) receives axonal projections from the pontine A5, A7 and subcoeruleus (subC) neurons, whereas projections to the adjacent viscerosensory nucleus of the solitary tract (NTS) originate in the A5 and A6 groups and to a much lesser extent in A7 or subC (Rukhadze & Kubin, J. Chem. Neuroanat. 2007). To further elucidate the anatomical basis of these differences, we now investigate the termination patterns of PNN in the XII and NTS using anterograde tracing in Long-Evans rats designed to express Cre element in tyrosine hydroxylase (TH)-synthesizing neurons. In four rats, we injected 100-400 nl of adeno-associated viral vector containing Cre-dependent, double-floxed sequences for channel rhodopsin-2 and enhanced yellow fluorescent protein (EYFP) into the dorsolateral pons. After 29-64 days, the animals were perfused and fluorescent double-labeling revealed strong expression of EYFP in TH-positive A7 and subC neurons in all animals, with additional labeling of A6 neurons in one animal. EYFP was then revealed in medullary sections using Ni-enhanced horseradish peroxidase reaction to visualize fine noradrenergic terminals in the XII and NTS. When all noradrenergic terminals are labeled regardless of their cellular origin, their density is higher in the NTS than in XII and within XII they are most dense in its ventromedial quadrant. In contrast, following selective labeling of terminals originating in A7 and subC only, we observed a similar noradrenergic terminal density in NTS and all parts of XII. This suggests that the characteristic differences in noradrenergic terminal density between the NTS and XII and within the XII are caused by noradrenergic projections from other noradrenergic groups whereas A7 and subC contribute a relatively uniform density of noradrenergic innervation to both nuclei. This is consistent with A7 and subC mediating diffusely distributed, state-dependent noradrenergic modulation in functionally distinct regions.

Title: Electrical stimulation of the parabrachial nucleus induces reanimation from general anesthesia

Authors: *F. MUINDI[1], C. J. VAN DORT[1,2], J. KENNY[2], N. TAYLOR[2], K. SOLT[2], M. WILSON[1], E. N. BROWN[1,2]

Abstract: Background: The parabrachial nucleus (PBN) has been shown to play an important role in promoting arousal. Here, we tested whether electrical stimulation of the PBN is sufficient to induce reanimation (active emergence) from isoflurane general anesthesia. **Methods:** Mice were implanted with electroencephalogram/electromyogram (EEG/EMG) electrodes and also with a single bipolar insulated stainless steel electrode into the PBN (n=8) or the central inferior colliculus (n=7) (control area). After a minimum 7-day recovery period, a dose (0.9% ± 0.1 vol%) sufficient to maintain loss of righting was used. Electrical stimulation (30 seconds in length) was initiated from 30 μA and increased in intensity every 30 μA until the righting reflex was restored. All stimulations occurred during continuous isoflurane anesthesia. **Results:** In 5 of 8 mice, electrical stimulation of the PBN at 60 μA at 100 Hz rapidly induced behavioral arousal (kicking, clawing and lifting the head) and ultimately caused the restoration of the righting reflex during continuous isoflurance general anesthesia. In contrast, the same stimulation in the central inferior colliculus did not cause restoration of the righting reflex. Spectral analysis of EEG recordings revealed that the stimulation produced a significant decrease in EEG power in the delta (<4 Hz) range during PBN stimulations. **Conclusions**: Electrical stimulation of the PBN, but not the central inferior colliculus, is sufficient to induce reanimation during general anesthesia with isoflurane. These results suggest that the PBN may be used to accelerate recovery from general anesthesia and ameliorate anesthesia-related cognitive dysfunction.

Title: Common brain activity patterns during perception, imagery, and dreaming

Authors: *T. HORIKAWA[1], Y. HOSOKAWA[2,1], Y. KAMITANI[1]
[1]ATR, Kyoto, Japan; [2]NAIST, Nara, Japan

Abstract: Dreaming often accompanies visual experience, which appears to be phenomenally similar to stimulus-induced perception, and also to top-down mental imagery. It has been debated whether the neural mechanism underlying dreaming is perception-like or imagery-like. Our previous study (Horikawa et al., 2013) has shown that visual dream contents (object categories) can be predicted from fMRI activity patterns in the visual cortex during sleep by machine-learning decoders trained on brain activity induced by stimulus images containing objects. This “perception-to-dream” decoding indicates that perception and dreaming share neural representations of visual contents. Here we extend this approach to investigate the commonality and difference of neural representations between perception, imagery, and dreaming in brain areas known to be responsive to perception and/or imagery tasks. In addition to decoders trained on stimulus-induced brain activity (perception-trained decoders), we used decoders trained on brain activity during a task in which subjects visually imagined objects (imagery-trained decoders), to predict dreamed objects from brain activity during sleep. We found that the overall accuracies for the decoding of dreamed objects were comparable between the perception-trained decoders and the imagery-trained decoders. Interestingly, the perception-trained decoders outperformed the imagery-trained decoders in relatively lower-level areas, the ventral visual cortex and inferior parietal cortex, while the imagery-trained decoders outperformed the perception-trained decoders in higher-level areas, the dorsolateral prefrontal cortex and hippocampus. These results suggest that dreaming shares neural representations with perception and imagery in multiple brain areas with greater similarity to perception and imagery in lower and higher areas, respectively. Thus, the neural representation of dreaming may not be unilaterally perception-like or imagery-like, but consist of a unique mixture of perception-like and imagery-like brain states.

Title: Recovery of high-level visual functions in patients with lobectomy or hemispherectomy

Authors: *A. NESTOR[1], T. LIU[2], D. C. PLAUT[2], C. PATTERSON[3], M. BEHRMANN[2]
[1]Univ. of Toronto Scarborough, Toronto, ON, Canada; [2]Carnegie Mellon Univ., Pittsburgh, PA; [3]Children's Hosp. of Pittsburgh of UPMC, Pittsburgh, PA

Abstract: The recovery of perceptual functions that occur following cortical damage can offer key insights into the nature and plasticity of brain organization. In this respect, studies of individuals post-lobectomy/hemispherectomy offer a unique window into the nature and extent of cortical plasticity. First, in contrast with more common lesions, the extent of the damage in such patients can be extreme (i.e. an entire hemisphere in some cases) yet, at the same time, very well controlled - both cortical and subcortical structures of the remaining hemisphere are typically intact. Second, the extent of the recovery is often disproportionate relative to the extent of the damage - many compromised functions are regained partly or even completely. Our present work examines the neural basis of visual recovery in a population of children who have undergone surgical lobectomy or hemispherectomy of ventral cortex in either hemisphere. An fMRI investigation of high-level visual functions focused on cortical mapping of face, object and word form recognition. This investigation revealed more restricted activation to objects in the spared hemisphere of our patients relative to matched controls. In contrast, faces tended to elicit more extensive activation in the spared hemisphere of the patients relative to their controls. A further examination of language processing, including visual word forms, produced comparable selectivity maps across patients and controls. Overall, the current results suggest that basic compensatory mechanisms can underlie visual recovery (e.g., for the purpose of face recognition) but also that such mechanisms do not account for the full extent of the recovery (e.g., for language processing).

Title: Energy landscape of human brain activity during bistable perception

Authors: *T. WATANABE[1], N. MASUDA[2], F. MEGUMI[1], R. KANAI[3], G. REES[1]
[1]Inst. of Cognitive Neuroscience, Univ. Col. London, London, United Kingdom; [2]Dept. of Engin. Mathematics, Univ. of Bristol, Bristol, United Kingdom; [3]Ctr. for Consciousness Science, Sch. of Psychology, Univ. of Sussex, Brighton, United Kingdom

Abstract: Inter-individual variability in the structure of parietal and prefrontal cortex is highly correlated with the stability of bistable visual perception. Despite this well-known observation, the mechanisms bridging the gap between the brain structures and behaviour remain elusive. In the present study, we found such a link by characterising the energy landscapes of brain activity during bistable perception. By applying a pairwise maximum entropy model to fMRI signals recorded from human seeing a structure-from-motion stimulus, we found that the dynamics of brain activity during bistable perception could be described as fluctuating between three spatially distributed energy minima: visual-area dominant, frontal-area dominant, and intermediate states. For each participant, the transitions between these energy states well predicted behaviour: participants whose brain activity tended to be in the visual-area dominant state experienced more stable perception, whereas those whose activity transited to the frontal-area-dominant state reported more frequent perceptual switches. Moreover, these tendencies of brain activity dynamics were well correlated with inter-individual variability in grey matter volume of the focal cortical areas. These findings suggest that the dynamics of brain activity determined by the features of the energy landscape link individual differences in brain anatomy and subjective visual experience.

Title: Functional differences in processing preferred and non-preferred stimuli at object selective areas

Authors: ***U.-S. CHOI**[1], Y.-W. SUNG[2], Y.-B. KIM[1], Z.-H. CHO[1], H. YOON[3], S. OGAWA[2]
[1]Neurosci. Res. Institute, Gachon Univ. of Med. and Sci., Inchoen, Korea, Republic of; [2]Kansei Fukushi Res. Inst., Sendai, Japan; [3]Dept. of Art Therapy, Daegu, Korea, Republic of

Abstract: Some high-level visual areas show category-selectivity. Fusiform face area (FFA) is known specialized for face processing and Parahippocampal place area (PPA) for scene/building processing. In this study we investigated how a non-preferred stimulus affects to the response to a preferred stimulus through functional MRI (fMRI) responses in FFA and PPA evoked by a composite picture. The composite picture was made of a face picture imbedded into the center of a scene picture. The face in the composite picture was made sufficiently small (less than four degrees of visual angle) so that the perception of the scene was not disturbed by the face. The scene picture was large enough to cover the visual field of twenty eight by twenty one degrees. Three kinds of stimuli, composite, face-only and whole scene (scene-only) pictures, were used. The response in FFA to the composite picture was not different from that to the face-only picture. But the response in PPA to the composite picture was smaller than that to the whole scene picture. The response to composite picture in V1-peripheral site was smaller than that to the whole scene picture even though the composite picture in V1-peripheral site was exactly the same as that to the whole scene picture. When we replaced the face in the composite picture with an object picture, the responses to the composite picture in both PPA and V1-peripheral site were not different from those to the whole scene. These indicate that the effects of non-preferred stimuli on the responses to the preferred stimuli are different between FFA and PPA. The composite picture seems to be interpreted as the face at FFA but the face and scene in the composite picture seem to be separately processed at PPA.

Title: Preserved expert object recognition in a case of unilateral visual agnosia

Authors: ***J. RENNIG**[1], H.-O. KARNATH[1,2], M. HIMMELBACH[1,3]
[1]Div. of Neuropsychology, Ctr. of Neurology, Univ. of Tübingen, Tübingen, Germany; [2], Dept. of Psychology, Univ. of South Carolina, Columbia, SC; [3]Ctr. for Integrative Neuroscience, Univ. of Tübingen, Tübingen, Germany

Abstract: We examined a stroke patient (HWS) with a unilateral lesion of the right medial ventral visual stream. A high resolution MR scan showed a severe involvement of the fusiform and parahippocampal gyri sparing big parts of the lingual gyrus. In a number of object recognition tests with lateralized presentations of target stimuli, HWS showed remarkable deficits for contralesional presentations only. His performance on the ipsilesional side was unaffected. We further explored his residual capabilities in object recognition confronting him with objects he was an expert for. These were items he knew from his job as a trained car mechanic that were occupationally and personally relevant for him. Surprisingly, HWS was able to identify these complex and specific objects on the contralesional side while he failed in recognizing even highly familiar everyday objects. This observation of preserved expert object recognition in visual agnosia gives room for several explanations. At first, these results may be caused by enhanced information processing of the ventral system in the intact hemisphere that is exclusively available for expert objects. On the other hand, expert knowledge could also trigger top-down mechanisms supporting object recognition despite of impaired basic functions of object processing. Finally, a more efficient stimulus processing for expert objects might simply not require complete resources of an intact ventral stream.

Title: Tracking dynamic mental imagery in early visual cortex

Authors: *A. ALBERS, P. KOK, R. BOYACIOğLU, I. TONI, F. P. DE LANGE
Radboud Univ. Nijmegen, Donders Inst. For Brain Cognition and Behaviour, Nijmegen, Netherlands

Abstract: Previous studies suggest that the early visual cortex can hold information about visual content that is kept in working memory (Serences et al, 2009; Harrison & Tong, 2009), or generated through imagery (Albers et al, 2013). These findings are in line with the notion that the primary visual cortex can function as a blackboard that represents both bottom-up stimulus input and top-down mentally generated content. However, it is an open question what the role of early visual cortex is during mental transformations of visual content such as during mental rotation, where an imagined stimulus is rotated from a starting orientation into a final orientation (Shepard & Metzler, 1973). Here we asked whether the early visual cortex is also continuously involved in this dynamic process, or only stores the outcome of the mental transformation. To address this question we measured neural activity in early visual cortex with fMRI at high temporal resolution (TR = 210 ms) using a multiband MRI sequence, while participants (N=7) imagined and mentally rotated an oriented stimulus grating by 60, 120 or 180 degrees. After this mental transformation subjects were required to keep the rotated image in mind for 6 seconds and subsequently compare it to a probe that appeared on the screen. Importantly, the grating to be imagined and rotation angle were both symbolically cued, to ensure that all imagery-related activity was independent from bottom-up stimulation. In a separate localizer session, we measured the brain response to unattended perception of gratings and retinotopically mapped V1, V2 and V3. This approach allowed us to dynamically track stimulus representations in early visual cortex over time. Using Multivariate Pattern Analysis (MVPA) methods we could successfully track which of 6 different orientations was perceived by participants during the localizer. During mental imagery trials, neural activity patterns in early visual cortex changed over time and eventually reflected the orientation of the imagined stimulus after the mental transformation. Furthermore, preliminary results show that neural activity patterns in a temporal window between the start cue and before the end of the transformation period appeared to reflect

intermediate representations of the starting stimulus and subsequent rotation process, suggesting that early visual cortex is involved in the transformation process itself. These findings extend the role of early visual cortex to the dynamical generation of mental content.

Title: Neural representation for properties determining the navigability of a scene

Authors: J. KANG, H. I. SAIR, *S. PARK
Johns Hopkins Univ., Baltimore, MD

Abstract: Navigating in a natural environment is fundamental to everyday functions and interactions of an individual. Although the importance of the navigability in a scene has been mentioned in previous studies, exact features of natural scenes that determine the navigability are not well defined. In this study, we investigate which features in a scene drive differences in the navigability judgment of the scene, and how these features are represented neutrally to guide our action in a natural environment. In an fMRI scanner, participants (N=7) were presented with 80 different scene images that depict natural closed environments (e.g., pictures of various views of forests). In a separate behavioral session using Amazon Mechanical Turk, each of these scenes was independently rated on 13 navigationally relevant properties by asking participants to answer questions such as “How clear of a path is in the scene?” While participants were in the scanner, we observed multi-voxel patterns of neural activity in the following regions of interests: the parahippocampal place area (PPA), the restroplenial cortex (RSC), the transverse occipital sulcus (TOS) and V1. Using an iterative variant (Chan *et al*., 2010) of split-half correlation analysis (Haxby *et al*., 2001), we computed similarity matrices of multi-voxel pattern activity for all possible binary pairs of 6 functional runs for each ROI. From the similarity matrices, we produced multi-dimensional scale (MDS) plots and investigated grouping of natural scenes based on the multi-voxel pattern activity. The similarity matrices and MDS plots were re-sorted based on behavioral ratings of each scene properties asked in the 13 questions, as well as groups of principal scene properties that were determined by principal component analysis of the 13

questions. Correlation values between behavioral similarity matrices and neural similarity matrices are computed. We hypothesized that different regions of interests will show different patterns of correlation depending on the nature of navigational features that the matrix is sorted with: similarity patterns of multi-voxel data in LOC will highly correlate with behavioral ratings about object-based property, such as the size, moveability and permanence of objects in a scene. Similarity patterns of multi-voxel data in the PPA will correlate highly with behavioral ratings about the spatial layout in a scene, such as the clearness and straightness of a path. RSC and TOS patterns of multi-voxel data will highly correlate with both the questions about the structure and functional affordance of a scene, such as the clearness of a path, enjoyability or easiness to continue forward or back.

Title: Temporospatial entropy- and phase-based connectivity in the tilt illusion: The effects of context in perception

Authors: *F. J. PARADA[1,2], L. MORAVEC[1], B. EMERICK[1], O. SPORNS[1], T. BUSEY[1]
[1]Psychological & Brain Sci., Indiana Univ., Bloomington, IN; [2]Harvard Med. Sch., Harvard Univ., Boston, MA

Abstract: A tilt illusion perception task was used in order to measure the effect of context on neural oscillations elicited by visual perception. In the tilt illusion, perception of line orientation is influenced by the orientation of surrounding lines. If the angle difference between stimulus and surround is <50º, the center lines are repelled and appear turn or tilt further away from the surround (Wenderoth & Johnstone, 1988). In our experiment, half of the trials presented the illusion by having the center stimulus flush with the background while the other half had a 1.0-degree gap between the stimuli and background, not presenting the illusion. We collected 32-channel electroencephalographic (EEG) signals from 6 participants (3 males). Data were sampled at 500Hz/channel and filtered from 0.1 to 100 Hz. Each participant ran 2 sessions in different days, later merged into a single data matrix per subject. Independent components analysis was used to remove artifacts (Delorme & Makeig, 2004). Data were Morlet-transformed

into analytic signal (34 frequencies, 4-70 Hz). Cross-spectral density was used to compute debiased weighted phase-lag index connectivity (dwPLI, Vinck et al. 2011). The amount of information measured by entropy of dwPLI for illusion-present and illusion-absent trials was used in order to obtain dwPLI-based mutual information (MI) connectivity in the time-frequency domain. dwPLI-based MI connectivity was then converted into a standard Z-score (MIz) using non-parametric permutation testing. MIz and dwPLI connectivity were analyzed to determine oscillatory connectivity patterns elicited by the tilt illusion. Subject- and group-level robust statistics were performed on both connectivity measures using non-parametric permutation testing framework. The success of our manipulation was reflected by behavioral responses showing an inverse relationship between annulus presence and perception of tilt illusion. MIz connectivity results suggest that information carried by the phase of beta oscillations significantly differs between illusion-present and illusion-absent trials (~170 to ~280 ms). dwPLI connectivity results show that the phase of gamma (~350 ms) and alpha oscillations (~170 ms) is more consistent across illusion-present trials when compared to illusion-absent trials in frontal and occipital scalp. In contrast, phase consistency in the beta range (~200 to ~250 ms) is greater for illusion-absent trials in parietal scalp when compared to illusion-present trials. Our data suggests that phase scattering in the beta range between 200 and 300 ms is crucial for large-scale perceptual information integration in the tilt illusion.

Title: Cortical neuronal oscillations modulated by respiration

Authors: *D. H. HECK[1], A. BABAJANI-FEREMI[2,6], R. REZAIE[3], Y. LIU[4], A. PAPANICOLAOU[5,6,2]

Abstract: Oscillations of neocortical neuronal activity in the theta (4-8Hz), beta (12-30 Hz) and gamma (30 - 80 Hz) frequency ranges have been implicated in sensory perception, attention, decision-making, problem solving and memory formation. Patterns of cortical oscillations change during early brain development and with normal aging and are abnormal in patients afflicted with mild cognitive impairment, age related dementia, Alzheimer's disease and cognitive disorders such as autism or schizophrenia. However, our understanding of the origins and neuronal mechanisms controlling cortical oscillatory activity is still fragmented. Here we report new findings showing that respiration serves as a rhythm generator for the modulation of neuronal oscillatory activity in sensory, motor and association cortical areas in humans and mice. Specifically, magnetoencephalographic (MEG) recordings of cortical activity in human subjects and extracellular recordings of cortical spike and local field potential activity in awake mice showed respiration-locked power-modulations of neuronal oscillations in the theta, alpha and beta frequency bands in both species and respiration-locked modulations of single unit spike firing in mice. In mice oscillations in the gamma frequency band also showed modulation of power phase locked to respiration. The average respiratory rates of mice and humans at rest are around 3 and 0.3 Hz, respectively. Mouse resting respiration is thus within the delta (1-4 Hz) frequency band, within which we found strong phase coupling of spike and LFP activity to breathing. Time-frequency analyses of visually evoked responses showed that visual-cortex response amplitudes were modulated as a function of respiratory phase, suggesting a role of respiration in modulating sensory processing. In imaging studies cycle-by-cycle respiration-related signal fluctuations are typically considered to be of non-neuronal origin, and are disregarded and eliminated from the signal. However, our new findings suggest that respiration does modify spontaneous and sensory evoked cortical neuronal activity at the single unit and population level and must be taken into account when analyzing neuronal processes in the neocortex. In mice we have identified olfactory bulb activity as the main driving force behind respiration-locked cortical delta-band oscillations. Sine the olfactory system is relatively less prominent in humans. We suggest that the sensory drive behind respiration-locked cortical activity in humans is more likely the result of summed contributions from mechanical and chemical sensors in the airways, lungs, chest and abdomen.

Title: Fronto-occipital beta band phase synchronization underlying perceptual closure process in two-tone visual image presentation

Authors: *Y. KAKIMOTO, A. OKI, H. SAGAWA, H. TAGAWA, O. ARAKI
Tokyo Univ. of Sci., Tokyo, Japan

Abstract: “Perceptual closure”, which is the recognition of fragmentary visual stimuli as a complete one, is an important ability to identify visual objects from insufficient inputs. To induce the perceptual closure, two-tone (TT) images, which are made from the monotone images by binarizing with appropriate threshold values, were generally used. Although the TT images appear to be meaningless at first glance, the subjects can gradually recognize the contents with appropriate interpretation. Most of the previous studies compared the neural activities before and after viewing gray scale version of the TT images and revealed that widespread cortical regions (the occipital and the temporal visual cortex, parietal cortex and the prefrontal cortex) correlated with visual disambiguation process. In addition, recent researches reported the enhancement of functional interaction between these brain regions in the perceptual closure. However, it remains unclear about the spatiotemporal brain dynamics in the spontaneous perceptual changes from the state to perceive incoherent visual image to the state to achieve the perceptual closure. To address this issue, we recorded electroencephalography in the 10 subjects during a TT image task. The EEG data was performed time-frequency analyses by using wavelet transformation and Phase locking value (PLV) was used for the index of the functional interaction. In this study, the TT images were presented intermittently. The degraded level of the presented images were gradually changes from hard to easy. Subjects were instructed to respond if they recognized the contents of the presented images by pressing the button as quickly as possible. The subjects responded at 50.0 % and mean response times were 623 ms. EEG results showed that high PLV of the beta frequency was observed in 50 ms after the onset of the TT image in the presentation block in which the subject pressed the button. However, this beta band PLV enhancement was not seen in the previous presentation block. These results suggest that the beta phase synchronizations between the frontal and the occipital area contributes to the perceptual closure process and functional coupling between the frontal and the occipital areas reflects completion of conscious object recognition.

Title: Prefrontal-parietal EEG correlation during motor imagery in expert video game players

Authors: *M. L. ALMANZA, J. LLAMAS, M. A. GUEVARA, M. HERNÁNDEZ-GONZÁLEZ
Inst. De Neurociencias, Guadalajara, Mexico

Abstract: The aim of this study was to characterize the prefrontal-parietal EEG correlation in experienced video game players (VGPs) in relationship to individuals with little to no videogame experience (NVGPs) during a motor imagery condition for an action video game. The participants from both groups viewed a first person shooter (FPS) gameplay of Halo Reach, during five minutes. None of the participants was notified about the content of the video before watching it. Only the VGPs showed an increased right intrahemispheric prefrontal-parietal correlation (F4-P4) in the gamma band (31-50 Hz) during the observation of the gameplay. This data provide novel information about the participation of the gamma band during motor imagery for an action video game. It is probable that this major degree of coupling between prefrontal and parietal cortices could represent a characteristic pattern of the brain functionality in VGPs when they make a motor representation.

Title: Variations on the quartet illusion

Authors: S. VATTIKUTI[1], *C. C. CHOW[2]
[1]NIH/NIDDK, Bethesda, MD; [2]Lab. of Biol. Modeling, NIH/NIDDK, BETHESDA, MD

Abstract: Motion perception is not simply encoded by single neurons but by networks of neurons that transform spatiotemporal data to sense motion events. A consequence of this is that our brains can be fooled into perceiving motion in the absence of actual movement. This is called apparent motion. The quartet illusion produces this phenomenon by alternating dots set at opposing corners of a square. It is also observed that the perceived trajectories alternate between horizontal and vertical motion despite a constant stimulus; a form of multistable perception. We present new manipulations to the quartet illusion to gain insight into motion detection and perceptual rivalry. For example we show how changing the interval between dot transpositions affects the dominant percept duration.

Title: Visual number beats abstract numerosity: Format-dependent representations of Arabic digits and dot patterns in the human parietal cortex

Authors: *J. BULTHE, B. DE SMEDT, H. OP DE BEECK
KU LEUVEN, Leuven, Belgium

Abstract: In numerical cognition there is a well-known but contested hypothesis that proposes an abstract representation of numerosity in the human intraparietal sulcus (IPS) as the explanation for the common activation in this brain region by different numerical formats. On

the other hand, researchers of object cognition have suggested a very different type of representation in IPS, namely that this activity simply correlates with the number of visual objects or units that are perceived. We contrasted these two hypotheses by analyzing multivoxel activity patterns elicited by dot patterns and Arabic digits of different magnitudes while 12 participants were explicitly processing the represented numerosity in a fMRI experiment. Correlational multivoxel activity patterns analysis showed that the activity pattern elicited by the digit '8' was more similar to the activity pattern elicited by one dot, with which the digit shares the number of visual units, than to the activity pattern elicited by eight dots, with which the digit shares the represented abstract numerosity. Also, a multivoxel pattern classifier trained on one format (e.g. dots) and tested on the other format (e.g. Arabic digits) sharing the same numerosities (e.g. 2 dots versus 4 dots to digit 2 versus digit 4) showed no overlapping activity patterns between the two formats in the IPS or any other brain regions. Even more, that same multivoxel pattern classifier trained to differentiate one dot from eight dots, classified all Arabic digits in the one dot pattern category, irrespective of the numerosity symbolized by the digit. These results were consistently obtained in the IPS and its sub-regions, and in many other brain regions. As predicted from object cognition theories, the number of presented visual units forms the link between the parietal activation elicited by symbolic and non-symbolic numbers, meaning that activity in the IPS during processing numbers reflects object individuation and identification. The current study is difficult to reconcile with the hypothesis that parietal or IPS activation elicited by numbers would reflect a format-independent representation of number, what was previously thought in numerical cognition.

Title: What is likely to happen next? Neural correlates of probabilities of future events

Authors: *S. TRAPP[1], J. LEPSIEN[2], S. KOTZ[3], M. BAR[4]
[1]Neurol., Max Planck Inst. For Human Cognitive and Brain Sci., Leipzig, Germany; [2]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany; [3]Sch. of Psychological

Sciences, The Univ. of Manchester, Manchester, United Kingdom; [4]Gonda Ctr. for Brain Research, Bar-Ilan Univ., Tel Aviv, Israel

Abstract: For adaptive behavior and decision-making, it is necessary to take into account the relative likelihood of future input and scenarios. In the context of reinforcement learning, a number of studies have shown that the BOLD response is sensitive to the probability that a reward is given. However, the regions identified with those studies (e.g., striatum, mesial prefrontal cortex) are considered to execute more generic evaluation processes and are not directly related to the representation of perceptual information. As of yet, the question of whether and how the brain codes for the occurrence probability of perceptual information in stimulus-specific areas remains to be addressed. Here, we used event-related functional magnetic resonance imaging to address this issue. Eighteen subjects (mean age: 26.3, 10 females) were trained in two behavioral sessions before scanning to learn the correct order of pictures within a sequence. The task was the detection of a rare deviant of this learned order. The sequences consisted of three consecutive pictures; the type of one of these pictures was either a face or a house, with either a high or a low probability of occurrence. Each sequence was preceded by a cue that gave participants probabilistic information about which picture type to expect next. After training, subjects repeated the task in the scanner. This allowed us to examine probability-related, anticipatory modulation of activity in stimulus-specific areas (fusiform face area; FFA, and parahippocampal place area; PPA). A region-of-interest analysis showed that activity in FFA was higher for high expectation as compared to low expectation of faces. The data demonstrate that the brain flexibly distributes vascular resources according to the relative likelihood of future perceptual input. These data are in line with the hypothesis of a “Bayesian brain”, which states that the brain codes information probabilistically.

Title: Neural representation of visual fractals

Authors: *T. P. O'CONNELL[1], M. M. CHUN[1,2]
[1]Psychology, Yale Univ., New Haven, CT; [2]Neurobio., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Visual fractals are complex, self-repeating visual patterns generated through recursive application of simple mathematical rules. The hallmark feature of visual fractals is the presence of identical or nearly identical visual structure present at multiple scales. Visual fractal structures are present throughout the natural world, including river networks, tree branches, and blood vessels. The ubiquitous presence of fractals throughout the natural world suggests that abstract, artificially generated fractals may preserve visual features necessary for representing natural visual stimuli (e.g., scenes, objects, faces). While fractals have previously been used as visual stimuli in cognitive neuroscience research, the exact nature of their neural representation in humans is not known. Here, we investigated the sensitivity of different category-selective visual brain regions to the visual features preserved in artificial fractals. We addressed this question using functional Magnetic Resonance Imaging (fMRI) and multi-voxel pattern analysis of blood-oxygen-level-dependent signal elicited during viewing of visual fractals. A factorial set of visual fractals was generated using three structures and three color-schemes. Neural activity was assessed in eight subjects during a 3 alternative-forced-choice fractal structure discrimination task using fMRI. We restricted our analyses to five regions of interest known to be specifically sensitive to natural visual categories: scene-selective parahippocampal place area (PPA), retrosplenial cortex (RSC), and occipital place area (OPA), object-selective lateral occipital cortex (LOC), and face-selective fusiform face area (FFA). Spatial patterns of BOLD signal extracted from each region of interest were used as features to predict fractal structure and color using support-vector machine classification. We found that fractal structure could be reliably predicted from patterns of BOLD activity in the scene-selective OPA ($p < 0.0008$) and the object-selective LOC ($p < 0.0005$). This suggests that artificial visual fractal structures preserve visual features necessary for the neural representation of scenes and objects. We will discuss the potential application of visual fractals as substitutes for natural scenes and objects in vision research.

Title: Influence of lexical status, orthographic similarity and semantics on the multi-voxel response of the visual word form area

Authors: *A. BAECK[1], D. KRAVITZ[2], C. BAKER[3], H. OP DE BEECK[1]
[1]Univ. of Leuven, Leuven, Belgium; [2]The George Washington Univ., Washington D.C., DC; [3]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Previous studies demonstrated that a region in the left fusiform gyrus, often referred to as the "visual word form area" (VWFA), is responsive to written words, but the precise functional role of VWFA remains unclear. In the present study, we investigated the influence of orthographic similarity, lexical factors and semantics on the multivoxel response patterns to written stimuli. Using high-resolution fMRI at 7 Tesla, we scanned 16 participants to compare the organization of visual word representations in VWFA to the organization in early visual cortex and a language region in the superior temporal gyrus. Sets of four letter words and pseudowords were presented, in which orthographic similarity was parametrically manipulated. Further, real word stimuli with no orthographic overlap were semantically related (example real word stimulus set: beat-feat-flat-flag-flog). We found that VWFA is responsive to the lexical status of a stimulus, but both real words and pseudowords were further processed in terms of orthographic similarity. No evidence was found for a role of semantics in VWFA. In contrast, the early visual cortex was only responsive to the visual aspects of the stimuli. In the left superior temporal gyrus an interaction was found between lexical status and orthography: real words, when not semantically related, are organized according to orthographic similarity, while no functional organization was found for pseudowords. These findings indicate that VWFA represents the word/non-word status of letter strings as well as their orthographic similarity.

Title: Perception of sound-encoded faces selectively activates the left fusiform face area in congenitally blind humans

Authors: P. L. PLAZA[1], L. A. RENIER[2], A. G. DE VOLDER[2], *J. P. RAUSCHECKER[1]
[1]Neurosci., Georgetown Univ. Med. Ctr., WASHINGTON, DC; [2]Inst. of Neurosci., Univ. Catholique de Louvain, Brussels, Belgium

Abstract: Currently, little is known about the role of sensory experience in the development of functionally specialized cortical modules. Sensory substitution devices (SSD) offer a unique opportunity to investigate the functional specialization of "visual" cortex in congenitally blind (CB) subjects by conveying "visual" information via a preserved (substituting) sensory modality (e.g. hearing). The purpose of the present study was to test to what extent face- and house-sensitive visual brain areas develop and maintain their functional role in CB subjects and can be recruited using an SSD. We used functional magnetic resonance imaging and an SSD that converts visual images into sounds to identify the brain areas recruited during the perception of faces and houses in CB and sighted control (SC) subjects. Brain activity was monitored in these subjects while they were discriminating faces and houses encoded into sounds or perceived visually (in SC subjects only). The fusiform face area (FFA), the parahippocampal place area (PPA) and the lateral occipital complex (LOC) were identified in sighted subjects under visual conditions using a functional localizer consisting of pictures of famous persons and real houses. Then, region-of-interest analyses were performed on the data acquired in both CB and SC subjects when the SSD was used to discriminate schematic drawings of faces and houses. Results indicate that the left LOC was activated under both of these conditions in both groups, while the left FFA was activated during the auditory face discrimination condition in CB subjects only. No significant brain activity was found in the PPA in CB or SC subjects at the group level. The specific recruitment of the FFA during the perception of sound-encoded faces in CB subjects represents new evidence about the development of functional specialization of this region in the absence of visual inputs.

Title: Human brain mapping metamodel

Authors: *C. C. LEITH[1], J. ROSENGARTEN[2], P. EPSTEIN[3], L. ROBBINS[4], L. SIEGEL[5], H. SUN[1]
[1]Neurodynamics Res. Inst., HIGHLAND PARK, IL; [2]Smart Scan MRI, Chicago, IL; [3]Advanced Neurodiagnostics, Chicago, IL; [4]Robbins Headache Clin., Chicago, IL; [5]Illinois Bone & Joint Inst., Chicago, IL

Abstract: **Introduction:** In all human brain mapping work the fundamental assumption is that perception, awareness and preparation for response of a subject can be inferred from the brain activation map. It relies on a convoluted and obscure map from the understanding, cognition and freewill of the mind to neural impulses in the brain. A different theoretic frame is needed to clarify what to expect from such a map. **Method:** We examined our neuroimaging data acquired from a few groups of patients (38 brain lesion preoperative, 90 chronic migraine, 56 fibromyalgia, 4 Asperger and 150 healthy controls). All subjects were scanned with our Adapted Diffusion Tensor Imaging method (aDTI) (the preoperative 38 scanned with BOLD fMRI). We checked the protocols for image acquisition and analysis, focusing on the typical work flow as followed by most labs. The metamodel was developed under this situation. **Result:** We found that the subjectivity of the patient is not avoidable in any experiment. It simply arose from the subject's understanding, memorizing and executing of the experimental task. Choices or freewill were always present. In attempting to capture brain activity the BOLD fMRI took the local blood flow as the surrogate of it. The aDTI imaged water diffusion anisotropy change as modulated by neural impulses in the axonal fiber tracts. From the brain activation map we inferred the probable firing of neurons under a few marked areas, but we were never sure about the unmarked areas as inactive. The metamodel was formulated as shown in the Figure. **Conclusion:** The metamodel indicates that oI, the true mind is the prime mover and that sI, the apparent mind is only endowed with the feelings of awareness and freewill. It implies an inconvenient truth that sI is an illusory scratch pad or simulator for oI to interact with others. The one self "I", the owner, cannot escape from responsibilities. Clearly, oI has always evolved regardless of sI's knowledge. The inverse transform forewarns us taking precautions in conceptualizing findings in oI with our sI habit, and in claiming centers, streams or netwoks in the highly distributed CNS.

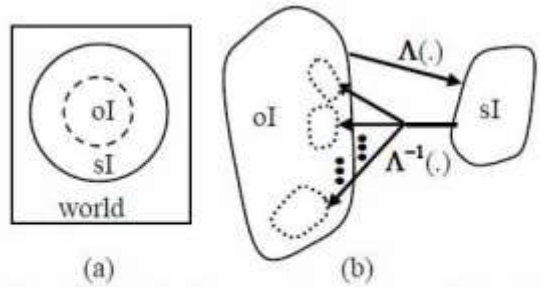

Fig. Human brain mapping metamodel. (a) To probe the mind of a self identity "I", we must first realize its objective representation "oI", the ever-evolving ensemble of neural impulse trains. The interaction with the world was left to the subjective representation "sI", the subject matter of psychological inquires, or, the apparent mind as we all are familiar with. In contrast oI was the rather unfamiliar true mind and the subject matter of neuroscience. (b) In essence sI served as the "broker" for oI in dealing with the world, and the brokerage called for a conversion or transform Λ(oI)→sI in mathematical terms. Knowing oI fully implied knowing sI completely. However, the inverse transform Λ^{-1}(sI) was different, discrete and patchy, hinting on oI not completely knowable through sI.

Informatics, [5]Dept. of Neurosurg., Meiji Univ. of Integrative Med., Nantan, Kyoto, Japan

Abstract: Binocular rivalry has been extensively investigated by neuroscientists exploring the neural substrates of visual awareness. Many fMRI and electrophysiological studies have revealed that multiple stages of visual processing, from the thalamus to the visual cortex and fronto-parietal regions, are involved in subjective visual awareness. However, these studies have yielded inconsistent results regarding the relationship between visual awareness and visual processing hierarchy. Human and monkey fMRI studies have repeatedly shown that activity in V1 as well as extrastriate visual areas correlates with modulations of visual awareness during binocular rivalry. In contrast, several monkey electrophysiological studies have reported that only a small fraction of neurons in early visual areas exhibit spiking activity correlated with visual awareness, whereas a large proportion of neurons in high-level visual areas showed correlated activity. In the present human fMRI study, we found two distinct patterns of activity in retinotopic visual areas during binocular rivalry, each of which were consistent with previous fMRI or electrophysiology. We measured brain activity while subjects viewed a novel binocular rivalry stimulus, which consisted of a flashing mask presented to subjects' dominant eye and a rotating checkerboard probe presented to the other eye. Subjects' visual awareness of the probe fluctuated due to strong interocular suppression, called continuous flash suppression. The rotating probe allowed us to measure not only the response modulations around the time of perceptual transitions but also the responses evoked by the physical onset of the probe whether it was suppressed or dominant during binocular rivalry. The onset responses were larger when it was visible than invisible in all of the retinotopic visual areas we measured (V1, V2, V3 and V4v). This elevation of the responses increased along the visual processing hierarchy, consistent with previous electrophysiology. On the other hand, the response modulations around the time of perceptual transitions were equally large across in all of the areas measured, which is consistent with previous fMRI studies. Our results suggest that the discrepancy between fMRI and electrophysiology may not be an artifact due to the intrinsic signal difference, but may arise from two distinct processes in retinotopic visual areas underlying binocular rivalry.

Title: Effects of temporoparietal tDCS on EEG relative powers and cybersickness in virtual navigation

Authors: *H. JEON, Y. CHUN, C. PARK, T. W. WENDIMAGEGN, J. JEONG, H. KIM
Dept. of Psychology, Korea Univ., Seoul, Korea, Republic of

Abstract: Cybersickness refers an uncomfortable state in virtual navigation. Although a number of studies have tried to find ways to eliminate cybersickness, an optimal method of avoiding cybersickness has not been established. Recently, studies using transcranial direct current stimulation (tDCS) demonstrated modulations of sensation and perception. Kyriakareli et al. (2013) reported that temporoparietal tDCS could manipulate the thresholds of the vestibulo-ocular reflex (VOR) and motion perception, which might be important factors that modulate cybersickness. Thus, we investigated whether temporoparietal tDCS can mitigate cybersickness in virtual navigation. Thirteen participants were randomly assigned into a tDCS (CP6-anodal/CP5-cathodal stimulation, 1.0 mA, 15 min) group or a sham-control group (same site as tDCS group, 1.0 mA, 30 s). A static image from a movie clip for virtual navigation was presented to participants for five minutes before tDCS as a baseline, and the movie clip for virtual navigation was presented to participants for ten minutes after tDCS to induce cybersickness. Electroencephalograms (EEGs) were recorded on twelve electrode sites (F3, Fz, F4, C3, Cz, C4, P3, Pz, P4, O1, Oz, and O2) on the scalp corresponding to the international 10/20 system before and after tDCS, and relative power analysis was examined. Our results indicated that the relative beta power in the tDCS group was significantly higher than that in the sham-control group on the Oz site. Additionally, the relative theta power in the tDCS group was marginally lower than that in the sham control group on the Cz site. Based on previous observations (Chen et al., 2010; Kim et al., 2005) demonstrating a decrease in beta power and an increase in theta power in cybersickness, the results of the present study suggest that the application temporoparietal tDCS could be an effective method to reduce cybersickness.

Title: The dissociation of different measures of cortical inhibition in the visual system, and their use for non-invasive monitoring of epilepsy susceptibility

Authors: *P. YAZDANI[1], J. READ[1], R. WHITTAKER[3], R. GEORGIOU[2], A. TREVELYAN[2]

Abstract: Accurate seizure prediction algorithms would transform the lives of people living with epilepsy. They would also provide information about disease progression. One theory suggests that the timing of seizures reflects fluctuations in the quality of cortical inhibition. Non-invasive assays of cortical inhibition may, therefore, provide clinically useful information. Visual psychophysics assays have been used in schizophrenia (Tadin et al. J.Neurosci, 2006), autism (Koldewyn et al. Brain, 2010) and major depressive disorders (Golomb et al., J.Neurosci., 2009). To investigate whether such tests may also be useful in assessing seizure risk, we investigated the performance in different visual cortical inhibition assays and whether this co-varied between tasks. We have recruited 153 volunteer control subjects with no history of neurological disorder and 39 patients with clinically confirmed diagnosis of epilepsy. The control subjects ranged in age from 17.3 to 69.0 (mean 36.6 +/- 17.3years); patients range, 17.0 to 82.3, (mean 42.7 +/- 18.6 years). Some patients were tested soon after diagnosis before anti-epileptic medication was started. Others had long standing epilepsy, and medication was maintained. The duration of epilepsy ranged from a few months to 34 years. Two different stimulus paradigms were used: (1) a two-choice motion discrimination paradigm (Tadin et al, 2003; left-right choice of movement of sinusoidal gratings“(Gabor patches”); small versus large stimuli, at either high / low contrast) and (2) a four-choice, stationary annulus paradigm (Serrano-Pedraza et al, 2012; identification of location of an oriented sinusoidal, orthogonal or parallel to a background sinusoidal display; high and low contrast). Duration thresholds were derived from fits of psychometric functions, and used to derive surround suppression indices (SSIs) for the two tests. There was a large variance in these measures, but further analysis suggested a clear difference between the two different test paradigms. For instance, age was an important confounding variable in the Tadin SSI, showing a highly significant reduction with increasing age in all groups, but not for the annulus SSI. Also,

the Tadin and annulus SSIs were not correlated across populations, or over repeated measures within single individuals. We will also present analyses examining the longitudinal variance in individual patients and control subjects.

Title: Effect of anticipation triggered by prior dyspnea experience on brain activity

Authors: *H. NAKAI[1], K. TSUJIMOTO[2], T. FUCHIGAMI[3], S. OMATSU[4,5], H. NAKANO[6,5], S. MORIOKA[5]
[1]rehabilitation, Higashi Osaka Hosp., Osaka City, Japan; [2]physical science, Natl. Inst. for Physiological Sci., Aichi, Japan; [3]Okuma Central Hosp., Hyogo, Japan; [4]Murata Hosp., Osaka, Japan; [5]Kio Univ., Nara, Japan; [6]Yamato Univ., Osaka, Japan

Abstract: Objective: Prefrontal cortex oxygenated hemoglobin (oxy-Hb) concentration is closely associated with dyspnea. Dyspnea is influenced not only by physical activity, but also by visual stimuli, and several studies suggest that the oxy-Hb concentration changes in response to certain external stimuli. However, the relationship between brain activity, oxy-Hb trends, and the discrepancy between anticipated and actual dyspnea remains unknown. This study explores the influence of anticipation triggered by previous episodes of dyspnea on brain activity. Methods: Fifteen healthy volunteers with a mean age of 25.0 ± 3.0 years and a mean maximal peak inspiratory pressure of 78.0 ± 26.4 cmH2O (Micro-Spirometry) participated in the study. Each experimental trial were viewing representations of 20 s, breathing resistance of 30 s, and 20 s selective Borg scale. Volunteers viewed a random combination of photographs showing pleasant, neutral, and unpleasant representations. The subjects were instructed to expect a breathing resistance identical to the photograph. After viewing the image, breathing resistance was randomly administered to the subjects as identical to, easier, or harder than that shown in the image; the image and resistance were identical 33% of the time and discordant 66% of the time. The breathing resistances (7 mmHg, PI max 15%, PI max 30%) were induced using the Threshold IMT. The subsequent brain and sympathetic nervous system activities were assessed

using the Borg scale for psychophysical, tracers of sympathetic nervous system activity, and a functional near-infrared spectroscopy for brain activity. Results: The dorsolateral prefrontal cortex oxy-Hb concentration increased when unpleasant images were shown significantly ($p < 0.05$). The right medial prefrontal cortex (rMPFC) oxy-Hb concentration increased at PI 30% max intensity in subjects shown a pleasant image significantly compared with subjects shown an unpleasant ($p < 0.01$). Moreover, the activated rMPFC area was significantly correlated with the magnitude of perceived dyspnea ($R = 0.6$; $p < 0.01$). The sympathetic nervous system activity did not significantly change. Conclusion: These results suggest that rMPFC activity is correlated to the magnitude of dyspnea in subjects perceiving an unpleasant intensity regardless of any previous positive expectations.

Title: Dissociable roles of hippocampal subfields in episodic simulation

Authors: *E. M. STEIN[1], V. C. MCLELLAND[2], A. DEVITT[3], D. L. SCHACTER[4], A. R. PRESTON[1], D. ADDIS[3]

Abstract: Controversy has emerged regarding the role of the hippocampus in episodic simulation tasks that require individuals to imagine future events. While some studies have shown hippocampal lesions impair episodic simulation, others have shown spared performance.

One possibility is that episodic simulation engages multiple processes supported by different hippocampal regions. To resolve conflicting findings from patient research, it is therefore important to determine how individual hippocampal subfields contribute to episodic simulation. In the present study, we used high-resolution fMRI combined with an episodic simulation task that required participants to generate future scenarios using elements from their existing memories. During scanning, participants were presented with recombined sets of person, place, and object details selected from their own memories and were asked to imagine a future event that comprised those details. Participants then rated how much detail was generated during each simulation. After scanning, participants were given a surprise memory test for the imagined events that required recall of the missing person, place or object when cued with two other event details. Our goal was to distinguish hippocampal responses that relate to the successful encoding of imagined events from those that track the amount of detail generated during episodic simulation. We found that left anterior CA1 engagement during episodic simulation was related to later memory for the imagined events, with greater activation for remembered relative to forgotten events. Importantly, the response in this region was not related to the amount of detail generated during simulation. In contrast, activation in left posterior dentate gyrus/CA2,3 increased with the level of detail generated during simulation but was not related to subsequent memory for imagined events. These findings thus suggest dissociable roles for the dentate gyrus/CA2,3 and CA1 in episodic simulation, with dentate gyrus/CA2,3 supporting retrieval of detailed information from existing memories and CA1 supporting encoding of imagined scenarios into memory. Moreover, the localization of successful encoding responses and detail effects to anterior and posterior hippocampus respectively is consistent with theoretical frameworks suggesting that these regions serve distinct memory functions that may extend to episodic simulation. Collectively, our findings implicate multiple hippocampal processes in episodic simulation and thus suggest that the precise nature of hippocampal lesions may determine whether an individual patient is able to imagine the future.

Title: Memory reconsolidation and updating: The role of memory strength and context

Authors: *K. C. NEWMAN-SMITH, R. L. GOMEZ, L. NADEL
Univ. of Arizona, Tucson, AZ

Abstract: Reactivated memories become labile and can be updated with new information in an adaptive process called memory reconsolidation. Previously we showed that spatial context helps determine when memory updating occurs (Hupbach, Gomez, Hardt, & Nadel, 2007). It remains unclear how the nature and strength of new experiences influence the likelihood they will participate in this memory updating process. We used a modified directed-forgetting paradigm to understand the extent to which the strength of novel information interacts with two aspects of context (spatial or item-based) to influence memory reconsolidation. Participants were randomly assigned to two groups, Same-Spatial context (SSC) or Different-Spatial context (DSC). At Session 1, participants learned 20 objects (Set 1) paired with associated sounds (e.g. an image of a train with the sound of a moving train). At Session 2, 48-hours later, participants returned to the same room as Session 1 (SSC) or a different room (DSC). In both conditions half of the Set 1 sounds were played, reactivating Set 1 memory via this item-based context (Newman-Smith, Nadel, Gomez, & Scalf, in prep). Thus participants in SSC experienced two types of context reactivation, spatial and item-based, while those in DSC experienced item-based reactivation alone. Participants then learned Set 2 comprised of 28 new objects. Half were surrounded by a blue border (Remember objects), half were not (Forget objects). Participants were instructed to remember only the bordered objects. At Session 3, 48 hours after Session 2, recognition memory for Set 1 and Set 2 items was tested. Reconsolidation is reflected in intrusions, defined as items from Set 2 recognized as being learnt in Session 1. If the strength of newly presented information influences the likelihood of updating there should be an intrusion difference of Remember items and Forget items between conditions. Remember items intruded into Set 1 memory in the SSC condition only, while Forget items intruded in both SSC and DSC conditions, suggesting an interaction between memory strength and spatial context Strong items (the Remember items) are linked to a specific context, while weak items (the Forget items) are not. The absence of linkage between the Forget items and the Set 2 context in which they were learned allows them to integrate more easily into the Set 1 memory. These results show that the strength of new information interacts with context to determine the likelihood that any particular item will become part of an updated, reconsolidated, memory.

Title: The Simpson's Paradox and functional connectivity in fMRI

Authors: *R. P. ROBERTS, S. HACH, L. J. TIPPETT, D. ADDIS
The Univ. of Auckland, Auckland, New Zealand

Abstract: **Objective**: Functional connectivity (FC) analyses determine the inter-relationship of brain regions, either during rest or during a cognitive task, by assessing the correlation of activity in one brain region (a seed) with that in other brain regions. Some analyses assess this correlation within subjects while others perform an across-subject correlation. An important phenomenon relevant to the relationship between these two forms of FC analysis is the "Simpson's Paradox". This occurs when an effect present in an across-subject analysis is absent or reversed within the individuals present in the analysis. Using an event-related fMRI dataset (N=16) with two conditions (semantic and episodic memory), we assessed whether regions exhibiting FC as indexed by across-subject correlations (seed partial least squares, PLS) also reliably show FC within the individuals in the dataset. **Methods**: A task-PLS analysis revealed increased activity for episodic memory (relative to sematic memory) in bilateral hippocampal (HC) clusters. The peak voxel of these clusters were chosen as seeds for a seed-PLS analysis that assessed which regions show across-subject correlations with each seed during the semantic and episodic memory tasks. Within-subject FC was assessed by first calculating, for each voxel within each subject, the percent signal change for each trial. These values were then correlated with percent signal change values for the left and right HC seed. From this, an across-trial r-value was calculated for each voxel, within each condition, for each subject. An r-to-z transform was then computed for each r-value. For those regions showing an effect from the seed-PLS analysis, z-scores from the within-subject analysis were analysed to determine if the across-subject effects observed in the seed-PLS analysis was also present within individual subjects. **Results**: The seed-PLS (across-subject FC) analysis revealed a number of regions exhibiting differential FC with the HC seeds during the episodic but not the semantic memory task. While some of these regions showed similar patterns for the within-subject FC analysis, there were also many regions that showed no effect or the opposite trend to the results of the across-subject FC analysis. **Conclusion**: Our results show the Simpson's Paradox is evident in FC research, and researchers should avoid assuming that across-subject correlations between two regions necessarily imply a within-subject correlation between the regions. Further developing our understanding the

functional differences reflected by across- versus within-subject brain correlations will enable more accurate interpretations of FC results.

Title: Representation of subjective memory strength and visual category by single neurons in the human medial temporal lobe during memory retrieval

Authors: S. YE[1,4], M. KOROMA-LE BRAS[7,4], O. TUDUSCIUC[2], I. ROSS[8], J. M. CHUNG[5], A. N. MAMELAK[4], *U. RUTISHAUSER[4,3,1,5,6]
[1]Computation and Neural Systems, [2]Humanities and Social Sci., [3]Div. of Biol. and Biol. Engin., Caltech, Pasadena, CA; [4]Neurosurg., [5]Neurol., [6]Biomed. Sci., Cedars-Sinai Med. Ctr., Los Angeles, CA; [7]Dept. de Biologie, École Normale Supérieure, Cachan, France; [8]Neurosurg., Huntington Mem. Hosp., Pasadena, CA

Abstract: Episodic memories allow us to remember not only that we have seen an item before (familiarity) but also provide a subjective impression of how sure we are that we have seen an item before (confidence). The neuronal mechanisms of confidence judgment about one's own memories are poorly understood. The medial temporal lobe (MTL) plays an important role in both the estimation of memory strength as well as visual categorization, but how these processes interact is unclear. We recorded single neurons in the MTL of patients implanted with depth electrodes for the purpose of localizing epileptic seizures. Patients viewed a sequence of 100 images (50 novel, 50 familiar). Images were chosen from five visual categories (people, animals, vehicles, foods, houses). Patients rated each image as new/old on a 1-6 confidence scale. Patients were able to assess the quality of their memories: the average area under the curve (AUC) of the behavioral Receiver Operating Characteristics (ROC) was 0.78±0.06 (all errors are ±s.d.) and

their response was faster when made with high vs. low confidence (1.56±0.80 sec vs. 2.52±1.32 sec, $p < 0.001$). We recorded 1193 neurons from the hippocampus and amygdala from 28 patients in 46 sessions. We quantified the responses using single-neuron ROC analysis. 95 (8%) of units differentiated new from old stimuli (NO neurons) and their AUC was larger for images remembered with high compared to low subjective confidence (0.68±0.05 vs. 0.63±0.05, $p<0.001$). This indicates that the neuronal response contained more information when memories were retrieved with high confidence. A separate group of 134 (11%) neurons differentiated the visual category of the displayed stimuli. There was no significant overlap between the two groups. We performed regression analysis and used the effect size to quantify how much of the neuronal variance could be attributed to visual category and/or familiarity. We found that category neurons only explained variance due to visual category but not familiarity (peak ω^2 was 2.36% vs 0.57%, respectively; $p < 0.001$), and vice versa (peak ω^2 was 0.65% vs. 5.87%, respectively; $p < 0.01$). We analyzed all recorded neurons together to quantify neuronal dynamics. The effect size of visual category peaked ~400ms before that for memory (new/old). Only the familiarity-related effect size was modulated by subjective memory strength. The memory signal was ≈3 times more informative (mutual information) when retrieval occurred with high compared vs. low confidence. We conclude that NO and category neurons are two distinct functional neuronal populations.

Title: Human entorhinal neurons activate at multiple related locations in an environment

Authors: *J. MILLER[1], I. FRIED[2], J. JACOBS[1]
[1]Drexel Univ., Philadelphia, PA; [2]Dept. of Neurosurg., Univ. of California Los Angeles, Los Angeles, CA

Abstract: The ability to remember and navigate our environment is critical for everyday life. Our understanding of the neural basis of navigation is based largely on the hippocampal place cell, whose activity represents a specific location in a spatial environment. An open question underlying the nature of place cells is distinguishing which aspects of place cell activity emerge from intrahippocampal computations and which are present outside of the hippocampus. We investigated this topic using human single neuron recordings from neurosurgical patients as they performed a virtual navigation task, traversing similar-looking pathways of a larger virtual environment. We found that many cells in the entorhinal cortex (EC), but not hippocampus, exhibited repetitive patterns of activation at the same relative locations on different paths. This result suggests that the EC codes broad non-specific features of an environment that could be used to represent commonalities between different spatial settings, and that this code may be the building block of more specific neural representations.

Title: An analysis of human navigation-related theta oscillations using spike triggered field potentials and autocorrelations

Authors: *T. J. COFFEY[1], J. JACOBS[2], N. BURGESS[3]
[1]Computat. Neurosci. Lab., Drexel Univ., Lansdale, PA; [2]Computat. Neurosci. Lab., Drexel Univ., Philadelphia, PA; [3]Inst. of Cognitive Neurosci. & Dept. Anat., Univ. Col. London, London, United Kingdom

Abstract: An issue of theoretical importance is understanding whether hippocampal theta oscillations play a critical role in the neuronal processes underlying mammalian navigation. We analyzed human theta oscillations by examining the oscillatory timing in the spiking of individual neurons with temporal auto-correlation (AC) analyses as well as time-frequency and spike-triggered averaging analyses of oscillations in the local field potential. This two-pronged approach is helpful because previous AC analyses of cross species differences in the theta

rhythmicity of entorhinal grid cells (Yartsev et al., 2012) were hard to interpret because very low firing rates can preclude detection of high frequency modulations (Barry et al., 2012). Our results indicate that humans exhibit oscillations in the hippocampus and entorhinal cortex during navigation at various frequencies, including ~3Hz and ~8Hz. However, AC methods perform relatively poorly above 3 Hz, detecting few oscillatory cells as compared to the LFP method. These findings suggest that methods based on local field potentials can provide a clearer picture of network oscillations, at least in humans, as also seen in studies of spike-field coherence (Rutishauser et al., 2010). We discuss why this may occur, perhaps owing to the intermittent nature of human hippocampal spiking.

Title: Human hippocampal theta oscillations are traveling waves

Authors: *H. ZHANG[1], J. JACOBS[2]
[2]Biomed. engineering, [1]Drexel Univ., Philadelphia, PA

Abstract: The hippocampal theta oscillation is widely considered as playing a key role in coordinating neuronal activity to support memory and cognition. Recently it was found in rodents that theta waves travel in a progression along the length of hippocampus (Lubenov & Siapas., 2009). This altered our view of hippocampal computation by suggesting that theta oscillations reveal how different neural assemblies activate sequentially. We know from previous work that hippocampal theta oscillations in humans have distinctive properties compared to rodents, including a slower frequency. Thus here we tested whether human theta oscillations are traveling waves by examined brain recordings from epilepsy patients that had electrodes implanted at multiple locations within the hippocampus. These multisite recordings allowed us to measure how hippocampal theta waves propagate spatially in humans. Our analyses revealed that human theta oscillations move in a posterior-to-anterior direction through the hippocampus, which is directly analogous to the dorsal-ventral traveling waves found in rodents. Traveling

theta waves occurred at a range of frequencies, unlike the ~8-Hz oscillations found in rodents. The temporal frequency of these theta waves correlated with the speed of spatial propagation, such that there is a fixed spatial frequency of ~9 degrees per centimeter. This correlation between theta's frequency and speed of propagation supports models of theta generation based on coupled oscillators.

Title: Structural differences in hippocampal and entorhinal gray matter volume support individual differences in first-person navigational ability

Authors: *K. R. SHERRILL[1,2], E. R. CHRASTIL[1,2], I. ASELCIOGLU[1], M. E. HASSELMO[1], C. E. STERN[1,2]
[1]Ctr. for Memory and Brain, Dept of Psych & Brain Sci., Boston Univ., Boston, MA; [2]Athinoula A. Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hosp., Boston, MA

Abstract: The ability to successfully navigate in the world varies dramatically across individuals. Recent functional MRI studies from our lab have demonstrated that the hippocampus supports goal-directed navigation (Brown, Hasselmo, and Stern, 2014; Sherrill et al., 2013; Brown and Stern, 2013), and previous studies have linked hippocampal volumetric differences to topographical and spatial abilities (Maguire et al., 2006; Bohbot et al., 2007; Iaria et al., 2008; Schinazi et al., 2013; Brown et al., 2014). The current imaging study related differences in behavioral performance during active first-person perspective and survey-perspective navigation in a landmark-free open field environment to differences in brain morphology using voxel-based morphometry. An fMRI paradigm compared goal-directed navigation in an open field environment from either a first person perspective (FPP) or Survey perspective (Sherrill et al., 2013; Sherrill et al., *in prep*). Participants (N = 57, mean age 21.84 ± 3.56 (SD), 30 males) underwent structural and functional MRI scanning. Behaviorally, participants reached the goal with precision from the FPP in 64.84% of the trials (SEM 2.66) and

from the Survey perspective in 75.89% of the trials (SEM 2.35). We used SPM8 to conduct both functional and voxel-based morphometry (VBM) analyses, analyzing the relationship between brain morphology and navigational accuracy in both the FPP and Survey perspectives. Our analysis included regressors for whole brain volume, age, sex, and FPP and Survey navigational accuracy. Our results demonstrate significant morphometric differences in the right hippocampus (head, body, and tail), left hippocampal tail, right entorhinal cortex, and left thalamus ($p<0.05$, k = 946) related to first-person navigational accuracy. In contrast, successful navigation from the Survey perspective was significantly correlated with morphometric differences in the left supplementary motor region and right angular gyrus but did not demonstrate a correlation with medial temporal lobe regions. Our results support the idea that individual differences in goal-directed navigation relate to underlying structural differences in the hippocampus and entorhinal cortex, regions thought to be critical to human navigation. More specifically, our results suggest this structural-functional relationship depends on the reference frame, with hippocampal and medial temporal lobe regions correlating more with egocentric first-person navigational abilities. These results extend our understanding of the link between brain structure and the diverse cognitive processes involved in spatial navigation.

Title: Combined working memory exercise and prefrontal transcranial direct current stimulation influences cognitive control

Authors: *B. M. ROBERTS, S.-F. WANG, M. MONTCHAL, B. WANCEWICZ, C. CARTER, C. RANGANATH
Ctr. for Neurosci., Univ. of California, Davis, Davis, CA

Abstract: Neuroimaging and electrophysiological studies have suggested that activation of the dorsolateral prefrontal cortex (DLPFC) is important for optimal cognitive function, but there is a lack of causal evidence for the role of cortical excitation in human cognitive performance. Studies that manipulate neural activity are necessary in order to provide a better understanding of

the mechanisms involved in cognitive function. In this study, anodal transcranial direct current stimulation (tDCS) was implemented to stimulate the DLPFC during a working memory exercise (visuospatial n-back task), in order to determine the effects of DLPFC activation on cognitive control (Dot Pattern Expectancy (DPX) task) and episodic memory (Relational and Item-Specific Encoding (RiSE) task). 20 healthy young adults received both active anodal and sham stimulation during two separate visits. During each visit, subjects first completed practice blocks of all tasks. After practice, two rubber electrodes encased in saline-soaked sponges were placed on the scalp with the anode over the left DLPFC (electrode site F3) and the cathode over the right supraorbital region. Current was applied at 2mA for 20 minutes for the active condition. For the sham condition, current was applied at 2mA for 30 seconds, and then was turned off for the remainder of the session. Subjects were blind to their condition. During stimulation, subjects completed a working memory exercise, which consisted of blocks of 2-back and 3-back of the visuospatial n-back task. Following stimulation, subjects completed the DPX and RiSE tasks during EEG recording from 32 scalp sites. Behavioral results indicate that performance on the DPX task was dependent upon the stimulation condition, as indicated by a significant interaction between error type and stimulation condition (ANOVA: $F [1, 38] = 4.889$; $p = 0.033$). Specifically, errors on trials in which a non-target cue was followed by a target probe (BX trials) improved for the active stimulation condition relative to sham, while trials in which a target cue was followed by a non-target probe (AY trials) showed increased error rates. Results from the RiSE task also revealed a trend for improved performance on the associative recognition trials, but results were not significant. Further analysis will focus on the EEG correlates of cognitive performance following stimulation. These findings provide causal evidence for DLPFC excitation in cognitive control, as well as provide insight into the potential for using brain stimulation as a therapeutic to optimize cognitive function, particularly in disorders characterized by disrupted prefrontal function, including schizophrenia.

Title: Encoding related delay period activity in hippocampal subfields and medial temporal cortex during delayed matching to sample: A high-resolution fMRI study

Authors: *R. K. NAUER[1,2,3], A. S. WHITEMAN[3,2,1], M. F. DUNNE[4,2], C. E. STERN[1,2,3], K. SCHON[4,2]
[2]Ctr. for Memory and Brain, [3]Dept. of Psychological and Brain Sci., [1]Boston Univ., Boston, MA; [4]Dept. of Anat. and Neurobio., Boston Univ. Sch. of Med., Boston, MA

Abstract: The goal of this study was to more precisely elucidate the contributions of medial temporal lobe (MTL) and hippocampal subfields to working memory and long-term memory encoding using a delayed matching to sample (DMS) design. Previous fMRI studies have indicated that MTL cortices and the hippocampus are recruited for stimulus maintenance during a delay period, and that this delay period activity is linked to subsequent recognition memory (Schon et al., 2004, 2005). Single-unit and slice-recording studies and computational models suggest persistent spiking mechanisms in entorhinal and hippocampal neurons may support both working memory maintenance and episodic encoding. Because the entorhinal cortex (EC) relays incoming information to the hippocampus via direct projections to the dentate gyrus (DG), CA1, and CA3 subfields, we hypothesized that these regions would show encoding related BOLD activity during the delay period. Participants underwent high-resolution fMRI optimized for MTL cortex and hippocampal subfield contributions (Philips Achieva, 3.0T, TR=2s, 1.5mm^3 isotropic voxels) while performing a DMS task in which they viewed a series of 144 unfamiliar complex outdoor scenes. For each DMS trial, an initial scene was shown (2 sec), followed by a 10-sec delay period, followed by a second scene (2 sec). Participants were asked to make a judgment of whether the second scene was a match to the initial scene for that trial. Approximately 15 minutes after the scanning session, participants performed a surprise subsequent recognition memory test (SMT) using a confidence rating scale to distinguish all 144 DMS scenes from an equal number of content similar lures. We examined delay period activity predictive of subsequent recognition memory. Regions of interest included MTL cortex (EC, PrC, parahippocampal cortex) and hippocampal subfields (CA1, DG/CA3, subiculum), and were manually traced on T1-MPRAGE images (1mm^3 isotropic voxels). Preliminary group analysis (N = 15; 21.4 ± 3.2 years) of the delay period activity showed that increased activation in DG/CA3, CA1, and on the EC/PrC border, predicted high confidence subsequent recognition memory. Our data support previous work demonstrating a subsequent memory effect in the EC/PrC region, and extend previous findings by showing encoding-related delay period activity in CA1 and DG/CA3 hippocampal subfields.

Title: To be, or not to be, remembered: Patterns of memorability in the medial temporal lobe

Authors: *W. A. BAINBRIDGE[1], D. D. DILKS[3], A. OLIVA[2]
[1]Dept. of Brain and Cognitive Sci., [2]CSAIL, MIT, Cambridge, MA; [3]Dept. of Psychology, Emory Univ., Atlanta, GA

Abstract: We are constantly encoding the world around us into memory, but remembering only some images of faces or places, while forgetting others. These images differ in their memorability - a predictive value of whether a novel stimulus will be remembered or forgotten that is highly consistent across observers (Bainbridge et al., 2013; Isola et al., 2011). The current study investigates how memorability is represented in a classic memory-related cortical region, the medial temporal lobe. In an fMRI study, human observers (N=16) viewed images of faces and scenes that were determined a priori as being highly memorable or highly forgettable, and viewed them only once each. While in the scanner, participants performed an orthogonal categorization task (i.e., male/female for faces; indoor/outdoor for scenes). Participants were not aware of any memory-related nature to the study, and completed a post-scan memory test. Stimuli were controlled for both low-level image statistics (i.e., spatial frequency, color), as well as higher-level attribute information (i.e., gender, race, attractiveness, and emotion for faces, and indoor/outdoor, natural/manmade, and no faces or animals for scenes). Despite these tightly controlled visual and semantic attributes, significant differences in BOLD activity were found between memorable versus forgettable images in regions of the medial temporal lobe: the amygdala (for faces only), perirhinal cortex, and parahippocampal cortex. In addition, multivoxel pattern analyses found significantly high pattern classification accuracy for memorable images versus forgettable images in the hippocampus, perirhinal cortex, and parahippocampal cortex. Neither univariate nor multivariate effects of memorability were found in the entorhinal cortex. These results indicate that i) even when an image is first perceived, the medial temporal lobe is distinguishing images that should be later remembered versus forgotten, and ii) image

memorability can be utilized as a general image attribute that is linked to stereotyped cortical activity.

Title: Cortical representation of serial position information in temporal sequences

Authors: ***L.-T. HSIEH**[1,2], C. RANGANATH[1,2]
[1]Ctr. for Neurosci., [2]Dept. of Psychology, UC Davis, Davis, CA

Abstract: The ability to remember what happens when is critical for human memory functions. Previous studies in animals have shown that the hippocampus is critical for representing time between sequential events, but little is known about whether or how serial order information about learned sequences is represented by the hippocampus and other brain regions. Our recent fMRI study (Hsieh et al., 2014) showed that multivoxel hippocampal activity patterns specifically carry information about objects in temporal position, indicating conjunctive object-by-position coding in the hippocampus, in contrast to nearby perirhinal and parahippocampal cortices whose activity patterns are sensitive to object and serial position information, respectively. To further examine the role of other cortical regions in temporal sequence representation, we conducted multivoxel pattern analyses on the same data set, this time focusing on cortical regions of interest (ROIs) that have been implicated in episodic retrieval. The experiment consisted of a pre-scan learning phase and a post-learning MRI retrieval session. During the learning phase, participants learned five "Fixed" and one "Random" sequences. Each sequence consisted of five distinct objects and the order of the objects was always constant for the "Fixed" sequences. For the "Random" sequence, it always consisted of the same five objects but the order of the objects was always random. Thus, participants were able to learn about each object in the "Random" sequence, but could not consistently associate an object with any serial position. Next, they were scanned during exposure to multiple repetitions of these sequences while making a series of semantic judgments on each presented object. Pattern analyses were

conducted on data extracted from individual cortical ROIs. Cortical ROIs were identified using an automated parcellation procedure implemented in Freesurfer which defines regions based on individual participant's gyral and sulcal anatomy. Preliminary results show that many ROIs in prefrontal and parietal cortex, exhibited pattern similarity profiles that are indicative of coding of serial position across fixed and random sequences, whereas ventral stream ROIs show profiles that are consistent with object-specific coding. Importantly, none of these cortical ROIs exhibit patterns that are similar to the conjnuctive object by position coding seen in the hippocampus.

Title: A high-resolution fmri investigation of temporal memory within the medial temporal lobe

Authors: *J. M. ROBERTS, Z. M. REAGH, E. MURRAY, M. A. YASSA
Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: The encoding of the temporal relationship between previously experienced events is an important aspect of episodic memory. The ability to remember that "A happened before B" is a critical basis for causal inferences, and is therefore a crucial component of an animal's ability to learn to modify behavior in order to increase its odds of survival. Previous studies of memory for temporal sequences and the recent discovery of "time cells" suggest that the medial temporal lobe (MTL) plays a role in encoding time within memory. Further, the discovery that many cells acting as "time cells" within the MTL also act as "place cells" or "grid cells" suggesting that temporal memory and spatial memory may share neural processes within the MTL. We used high-resolution BOLD fMRI techniques to investigate the role of sub-regions of the MTL in processing the temporal aspects of memory. The behavioral task used in the study was designed to examine the effects of temporal interference (operationally defined in terms of the number of intervening items) on temporal order discrimination (operationally defined as correct judgment of "which came first?") Behaviorally, we observed that temporal order discrimination performance increased linearly as we reduced temporal interference, consistent with our prior

work (Roberts et al., in press). This parametric modulation was a necessary pre-condition before using the task to possibly examine a pattern separation process in the temporal domain using high-resolution fMRI. Our fMRI analyses found signals in the CA1 and DG/CA3 regions that were modulated by accuracy and by amount of temporal interference. Our findings are consistent with a role for hippocampal subfields in temporal order memory processes and potentially a pattern separation process.

Title: Learning contextual significance in the medial temporal lobe

Authors: *L. A. LIBBY[1], M. C. INHOFF[1], B. C. LOVE[3], C. RANGANATH[1,2]
[1]Psychology, [2]Ctr. for Neurosci., UC Davis, Davis, CA; [3]Exptl. Psychology, Univ. Col. London, London, United Kingdom

Abstract: Learning the contextual significance of environmental cues is critical for navigating everyday life, but relatively little is known about the neural underpinnings of this process. Medial temporal lobe (MTL) regions have been shown to code for contextual regularities, and prefrontal cortex (PFC) function has been associated with the use of explicitly-cued contextual rules, but it is unclear if and how these regions are involved in the learning and deployment of context-guided rules for behavior. To address this question, we tracked the evolution of neural patterns across the learning of a complex set of associative rules. During fMRI scanning, participants were presented with sixteen repeating sequences of three objects. In each sequence, the first two objects (Cue 1 and Cue 2) were drawn from a set of 3D renderings of novel objects; the third object (outcome) was either a hat or a glove. During presentation of Cue 2, participants predicted whether the third object would be a hat or glove, and feedback on their prediction was

provided in concert with the outcome. No single cue was independently predictive of hat or glove outcome; it was only through integration between Cue 1 and Cue 2 that participants could make accurate predictions. Critically, some pairs of Cue 1 objects preceded the same Cue 2-outcome associations such that these Cue 1 pairs provided overlapping contextual information that could guide ensuing prediction responses. We predicted that, over the course of learning, brain regions coding for contextual significance activated by Cue 1 would increasingly show greater neural similarity between pairs of trials with the same Cue 2-outcome associations, compared to different associations. Single-trial parameter estimates corresponding to activity evoked by the Cue 1 phase of each trial were calculated and entered into multivoxel pattern similarity analysis. Searchlight analysis revealed MTL and anterior PFC clusters that coded for Cue 1 contextual significance. A computational modeling approach applied to individual subject outcome prediction responses revealed differences in the relationship between prediction success and context coding in these regions that was dependent upon the shape of the learning curve. Planned analyses will relate model-based metrics of contextual significance learning to voxel activity patterns on a trial-by-trial basis.

Title: Tracking location during complex human path integration recruits hippocampus and retrosplenial cortex

Authors: *E. R. CHRASTIL[1,2,3], K. R. SHERRILL[1,2,3], M. E. HASSELMO[1,2], C. E. STERN[1,2,3]
[1]Dept. of Psychological & Brain Sci., Boston Univ., Boston, MA; [2]Ctr. for Memory and Brain, Boston, MA; [3]Athinoula A. Martinos Ctr. for Biomed. Imaging, Charlestown, MA

Abstract: Path integration is the constant updating of the navigator's position and orientation within the environment during movement, and it has been studied extensively in animals. In humans, fundamentals for path integration have been localized in the medial temporal lobe

(MTL), and hippocampal activity predicts accuracy in a triangle completion path integration task (Wolbers et al., 2007) and goal-directed navigation tasks (Sherrill et al., 2013; Brown et al, 2014; Brown and Stern, 2013). The retrosplenial cortex (RSC) and posterior parietal cortex (PPC) may play a key role in tracking movement. In addition, specific aspects of movement such as distance traveled, arc degrees traveled, and time traveled could influence processing (Chrastil, 2013). This experiment used fMRI to test the hypothesis that the hippocampus, RSC, and PPC support human path integration. 24 participants performed a location-tracking task (loop closure) while undergoing fMRI scanning. In the Loop Closure task, participants viewed a short video (5-25 sec) of a virtual environment (random poles on a textured ground plane), with movement traveling in a loop pattern. Movement was varied such that it either formed a complete circle to return to the start location, only traversed part of a circle, or overshot the start location. The design included variance in loop radius and travel speeds. After each video, participants indicated whether the loop movement ended at the loop's start location or in a different location. Successful loop closure required participants to track their location throughout the movement relative to the start location. During event-related fMRI scanning, 36 trials were collected across six 10-minute scans (3 T Siemens TrioTim MRI scanner, 3.4x3.4x3.4 mm voxels, TR = 2s, 33 slices, flip-angle = 85o). To examine brain regions recruited for successful loop closure, our univariate analysis contrasted Correct > Incorrect Trials. These results demonstrated significantly greater activity in the right hippocampus, left RSC, bilateral precuneus, and bilateral medial prefrontal lobe, suggesting these areas play a role in accurately tracking location during movement. In addition, parametric analyses were carried out examining distance traveled from start location, arc degrees traveled, time traveled, and distance relative to the goal. Preliminary results show that multiple brain regions track these parameters, including caudate, thalamus, cingulate, superior parietal lobule, and lateral prefrontal cortex. Together, our results suggest that regions within the MTL, RSC, and medial prefrontal cortex support successful location tracking during human path integration.

Title: Encoding related activity in the hippocampus and medial temporal lobe cortex is modulated by aerobic fitness and BDNF in humans

Authors: *M. F. DUNNE[1], A. S. WHITEMAN[2,3], R. K. NAUER[2,3], C. E. STERN[2,3], K. SCHON[4,3]
[1]Anat. and Neurobio., Boston Univ., Somerset, MA; [2]Dept. of Psychological and Brain Sci., [3]Ctr. for Memory and Brain, Boston Univ., Boston, MA; [4]Dept. of Anat. and Neurobio., Boston Univ. Sch. of Med., Boston, MA

Abstract: Convergent evidence from human studies and animal models suggest aerobic exercise and fitness may alter brain morphology and improve cognition. In rodents, running is thought to enhance hippocampal dependent memory performance, possibly by increasing expression of the neurotrophin BDNF in hippocampus and upregulating adult neurogenesis in the dentate gyrus (DG). Recent studies in humans suggest aerobic fitness may be associated with cerebral blood volume in the DG (and possibly the entorhinal cortex - EC; Pereira et al., 2007) and with hippocampal activity during virtual navigation (Holzschneider et al., 2012). Here, we sought to examine whether aerobic fitness and BDNF modulate brain activity in specific medial temporal lobe (MTL) cortex and hippocampal subregions in humans. We examined this question by using a standard graded treadmill test of aerobic capacity (VO_2 peak), blood draws for serum BDNF, and high-resolution fMRI (Phillips Achieva, 3.0T, TR = 2s, resolution = 1.5 mm^3) optimized for precise localization of task-related activation within the MTL. We scanned participants as they performed a variant of a delayed match to sample (DMS) task known to recruit the hippocampus and EC/perirhinal cortex (Schon et al., 2004, 2005). Participants learned a set of 144 trial unique but content similar outdoor scenes in the context of a DMS paradigm (Nauer et al., SfN abstract 2014). After fMRI scanning, participants performed a surprise subsequent memory test for all 144 old scenes, randomized with an equal number of content similar lures. We used SPM8 for analysis and ANTs software (Avants et al., 2011) for cross participant alignment of manually traced regions of interest (EC, perirhinal, and parahippocampal cortex; hippocampal subregions CA1, DG/CA3, and subiculum). Consistent with our previous work (Whiteman et al., 2014), preliminary analysis (N = 16) showed that a subsequent memory effect (remembered > forgotten) was modulated by both BDNF and aerobic fitness throughout the MTL cortex and hippocampus. In addition, aerobic fitness was positively associated with volume in the EC. Our study extends findings from rodent models to humans and supports the idea that aerobic fitness impacts structure and function in the entorhinal-hippocampal memory system.

Title: Are familiarity-based memory representations in human perirhinal cortex distributed

Authors: *C. B. MARTIN[1], R. A. COWELL[2], P. L. GRIBBLE[1], S. KöHLER[1,3]
[1]Western Univ., London, ON, Canada; [2]Univ. of Massachusetts Amherst, Amherst, MA;
[3]Rotman Res. Institute, Baycrest Ctr., Toronto, ON, Canada

Abstract: Over the past decade, much neuropsychological and functional imaging research has focused on identifying the brain regions related to familiarity and recollection. One prominent proposal that has emerged from this research stipulates that perirhinal cortex (PrC) supports familiarity-based item recognition, whereas hippocampal contributions are not critical for this process. Relatively little is known about how familiarity signals are coded in human PrC. Here, we started addressing this question using multivoxel pattern analysis to examine right PrC activity associated with the perceived familiarity of faces. A linear classifer allowed us to extract a pattern that successfully distinguished between perceived familiarity and novelty (Martin et al., 2013, Journal of Neuroscience, 33, 10915-23). We next sought to characterize the spatial distribution of this pattern. This issue is important given that recent research has pointed to a functionally defined contiguous region that responds differentially to faces in right PrC (i.e., a 'face patch'; O'Neil et al., 2014, NeuroImage, 92, 349-55). The diagnostic voxels that allowed for successful classification were widely distributed across right PrC; only 18% of voxels in the pattern that allowed us to distinguish between subjectively familiar and novel faces overlapped with the functionally defined face patch that was identified using data from an independent localizer. In line with this finding, attempts to classify familiar and novel faces using the restricted set of voxels that comprise the contiguous face patch were unsuccessful. Critically, the distributed set of voxels that did allow for familiarity-based classification still showed category-specificity (i.e., a strong response to faces than objects and scenes). We next explored the notion of distributed representation at the level of distributed information content. In this set of analyses we found evidence that pattern classifier performance does not merely reflect sensitivity to a spatially distributed mean difference between familiar and novel trials. This latter outcome was found to be related to the fact that the pattern included decreases as well as increases in signal

between familiar and novel trials. Taken together, the current findings offer promising initial evidence that argues in favor of distributed familiarity representations.

Title: Relationship of hippocampal subfields to memory performance changes with age

Authors: ***S. G. TRAVIS**[1], Y. HUANG[1], F. OLSEN[1], R. CARTER[1], E. FUJIWARA[1], P. SERES[2], N. V. MALYKHIN[1]
[1]Ctr. for Neurosci., [2]Biomed. Engin., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Background: Whole hippocampal volumes can decline with age and predict episodic memory performance; however it is unclear how volumes of subfields within the hippocampus (HC) decline with age, and how this affects their relationship with episodic memory over an entire lifespan. Most structural MRI studies have examined the HC subfields within a single subregion of the HC and used specialised experimental memory paradigms. The purpose of the present study was to determine the association between volumes of whole HC and HC subfields with performance on a standard neuropsychological assessment of memory. Methods: We recruited 103 healthy participants from the ages of 18 to 85, and used a median split in age to determine young and old groups. Participants were screened neurodegenerative and psychiatric disorders. Ultra high resolution MRI datasets were acquired on a Varian 4.7T scanner. The HC subfields - the cornu ammonis 1-3 (CA), dentate gyrus (DG), and subiculum (SUB) - were segmented manually within three hippocampal subregions - the head, body and tail. Participants were administered the Wechsler Memory Scale, 4th edition (WMS-IV) to assess performance in the Visual Memory Index (VMI), Auditory Memory Index (AMI), Visual Working Memory Index (VWMI), and the Delayed and Immediate Memory Indicies (DMI and IMI). Pearson correlations were used to determine relationships between age, subfield volumes, and memory performance. Results were corrected for multiple comparisons using Bonferroni correction. Results: All memory indexes correlated negatively with age (AMI $r=-.48$, $p<.001$; VMI $r=-.76$,

p<.001; VWMI r=-.74, p<.001; IMI r=-.67, p<.001; and DMI r=-.69, p0.27, p0.28, p.28, p<.008), however not the HC Head or Tail. Conclusions: In general, total HC, total HC body and total DG volumes were the most predictive of memory performance. Over the entire lifespan, the dentate gyrus may play the most central role in aging of all hippocampal subfields. This is true not only in neurodegenerative disease processes, but in a sample of healthy individuals.

Title: Oculomotor capture by aversive stimuli in the absence of contingency knowledge

Authors: *L. HOPKINS, F. J. HELMSTETTER, D. E. HANNULA
Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Can stimuli associated with an aversive event via Pavlovian fear conditioning capture attention even when participants cannot explicitly report the association? In a recent eye tracking investigation, we found that individuals look disproportionately at items in a complex scene that predict the presence or absence of shock. Critically, this differential viewing effect was evident before participants were aware of the item's value. Here, we investigate whether or not eye movements are captured involuntarily by a conditional stimulus (CS) when this pattern of viewing runs counter to task demands. To address this question, we developed a novel variant of the irrelevant singleton paradigm that has been used to study attention capture. Subjects performed a two-part task while their eye movements were recorded. During an initial training phase displays consisted of eight red objects located on an imaginary circle surrounding central fixation. One object was either a horizontal or vertical rectangle, and the remainders were circles. Subjects were instructed to fixate the rectangle as quickly as possible because slow performance would elicit a shock. In reality, shock delivery was predetermined. One rectangle (e.g., horizontal) was paired with shock on 80% of the trials (CS80) while the other (e.g., vertical) was paired with shock on 20% of the trials (CS20). During a subsequent test phase, each trial began with the presentation of eight red circles surrounding a central fixation point. Following a 1s exposure to this display, one circle changed from red to gray and subjects were told to fixate the

gray circle as quickly as possible. The CS80 appeared in the display coincident with this change on 1/3 of the trials; the CS20 was presented on another 1/3 of the trials. After the test phase, subjects completed a post-experimental questionnaire designed to evaluate contingency awareness. It was predicted that oculomotor capture would occur most often when the CS80 was present in the test display. During training, saccades to CS80s were faster than to CS20s. This effect seems to reflect a gradual acquisition of contingency knowledge, as faster saccades to CS80s only occurred during the last half of the training session. During test, subjects were slower to fixate the target when a CS was present. As predicted, eye movements were captured more often by the CS80 than the CS20, an effect that did not depend on explicit knowledge of the imposed contingencies Together, these results suggest that eye movements can be captured by an aversive item involuntarily and without awareness of learned associations.

Title: Contextual significance shapes item representations in the medial temporal lobe

Authors: *M. C. INHOFF[1], L. A. LIBBY[1], B. C. LOVE[3], C. RANGANATH[2]
[1]Psychology, [2]Ctr. for Neurosci., UC Davis, Davis, CA; [3]Exptl. Psychology, Univ. Col. London, London, United Kingdom

Abstract: Models of medial temporal lobe (MTL) function hold that individual MTL regions support the processing of different aspects of memory. Specifically, the perirhinal cortex (PrC) and parahippocampal cortex (PhC) are thought to represent information about items and contexts, respectively, while the hippocampus functions to bind this item and context information. Recent investigations have also implicated the MTL in representing environmental regularities and in biasing behavior based on a prior encoding context. Despite this, it is

unknown whether contextual significance, or predictive validity for future events, can influence item representations. To address this question, neural pattern similarity was assessed before and after participants learned to predict whether 16 fully crossed pairs of 8 novel objects were associated with either a hat or glove outcome. Object pairs and outcome information were presented sequentially during learning; half of the objects were always presented first in a pair (Cue 1), while the remaining half were always presented second (Cue 2). Participants were asked to predict the category outcome associated with the pair during Cue 2 presentation, and were subsequently given feedback on their choice. Critically, object pair-category outcome sequences were designed to create subsets of Cue 1 objects with shared contextual significance, or shared information about possible Cue 2-outcome associations. For example, Cue 1A and Cue 1A' both resulted in a hat outcome when paired with Cue 2C, and a glove outcome when paired with Cue 2D. This manipulation allowed for an assessment of whether item representations in the MTL, as measured by multi-voxel activity patterns, were modulated by learning the contextual significance of each object in the full set of object pair-outcome sequences. Preliminary analyses indicate that regions in PrC and PhC showed learning-related changes in object representations that were linked to behavioral performance at the end of learning. Future analyses will apply computational modeling techniques to relate differences in contextual learning to neural changes in object representations.

Title: Disparateness of episodic details modulates default network activity during future simulation

Authors: *D. ADDIS[1], R. P. ROBERTS[1], V. VAN MULUKOM[1], R. SUMNER[1], C. L. GRADY[2], D. L. SCHACTER[3]
[1]Sch. of Psychology, The Univ. of Auckland, Auckland, New Zealand; [2]Rotman Res. Inst., Toronto, ON, Canada; [3]Dept. of Psychology, Harvard Univ., Cambridge, MA

Abstract: Objectives: Remembering the past and imagining the future recruit a common network including many regions of the default-mode network. However, previous work has shown that some nodes of this network (e.g. the hippocampus) produce a greater BOLD response when imagining relative to remembering. One interpretation for this increased default network activity is that imagining the future requires the flexible integration of details from disparate memories to produce a coherent imagined scenario. The current study directly tested this hypothesis by manipulating the degree of disparateness of memory details incorporated into an imagined scenario. **Methods**: In a pre-scan session, participants reported 120 people, locations and objects from 3 social spheres (i.e. 40 per sphere) they had encountered in the previous 5 years. These details were recombined to create 90 person/location/object sets where the 3 details all came from the same social sphere (low disparateness) or the 3 details each came from a different sphere (high disparateness). In the fMRI session, participants were presented with 45 low and 45 high disparateness trials in an event-related design; for each trial, they had to silently imagine a future scenario involving all 3 details (10 *s*) and make a button press once they had constructed an event. This was followed by rating the preceding imagined scenario for amount of detail (4 *s*). In addition, a semantic/visuospatial control task was also presented. **Results**: Behavioural results showed that scenarios in the low disparateness condition were constructed more quickly and rated as more detailed than scenarios in the high disparateness condition. A mean-centred partial least squares analysis produced a significant latent variable showing increased activity in default-mode network regions for both simulation conditions relative to the control task. Importantly, analysis of the brain scores demonstrated that this network was more strongly engaged in the low versus high disparateness condition. **Conclusion:** The finding of reduced default-network activity when constructing simulations from highly disparate episodic details is likely due to participants not being able to successfully integrate the details from different social spheres into a coherent scenario. One potential avenue for future research is to adopt an individual differences approach to determine if certain traits (e.g. cognitive flexibility or creativity) are associated with the ability to imagine scenarios involving highly disparate memory details.

Title: Hippocampal theta during encoding predicts subsequent attentional deployment

Authors: *E. PATAI, M. WOOLRICH, G. SALVATO, A. NOBRE
Oxford Ctr. For Human Brain Activity, Oxford, United Kingdom

Abstract: Spatial and contextual associations in long-term and short-term memory are known to depend on a network of areas centred around the hippocampus, and theta-band activity has been implicated in the integration of information across the brain areas involved. Much less well understood is whether and how learned spatial and contextual associations can guide attention when individuals anticipate target events within learned contexts. In this experiment, we used magnetoencephalography (MEG) to explore the neural signatures of item-context encoding, using a paradigm based on contextual cueing developed in our lab. We were interested in how the encoding of spatial locations of objects in complex scenes would develop across learning, and how this would relate to deployment of attention to those spatial locations in a subsequent memory-guided attention paradigm. Using a beamforming technique, we found a theta network of areas involving the left and right hippocampus, right parahippocampal cortex, precuneus, and medial prefrontal cortex, as well as a network of areas in the alpha range, including anterior cingulate cortex, frontal eye-fields and intraparietal sulci. Additionally, the magnitude of hippocampal theta during learning was correlated with subsequent lateralized alpha-band activity when subjects were utilizing their memories to deploy attention. Our results reveal co-activation of traditionally segregated memory and attention networks within different frequency bands, which interact during encoding, as well as predict the strength of memory-based attentional bias.

Title: Human perirhinal cortex supports frequency judgments as well as judgments of cumulative lifetime familiarity

Authors: *D. DUKE[1], B. BOWLES[2], C. B. MARTIN[1], S. R. ROSENBAUM[3,4], K. MCRAE[1], S. KÖHLER[1,4]
[1]Western Univ., London, ON, Canada; [2]Dept. of Neurosci., UC Berkeley, Berkeley, CA; [3]Dept. of Psychology, York Univ., Toronto, ON, Canada; [4]Rotman Res. Institute, Baycrest Ctr., Toronto, ON, Canada

Abstract: Neurophysiological research in non-human primates has revealed differences between recency and cumulative familiarity signals in the anterior temporal lobe, including perirhinal cortex (PrC). These signals are thought to contribute to recognition-memory, independent of successful recollection of episodic detail about a pertinent prior exposure. To date, most studies in humans employing meaningful stimuli to probe recognition memory have addressed recency rather than cumulative lifetime familiarity. While it has been demonstrated that humans can judge the cumulative familiarity of verbal concepts over a lifetime of experiences (e.g., how familiar are you with aardvarks?) in a reliable manner, little is known about the neural mechanisms that support this ability. Here, we asked whether a left anterior temporal-lobe lesion that includes PrC but spares the hippocampus is associated with abnormalities in the assessment of lifetime familiarity in an individual (NB) with previously documented isolated impairments in recency (i.e., familiarity in recognition memory tasks with recent study exposure; Bowles et al., 2007, *PNAS*,16382-7). We also examined whether a selective hippocampal lesion with sparing of perirhinal cortex would be associated with normal performance in a developmental amnesic individual (HC) with documented deficits in the recollection of lifetime episodes (Rosenbaum et al., 2011, *Neurocase*, 394-409). NB demonstrated abnormal and less consistent lifetime familiarity assessment relative to healthy controls over multiple testing sessions. Furthermore, NB's familiarity ratings were abnormal regardless of whether probed with verbal labels or visual images of object concepts. Patient HC, by contrast, provided lifetime familiarity judgments that did not differ from those of controls, despite her established autobiographical memory impairment. In a second study we employed fMRI to determine whether PrC carries both lifetime familiarity signals and signals of recency for the same type of verbal concepts in healthy individuals. In order to probe recency with a task format similar to that used in the assessment of cumulative lifetime familiarity, we asked participants to judge the frequency of exposure to these stimuli in a study phase. An area in left PrC was the only cortical region in which activity tracked heightened impressions of lifetime familiarity (via increases BOLD signal) as well as the perceived frequency of recent exposures (with decreases). Together, these data strongly suggest that PrC is not only crucial for the assessment of recent changes in familiarity, but is also crucial for judging cumulative lifetime familiarity.

Title: Connectivity between the perirhinal cortex and V2 in young and older adults

Authors: ***L. CACCIAMANI**[1], E. WAGER[1], M. A. PETERSON[1,2], P. E. SCALF[1]
[1]Psychology Dept, [2]Cognitive Sci. Program, Univ. of Arizona, Tucson, AZ

Abstract: Prior research showed that the perirhinal cortex (PRC) is sensitive to the familiarity vs. novelty of whole objects, and also of the parts comprising them. Specifically, for objects in the right visual field (RVF), BOLD activity in the PRC was highest for Familiar Configurations, moderate for Control Novel Configurations in which both the configuration and the parts comprising it were novel, and lowest for Part-Rearranged Novel Configurations, created by spatially rearranging the parts of paired familiar configurations (Peterson et al., 2012). Moreover, activation in V2, a low-level visual area that represents object parts, was greater for the same familiar parts when they comprised a familiar configuration rather than a novel configuration. That the V2 activity pattern mimicked that of the PRC suggested that feedback from the PRC modulated responses in V2, but no connectivity analyses were performed. In the current study, we used BOLD fMRI and functional connectivity analyses to directly investigate whether the PRC modulates responses in V2, and whether this modulation changes with age. Young and older adults performed an object decision task on silhouettes presented in the periphery. Young subjects showed the expected linear pattern of BOLD activation in the left hemisphere (LH) PRC for RVF silhouettes: Familiar > Control Novel > Part-Rearranged Novel Configurations, $p < .05$. Older subjects did not show this linear pattern in the LH PRC, $p > .10$, consistent with the hypothesis that PRC functioning declines with age (c.f., Ryan et al., 2012). A functional connectivity analysis using the LH PRC as the seed region of interest revealed a significantly stronger coupling between the LH PRC and LH V2 for RVF presentations in young than in older adults, $p = .05$. Results support the hypothesis that top-down feedback from the PRC modulates responses in V2, consistent with a dynamic, interactive view of object perception. That this

feedback was significantly reduced in older subjects might indicate an age-related decline in the PRC, its functional connections to low levels, or both. This project is the first to use functional connectivity analysis to demonstrate the influence of the PRC on responses of a lower-level brain region.

Title: Context and memory phase dependent effects of stress on extinction memory in a predictive learning task

Authors: *O. T. WOLF[1], T. C. HAMACHER-DANG[2,3]
[1]Cognitive Psychology, GAFO 02, Ruhr-Universitaet Bochum, Bochum, Germany; [2]Cognitive Psychology, Ruhr Univ. Bochum, Bochum, Germany; [3]Intl. Grad. Sch. of Neurosci., Bochum, Germany

Abstract: Psychotherapeutic treatment of anxiety disorders, e.g. via exposure therapy, typically relies on the principle of extinction. Recovery effects such as spontaneous recovery or renewal indicate that extinction does not lead to an erasure of the memory trace but constitutes a form of new inhibitory learning mediated by the prefrontal cortex. Stress modulates episodic memory in a phase-dependent way, with impairing effects on retrieval and enhancing effects on consolidation. First evidence suggests that this might also be the case for extinction memory. In three studies applying a predictive learning task in the form of a renewal paradigm, we investigated how stress affects extinction memory along the time course of its acquisition, consolidation and retrieval. On three consecutive days, participants learned an association between stimuli and outcome in one context on day 1, underwent extinction in a second context on day 2 and were tested for retrieval in both contexts on day 3. We induced stress via the socially evaluated cold pressor test prior to retrieval testing on day 3 (study 1), directly after

extinction learning on day 2 (study 2) or 20 minutes before extinction learning (study 3). As assessed by salivary cortisol and blood pressure, stress induction proved to be successful in all studies. A renewal effect was present, as reflected by stronger recovery of responding when retrieval was tested in acquisition context trials compared to extinction context trials. In study 1, stressed participants showed impaired retrieval of extinction memory. In contrast, stress directly after extinction learning (study 2) enhanced the consolidation of extinction memory, as indicated by reduced spontaneous recovery on day 3. This effect, however, was restricted to the extinction context. Pre-extinction stress (study 3) in contrast, strengthened extinction memory independent of context. Our results indicate that stress hormones modulate extinction memory in a predictive learning task in a phase dependent manner. Moreover these effects are context dependent most likely reflecting a stress induced modulation of hippocampal plasticity.

Title: Functional connectivity from the human entorhinal cortex: A cortico-cortical evoked potential study

Authors: *H. TAKEYAMA[1,2], R. MATSUMOTO[3], K. KOBAYASHI[2], K. USAMI[2], A. SHIMOTAKE[2], T. KIKUCHI[4], T. KUNIEDA[4], S. MIYAMOTO[4], R. TAKAHASHI[2], A. IKEDA[3]
[2]Dept. Neurol., [3]Dept. Epilepsy, Movement Disorders and Physiol., [4]Dept. Neurosurg., [1]Kyoto Univ., Kyoto City, Kyoto, Japan

Abstract: Background: Entorhinal cortex (EC), the important subregion in the medial temporal lobe memory network, has been considered to have rich connections to various cortical regions as well as to the hippocampus and the classical Papez circuit. The knowledge of connectivity mostly came from the non-primate tract-tracing studies, and thus little is known in humans. We aimed to clarify its connectivity by means of an electrical, tract tracing method of cortico-cortical evoked potential (CCEP) (Matsumoto et al., 2004). Methods: We recruited 7 patients with

medically intractable temporal lobe epilepsy, who underwent invasive presurgical evaluations with subdural electrodes (3 men, age 17-52, 56-102 electrodes). Single-pulse electrical stimulation was delivered to a pair of electrodes on EC and that 2 cm lateral to EC (non-EC: mainly on the anterior fusiform gyrus). Evoked responses time-locked to stimuli (CCEPs) were recorded from the rest of the cortices covered by subdural electrodes. Results: In all 7 patients, EC stimulation evoked early positive potentials of similar waveform and latency within the subjects across almost all electrodes in the temporal, parietal and frontal cortices [Latency of the positive potential: average across electrodes within the subjects, mean 17.5 ms (range 9.5-34.9 ms), SD within the subjects, mean 3.1 ms (range 0.8-9.8 ms)]. This sharp positive potential was generally followed by a blunted, rather sustained negative potential. In contrast, in non-EC stimulation, the positive potential of longer latency was observed at significantly fewer electrodes than in EC stimulation ($p<0.05$, Wilcoxon ranking scale test). Remote isolated CCEP fields, which usually reflect direct cortico-cortical connections, were significantly fewer in EC stimulation than in non-EC stimulation ($p<0.05$, Wilcoxon ranking scale test). Discussion: In the present CCEP study using subdural electrodes, uniform sharply contoured positive potentials were broadly recorded from various cortical regions. This far field potential like responses may indicate that EC has rich connections to various cortical regions probably through subcortical structures such as thalamus, or that EC stimulation simply induced widely distributed electric field due to volume conduction. Further complementary studies with different methodologies are needed to establish the EC connectivity in humans.

Title: Properties of spatial contextual representation within the human hippocampus during episodic memory retrieval

Authors: *C. KYLE, J. STOKES, A. EKSTROM
Univ. of California, Davis, Davis, CA

Abstract: Spatial context forms an integral part of our memory for events yet the neural basis in humans remains unclear. While rodent hippocampal place cells code specific spatial environment and remap in response to changes in landmark configuration, how the human hippocampus codes changes in spatial context is not known. To test this issue, nineteen participants learned the configurations of four virtual reality cities of varying similarity. City 1 and City 2 shared landmark identity and spatial geometry but contained conflicting landmark-location pairings; City 3 involved the same landmarks but with a new spatial geometry while City 4 involved novel landmarks in a novel configuration. Following encoding, participants retrieved information about the recently learned cities by making judgments about their relative distances while undergoing high-resolution hippocampal imaging (1.4x1.5x1.9 mm voxels). A one way ANOVA on performance and reaction time revealed a main effect of city, driven by lower performance and higher reaction time in city 3 (repeated landmarks, novel configuration)(Performance: $F(3,19)=20.9$, RT: $F(3,19)=7.8$, $p<.01$). Examining univariate activation patterns, a 4x5 City by subregion ANOVA revealed a main effect of subregion $F(4,19) = 2.8$, $p=.03$, and a marginal city by subregion interaction $F(12,19) = 1.7$, $p= .058$. Multivariate pattern analyses also revealed differences in voxel pattern similarity for retrieving details from the same vs. different cities. Together, these results suggest the importance of the hippocampus to retrieving details of recently learned spatial layouts. They further suggest that neural patterns during retrieval vary for different cities, consistent with the idea of "remapping."

Title: Distinct white matter correlates of intelligence, recall and recognition: Evidence from developmental amnesia

Authors: *A. M. DZIECIOL[1], E. Z. PATAI[1,2], K. K. SEUNARINE[1], C. A. CLARK[1], F. VARGHA-KHADEM[1]
[1]UCL Inst. of Child Hlth., London, United Kingdom; [2]Dept. of Psychiatry, Univ. of Oxford, Oxford, United Kingdom

Abstract: Developmental amnesia (DA) is a selective episodic memory disorder associated with hypoxia-induced bilateral hippocampal atrophy. Previously, we reported evidence of white matter damage in patients with DA (Dzieciol et al., SfN 2012). Here, we examine white matter abnormalities in DA using tract-based spatial statistics (TBSS; Smith et al., 2006), a quantitative method of analysing diffusion tensor properties. Fractional anisotropy (FA) relates to the directionality of water diffusion, whereas mean diffusivity (MD) relates to the magnitude of diffusion regardless of its direction. In the brain's white matter low FA and high MD can both indicate damage. Echo-planar MR images were acquired on a 1.5 T Siemens scanner with an isotropic set of 20 directions at b=1000 s/mm2, repeated 3 times in a single scan session. Fifteen patients with DA (age range 10 - 35 years), 14 patients with hippocampal atrophy and memory impairment (age range 8 - 16 years) and 29 age- and gender-matched controls participated. Results showed that compared to controls, patients had global reductions in FA and widespread increases in MD throughout the core white matter tracts. To follow-up, we carried out a region-of-interest analysis on mean FA in the white matter skeleton, and in memory-relevant white matter tracts within the medial-temporal lobe: the hippocampal cingulum and the fornix. We uncovered two double dissociations between the neural correlates of the patients' intelligence and memory. First, across the entire patient group, mean FA in the white matter skeleton predicted full scale IQ, but not the memory quotient (MQ). Conversely, mean FA in the fornix was related to MQ, but not to IQ. Second, FA in the fornix was the strongest predictor of patients' verbal recall ability, whereas FA in the hippocampal cingulum was the strongest predictor of auditory recognition in a stepwise regression with backward elimination. Neither verbal recall nor recognition scores were correlated with FA in the white matter skeleton. Interestingly, regional estimates of FA were superior to estimates of hippocampal volume as predictors of memory outcomes. In conclusion, these results suggest that diffuse white matter damage does not contribute to the memory deficits of patients exposed to early hypoxic-ischaemic injury, but it does relate to patients' intellectual function, while local damage in the fornix and the cingulum contributes to recall and recognition processes, respectively. These findings provide new evidence of a separation between neural substrates of recall and recognition in the white matter of the medial temporal lobe.

Title: Effects of varying cloze probability on prediction and integration during sentence processing

Authors: *K. P. REVILL
Emory Univ., Atlanta, GA

Abstract: Understanding sentences involves identifying single words, integrating those words into the grammatical and semantic structure of the unfolding sentence, and using situational and background knowledge to further comprehend the intended meaning. The interplay of information across these levels shapes online comprehension during sentence processing. Prior eyetracking work has shown rapid effects of sentence context on sentence-final spoken word recognition, with participants making anticipatory eye movements to potential objects following a constraining verb and showing less competition from phonologically similar words that are semantically inconsistent. In the ERP literature, the N400 component is modulated by prediction error, with smaller N400s for expected words in highly versus moderately constraining sentences and smaller differences between expected and unexpected words in less constraining sentence contexts. Existing fMRI studies of sentence comprehension have focused almost exclusively on activation differences between expected, unexpected, and anomalous words in highly constraining sentence contexts. The goal of this study is to examine the effects of varying sentence constraint strength on brain activation during sentence processing, both during the accumulation of sentential information and upon encountering a sentence-final word that is either expected or unexpected given the prior context. Sixteen subjects performed an anomaly detection task on the final word of 120 sentences varying in cloze probability from 0 to 1. Sentence final words were expected, unexpected but sensible, or anomalous. Sentences were presented word-by-word, with each word presented centrally for 300ms with a 200ms ISI. A 2-4s delay between the penultimate and final word allowed separation of predictive processing from integration of the sentence-final word. Delay period activity was modulated by the cloze probability of the sentence, with a positive relationship between cloze probability and activation in left middle

frontal gyrus (MFG) and a negative relationship in anterior aspects of the left middle and superior temporal gyri (STG). The sentence's cloze probability had no effect on activation for expected words. Activation during the integration of an unexpected word was affected by cloze probability, with increased activity for unexpected endings of high constraint sentences in left posterior STG and left MFG. These results suggest that predictive processing in language comprehension may activate specific representations at more controlled levels of processing while reducing competition or easing integration costs at lower levels.

Title: Native bilingualism shapes the structure of Heschl's gyrus

Authors: *J. A. BERKEN[1,2], K. MOK[1], J.-K. CHEN[1], V. GRACCO[2], S. BAUM[2], K. WATKINS[3], D. KLEIN[1,2]
[1]Cognitive Neurosci., Montreal Neurolog. Institute, McGill Univ., Montreal, QC, Canada; [2]Ctr. for Res. on Brain, Language, and Music, Montreal, QC, Canada; [3]Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom

Abstract: Successful discrimination of novel speech sounds has been shown to correlate with increased volume of Heschl's gyrus (HG). In addition, it appears that early bilinguals have larger HG compared to monolinguals. Previous work from our lab demonstrated alterations in brain structure in early bilinguals, but to date, few studies have investigated brain anatomical differences in individuals who acquire two languages from birth. Here, we used a whole-brain cortical thickness measure to compare three groups of subjects matched for age, intelligence, and years of formal education: (1) highly proficient French-English simultaneous bilinguals (two languages acquired from birth; N = 16), (2) highly proficient French-English sequential bilinguals (second language acquired after age 5 years; N = 17), and (3) English monolinguals (N = 19). We found that simultaneous bilinguals had significantly greater cortical thickness in right HG than both sequential bilinguals and monolinguals. In contrast, sequential bilinguals did not

show a similar cortical thickness increase in HG relative to monolinguals. These findings suggest that an early perceptual bilingual experience is reflected in the structural plasticity of HG.

Abstract: The left inferior frontal cortex is known to be involved in phonological processing and speech. In particular, it has been reported that the Brodmann's Areas (BA) 45 and 46 are associated with phonological processing and that rote rehearsal activates BA44 in the left hemisphere. However, it has been reported that the activation of the broca's area in people who stutter (PWS) was lower than that in people who not stutter (PWNS). This study examined the cerebral blood responses in the left inferior frontal cortex for speech production in PWS and PWNS by means of non-invasive near-infrared spectroscopy (NIRS). All subjects were native Japanese speakers and right-handed. They were instructed first to read silently and to remember a displayed word (visual response) for an interval of random length (0.5 to 3.0 s), and later to pronounced it as soon as the "+" sign was seen on the screen. Four word categories were used as stimuli: Japanese familiar (F), unfamiliar (U), and pseudo- words (P) and 5 control prolonged vowels (C). NIRS recording was done with photomultipliers illuminated through the head tissue by alternating near-infrared lasers at 3 wavelengths (FOIRE 3000, Shimadzu, Japan). The changes in oxygenated and deoxygenated hemoglobin concentrations were calculated with modified Bear-Lumbert approximation. Unlike functional magnetic resonance imaging, the measurement of NIRS was recorded continuously during the task period included speech. The oxygenated hemoglobin data were analyzed with 2-way ANOVA by means of individual beta

values derived from the general linear model analysis. Significant interaction effects were found between the subject groups and word categories in cerebral blood response at the left BA46. The response to P in PWS was significantly higher than that in PWNS. Within PWS, the response to P was significantly higher than that to F. Within PWNS, the response to P was significantly lower than that to F. Whereas the broca's area (BA44 and 45) had not a significant difference between the subject groups. These findings suggest that the left BA46 is associated with word familiarity of the left BA46 was different between PWS and PWNS in speech production.

Title: Impairment in sentence comprehension in patients with the behavioral variant of frontotemporal degeneration

Authors: *R. B. WILLIAMS, K. RASCOVSKY, M. GROSSMAN
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Impairment in sentence comprehension, a complex process that requires both grammatical and working memory, has been observed in patients with bvFTD. These patients are known to suffer from executive and social deficits, as well as grammatical expression deficits in a semi-structured speech sample, although they are not aphasic. To elucidate the basis for the comprehension impairment, we analyzed the relationship between grammatical comprehension

and performance on language, working memory, and executive measures. We compared the scores on all measures in patients with bvFTD with the scores of patients with amnestic Mild Cognitive Impairment (aMCI) and healthy elderly controls. Patients with bvFTD (n=23), aMCI (n=13) and controls (20) were evaluated with a two-alternative sentence-picture matching task, in which patients chose the picture best described by a sentence that depends on grammatical interpretation. Semantic memory was also assessed, using Pyramids and Palm Trees (PPT) and Boston Naming Test (BNT); executive functioning using Trails B (TB), FAS Category Fluency (CF), and the Visual Verbal tests; and working memory using Digit Span backwards (DB). We found significant impairment in overall sentence comprehension bvFTD participants compared to controls ($p < .001$), and aMCI ($p=.052$). Within the sentence comprehension task, there was no effect for grammatical structure or working memory. bvFTD patients' sentence comprehension performance correlated with scores on both the semantic measure PPT ($r=.68$, $p<.002$) and the executive measure FAS ($r=.54$, $p<.01$). These findings suggest that bvFTD subjects are impaired in grammatical comprehension, and, although these participants are not aphasic, contributing factors to this impairment appear to include deficits in executive functioning and semantic memory.

Title: A functional mri study of the relationship between concise chinese aphasic test scoring and resting state functional connectivity in post-stroke aphasia

Authors: *P.-C. TSAI[1], C.-E. TSENG[2], F.-P. YANG[2], C.-M. LIN[3], B.-S. YIP[1], S.-H. LIN[1], T.-M. CHIANG[4], L.-Y. TSENG[1], L.-Y. HUNG[1], L.-W. KUO[5]

Abstract: Resting-state studies organized with aphasic stroke patients are limited. We explored whether patients with better speech ability showed differences in resting-state functional

connectivity. Five right-handed stroke patients with aphasia and left middle cerebral artery territory infarction were included in the study. Stroke patients received Concise Chinese Aphasia Test and functional MRI scan 9-12 weeks after stroke. ROI-wise functional connectivity (FC) analysis was performed using the REST toolkit (Song et al., 2011). The analysis included six networks: the language network (LN), left central executive network (LCEN), right central executive network (RCEN), dorsal default mode network (dDMN), and ventral default mode network (vDMN). We explored the FC between these five networks and correlated the results with CCAT scores. Significant correlations between the CCAT scores and the LN-dDMN FC were observed. When the patients showed worse capability at Figure-Word Imitation subscale, the FC of these five networks were all augmented significantly except LN-LCEN and vDMN-LCEN. The Figure-Substance Pairing scoring showed a significant negative correlation with diffuse FC except dDMN-vDMN, LN-LCEN and vDMN-LCEN. The FC of LN-RCEN and dDMN-RCEN correlated negatively with Auditory Comprehension subscale scoring. We also observed significant negative correlation between the RCEN-LCEN FC and performance in Spontaneous Writing subscale. These preliminary results suggest that increased FC in these five networks is related with the severity of aphasia and consequently may aid in understanding of the neural mechanisms underlying the post-stroke aphasia. Title: Perception of degraded low-context speech in early psychosis

Authors: D. LADOWSKI[1], E. ABDELMOTAAL[2], *I. S. JOHNSRUDE[1]
[1]Psychology, [2]Psychiatry, Queen's Univ., Kingston, ON, Canada

Abstract: Individuals who experience a shorter duration of untreated schizophrenia have more favourable mental health outcomes (Hegelstad et al., 2012). In order to identify suitable candidates for early intervention, sensitive screening techniques must be developed. Previous research has identified cognitive distortions that can appear in the early or prodromal stages of psychosis and may underlie or predict the presence of psychotic symptoms. For example, reality-testing deficits can lead to misidentification of internal thought as external speech, and the inappropriate assignment of meaning or salience to otherwise meaningless or unimportant stimuli (Bentall, 1990). Individuals with schizophrenia are thought to be driven to make sense of these anomalous perceptionsl; and this may explain delusions and hallucinations (Kapur, 2003). In the present study, participants (14 recruited from an early psychosis clinic, 17 demographically matched controls) listened to 180 sentences degraded by noise (with signal-to-noise ratios of 0, -2, or -4dB) and were asked to report as many words from each sentence as they could. Sentences either had strong semantic context (e.g., “Her new skirt was made of denim”) or were syntactically matched but with weak context (e.g., “Her good slope was done in carrot”). Both groups reported fewer words as noise level increased, and more words from the high-context than the low-context condition ($p < .001$). These two factors also interacted such that context had a bigger effect on word report in low noise than in high noise. The results also indicate a tendency for the clinical group to produce more intrusion errors (words not in the original sentence), particularly in low context materials, which may be reflective of early reality-testing impairments. These findings are promising, and encourage the further investigation of tasks involving perceptual ambiguity for the detection of early cognitive markers of psychosis. Bentall, R. P. Title: Down syndrome children's ability to infer a referent

Authors: *N. ARIAS-TREJO, J. B. BARRÓN-MARTÍNEZ, T. JASSO LÓPEZ, E. A. ALVA CANTO
Facultad de Psicología, UNAM, Mexico, Mexico

Abstract: Typically developing children (TD) learn hundreds of words during their first years of life. Different strategies such as word-object constraints, social cues and fast-mapping enable them to do this not only at a rapid speed but also with a low-error range. Besides learning words, children need to learn grammatical rules too; although learning formal linguistic rules such as grammatical gender and number may be challenging, these rules in fact can accelerate language processing. In Spanish the understanding of the information related to gender (words ending in 'a' tend to be feminine and words ending in 'o' masculine) and number ('s' or 'es' ending for plural) results in a more efficient and rapid language processing. Recent investigations have established that young TD children are sensitive to gender grammatical agreement between articles and nouns. Nonetheless, it remains to be explored whether children with mental disabilities, such as Down syndrome (DS) also benefit from grammatical gender cues to anticipate a familiar referent. We explored in a preferential looking task whether both DS and TD children with 30-month-old mental age use singular indefinite articles (un-una in Spanish) to find a target before it was labeled. In each trial, children saw during 2000 ms two pictures (target-distracter), during this period the carrier phrase 'mira' was heard. At 2000 ms children heard a masculine ('un') or a feminine ('una') article; finally, at 4000 ms the target name was heard. In half of the trials, the nouns had a regular ending matching its gender (e.g., 'o' for masculine and 'a' for feminine). The other half of the trials introduced nouns with an irregular ending (e.g., 'e' for masculine or feminine). The results indicated that both groups, DS and TD children with a 30-month-old mental age, anticipated the target referent by using the information contained in the indefinite article (un-una). Importantly, children were able to correctly anticipate the target when facing regular (ending in 'a' or 'o') or irregular nouns (other ending). The outcome of this research demonstrates that DS children, as well as their TD peers, can use gender information embedded in an article to anticipate a referent. This use influences a more rapid and accurate online language processing by allowing disambiguation of familiar items irrespectively of hearing their names. This is the first demonstration of sophisticated comprehension abilities in children with DS. We will discuss the results in light of a paradoxical deficient speech production in these children.

Title: Abbreviated pyramids and palm trees test effectively discriminates semantic-variant progressive aphasia from other variants of primary progressive aphasia

Authors: *K. COHEN[1], C. MCMILLAN[1], K. RASCOVSKY[1], C. ONYIKE[3], V. M.-Y. LEE[2], J. Q. TROJANOWSKI[2], A. HILLIS[4], M. GROSSMAN[1]

Abstract: Primary progressive aphasia (PPA) is a pathologically heterogeneous neurodegenerative disease that affects language. PPA is classified into three variants: semantic (svPPA), logopenic (lvPPA), and nonfluent/agrammatic (naPPA), which are diagnosed on the basis of converging clinical, imaging, and genetic/neuropathological evidence. Although clearer diagnostic criteria for PPA variants have been defined (Gorno-Tempini et al., 2011), objective clinical tests are needed to better distinguish language deficits between variants so more reliable diagnoses can be made. Gorno-Tempini et al. observed that while all variants of PPA show impairment with object naming, svPPA has pronounced single-word comprehension deficits

which can make diagnosis of this variant more straightforward than diagnosis of lvPPA or naPPA. Moreover, single-word comprehension deficits in svPPA are more commonly seen with concrete object concepts, compared to abstract concepts, and are most frequently associated with larger semantic memory impairments. We used a modified nonverbal semantic task, Pyramids and Palm Trees (PPT) (Howard & Patterson, 1992), to examine semantic memory of concrete object concepts between groups of each variant. The task is administered across two modalities, pictures and words, and includes 14 cross-culturally validated items. Pathology-confirmed PPA patients, svPPA (n=22), lvPPA (n=20), and naPPA (n=8), completed the task. Patients were instructed to point to which of the two objects on the bottom best go with the target object above. Because some participants completed all 14-items across trials that included a combination of both modalities, or only one modality, the scores used for the analysis were prioritized: (1) pictures, (2) words, or (3) mixed - a combination of picture and word items, if other data was not available. A Kruskal-Wallis analysis across all groups was significant ($X2=11.57$; $p<0.003$). svPPA patients were significantly impaired in the abbreviated 14-item PPT compared to lvPPA ($U=107$; $p=0.003$) and naPPA ($U=34.5$; $p=0.01$) patients, while lvPPA patients do not differ from naPPA ($U=75$; $p=0.77$). Additionally, svPPA patients had significant semantic memory impairments compared to lvPPA and naPPA patients. The abbreviated 14-item PPT task provides an efficient and objective clinical test to discriminate svPPA patients from other PPA variants.

Title: Dysgraphia in patients with the behavioral variant of frontotemporal degeneration and primary progressive aphasia

Authors: *E. MORAN, R. WILLIAMS, S. ASH, K. RASCOVSKY, M. GROSSMAN
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Patients with primary progressive aphasia (PPA) demonstrate language production difficulties in spoken communication, including errors of grammatical structure as well as speech-sound errors. Patients with behavioral variant frontotemporal degeneration (bvFTD) also have speech production deficits. However, studies of written production in PPA and bvFTD have been rare. We analyzed production of a written sentence about the weather in 65 patients, including nonfluent/agrammatic PPA (naPPA, n=8), logopenic variant PPA (lvPPA, n=16), semantic variant PPA (svPPA, n=6) and bvFTD (n=35). Patient groups were matched for MMSE and education ($p>0.05$). Two independent raters, blind to patient diagnosis, analyzed written sentences for grammatical errors. We also analyzed other writing errors, including: Real word errors, subdivided into phonologically-related and semantically-related substitution errors; and Non-word errors, subdivided into phonologically-plausible and phonologically-implausible substitution errors. Groups were matched for the number of words they attempted to write ($p=0.432$). A chi-square test showed a significant group difference for grammatical errors, [$X2(4)=10.59$, $p=0.032$]. Relative to one control subject (6.3%) who made a grammatical error, 5 naPPA patients (62.5%), and 4 svPPA patients (66.7%), 8 lvPPA patients (50%), and 12 bvFTD patients (34.3%) produced grammatical errors in written sentences. We also observed a trend for producing other writing errors [$X2(4)=9.16$, $p=0.057$]. Although no control subjects committed other writing errors, 8 bvFTD patients (22.9%), 2 svPPA patients (33.3%), 2 naPPA patients (25%), and 6 lvPPA patients (37.5%) committed other writing errors. The majority of other writing errors were phonologically plausible non-words (46.9%), followed by phonologically implausible non-words (25%). Errors in written expression are common among patients with bvFTD, svPPA, naPPA, and lvPPA. The presence of grammatical and other writing errors occurred despite the presence of a written record and the opportunity to correct production. Grammatical errors thus cannot be attributed entirely to a short-term memory deficit, and letter substitutions cannot be easily attributed to motor speech abnormalities.

Title: Self-monitoring after stroke: A case study

Authors: *S. MEEKINGS[1], S. EVANS[2], F. GERANMAYEH[3], R. WISE[3], S. K. SCOTT[2]
[1]UCL, London, United Kingdom; [2]Univ. Col. London, London, United Kingdom; [3]Imperial Col. London, London, United Kingdom

Abstract: Many aphasic patients show an impaired ability to monitor and repair errors in their own speech (Wepman, 1958). Puzzlingly, this deficit occurs even in patients with relatively intact comprehension abilities (Schlenck et al, 1987) and seems to apply only to on-line monitoring, since patients are able to detect errors in a recording of their own voice (Maher, Rothi & Heilman, 1994). In a unique variant of this problem, we report the case of a patient experiencing difficulties hearing his own voice following stroke. This patient, a 48-year-old man, presented with a frontal lesion caused by a left middle cerebral artery infarct. His language abilities were assessed using the Comprehensive Aphasia Test (Howard, Swinburn & Porter, 2004). He displayed difficulties with fluent and syntactically correct speech production, contrasted with relatively intact comprehension abilities. Although there was no evidence of hearing loss, the patient reported experiencing his own voice as either inaudible or occurring at a delay of up to half a second. We attempted to determine whether this was a general sound or speech perception deficit by administering a task that required him to hear and make fine temporal distinctions between sounds. In this task, we asked him to determine whether two sounds played in succession (with the delay between them adaptively determined by a staircase procedure) occurred at the same time or not. He was able to accurately complete the task with nonspeech sounds, another person's voice, and a recording of his own voice, confirming that his perception of externally generated sounds was in the normal range. When given delayed auditory feedback of a live speaker, he described the mismatch between seeing the person speak and hearing their voice as similar to his experience of his own voice. He reported an inability to perform tasks normally dependent on self-monitoring, such as singing and mimicry. In particular, his performance on a task involving speaking over noise is discussed and compared with Oomen, Postma & Kolk's (2001) finding that patients with Broca's aphasia find noise masking less disruptive than healthy controls.

Title: Affective prosody in adults with william syndrome

Authors: ***N. WOO-VONHOOGENSTYN**[1], P. LAI[1,2,3], J. REILLY[2], U. BELLUGI[1]
[1]Salk Inst., San Diego, CA; [2]San Diego State Univ., San Diego, CA; [3]Univ. of California San Diego, La Jolla, CA

Abstract: Williams Syndrome (WS) is a rare neurodevelopmental disorder in which individuals exhibit a predisposition for social interaction, reflecting an unusual hyper-social phenotype. Past research has shown how those with WS use language in the service of their social drive. Specifically, their use of linguistic social evaluative devices e.g. intensifiers, character speech, far exceeds that of typical developing (TD) individuals (Reilly et al., 2004). Here we explore how affective prosody might also be recruited in the WS appetitive drive for sociability. In children with WS, Lando (2006) reported differences between F0 mean and an increased variation in pitch in children with WS compared to TD children. The goal of this study is to examine the use of affective prosody in adults with WS in response to emotional scenes. Narratives from the wordless picture book, Frog, where are you? (Mayer, 1969), were collected from 17 individuals with WS and 17 TD individuals. Language from four frames conveying distinct emotions was examined: Surprise, Anger, Distress, and Happy. PRAAT, a linguistic program that parses out the various aspects of prosody was used to analyze fundamental frequency (F0) mean, (F0) standard deviations, and (F0) range, along with two speech production variables; words per minute (WPS) and story frame length (SFL). Frame one was appointed as a neutral frame to establish a baseline. There were no differences in WPS and SFL between groups. There were no differences in overall prosodic measures between groups. However, A paired T-test was conducted to evaluate within group differences between emotions. The WS group had significant differences between surprise (M = 146.9) and distress (M = 168.32) p = .005, and surprise and happy (M = 171.33) p = .009 but the TD group did not show

any significant differences between emotions. This study examined whether adults with WS elicit a broader range of affective prosodic patterns, in comparison to TD's, while narrating emotional frames. These results suggest that the WS group was more emotionally engaged in the story. In contrast the TD group exhibited similar emotional responses across all frames, suggesting more cognitive distancing in their storytelling. This study can add to the social and linguistic profiles of adults with WS. Differences in affective prosody in adults with WS may reflect underlying emotional mechanisms that may contribute to their unique social qualities. Further research could examine affective prosody using a different median to elicit an emotional narrative (e.g., from a biographical interview or elicited emotional narratives from an auditory stimuli).

Title: More than Speech? Tone discrimination deficits correlate to atrophy in the logopenic variant of primary progressive aphasia

Authors: *A. ISENBERG[1], J. REILLY[2], M. GROSSMAN[1]
[1]Dept. of Neurol., Univ. of Pennsylvania, Philadelphia, PA; [2]Dept. of Communication Sci. & Disorders, Temple Univ., Philadelphia, PA

Abstract: The logopenic variant of primary progressive aphasia (lvPPA) is characterized by progressive impairments in single word retrieval and repetition. One hypothesis attributes this to degradation of the phonological short-term memory network (Gorno-Tempini et al 2008). Consistent with this view, structural imaging in lvPPA has shown gray matter (GM) atrophy predominantly in left hemisphere posterior peri-Sylvian regions (Gorno-Tempini et al 2008), an area implicated in short-term memory. Similar regions have been previously implicated in non speech tasks involving auditory-verbal short-term memory (Hickok, 2009). Auditory discrimination tasks rely on both auditory-verbal short-term memory and auditory perceptual processes to discriminate between two sounds. This implicates several cortical areas including auditory association cortex and the more posterior peri-Sylvian regions identified in auditory-verbal short-term memory tasks. Here we examine the contribution of GM atrophy in lvPPA to performance on an auditory discrimination task using pure tones to examine whether deficits are specific to language and phonological processing. We recruited lvPPA patients (N=13) who were diagnosed using published criteria (Gorno-Tempini et al, 2011), explicitly, this included verbal short-term memory deficits. Healthy senior controls (N=12) were comparable for demographic variables. Participants heard pairs of pure tones and made same-different judgments. We performed volumetric MRI analyses in lvPPA relative to seniors, and regression analyses to relate lvPPA performance on the discrimination task to GM atrophy. Patients were significantly impaired in their judgments relative to controls. lvPPA had left lateralized GM atrophy in posterior peri-Sylvian, temporal and parietal regions. Regressions related deficits on the discrimination task to GM atrophy in a posterior portion of the superior temporal gyrus as well as regions in the inferior parietal lobe previously associated with pitch discrimination (Zarate and Zatorre, 2008). These data suggest the atrophy patterns observed in lvPPA patients impact a large-scale neural network involving broad posterior peri-Sylvian cortical regions. Impairments are observed in the auditory-verbal short-term memory system, including pure tone discrimination deficits, suggesting more than phonological processing is affected by their short-term memory deficits. These findings suggest a neuroanatomic basis for auditory-verbal short-term memory processing in patients with a focal neurodegenerative condition.

Title: Language neurodevelopment in children aged 6 to 8 months old: Its relation to gender, mother's age and educational level

Authors: *S. N. CAZARES[1], G. RIZO[2], S. LEÓN[2], T. VILLASEÑOR[3]
[1]10, Univ. De Guadalajara, Zapopan, Mexico; [2]Salud Publica, [3]Neurociencias, Univ. De Guadalajara, Guadalajara, Mexico

Abstract: Introduction Neurodevelopment is a brain maturation process that involves genetic and epigenetic factors. Language acquisition depends on brain maturation as well as environmental stimulation. Early language development in children includes characteristically crying and babbling with vowel and consonant elements (6-8 month). The mother-child relationship at this stage plays a crucial role for language acquisition. The voice exchange establishes communication networks that increasingly become complex. Bayley scales are reliable instruments that accurately measure child cognitive and language development. Objective The aim of this work was to compare the performance of language development in children aged from 6 to 8 months old, considering the baby's gender, as well as the mother's age and schooling. Methodology Participants were 55 children from 6 to 8 months old based on Guadalajara, Jalisco, Mexico, assessed with Bayley Scales of Infant Development III. This scale evaluates receptive and expressive language components, which are important in diagnosing critical delays. The expressive communication subtest includes items that asses the young infant's ability to vocalize. Receptive communication subtest focus on the child's ability to comprehend and respond appropriately to word and requests. Results We complete a sample comprised of 55 children including 28 girls (50.9%) and 27 boys (49.1%). The mean age was 7.29 (± 0.62) months. The average mother's age was 22.57 (± 5.78) years old with a mean schooling of 4.27 (± 1.59) years. Bayleys assessment revealed that Girls (98.64) scored slightly higher than boys (94.22). Children with mothers aged 14-19 years and with 5-9 years of schooling obtained better performance (99.44 and 97.22 respectively). Intergroup and intragroup analysis revealed no significant differences for age and schooling.

Title: Constructing the white matter networks of semantic processing with healthy and patient populations

Authors: *Y. FANG[1,2], S. ZHONG[2], G. GONG[2], L. SONG[3], Z. HAN[2], Y. BI[2]
[1]State Key Lab. of Cognitive Neurosci. and, Beijing, China; [2]State Key Lab. of Cognitive Neurosci. and Learning., Beijing, China; [3]Rehabil. Col. and China Rehabil. Res. Center, Capital Med. Univ., Beijing, China

Abstract: Semantic memory stores the general knowledge of objects, people, and facts and is central to a wide range of cognitive processes. Decades of research have investigated the cortical regions (Binder et al, 2009) and major white matter (WM) tracts that support semantic memory (Han et al., 2013). An important gap between these two lines of research is that their correspondence is elusive given that the major white matter tracts identified connected numerous cortical regions. In this study, we construct a first whole-brain white matter "network" for semantic processing by directly tracking WM connections among all cortical regions (as nodes) in healthy populations and testing the effects of observed WM connections (edges) in semantic processing in patients. In a first step, we build a whole brain white matter connectivity network by conducting tractography using diffusion imaging data by 48 healthy participants, rendering a network contained 688 white matter "edges" across 90 cortical and subcortical "nodes" (Fig 1a). We then tested the relationship between the integrity of the obtained WM edges and semantic performance across 80 brain damaged patients. Semantic performance was obtained by performing principal component analyses in 8 semantic and nonsemantic tasks. Edge integrity was measured both by lesion percentage and mean fractional anisotropy. For semantic processing, we obtained 42 WM edges for lesion percentage analysis and 37 ones for mean fractional anisotropy analysis, with the cortical nodes they connect elucidated. The majority of the semantic edges landed on left inferior fronto-occipital fasciculus, left anterior thalamic radiation, and left uncinated fasciculus (Fig 1b). Using graph analyses we identified five hubs nodes with top degree (number of connections) and betweenness, including orbital part of inferior frontal gyrus, orbital part of middle frontal gyrus, insula, and thalamus and hippocampus. The results highlight the critical roles of distributed white matter connections among specific temporal and frontal regions in semantic processing.

Title: Impaired sentence expression in amyotrophic lateral sclerosis

Authors: *S. ASH, C. OLM, C. T. MCMILLAN, A. BOLLER, D. J. IRWIN, L. MCCLUSKY, L. ELMAN, M. GROSSMAN
Neurol, Univ. Pennsylvania Sch. Med., PHILADELPHIA, PA

Abstract: Background: Recent studies have shown that patients with amyotrophic lateral sclerosis (ALS) may have a cognitive impairment in addition to a progressive motor disorder. There is evidence that language deficits may be prevalent in ALS, but the precise nature of such deficits has not been established. Most studies of language functioning in ALS have examined the production or comprehension of single words; there have been few studies of connected, spontaneous speech in these patients. The objective of this study was to assess sentence-level language production impairments in ALS. Methods: We examined features of spontaneous speech production in 26 patients with ALS and 19 healthy seniors. The subjects were asked to narrate the story from a wordless children's picture book, Frog, Where Are You?, by Mercer Mayer. The narrations were recorded digitally, transcribed, and analyzed for speech output, fluency, lexical access, and grammaticality. Regression analyses related grammaticality to gray matter (GM) atrophy and white matter (WM) reduced fractional anisotropy (FA). Results: Patients with ALS were impaired relative to control subjects on measures of speech production, including quantity of speech produced, speech rate, speech sound errors, and grammaticality. The measures of fluency and articulation were related to the extent of motor impairment associated with the disease. Impaired grammaticality was observed in the entire cohort of patients, in the subset of patients who did not exhibit significant executive deficits (n=22), and in the subset of patients who did not have a motor impairment causing dysarthria (n=20). Grammaticality correlated with overall cognitive status but not with the extent of a motor disorder. Regressions related grammatical expression difficulty to GM atrophy in left inferior frontal and anterior temporal regions, areas associated with grammatical expression. Regressions also related grammatical impairment to reduced FA in dorsal and ventral WM tracts that are thought to play a role in sentence processing. Conclusions: Patients with ALS exhibit deficits in sentence-level language expression. While difficulty related to the physical requirements of speech production is associated with their motor disorder, a central deficit in grammatical expression appears to a component of the cognitive disorder found in ALS.

Title: Cerebellar tDCS alters articulation and verbal fluency: Location and polarity effects

Authors: *C. J. STOODLEY[1], M. K. SWEARS[1], A. DESKO[2], P. E. TURKELTAUB[2,3]
[1]Psychology, American Univ., Washington, DC; [2]Neurol., Georgetown Univ., Washington, DC; [3]Res. Div., MedStar Natl. Rehabil. Hosp., Washington, DC

Abstract: The cerebellum is thought to be involved in both motor and cognitive aspects of language. Cerebellar lesions can lead to dysarthria or to difficulties on naming and fluency measures, depending on the location of damage. This topography is supported by neuroimaging studies which show that articulation engages the articulatory muscle representation in anterior cerebellar lobule V extending into medial lobule VI, whereas verb generation and fluency tasks engage lateral parts of right lobule VII, which shows anatomical and functional connectivity with left frontal and parietal networks. We examined this topography for language function using anodal and cathodal transcranial direct current stimulation (tDCS) applied to two different cerebellar locations: the "motor" position (3 cm lateral to the inion) over the right anterior lobe, and the "cognitive" position (4 cm lateral to the inion and 1 cm down) over the right posterolateral cerebellum (lobule VII). The reference electrode was on the right deltoid. Healthy participants (39 females, 22 males; mean age 23.2 ± 5.6 years) completed articulation and fluency measures pre- and post- 20min of 2mA tDCS of motor (n=16 anodal, 7 cathodal), cognitive (n=15 anodal, 7 cathodal), or sham tDCS (n=16). After motor tDCS, participants in both the anodal and cathodal groups articulated fewer syllables of "ba" in a 30s period than the cognitive and sham groups. Anodal cerebellar tDCS did not selectively affect phonemic fluency, as all groups showed modest improvement/practice effects post-tDCS. However, cathodal tDCS to the cognitive position improved phonemic fluency to a greater degree than in either the motor or sham groups. During semantic fluency, anodal and cathodal tDCS to the motor position improved performance, but performance was negatively affected by both anodal and cathodal tDCS to the cognitive position. These preliminary findings indicate that, depending on electrode position and current polarity, cerebellar tDCS can differentially affect performance on articulation and fluency tasks. These findings are consistent with the concept that the cerebellum modulates both motoric and cognitive aspects of language.

Title: Relationship between gene expression profiles, structural neuroimaging, and clinical phenotypes in 22q11.2 microdeletion syndrome

Authors: *M. JALBRZIKOWSKI, R. JONAS, A. PATEL, L. KUSHAN, F. GAO, G. COPPOLA, C. E. BEARDEN
UCLA, Los Angeles, CA

Abstract: Introduction: 22q11.2 deletion syndrome (22q11DS) is a recurrent copy number variant associated with elevated rates of neuropsychiatric symptoms, particularly psychosis (≈30%), and brain structural abnormalities. Here we sought to examine how variability in gene expression profiles of 22q11DS patients may relate to psychotic symptomatology and brain morphology. Methods: Fifty-six 22q11DS patients were enrolled. Clinical symptomatology was assessed with the Structured Interview for Prodromal Symptoms (SIPS). We acquired high-resolution T1-weighted structural scans (sMRI), which were processed through a Freesurfer pipeline with manual editing. RNA was extracted from whole blood using the PAXgene extraction kit (Qiagen). Whole-genome transcriptional profiling was performed using Illumina Human HT-12 microarrays. We then conducted Weighted Gene Coexpression Network Analysis (WGCNA), a systems biology approach used to identify networks of co-expressed genes in relation to phenotypic data. To test for significance of over-representation of brain-expressed genes within identified modules, we ran hypergeometric probability tests (phyper function in R). Results: WGCNA identified 3 gene expression modules (Green, Purple, Yellow) significantly associated with psychotic symptom expression, as well as surface area measures, in 22q11DS patients. None of the genes within these modules fell within the typically 22q11.2 deleted region. Hypergeometric tests revealed significant enrichment of brain-expressed genes in all three modules. Genes co-expressed in these modules were predominantly down-regulated in 22q11DS participants with more severe psychotic symptoms (Green: p=.01, Purple: p=.001, Yellow: p=.001). Surface area in the left inferior temporal, rostral middle frontal, fusiform and right superior temporal regions was significantly associated with all 3 modules (p-value range: .05-

.006). Reduced surface area in these cortical regions was associated with down-regulated gene expression in these modules. Conclusion: Peripheral changes in gene expression are significantly related to psychotic symptomatology and underlying brain structure in 22q11DS patients. Brain regions associated with these gene expression profiles have been previously associated with idiopathic schizophrenia, providing further support for the use of peripheral tissue in the study of Mendelian forms of complex brain diseases.

Title: Prospective evaluation of the sensitivity and specificity of cognitive tasks for diagnosis of the cerebellar cognitive affective syndrome

Authors: ***F. HOCHE**[1], L. C. HORTON[1], J. A. HARDING[1], S. MANCUSO[2], R. RANGAMANNAR[2], M. G. VANGEL[3], J. C. SHERMAN[2], J. D. SCHMAHMANN[1]
[1]Massachusetts Gen. Hosp., Boston, MA; [2]Massachusetts Gen. Hospital, Psychology Assessment Ctr., Boston, MA; [3]Massachusetts Gen. Hospital, Martinos Ctr. for Biomed. Imaging, Boston, MA

Abstract: Background: The constellation of deficits in executive function, spatial cognition, linguistic processing and affect regulation following cerebellar injury is the cerebellar cognitive affective syndrome (CCAS; Schmahmann and Sherman, 1998). Clinicians may miss the cardinal signs of CCAS on current brief tests of mental function that were not designed to detect these impairments. Tests are also needed to differentiate cerebellar from extracerebellar damage when neuropathology is not confined to the cerebellum, as in the spinocerebellar ataxias. We aim to delineate a brief set of cognitive tests to detect the CCAS in patients with cerebellar lesions, and to determine which deficits reflect the cerebellar versus noncerebellar component of cognitive impairment in patients whose underlying neuropathology includes, but is not confined to, the cerebellum. Methods: A battery of neuropsychological tests was administered to all patients with

cerebellar disease (n=71, AC); divided into n= 35 patients with isolated cerebellar pathology (IC) and n= 36 patients with complex cerebrocerebellar pathology (CC) and 59 age, gender and education matched healthy controls. Results: Significant impairments were found in the previously identified domains of the CCAS, both on standard and bed-side tests of executive function, visuospatial performance, working memory, sustained attention and language. For example, AC patients were impaired relative to controls on the Trails Test, a standard neuropsychological test of executive function ($p<0.0001$; Binomial tests with parameter 0.1), and error rate on the Go/No-Go Test, a short bedside test of mental flexibility was greater in AC patients than controls ($p=0.04$, Poisson regression). Selected bedside and neuropsychological tests differentiated IC patients from CC patients, including the Judgement of Line Orientation Test that was more impaired in CC patients than IC patients (p=0.05, Wilcoxon test). Discussion: These data provide insights into distinguishing the cognitive consequences of cerebellar versus extracerebellar pathology, and they will be used to construct a short bedside test sensitive to the CCAS.

Title: Competitive interactions between emotion and reward in the amygdala and striatum

Authors: *S. PADMALA, W. ZHAN, L. PESSOA
Univ. of Maryland, College Park, MD

Abstract: Performance improves in a diverse set of perceptual and cognitive tasks when performance-based monetary rewards are possible. At the same time, task-irrelevant negative stimuli often interfere with performance. Because investigations of how reward and negative stimuli impact brain and behavior have been largely independent of each other, our knowledge about their interactions remains rudimentary. In the current functional MRI study, we

investigated this question by manipulating both reward and emotion in a factorial design. Participants (N=32) performed a variant of the monetary incentive delay task during which a simple discrimination task was preceded by a face stimuli that served as a cue. Facial stimuli of one particular gender (e.g., male) indicated that there was a chance of winning extra monetary reward based on performance, whereas faces of the other gender (female) indicated no chance of reward. Further, half of the stimuli for each gender had neutral or fearful expressions that were irrelevant to the task. Behavioral RT data revealed a significant Motivation (reward, no-reward) x Emotion (fearful, neutral) interaction, such that behavioral improvements during reward (vs. no-reward) trials were reduced with fearful face cues compared to neutral ones. Paralleling the behavioral data, brain imaging results revealed interaction patterns in the left ventral caudate, posterior cingulate cortex, and portions of bilateral parietal cortex. In all these regions, the interaction pattern revealed that reward-related responses were decreased during fearful compared to neutral face cues. We also observed a significant interaction in the left amygdala but with a different pattern; specifically, differential fearful vs. neutral responses to faces were reduced for reward-signaling compared to no-reward-signaling gender cues. Together, our findings revealed distinct competitive interactions in key sub-cortical regions: reward-related responses in the striatum were opposed by negative emotion, whereas emotion-related responses in the amygdala were opposed by reward. Our results highlight how appetitive-aversive interactions contribute to sculpting brain responses when behavior must integrate competing signals.

Title: The cognitive and neural basis of myopic decisions induced by negative emotional priming

Authors: *X. LI, S. GUAN, J. LUAN, L. CHENG
East China Normal University,, Shanghai, China

Abstract: Previous studies about the influence of emotion on inter-temporal choice have been unconsistent due to the approaches to inducing emotions or the materials that induced emotions. In the present study, we first induced temporal emotional changes by presenting affective pictures in a trial-to-trial paradigm. Then we investigated the influence of emotional changes on performance of intertemporal choice task. We found that temporal negative priming resulted in much higher percentages of trials during which smaller-but-sooner rewards were chosen compared to temporal positive priming and neutral priming. In order to explore the cognitive basis of such an effect, we investigated how the emotional contexts affected time perceptions and response inhibition. When subjects conducted the time reproduction tasks, we found response times in negative priming conditions were significantly shorter than in positive and neutral conditions, which indicated that negative priming made humans overestimate the subjective experience of time. Meanwhile, temporal changes of emotion did not alter the performances of Go/NoGo task including commission errors and omissions. Therefore, we proposed that the myopic decisions induced by emotions are assosicated with altered time perceptions. Finally, we tried to explore the neural mechanism for such myopic decisions, we recorded the brain responses by employing an EEG/ERP technique when subjects performed intertemporal choices in different emotional contexts. We found that negative priming generated larger later positive components (LPCs, a time window from) around 600ms after the affective picture to the responses to alternative choices at the electrodes in posterior parietal area compared to neutral and positive priming. No differential LPCs were found in frontal areas. We proposed that the patrietal lobe might be involved in the modulation of emotion on the intertemporaldecisions.

Title: Perceptual and physiological differences between genuine and posed emotional vocalizations

Authors: *S. H. CHEN[1], S. EVANS[1], C. F. LIMA[1,2], N. DEMNITZ[1], D. BOEBINGER[1], S. SCOTT[1]
[1]Inst. of Cognitive Neurosci., London, United Kingdom; [2]Univ. of Porto, The city of Porto, Portugal

Abstract: The ability to understand the thoughts and emotions of others is an important human behaviour. One aspect of this ability may be the skill to detect whether emotional expressions reflect a genuine emotional state or not. Indeed, a failure to distinguish genuine expressions from posed ones (i.e., non-genuine) may put one at a disadvantage in social interactions. In this study we recorded six speakers (three male) producing genuinely felt and posed positive (laughter) and negative expressions (crying), and asked a separate group of listeners to rate the recordings on a number of different scales. The emotional sounds were rated on 7-point Likert scales for their perceived authenticity, the frequency with which participants estimated they could encounter the sounds in everyday life, and the degree to which they perceived the speakers were in control of the expression. Eleven adult participants (nine female) rated 50 genuine and 50 posed laughs and 50 genuine and 50 posed cries. The ratings data were submitted to 2x2 repeated measures ANOVAs with factors: expression (positive/negative) and authenticity (genuine/posed). Authentic positive expressions were rated to be higher in authenticity than negative ones ($F(1,49)=102.305$, $MSE=0.062$, $p<0.001$), and genuine emotional vocalizations were rated as more authentic than posed ones ($F(1,49)=37.6$, $MSE=2.761$, $p<0.001$). However, laugh tokens were considered to be more genuine than crying tokens ($F(1,49)=6916.073$, $MSE=0.009$, $p<0.001$). Frequency ratings results showed that genuine emotional expressions were perceived to occur more frequently in everyday life than posed expressions ($F(1,49)=4.453$, $MSE=0.425$, $p<0.05$), and laughs were heard more frequently than cries ($F(1,49)=486.701$, $MSE=0.418$, $p<0.001$). Results of ratings of degree of control showed that the difference of control level between genuine and posed laughs were larger than that of cries ($F(1,49)=49.092$, $MSE=0.352$, $p<0.001$), also, genuine emotional tokens were perceived to be under less control than posed ones ($F(1,49)=166.464$, $MSE=0.592$, $p<0.001$). Our results suggest that listeners are indeed able to differentiate genuine from posed positive and negative emotional expressions. Cries were rated to be less genuine than laughs, which may be due to the fact that people are exposed to crying less frequently than laughter in everyday life. On-going work examining physiological responses with GSR, pupillometry and heart rate measurement to the described authenticity distinction will be discussed.

Title: Development of an eeg-based neural decoding system as an affective evaluation tool

Authors: *T. FUJIMURA, R. P. HASEGAWA
AIST, Tsukuba, Ibaraki, Japan

Abstract: An event-related potential (ERP) such as P300 has been traditionally detected, as a marker of cognitive function, by averaging a couple dozen trials in which targets (a stimulus to be selected in mind) are presented in a sequence of stimuli (mostly non-targets). Decoding, however, should be accomplished with speed and precision as a practical neuromarketing system, which is able to provide feedback for a user. To this end, we used linear discriminant analysis (LDA) that is one of pattern classification methods to discriminate EEG in response to targets from that to non-targets. Discriminant score for each stimulus can be calculated in real time and a stimulus with the highest discriminant score is interpreted as a target. In this study, we developed a compact wireless EEG recording system with a software to make a real-time analysis of EEG data using the LDA. We examined a possibility of our neural decoding system as an affective evaluation tool. We hypothesized that affective targets captured more attention and hence elicited greater P300 than non-affective targets. We used a set of 8 emotional faces representing a variety of affective values. We also used a set of 8 simple figures as control stimuli. EEGs were measured while participants viewed a sequence of stimuli. There were 2 sessions for emotional faces as well as simple figures. Each session was consisted of 8 games. In each game, one of the stimuli was consistently the target; each stimulus including the target was presented 8 times, resulting in 64 trials. Participants were asked to make a silent counting for the target. Each stimulus was randomly presented for 750 ms, separated by a 250 ms-blank screen in a sequence. The results showed that LDA was superior to ERP averaging in terms of discrimination between targets and non-targets from EEG. The stimuli with significant affective values were more discriminated against than the stimuli without significant affective values when they were targets. This system using LDA might be practical neural decoding system for an affective evaluation tool.

Title: Don't crack a smile: An fMRI study on counterproductive effect of smile

Authors: *S. PARK[1], N.-Y. SHIN[2], S.-K. LEE[2], S. HAN[1]
[1]dept. of psychology, [2]Col. of Med., Yonsei Univ., Seoul, Korea, Republic of

Abstract: Facial feedback hypothesis suggests that a smile-like facial expression can increase positive feelings. For example, people reported higher amusement ratings for a cartoon when they held pens with their teeth than on their lips. However, several behavioral studies showed that the positive facial feedback effect was dependent on given circumstances. Our study aims to find neural underpinning of the counterproductive effect of smile and individual differences using fMRI. Before scanning, 15 participants practiced to make a smile with a wooden chopstick similar to the previous cartoon study until they could make the same facial expressions regardless of the chopstick for the subsequent fMRI sessions. In emotion-inducing period, participants were shown an emotional image (negative vs. positive vs. neutral). After the image given, one of two cue words (smile vs. neutral) which were used as indicators for participants to generate facial expression was presented above the image. Four emotional and neutral words were presented in four different colors in a subsequent emotional Stroop task. Smile effect difference index (SEDI) reflecting participants' attentional biases to negative words were calculated with reaction times recorded in the emotional Stroop task. Next, we explored the counterproductive smile effect by contrasting (negative smile SEDI - negative neutral SEDI) to (positive smile SEDI - positive neutral SEDI), calling it Smile Effect Scale (SES). SES was positively correlated with participants' Social Interaction Anxiety Scale (SIAS) scores, shown that participants who had relatively high scores in SIAS were attentionally more biased toward negative words when they had to smile in negative feelings. In analysis of the fMRI data, a whole-brain general linear model (GLM) with the contrast used to calculate SES applied in the emotional Stroop task identified activations in bilateral insula, anterior cingulate cortex and right amygdala. Simple regression analysis was also performed to explore SES-related brain regions modulated by SIAS. Right inferior frontal gyrus and bilateral anterior cingulate cortex were found in the emotional Stroop task. In the facial expression generation phase given prior to the emotional Stroop task, increased activations of bilateral inferior frontal gyrus and left insula was found. Our results show that smile-like facial feedback could be ineffective and even backfires for people in negative feelings (especially for individuals with high level of social anxieties) and it is associated with an emotional conflict related brain regions such as anterior cingulated cortex, inferior frontal gyrus and insula.

Title: The Multidimensional Auditory Affective Ratings Inventory (MAARI) and Computerized Emotion Recognition Toolbox (CERT): measuring facial responses to standardized, non-verbal, human vocalizations of emotion

Authors: ***M. D. MULLANE**[1], S. OKHOVAT[2], M. DIFLEY[2], J. MARTIN QUIROGA[3], S. ZIOGAS[2], M. BARTLETT[4], G. LITTLEWORT[4], A. A. CHIBA[2]
[1]Cognitive Sci. & Psychology, [2]Cognitive Sci., [3]Psychology, [4]Inst. for Neural Computation, UCSD, La Jolla, CA

Abstract: Emotional content in the world guides behavior, in part by influencing perception, memory, decision-making, and learning. There exists a voluminous literature detailing the impact of visual emotional information on various cognitive processes, making use of standard facial emotional expression coding (FACS) and emotional picture inventories (IAPS). Yet, there is a paucity of work elaborating on the influence of auditory perception of emotional information on cognitive processes. In order to examine the nature of physiological responses to human vocalizations of emotion, the Multidimensional Auditory Affective Ratings Inventory (MAARI) is being developed. To date, MAARI is an inventory of 650 spontaneous, non-verbal vocalizations of emotion, all of which hold ratings on dimensions of valence, arousal and authenticity. In order to understand whether the perception of these emotional sounds elicits emotional expressions that concur with the listener's subjective sound ratings, MAARI was presented to subjects along with video clips of facial expressions of emotion. Participants' facial expressions were recorded and analyzed using the Computerized Emotion Recognition Toolbox (CERT), which identifies facial action units (FACS), associated with prototypical facial expressions of emotion. Facial expressions of participants who exhibited a threshold level of reactivity to emotive facial expressions were then analyzed for FACS responses during their perception of emotive vocalizations. The result is a set of physiological measures associated with specific MAARI vocalizations. These measures, in conjunction with existing subjective ratings of valence, arousal and authenticity, provide a complete, standardized inventory of human

emotional vocalizations, making MAARI suitable for use as an experimental instrument to examine influences of auditory perception of non-verbal human expressions of emotion on the neural processes underlying aspects of cognition. MAARI might also be useful for gaining a further understanding of affective insufficiencies in various neurological disorders.

Title: Emotional arousal amplifies biased competition in visual processing

Authors: ***T.-H. LEE**[1], S. G. GREENING[1], N. SOSA[2], M. MATHER[3]
[1]Psychology, [2]Neurosci., [3]Davis Sch. of Gerontology, USC, LA, CA

Abstract: The arousal-biased competition (ABC) model predicts that arousal biases competition in favor of prioritized stimuli and against non-prioritized stimuli (Mather & Sutherland, 2011). Thus, the model predicts that arousal can lead to simultaneous enhanced processing of prioritized stimuli (by either top-down goal or bottom-up saliency) and impaired processing of non-prioritized stimuli. The goal of current fMRI study was twofold. First, it aimed to conceptually replicate the effect of competitive priority in emotional processing from recent neural evidence (Lee, Sakaki, Cheng, Velasco, & Mather, 2014). The second goal was to examine the role of the locus coeruleus (LC) in the ABC effects given it is a fundamental arousal modulator in the brain. To accomplish this goal, we used melanin-weighted MRI (e.g., Shibata et al., 2006) to localize individual's LC. Also cardiac and respiration signals were recorded to enhance the fidelity of the functional signals in the brainstem. Participants' arousal levels were manipulated on a trial-by-trial basis using fear-conditioned stimuli. In the main spatial detection task, we presented object-place image pairs as target stimuli, one of which was always given a brief luminance increase so as to render it visually salient. Participants were asked to identify the location of the salient target

location. Preliminary analyses revealed arousal-by-saliency interactions in lateral occipital complex (LOC) and parahippocampal place area (PPA); when the object image was salient, responses in LOC (i.e., responses to the prioritized object image) were enhanced on arousing compared with non-arousing trials. Simultaneously responses in PPA (i.e., responses to the non-prioritized place image) were reduced with arousal. In contrast, when the place image was salient, arousal enhanced responses in PPA whereas and reduced responses in LOC. That is, arousal biased competition in favor of prioritized information and against non-prioritized information, influencing subsequent perceptual process irrespective of stimulus type. Additional analyses will examine whether the LC plays a critical role in these arousal effects in visual processing. The current results support the ABC model by demonstrating that arousal enhanced visual processing for prioritized stimuli (i.e., increased brain response according to the prioritized stimulus categories) but simultaneously impaired processing of non-prioritized stimuli (i.e., reduced brain response to non-prioritized stimulus) compared with the non-arousing condition. The role of LC will be discussed in further detail.

Title: Individual differences in anxiety influence the integration of early sensory signals corresponding to aversive unconditioned stimuli

Authors: *S. G. GREENING, T.-H. LEE, M. MATHER
USC, Los Angeles, CA

Abstract: In anxiety disorders, external sensory cues can trigger responses ranging from mild fear to severe panic, the strength of which can depend on attention-related biases. Research has demonstrated that accurate fear-related trace conditioning requires attention to, and awareness of, the association between the conditioned stimuli (CS+/-; i.e., a tone) and the unconditioned

stimulus (US; a shock). Intriguingly, past studies have reported increased activity in the primary sensory cortices corresponding to the US on non-reinforced CS+ relative to CS- trials. However, the functional significance of this activity has not been thoroughly examined. We tested the prediction that individual differences in trait anxiety would correlate with primary somatosensory cortex (S1) activity on non-reinforced (i.e., no shock) CS+ trials. Furthermore, given the importance of attention and awareness in trace conditioning, we predicted that activity in S1 would be correlated with activity in attention-related areas such as dorsolateral prefrontal cortex (dlPFC). Twenty healthy volunteers completed a differential-tone trace-conditioning task while undergoing fMRI. Participants heard and responded to a high and low pitch tone, one of which was paired with shock (CS+) on fifty percent of trials, the second was never paired with shock (CS-). On reinforced trials a shock occurred to the 4th and 5th fingers of the left hand after a trace interval of 1.2 seconds; these trials were excluded from all analyses. An S1 anatomical mask was used as an a priori region of interest. Skin conductance response (SCR) confirmed that participants conditioned to the CS+ compared to CS-. Consistent with our prediction, we found a positive correlation between individual differences in trait anxiety and activity in right, but not left, S1 during CS+ versus CS- conditions. A left S1 seed-based functional connectivity analysis demonstrated that trial-wise S1 activity was positively correlated with regions of dlPFC. Finally, group-wise activity in right S1 was positively correlated with activity in regions involved in both the representation of the unconditioned stimulus (i.e., A1), and the representation of fear-related emotional reactivity (i.e., amygdala). Our findings indicate that trait anxiety influences the degree of reactivity in primary sensory cortices responsible for the encoding of unconditioned aversive stimuli, and this activity is positively related to activity in dlPFC. These results suggest that individual differences in both anxiety and attention mediate the integration of emotion-related sensory signals into neural networks implicated in fear-conditioned responding.

Title: Competitive stimuli as an effective intrinsic motivator in the study of affect during human performance

Authors: *J. S. METCALFE[1], A. PASSARO[1], S. GORDON[2], K. OIE[3]
[1]Translational Neurosci. Br., DCS Corp, Aberdeen Proving Ground, MD; [2]Knowledge Services Br., DCS Corp, Alexandria, VA; [3]Soldier Performance Div., US Army Res. Lab., Aberdeen Proving Ground, MD

Abstract: The dynamic constellation of psychological, physical, and physiological patterns that compose our emotional experiences, that is, our affective state, is an important influence on intra- and inter-individual differences seen during human performance in challenging, real-world contexts. However, because of the tight coupling between affective responses and task characteristics such as difficulty or complexity, it is difficult to distinguish independent versus mutually causal influences on affective state and performance. Here, we report preliminary findings that may support an hypothesis of an influence of motivation on affective responses that is independent of task performance. A sample of individuals who self-reported intrinsic motivation in competitive tasks were asked to perform a visual search and target classification task in a competitive video gaming context. An adaptive algorithm, denoted the "virtual competitor" (VC), simulated two degrees of challenge relative to each individual participant's real-time performance. This was accomplished by using a stochastic control system to manipulate the percentage of each 15-minute task condition that the participant was scoring higher than the VC. In the low-challenge condition, the participant outscored the VC approximately 80% of the time. The high-challenge condition, however, was chosen through pilot testing to be more closely matched at 50%. Because the VC was partly stochastic, participants were unaware of the relationship between their score and that of the VC. More importantly, task difficulty did not change with increased challenge, and this was verified by behavioral results that did not differ significantly as a function of condition. By contrast, the pattern of results across multiple subjective and psychophysiological measures indicated both physical and subjective responses were consistent with increased stress and, somewhat counterintuitively, positive affective valence as apparent challenge increased. We interpreted this in terms of an affective response driven by motivational processes. That is, participants' responses suggested a task experience that was more engaging and positive as competition increased, because the experimental manipulation structured putative rewards consistent with the subjects' intrinsic motivation by competition rather than on task-based performance measures.

Title: Effects of focusing on negative and positive attributes of self-image on self-esteem and psycho-physiology

Authors: *M. C. NIEDZIELA[1], E. CARBONE[2], P. BOLLS[3]
[1]HCD Res., Lansdale, PA; [2]HCD Res., Flemington, NJ; [3]Univ. of Missouri, Columbia, MO

Abstract: Social cues have subtle non-conscious effects via implicit priming of trait associations. Priming paradigms are valuable tools for assessing implicit self evaluation. In this novel preliminary study, we tested the hypothesis that an implicit positive or negative association with self mediates physiology and behavior towards self imagery. Attitudinal, perceptual and physiological components of self image were assessed. Seventeen female participants between ages of 18-35 yrs were recruited. For pre-test, participants completed the Rosenberg Self-Esteem Scale. Participants were primed "positive" or "negative" using a facial feature description task in which they were instructed to choose three positive or negative facial features (control case, chose 3 most frequently used makeup items) after which they viewed an image of their face for 15 sec. We measured the priming effect on self assessment self-esteem scales (Rosenberg Self-Esteem Scale (post-test)), electrophysiology and eye tracking. Electrophysiological data - facial electromyography (emotional valence), heart rate (attention), skin conductance (galvanic skin response, arousal) - were collected. With this novel paradigm, we investigated how social cues modulate one's implicit self-evaluation through physiological and behavioral measures. Though not significant, positive priming (mean= 0.2) prevented a decrease in self-esteem seen in negative (mean= -0.83) and control (mean= -1.0) groups after viewing self imagery. Eye tracking results showed that when negatively primed, participants avoided features they did not like while positively primed participants were more attracted to and looked longer at features they liked. Psycho-physiological measures showed that negative priming resulted in greater changes in emotion (corrugator supercilii muscle group, negative emotion; zygomaticus major and orbicularis oculi muscle groups, positive emotion). Positive priming had a greater effect on arousal levels. Both forms of priming decreased attention compared to control. The data provide a quantitative demonstration of how implicit cues, targeting a person's self-concept, influence the way we react physiologically and behaviorally. Further means of examining cognitive priming effects on physiology are outlined.

Title: Changes in autonomic arousal elicited by subcallosal cingulate DBS are associated with white matter connectivity to the mid-cingulate cortex

Authors: *C. INMAN[1], P. RIVA POSSE[2], K. CHOI[2], A. CROWELL[2], S. DANIELSON[1], S. GARLOW[2], H. MAYBERG[2], S. HAMANN[1]
[1]Psychology Dept., Emory Univ., Decatur, GA; [2]Dept. of Psychiatry, Emory Univ., Atlanta, GA

Abstract: Subcallosal cingulate (SCC) deep brain stimulation (DBS) has shown preliminary long-term efficacy and safety for treatment-resistant depression (TRD). Immediate changes in mood and behavior during intra-operative testing have also been observed. Spontaneous self-reported intra-operative effects include, "feeling lighter, calmer," and "more awake, more aware, more reactive;" indicative of changes in autonomic arousal. Autonomic changes have been observed within seconds of initiating acute stimulation and appear to relate to selection of the optimal white matter targets mediating long-term antidepressant effects. Optimal targets include locations in the white matter of the SCC whose structural connections reach the medial prefrontal cortex via the forceps minor pathway, subcortical regions via the uncinate fasciculus, and the mid-cingulate cortex via the cingulum bundle. Diffusion tensor imaging was acquired on 9 participants in an ongoing study of SCC DBS for TRD to aid in surgical planning and characterization of the white matter networks connected to the SCC. To assess the immediate effects of SCC DBS on mood, behavior, and autonomic reactivity, skin conductance response (SCR) and change in heart rate (HR) were measured during acute stimulation protocols performed during surgery, 1- and 3-months post-operatively. During surgery, increases in autonomic arousal correlated with stimulation to the most behaviorally effective contacts relative

to all other stimulations and sham. This finding is indicative of a highly location-specific effect on autonomic arousal. Correlation analyses show that these increases in autonomic arousal, particularly heart rate, positively correlate with the strength of white matter connectivity between the site of stimulation in the SCC and the mid-cingulate. In post-operative experiments, we found that as stimulation current amplitude was increased, both measures of autonomic arousal (SCR and HR) increased. In addition, post-operative stimulation of optimal versus non-optimal contacts increased autonomic arousal, also indicative of a highly location-specific autonomic response. These findings suggest that SCC DBS modulates activity through down-stream effects on brain regions involved in autonomic regulation that have strong white matter connectivity to the SCC. These findings are consistent with known anatomical connectivity of SCC to cingulate cortex and brainstem in humans and animals. Further, current- and location-dependent changes in autonomic arousal with SCC DBS provide a novel strategy for examining the interactions of affective experience and the autonomic nervous system.

Title: Neural mechanisms underlying effects of giving monetary reward and punishment on successful encoding of episodic memories in social and non-social context

Authors: *Y. SHIGEMUNE, T. TSUKIURA
Dept. of Cognitive and Behavioral Sci., Kyoto Univ., Kyoto, Japan

Abstract: The processing of rewards and punishments enhances episodic memories. Previous studies have reported that receiving monetary rewards and punishments enhances memory performance, and interaction between activations in the hippocampus and the reward-related region including the ventral striatum (vS) underpins this enhancement. However, there is little evidence how giving rewards and punishments modulates memory performance and memory-related neural mechanisms. Given that rewards and punishments are often given and taken in social context, we investigated this issue in both social and non-social contexts. Twenty-five college students participated in this study. During encoding with fMRI scanning, participants were presented with silhouette pictures as substitutes for students in another college (Human) and computer programs (Machine), and were required to judge whether they give monetary rewards (Reward), punishments (Punishment), or nothing (Control) to students and programs as the pictures. Participants were given a fictitious instruction that the students and programs would receive monetary rewards and punishments decided by the participants, and in return the students and programs would decide to give monetary rewards, punishments, or nothing to the participants. During retrieval, participants were presented with old and new silhouette pictures, and judged whether the pictures were old or new with two levels of confidence. Behavioral data of subjective ratings demonstrated that participants inferred other's intention and felt positive or negative emotion more strongly in Reward and Punishment than in Control, but the enhancement of inference and emotion in Reward and Punishment was larger in Human than in Machine. In addition, memories encoded in Reward and Punishment were remembered more accurately than those in Control, but there was no difference in the enhancing effects of memories between Human and Machine. In fMRI data, the lateral prefrontal cortex (lPFC) involved in the intention inference and the reward-related vS showed greater activations in Reward and Punishment than in Control, and activations in the hippocampus reflected the successful encoding of memories. In addition, correlation between activations in the hippocampus and lPFC was significantly higher in Reward and Punishment during the successful encoding of memories. These findings suggest that action of giving rewards and punishments could enhance successful encoding of memories in both social and non-social contexts, and that interactions between the lPFC and hippocampus could contribute to the memory enhancement.

Title: Relationship between brain activity and emotional state during multi task

Authors: ***T. OKAMURA**[1], U. YAMAMOTO[2], T. HIROYASU[2]
[1]Doshisha Univ., Kyotanabe,Kyoto, Japan; [2]DOSHISHA Univ., KYOTO, Japan

Abstract: Objective The purpose of this study is to investigate the relationship between the brain activity and the changes in the emotional state during multi task. This paper describes that the emotional influence of multi-task differs from person to person even if they do the same task using simplified Profile of Mood States (POMS). We measure the brain activation during the multi task using functional Magnetic Resonance Imaging (fMRI), to find out a relationship between the brain activation and the emotional state. Methods Eight healthy young men and eight healthy young women (22±1 years old) participated in this study. The subjects performed online letter matching tasks, which provide a multi task and a single task. The multi task consists of a simultaneous memory of two problems at the same time. On the other hand, the single task offers that the subject memories only one problem. In both of the experiments, we investigated the relationship between the brain activation and the emotional state. In the first experiment using fMRI, we measured the brain activation during the multi tasks and the single tasks. In the second experiment using POMS, we measured the emotional changes during both of the tasks. On the basis of the emotional changes caused by each task, we classified subjects to the high-stress group or the low-stress one.The subjects with increase in emotional changes are defined as the high-stress group and those with decrease of emotional changes are defined as the low-stress group. We compared the brain activation between the high-stress group and the low-stress group. Results There were the high-stress subjects and the low-stress subjects in both tasks. The emotional influences caused by each task differed from person to person even if they do the same task. When the subjects performed the multi task, the difference of activation in the Vermis between the high-stress group and the low-stress one was observed. When the subjects performed the single task, the difference of activation in the Cerebellum between the high-stress group and the low-stress one was exhibited. Although there is not a unique region about the multi task, the results suggested that the difference in the emotional state is concerned with the brain activation in Vermis. Conclusions The emotional changes in the multi task and the single task differed from person to person. The difference in emotional changes was concerned with the brain activation even if they do the same task. This paper suggested that the emotional state during the multi task is closely related to the brain activation in Vermis.

Title: Interpreting cognitive and physiological states from biometric sensors to predict performance degradation

Authors: *B. K. BRACKEN[1], S. GUARINO[1], W. DORIN[1], P. DIZIO[2], J. LACKNER[2], V. ROMERO[1], J. PFAUTZ[1]
[1]Cognitive Systems Div., Charles River Analytics, Cambridge, MA; [2]Psychology, Brandeis Univ., Waltham, MA

Abstract: Biometric techniques for sensing peripheral nervous system indicators (e.g., heart rate, blood pressure, and galvanic skin response), when analyzed and interpreted correctly, provide an opportunity to objectively assess and forecast cognitive, physical, and emotional human states. However, the accurate interpretation of biometric data depends on the environment in which the individual is performing and on the type of task the individual is undertaking. The effort described herein focused on (1) proving the feasibility of an approach to acquire, model, and interpret cognitive, emotional, and physical state from physiological data, and (2) forecasting the effect that state will have on cognitive performance. We first identified a set of inexpensive, commercially available, off-the-shelf sensors that are simple to use, robust enough to use in real-world environments, and provide access to the raw data. We used a Zephyr Bioharness to measure heart rate, breathing rate, skin temperature, and posture; a body-mounted 9-axis accelerometer, including a 3-axis gyroscope (to measure orientation), a 3-axis accelerometer, and a 3-axis magnetometer (to measure the direction of the Earth's ferromagnetic axis); an identical ship-mounted 9-axis accelerometer for collecting environmental motion information from the boat; and a mobile device (a 10-inch Samsung Galaxy tablet) to deliver cognitive tasks. Cognitive tasks included a working memory task (dual n-back task; (Jaegi et al., 2003), a problem solving task (basic arithmetic), and an inhibition task (Stroop task; (Stroop, 1935)). Once the data were collected, we used complex event processing methods to extract and fuse the best combination of indicators of motion sickness and cognitive performance based on previous findings in the literature and subject matter expert input. Next, we modeled the fused data with a hybrid computational approach to combine different types of indicators to infer symptoms of fatigue, mood, sickness, and motivation directly from data. We then used the modeled data to

forecast cognitive degradation due to motion exposure before the individual subjectively reported her symptoms. We present the results of our pilot experiment in which we demonstrated that we could feasibly anticipate motion exposure effects on cognition for a small subject population. We believe this approach can be used across a wide range of sensing devices, assessment environments, and human states of interest.

Title: Task-evoked skin conductance responses and intrinsic amygdala connectivity independently predict subjective experience of arousal

Authors: *C. XIA[1], A. TOUROUTOGLOU[1], M. ADEBAYO[1], C. CASO[1], M. STEPANOVIC[1], V. HUNTOON[1], J. ANDREANO[1], E. SIEGEL[2], K. QUIGLEY[2], B. DICKERSON[1], L. FELDMAN BARRETT[1,2]
[1]Massachusetts Gen. Hosp., Charlestown, MA; [2]Northeastern Univ., Boston, MA

Abstract: BACKGROUND: Previous psychophysiologic research has shown that skin conductance response during affective reactivity tasks is related to subjective experience of arousal (Lang et al., 1998). In a recent functional magnetic resonance imaging (fMRI) study from our laboratory, we demonstrated that subjective experience of arousal is also linked to amygdala intrinsic connectivity within the salience network (Touroutoglou et al., in press). However, no study has yet examined how the physiologic responses to affective stimuli combine with salience network intrinsic connectivity to predict subjective experience of arousal. Here, we hypothesized that task-evoked skin conductance response and resting-state connectivity strength within the salience network independently predict individual differences in the experience of arousal while viewing affective pictures. METHODS: An affective reactivity task was administered to 27 young adults during which they viewed 90 items ranging in valence and arousal from the International Affective Picture System. Participants rated their subjective

experience of arousal to each image and concurrent skin conductance responses were recorded. On a separate day, resting-state fMRI data were acquired for these same participants. A multiple linear regression analysis was carried out using the average number of skin conductance responses to high arousal images (versus neutral images) and intrinsic connectivity strength of the dorsal amygdala to the rest of the salience network as independent variables, and the mean arousal ratings of high arousal images (versus neutral images) as the dependent variable. RESULTS: Participants with an increased number of skin conductance responses to high arousal images (versus neutral images) reported more intense subjective experiences of arousal. Similarly, participants with stronger resting-state connectivity within the salience network reported more intense subjective experiences of arousal for these same images. However, the task-evoked skin conductance responses and resting-state salience network connectivity strength were not correlated with each other. A linear regression analysis showed that skin conductance response and resting-state salience network connectivity strength each significantly predicted unique variance in the subjective experience of arousal. CONCLUSIONS: Our findings suggest that skin conductance response to affective stimuli and intrinsic dorsal amygdala connectivity within the salience network provide independent and complementary contributions in predicting the subjective experience of arousal.

Title: Monitoring versus implementation in emotional top-down control

Authors: R. CLARKE, *T. JOHNSTONE
Psychology Dept., Univ. of Reading, Reading, United Kingdom

Abstract: Background Successful top-down control entails monitoring and signalling the need for control and the implementation of such control. Studies in the cognitive domain suggest that these processes are distinct, with medial prefrontal cortex (PFC), particularly dorsal anterior cingulate (dACC), implicated in monitoring the need for control and lateral PFC in the implementation of control. In this study we sought to test whether the top-down control of anxiety involves similar neural circuitry. Method 22 healthy participants aged 18-21 underwent fMRI scanning while they completed a visuospatial working memory (WM) task with two load levels, in either the absence or presence of threat of electric shock to induce anxiety. We proposed that high load and threatening trials would engage top-down control in order to overcome emotional interference. Furthermore, we predicted that control mechanisms engaged on such trials would persist to subsequent trials. We thus hypothesised that control trials preceded by safe trials would primarily engage mechanisms responsible for detecting and signalling the need for greater top-down control (i.e. dACC), whilst control trials preceded by threatening trials would primarily engage mechanisms responsible for implementing control (i.e. lateral PFC) due to such mechanisms having already been established on the preceding trial. Results Contrary to our previous studies, there was no behavioural effect of emotional interference, with threat of shock improving performance at both WM loads. Previous trial threat-level had no effect on performance. Imaging results, however, showed a differential pattern of PFC activation to control trials depending on previous trial threat. Consistent with our predictions dACC activation was greater for control trials preceded by safe trials, whereas right ventrolateral PFC (vlPFC) was greater for control trials preceded by threat trials. Conclusion Our results support a model in which dACC is associated with monitoring the need for top-down control and right vlPFC activation, specifically inferior frontal gyrus (IFG), with implementing control.

Title: Mindfulness Based Stress Reduction correlates with frontal lobe changes during mood induction fMRI

Authors: *B. B. BRADEN[1], T. K. GLASPY[1], T. PIPE[2], K. STEINKE[1], C. T. ELROD[1], L. C. BAXTER[1]
[1]Barrow Neurolog. Inst., Phoenix, AZ; [2]Col. of Nursing & Hlth. Innovation, Arizona State Univ., Phoenix, AZ

Abstract: Depression neural circuitry has been established in part through brain mapping during induction of a sad mood. Interventions such as medication and deep brain stimulation have been shown to modulate depression neural circuitry. We examined whether a behavioral intervention, Mindfulness Based Stress Reduction (MBSR), similarly modulates regional brain activity during emotional responsivity. Participants were 24 back pain patients, 13 of whom completed a 4 week MBSR class. The 11 Control participants were given MBSR reading material with no further instruction. All participants were evaluated for Beck Depression Inventory-II and Oswestry Low Back Pain and scanned on the same 3T Philips scanner a week before and after the MBSR training. During scanning, we used an fMRI mood induction paradigm that maps neural changes during transitions between sad and neutral moods. During the task, participants viewed alternating sets of sad (mourning people) or neutral (landscape) pictures for mood induction, signaling that they achieved the desired mood state (sad or neutral) with a button press. Individualized regressors linearly modeled the time periods during the attainment of sad and neutral moods. Parameters were TE/TR= 30/3000ms, FOV =24, 60x60 matrix, 40 contiguous slices 4mm thick collected in the axial plane. SPM8 was used for image processing and analyses. Paired t-tests indicated that both groups declined in depression scores (Controls; $p=0.05$, MBSR $p=0.08$ but only the MBSR group showed a significant decline in back pain symptoms ($p<0.02$; $p=0.1$ for Controls). At baseline, there were no group differences in fMRI responsivity. Post-intervention, the MBSR group showed greater BOLD signal in the middle anterior cingulate cortex (ACC; $p=0.035$, corrected), subgenual ACC ($p=0.043$, corrected), and left insula ($p=0.038$, corrected) during transitions from a sad to a neutral state, than the Control group. In summary, despite a mild improvement in depression in both groups, only the MBSR intervention improved back pain symptoms. FMRI results parallel these findings, showing greater frontal system engagement in regions important in awareness of internal states (insula) and cognitive awareness of emotional regulation (ACC). Further research is warranted to evaluate the neural correlates of MBSR as a behavioral intervention for distressed patient populations, including chronic back pain.

Title: Emotion-related N250 is generated near temporo-parietal junction and is evoked both by faces and by affectively valent non-social images

Authors: J. ATHILINGAM[1], J. JONES-ROUNDS[2], D. J. POST[3], B. L. GANZEL[2,4], *M. K. BELMONTE[5,6]

Abstract: Emotion recognition is a crucial component of social interaction that subserves the interpretation and comprehension of another actor's mental state. The current study aimed to factor out the process of emotion recognition from facial encoding by recording event-related potentials during emotion recognition of both social (face) and non-social (object) stimuli in 22 normal young adults. The N170, N250, P300, and late positive (LPP) event-related potentials were examined for the effect of task set (simple discrimination vs. emotion recognition), stimulus type (face vs. object), and valence (emotional vs. neutral). Whilst the N170 arose specifically in response to faces, P300 and LPP amplitudes increased with emotion regardless of stimulus type, suggesting that emotion processing and recognition are indeed separable from facial encoding. The LPP also seemed modulated by attention as its amplitude was greater during the emotion recognition task than during discrimination. Consistent with another recent report, the N250, the putative emotion recognition component, was greater in amplitude to neutral than to emotional faces during the emotion recognition task, possibly reflecting increased integrative processing associated with difficulty in perceiving an emotion. Independent component clustering and dipole source localisation revealed that the emotion-related N250, broadly distributed at fronto-central scalp electrode locations, is also associated with a more focal, opposite potential on occipito-parietal scalp consistent with a dipole generator near the temporo-parietal junction, a major node of information integration. These results provide evidence for a common mechanism of emotion perception in response to social and non-social stimuli, and convergent evidence for a posterior generator of the emotion-related N250.

Title: Music-induced mood improves retention in sensorimotor adaptation

Authors: K. WACLAWIK[1], L.-A. LEOW[1], *J. A. GRAHN[2]
[2]Dept. of Psychology, [1]Univ. of Western Ontario, London, ON, Canada

Abstract: During sensorimotor adaptation, individuals learn to adapt movements to distortions in sensory feedback. Rewarding feedback increases persistence of adapted movements after the distortion is removed. Positive music is also rewarding and thus might engage neural reward mechanisms during adaptation. Here, positive music increased retention of adapted movement more than negative music and silence. Rewarding feedback increased retention of adapted movements relative to no feedback. However, presence of both rewarding feedback and positive music decreased retention of the adapted movements relative to rewarding feedback alone or positive music alone. Therefore, positive music interacts with reward mechanisms during sensorimotor adaptation.

Title: Brain network for text based emoticons

Authors: *K.-W. KIM[1], S. LEE[1], B. JEONG[1], J. CHOI[2]
[1]Grad. Sch. of Med. Sci. and Engin., KAIST, Daejeon/ Yuseong-Gu, Korea, Republic of;
[2]Psychiatry, The Catholic Univ. of Korea Col. of Med., Daejeon, Korea, Republic of

Abstract: The text-based emoticons are a nonverbal communication tool of emotion and is a unique feature of human being. Human can extract emotional features from serial distribution of letters and/or symbols. However, little is known how the human brain recognizes emoticons and discriminate them laden with various emotions. The aim of our study was to investigate brain network for the emoticon processing using fMRI. Eighteen subjects (age=30.5±6.6 years, M: F = 10: 8) were recruited. All subjects gave written informed consent before participating in the study. They were interviewed to exclude any possible psychiatric diseases by a psychiatrist using DSM-IV criteria. The subjects didn't have any Axis-I psychiatric disorder and history of head trauma. The event-related task consisted of four emotional conditions of emoticons: happy, sad, angry/fearful, scrambled emoticons. The four different categorized emoticons were presented in pseudo-randomized order. During the fMRI scan, subjects were asked to respond by pressing a button, indicating whether the emoticon represented positive or negative emotion. The general linear model was used for linear combination of the modeled response to visual stimulation of happy, sad, angry/fearful and scrambled emoticons, excluding errors. Using FEAT of FSL software, we performed both preprocessing and statistical analysis for comparing the activation among 3 emotional and scrambled emoticons. Two distinct brain networks had important role in emoticons processing: the central executive network consisting of the dorsolateral prefrontal cortex (Z value: right=4.72, left=4.92) and the left posterior parietal cortex (Z=4.72), and the salience network consisting of the anterior insula (Z value: right=5.92, left=5.48) and the right anterior cingulate cortex (Z=5.48). The processing of emoticons was also associated with an increased activation as follows: the bilateral lateral occipital cortex (Z value: right=5.08, left=5.49), the left precentral gyrus (Z=5.28), and the left thalamus (Z=5.94) (corrected $p < 0.05$). Only sad emoticons subtracted from other conditions illustrated significantly different activity in salience network. The central executive and salience networks may play a significant role in cognitive and emotional processing of text-based emoticons.

Title: Common amygdalar functional coupling mechanisms underlie emotional bias and explicit memory following negative-emotional processing: An evaluative conditioning paradigm

Authors: *R. C. LAPATE, T. KRAL, K. AROOR, B. SCHUYLER, R. J. DAVIDSON
Univ. of Wisconsin-Madison, Madison, WI

Abstract: Emotional events typically leave long-lasting fingerprints on surrounding stimuli. A prototypical laboratory example is evaluative conditioning, whereby a novel neutral stimulus paired with a negative stimulus is subsequently rated as more negative. Evaluative conditioning is a context in which implicit emotional regulation is operative, but its neural mechanisms remain unclear. Here, we combined resting state and task-based indices of amygdalar functional connectivity to test whether the magnitude of evaluative conditioning across individuals is associated with amygdalar-prefrontal cortical (PFC) coupling mechanisms implicated in favorable emotion-regulatory outcomes. While in the scanner, healthy participants (N=72, 26 – 65 y old, 47 female) watched 72 negative, neutral and positive pictures presented for 4000 ms. Following the presentation of 2/3 of the pictures, neutral faces were flashed on the screen for 500 ms. Each neutral face was presented twice, and consistently paired with one picture valence. Resting state data were also acquired. Three days later, individuals were presented with the previously shown neutral faces, as well as foils, and asked to rate each face for likeability (indexing evaluative conditioning) and recognition (indexing stimulus memory). Although individuals reported on average not remembering the previously shown neutral faces, $t(70)= -7.9$, $p < .001$, faces following negative images were significantly less liked, $F(1,71) = 16.8$, $p < .001$, and better remembered, $F(1,71) = 9.7$, $p < .01$, than faces following neutral images. Task-based functional connectivity analysis (psychophysiological interaction) with the amygdala as a seed indicated that the negative coupling between the amygdala and common regions of the inferior frontal gyrus (IFG), insula (INS) and basal ganglia (BG; including putamen and pallidum) following negative (relative to neutral) pictures predicted less evaluative conditioning as well as greater recollection of neutral faces following negative (relative to neutral) pictures, $z > 2.3$, $p < .05$, whole-brain cluster-corrected for multiple comparisons. Further, positive coupling between the amygdala and the BG at rest predicted less evaluative conditioning and greater negative

coupling between the amygdala and the BG, INS, and IFG during the task, ps < .03. Thus, these results extend the functional relevance of amygdalar-PFC coupling to improved memory for and reduction of negative bias toward neutral stimuli following evaluative conditioning, while highlighting a role for amygdalar-BG coupling at rest in predicting amygdalar-PFC dynamics during a negative emotional challenge.

Title: The role of the human amygdaloid complex in fear conditioning: A functional connectivity analysis

Authors: ***S. YIN**[1], Y. LIU[3], A. KEIL[2], M. DING[1]
[1]Biomed. Engin., [2]Dept. of Psychology, Univ. of Florida, Gainesville, FL; [3]Ctr. for Mind and Brain, Univ. of California, Davis, Davis, CA

Abstract: The Role of the Human Amygdaloid Complex in Fear Conditioning: A Functional Connectivity Analysis Siyang Yin, Yuelu Liu, Andreas Keil, Mingzhou Ding Work in the rodent models of fear conditioning has demonstrated that the amygdaloid complex plays a central role in mediating defensive responses to conditioned threat cues. In human imaging studies of aversive conditioning, however, activation of the amygdala by the conditioned stimulus is not always observed. We examined this problem from a functional connectivity perspective. Functional magnetic resonance imaging (fMRI) data were recorded from 18 subjects during a classical differential fear conditioning paradigm. Two Gabor patches (45° and 135°) were used as conditioned stimuli (CSs). One Gabor patch, denoted as CS+, was occasionally paired with an aversive human scream used as the unconditioned stimulus (US; 25% reinforcement rate), whereas the other Gabor patch (CS-) was never paired with the US. Comparing BOLD activity evoked by the CS+ (in unpaired trials) and by the CS-, we found that ACC and insula, but not the amygdala, were selectively activated by CS+. Furthermore, applying the beta series method, the

time courses of single trial beta values from CS+ unpaired trials and from CS- trials were statistically indistinguishable in the amygdala. A ROI-based connectivity analysis showed that relative to CS-, a significant increase of functional connectivity between the amygdaloid complex and cortical structures including ventral anterior cingulate cortex (vACC), insula, and medial prefrontal cortex (mPFC) was observed for CS+. The connectivity change between amygdala and vACC/mPFC was negatively correlated with the subjects' heart rate change, whereas the connectivity change between amygdala and insula/putamen was positively correlated with the subjects' heart rate change. These results suggest that in the present paradigm the amygdala contributes to fear acquisition and autonomic response regulation via its functional interaction with other cortical and subcortical structures.

Title: Affective state is associated with changes in the neural response to threat

Authors: *N. G. HARNETT, M. D. WHEELOCK, K. H. WOOD, S. MRUG, D. C. KNIGHT
Psychology, Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: During Pavlovian fear conditioning, the unconditioned response (UCR) elicited by an aversive threat (i.e. the unconditioned stimulus; UCS) is diminished when preceded by a warning signal (i.e. the conditioned stimulus; CS). This phenomenon is called conditioned UCR diminution. Relatively limited research has studied the neural mechanisms of conditioned UCR diminution, and even less research has investigated whether UCR diminution is influenced by individual differences in emotion processes. A better understanding of the impact that individual differences in cognitive and emotional function have on the neural response to threat would provide valuable insights into this type of emotional learning. Therefore, the present study investigated neural activity, using functional magnetic resonance imaging, to identify brain

regions that mediate learning-related changes in the emotional response to a threat (i.e. conditioned UCR diminution). In addition, we assessed the effect that individual differences in locus of control and positive/negative affect have on conditioned UCR diminution in these brain regions. Whole brain analyses revealed conditioned UCR diminution within the insula, dorsomedial prefrontal cortex (PFC), dorsolateral PFC, and inferior parietal lobule. Whole brain regression analysis revealed that brain activity varied with positive/negative affect. Further, the relationship between brain activity and positive/negative affect appeared to vary depending on whether the UCS was predictable (e.g., UCS alone or UCS preceded by the CS+). These findings suggest that individual differences in affective state influence the neural response to threat, and are dependent on stimulus predictability.

Abstract: Privileged processing of cues that signal danger in the environment and initiation of appropriate defensive behaviors is essential for survival. Thus, it is reasonable to expect a strong

interaction between emotional processing and prompting of action tendencies. The aim of this study was to investigate how different threatening stimuli drive the activity of brain networks, especially in motor related areas. The direction of threat stimuli was the key factor manipulated to attempt to activate different defensive responses. We used functional MRI to investigate brain responses of 31 volunteers (14 women) during a simple motor task while they viewed 42 threat and 42 matched neutral pictures. Threat stimuli were divided into two sets - one set composed of photographs with a person directing a firearm toward the observer (directed towards threat), and another composed of photographs in which a person was pointing a fire arm away from the viewer (directed away threat). Matched neutral stimuli were also divided into two sets in a similar fashion. Each picture was presented for 5 sec and an overlapped central circle appeared between 3.7 to 4.2 sec after picture onset. Participants were instructed to press a button as quickly as possible whenever a circle appeared. Imaging data analysis was performed using AFNI, with directed threat, directed away threat, directed neutral and directed away neutral as regressors in the general linear model. We conducted a repeated-measures ANOVA at the second level analysis with the factors Valence (threat or neutral) and Direction (directed towards or directed away). We found a main effect of Valence (i.e., threat > neutral) in several regions including amygdala, visual cortex, mid cingulate cortex, precentral gyrus (PG), supplementary motor area (SMA) and insula. More focused ROI analysis also revealed an interaction between Valence and Direction in subset of these regions such that threat (vs. neutral) responses were stronger in directed towards compared to directed away condition. These results suggest that viewing of threatening pictures increase motor preparation, especially when threat is directed towards the observer, and probably reflects that different defensive reactions are implemented depending on the perceived threat level.

Title: Motivation counteracts aversive processing in the amygdala and visual cortex

Authors: *M. SIRBU, S. J. E. LANGESLAG, S. PADMALA, L. PESSOA
Psychology, Univ. of Maryland, College Park, MD

Abstract: Positive motivational processes such as those manipulated via monetary rewards typically improve cognitive task performance, whereas task-irrelevant aversive stimuli often interfere with performance. We have recently reported that performance-based rewards reduced the interference effect of task-irrelevant aversive stimuli in a behavioral setting (Padmala & Pessoa, Emotion, in press). In the current fMRI study, we sought to determine the neural correlates of this behavioral effect. In line with the behavioral findings, we hypothesized that rewards would lead to decreased aversive processing in regions such as the amygdala. Additionally, we investigated how aversive processing was influenced by distinct motivational manipulations: when participants sought monetary gains or when they avoided monetary losses. Participants (N=27) performed a visual discrimination task where on each trial they judged whether two circular grating stimuli (above and below fixation) had the same or different line orientation. Along with the grating stimuli, two faces of the same identity and expression (fearful or neutral presented to the left and right of fixation) served as task-irrelevant distractors. Positive motivation (i.e., seeking monetary gains), negative motivation (i.e., monetary loss avoidance), and control (i.e., no gains/losses) conditions were presented in a blocked fashion and signaled by a cue at the start of each block. At the end of each block, participants received feedback about their earnings in that block and their cumulative earnings. As expected, we observed distractor effects in the amygdala and fusiform gyrus such that fearful faces elicited stronger responses compared to neutral ones. We also observed evidence for an interaction between Positive motivation (reward, control) and Distractor type (fearful, neutral) in the amygdala and fusiform gyrus, such that increased fearful (vs. neutral) responses in the control condition were reduced during the reward condition. In contrast, we did not detect an interaction between Negative motivation (punishment, control) and Distractor type (fearful, neutral) in the amygdala. Our preliminary analyses suggest that potential reward reduces aversive distractor processing in the amygdala and visual cortex, thus potentially reducing their detrimental effect on behavior. Furthermore, these results support the notion that processing of aversive information is not obligatory (i.e., automatic) but can be modulated by motivational processes.

Title: Decoding spontaneous emotional states from neural activation during rest

Authors: *P. A. KRAGEL, A. R. HARIRI, K. S. LABAR
Duke Univ., Durham, NC

Abstract: As emotional states are conventionally elicited through stimulus presentation or internally-guided imagery, studying the nature of neural systems underlying emotion in the absence of experimental tasks remains a challenge. Identifying neural activity that corresponds to spontaneous fluctuations in emotional states may be important for characterizing individual differences in susceptibility to psychiatric illness, assessing the outcome of intervention strategies, and quantifying emotion elicitation in individuals who have little insight into their emotional experience. In the present study, we use multivariate classification models to predict the occurrence of basic emotional states (i.e., contentment, amusement, surprise, fear, anger, sadness, and neutral states) from patterns of neural activation during resting state fMRI. Utilizing classifiers trained on fMRI data from task-based emotion induction in an independent sample, we examined the frequency and temporal dynamics of emotional states spontaneously elicited at rest from a large sample of over 400 individuals. Additionally, we assessed whether individual differences in personality traits (i.e., neuroticism and extraversion) influence the occurrence of individual emotions at rest. We found that emotional states exhibited a non-uniform distribution during rest, with contentment being predicted the least and neutral states occurring most often. Analysis of temporal dynamics revealed significant changes in classification scores over time for all seven emotions. Notably, scores for classifying fear were the highest at the onset of resting-state scans - when participants were initially placed into the MRI scanner - and decreased over time. Regression analyses revealed that the frequencies of emotional states were associated with personality differences: the number of fear classifications increased with neuroticism, whereas the frequency of surprise increased and the frequency of sadness decreased with increasing extraversion. These findings demonstrate the capacity of multivariate biomarkers to detect emotional states at rest and illustrate their sensitivity to individual differences in personality traits that impact spontaneous emotional experience. Further, these results have practical implications regarding the nature of emotions at rest. As they are not uniformly distributed or temporally invariant, using a resting state baseline for task-based emotion induction may obscure or bias results, particularly depending on the personality traits of the sample.

Title: The neural response in humans is diminished to predictable and controllable threats

Authors: ***K. H. WOOD**[1], M. D. WHEELOCK[1], J. R. SHUMEN[1], L. W. VER HOEF[2,3], D. C. KNIGHT[1]
[1]Univ. of Alabama at Birmingham, Dept. of Psychology, Birmingham, AL; [2]Univ. of Alabama at Birmingham, Dept. of Neurol., Birmingham, AL; [3]Birmingham VA Med. Ctr., Birmingham, AL

Abstract: Susceptibility and resilience to stress is mediated, in part, by our ability to predict and control threats in our surroundings. Prior animal research has demonstrated a diminished emotional response in anticipation of predictable and controllable stressors, whereas unpredictable and uncontrollable stressors result in an enhanced emotional response. The present study was designed to better understand the effect of predictability and controllability on threat-related brain activation. Two groups of healthy volunteers participated in a novel Pavlovian fear conditioning study during functional magnetic resonance imaging (fMRI). Similar to prior animal research, the groups consisted of yoked pairs in which one group (Controllable Condition; CC) was able to terminate the unconditioned stimulus (UCS), and the other group (Uncontrollable Condition; UC) was not able to terminate the UCS. The threat-related fMRI signal response was diminished on predictable compared to unpredictable trials within the dorsolateral prefrontal cortex (PFC), dorsomedial PFC, ventromedial PFC (vmPFC), ventrolateral PFC, and posterior cingulate for both CC and UC groups. A predictability x controllability interaction was observed within the vmPFC and hippocampus. Specifically, the threat-related response within these brain regions was diminished on predictable vs. unpredictable trials for the CC. Further, the threat-related response was enhanced on predictable trials for the UC compared to the CC within the vmPFC and hippocampus. The current findings suggest the vmPFC and hippocampus play a key role in regulating the emotional response to a

threat. To our knowledge this is the first human neuroimaging study to demonstrate that controllability and predictability impact the emotional response elicited by the threat itself using a yoked fear conditioning paradigm. These findings provide a better understanding of the neural circuitry that supports the modulatory effects of predictability and controllability on the emotional response to a threat.

Title: Mobile brain/body imaging: Combined EEG and motion capture during a dart throwing visuospatial working memory task

Authors: *R. J. GOUGELET[1,2], M. MIYAKOSHI[2], A. BIRGER[1], J. LE[1], A. WOOTEN[1], S. MAKEIG[2]
[1]Cognitive Sci., UCSD, La Jolla, CA; [2]Swartz Ctr. for Computat. Neurosci., La Jolla, CA

Abstract: With an embodied cognition perspective at the forefront of recent cognitive theory, the link between brain activity and full body motion will become increasingly important. Few studies combine full body motion and electroencephalography (EEG), especially in visuospatial working memory tasks. This study involves humans performing a novel visuospatial delayed response working memory task. For each trial, a projector projects a target stimulus onto a 1.8 x 1.2 m white cork board, onto one of 17 fixed positions in the visual field of subjects. The target stimulus is similar to a dart board, with a bull's-eye surrounded by concentric circles corresponding to decreasing distance and point values. The subjects fixate on a center crosshair for a 3 s preparatory period, the target is displayed for 250 ms before the target either disappears for the target absent condition, or remains for the target present condition. After a randomly variable 3 to 9 s integer delay, the subjects throw a dart to the displayed or remembered position of the target, the dart's distance from the target is measured and they receive motivating points based on their performance. Continuous EEG data were collected using 128 active electrodes with a 512 Hz sample rate. Electrooculography (EOG) and electromyography (EMG) from the right throwing arm were also collected. EEG, EOG, and EMG data were analyzed using

EEGLAB. EEG data were epoched into 3 s periods at the start of the delay conditions. Epochs with excessive eye and muscle artifacts were removed. The continuous EEG data were also decomposed into maximally independent components using independent component analysis (ICA). Full-body kinematic motion data were collected from 32 LED locations on the limbs, torso, and head of each subject. A Shapiro-Wilk's test ($p > 0.05$) showed that both target absent and target present distance scores were not approximately normally distributed. A non-parametric two-sample Kolmogorov-Smirnov test between the target absent and target present conditions demonstrated that the distributions were significantly different between conditions ($p < 0.05$), with greater mean and median distance, greater variability, and greater kurtosis in the target absent condition, suggesting decreased precision and accuracy when throwing to remembered targets. These performance differences should be reflected in kinematic differences between conditions, but analyses are forthcoming. Preliminary EEG results show strong theta (4-7 Hz) activity in both target absent and target present conditions during the initial 3 s of the delay period, with distinct theta ICA components spatially localized to the frontomedial cortex.

Title: 2D:4D, mental rotations, SQ and EQ in a typical population

Authors: *P. T. ORR, C. E. LOWE, B. E. ZIMMERMAN, M. R. BUSCH
Psychology Dept., Univ. of Scranton, Scranton, PA

Abstract: Autism Spectrum Disorders (ASD's) are characterized by 3 major symptom domains: social withdrawal, impaired language development, and repetitive behaviors or restricted interests. One etiologic explanation suggests that this developmental pattern could result from atypical patterns of steroid hormone exposure. The Extreme Male Brain theory of Autism suggests that the pattern of behavior seen in children with ASD is similar to a stereotypically male pattern of behavior (low empathy and high systemizing) and that this may result from androgenic overexposure (Baron-Cohen, 2002). However, although the ratio of the length of the second digit of the hand to the fourth digit of the hand (2D:4D), a stable marker of the ratio of

androgens to estrogens to which a fetus is exposed in the uterine environment (Zheng & Cohen, 2011), is altered in individuals with an ASD, 2D:4D is not strongly associated with typical measures of the ASD behavioral phenotype, the Empathizing Quotient (EQ) and the Systemizing Quotient (SQ; Teatero & Netley, 2013; Honekopp, 2012) Mental rotation and other spatial working memory tasks typically show sex differences in performance (Voyer, Voyer & Bryden, 1995), and performance on these tasks are related to 2D:4D in both males and females (Peters, et al., 2007). Though not diagnostic, memory deficits have been identified in individuals with ASD's. Although verbal working memory appears to be intact, spatial working memory is disrupted (Williams, et al., 2005; Ozonoff & Strayer, 2001). As such, spatial working memory deficits may represent an independent behavioral dimension of ASD's, but there is little work investigating the relationship between spatial working memory, systemizing, and empathizing. 36 undergraduates (61.1% female), aged 18-24, were assessed using SQ, EQ, and a battery of cognitive tasks, including tests for word, shape, and face memory, and mental rotations. 2D:4D was also measured in these participants. Overall, there was no correlation between 2D:4D and EQ or SQ. There was a strong negative correlation between 2D:4D and mental rotations score in females for both left ($r(9) = -.736$, $p = .006$) and right ($r(9) = -.665$, $p = .025$) hands. There was also a strong correlation in females between right hand 2D:4D and errors in immediate recall of faces ($r(9) = .789$, $p = .004$) and shapes ($r(9) = .761$, $p = .007$), but not words. Mental rotations and recall were not significantly correlated with SQ or EQ. Overall, these results indicate that spatial memory is relatively independent of empathizing and systemizing and suggest that the ASD-related differences in 2D:4D should be examined in relation to spatial memory deficits, rather than SQ and EQ.

Title: Effects of estrogen receptor alpha gene on emotional processing in middle-age women

Authors: *M. SOLIS-ORTIZ, M. E. FAJARDO-ARAUJO, M. L. GUTIÉRREZ-MUÑOZ
Psico Fisiol, Inst. Invest Med, Univ. Guanajuato, Leon, Mexico

Abstract: There is evidence that recognition of emotional facial expressions change depending on the levels of estrogen in young women during the menstrual cycle. Estrogen receptor alpha gene (ESR1) polymorphisms have been associated with susceptibility to develop some cognitive deficits in middle-age women. The effect of these polymorphisms on emotional processing in women with low estrogen levels is not well known. The aim of this study was to examine the influence of the PvuII polymorphism of gene ESR1 on working memory for recognition of emotional facial expressions in healthy female. We genotyped 70 middle-age healthy women volunteers between 49 and 60 years old for the ESR1 polymorphisms, using DNA from peripheral blood leukocytes. We analyzed the effects of PP, Pp and pp genotypes on a working memory task for the recognition of emotional facial expressions, which included fear, sadness, anger, surprise and happiness. Number of correct responses, errors, omissions, reaction time and accuracy for each expression were computed. Women carriers of the pp genotype, with more estrogens receptor expression, did not show differences in task performance. In contrast, female carriers of the PP genotype, con lower estrogens receptor expression, showed more correct responses ($p=0.01$), fewer errors, reduced reaction time ($p=0.02$) and less omission. The accuracy in recognizing emotional expressions of sadness was significantly higher ($p=0.001$). These findings indicate that middle-aged women carriers of the PP genotype of ESR1gene influences on recognition of negative emotional expressions, probably due to the lower expression of receptors inducing emotional susceptibility.

Title: Cholinergic enhancement improves visual short-term memory performance

Authors: *S. M. YOUSEF[1,2], S. L. SHEREMATA[4], R. K. KANETA[3], A. N. HAREWOOD[2], M. A. SILVER[2,3]

[2]Vision Sci., [3]Sch. of Optometry, [1]Univ. of California, Berkeley, Berkeley, CA; [4]Psychology, George Washington Univ., Washington, DC

Abstract: Visual short-term memory (VSTM) refers to the retention of visual information from the immediate environment over brief intervals. In patients with mild cognitive impairment, pharmacologically increasing synaptic levels of acetylcholine (ACh) facilitates VSTM by boosting the rate of information processing (Bublak et al., 2011). We, therefore, hypothesized that cholinergic enhancement would improve VSTM performance in healthy subjects when stimulus duration limited memory performance. Synaptic ACh levels were elevated by administration of the cholinesterase inhibitor donepezil in a placebo-controlled, double blind crossover design. Subjects performed a color change detection task in which a set of colored squares was presented for either 100 or 200ms. Consolidation of the set was disrupted by subsequent presentation of a visual mask. In order to control task difficulty across subjects, we assessed the effects of donepezil for set sizes that were based on each subject's VSTM capacity (k), measured prior to the pharmacological manipulation. We found that for 100ms, but not 200ms, stimulus presentation, cholinergic enhancement improved VSTM performance. Consistent with the hypothesized role of ACh on information processing in VSTM, our results demonstrate that cholinergic enhancement improves VSTM performance when it is limited by stimulus presentation time.

Title: Temporal desynchronisation may underlie audio-spatial binding in working memory: An EEG study under anesthesia in humans

Authors: *T. MINAMOTO[1], T. IKEDA[2], K. ENDO[4], A. NAKAE[3], S. HAGIHIRA[3], Y. FUJINO[3], T. MASHIMO[5], M. OSAKA[1]
[1]Human Sci., [2]Engin., [3]Med., Osaka Univ., Suita, Japan; [4]Psychology, Kyoto Univ., Kyoto, Japan; [5]Toyonaka Municipal Hosp., Toyonaka, Japan

Abstract: Binding of stimulus features is thought to depend on neural synchronization across brain regions. Using the anesthesia-induced sedation, the present study examined its effect on audio-spatial binding. Given that the anesthesia disturbs neural synchronization, the feature binding should be impaired with the neural disturbance. Participants received either propofol or midazolam, and their performance of an audio-spatial working memory task was measured. In the task, two tones were given serially from either right or left speakers, and they remembered the tones and their location for two seconds delay. A probe tone was presented and they judged whether it was matched to one of the original tones from the original location. The task was given before anesthesia (baseline), and three different sedative phases (deep, moderate, and light). EEGs over the Cz and Fz were also measured during the task. Due to large amount of trial omissions under the deep anesthesia, the phase was removed from the analysis. As for the behavioral performance, participants showed impaired performance in the binding under the moderate phase in comparison to the baseline and the light phases. ERPs over the Cz and Fz did not differ among conditions, where positive component was obtained 400ms after the stimulus onset. However, oscillation between the two regions differed in the moderate phase in comparison to the baseline and light phases. Specifically, as opposed to our prediction, the oscillation in the beta-band remained strong across time in the moderate phase, while tentative decrease was observed in the other conditions 400-500ms after stimulus onset. The tentative decrement of the oscillation across regions may reflect functional dissociation of distinctive neural populations, and such a neural characteristic may play a critical role in feature binding.

Title: Differential encoding of behavioral tasks by stereotaxically recorded CA1 and CA3 neurons in human hippocampus

Authors: M. R. WITCHER[1], D. E. COUTURE[1], A. M. LAXTON[1], G. POPLI[2], M. J. SOLLMAN[3], C. A. SEXTON[4], S. A. DEADWYLER[4], *R. E. HAMPSON[5]

Abstract: Recent animal research has illustrated multineuronal ensemble firing patterns of CA1 based on the recorded discharge patterns of CA3 (Berger et al., 2011; Hampson et al., 2013), have specific discharge timing contributing to task-specific performance. Here we extend this work to study human memory formation and retrieval in patients suffering from pharmacologically refractory epilepsy who undergo intracranial monitoring with implanted electrodes for seizure localization.. Studies have shown this population to provide an excellent model to understand discharge patterns of single neuronal units within the mesial temporal lobe during learning and memory tasks (Suthana and Fried 2012), since patients do retain the ability to form new memories even when hippocampally-mediated memory formation is altered by epilepsy, (Suthana, Haneef et al. 2012). These recordings thus provide valuable insight into the mechanisms underlying human memory encoding and formation. Adult subjects underwent surgical implantation of FDA-approved hippocampal electrodes with recording site capable of field potential (macro-) and single-unit recording (micro-) recording (Ad-Tech Medical Instrumentation Corporation, Racine, WI) for localization of seizures. Inclusion in this study was voluntary and consented separately from the surgical procedure and all study participants underwent appropriate clinical epilepsy screening evaluations. A frameless Brainlab Cranial Navigation System (BrainLab North America, Westchester, IL) was used to plan and guide electrode entry points, stereotaxic electrode trajectories and targets within the CA3 and CA1 subfields of each hippocampus. Electrode localization was confirmed using postoperative MRI. Single unit neural activity was isolated and recorded using Plexon MAP or Blackrock Cervello electrophysiological recording systems. Neurocognitive experiments consisted of visual object-oriented Delayed-Match-to-Sample and spatial-oriented Paired Associate Learning tasks. Results yielded similar task-related firing correlates for CA1 and CA3 on both DMS and PAL tasks, but differential firing between anterior/posterior hippocampal locations as well as differences in event-related encoded in the object vs spatial tasks. Hippocampal neurons exhibited the same differential encoding and correlation to successful vs. failed behavioral outcome as shown in prior rodent and nonhuman primate studies, suggesting the utility of this model for eventual testing of a neural prosthetic for human memory.

Title: Conscious control over the BOLD effect in the DLPFC is linked with task performance

Authors: *M. S. SHERWOOD[1,2], J. H. KANE[1], M. P. WEISEND[1], J. G. PARKER[1,2]
[1]Wright State Res. Inst., Dayton, OH; [2]Dept. of Biomedical, Industrial and Human Factors Engin., Wright State Univ., Dayton, OH

Abstract: Neurofeedback training (NFT) using real-time functional magnetic resonance imaging (rt-fMRI) can be used to train localized, conscious regulation of neuronal activity in humans. As a therapeutic technique, rt-fMRI NFT has been shown to successfully reduce the symptoms of a variety of neurologic disorders. To date, few studies have examined the use of rt-fMRI NFT to enhance cognitive performance. This work investigates the utility of rt-fMRI NFT as a tool to enhance human cognition by training healthy individuals to consciously control activity in the left dorsolateral prefrontal cortex (DLPFC). A cohort of 18 healthy participants underwent rt-fMRI NFT of the left DLPFC in five training sessions completed across two weeks. Working memory (WM) performance was evaluated before and after the two-week training regimen using two computerized tests, one of which was a dual-task. Standard statistical tests were used to investigate brain control performance of the group across training sessions, the group change in WM after the 2-week training regimen, and the relationship between individual brain control and performance on the WM tasks. The group demonstrated a significant increase in the ability to self-regulate the left DLPFC across sessions and a significant improvement in task performance after the 2-week training regimen. Additionally, individual brain control was found to correlate positively with performance on two of the three tasks performed. These results provide the evidence that humans can increase conscious control of the left DLPFC using NFT from rt-fMRI. Furthermore, these results indicate that an increased ability to self-regulate the left DLPFC is associated with superior WM performance. This study provides the foundation for future controlled studies to further investigate the effect of NFT from rt-fMRI on cognition.

Title: Investigating the effects of 4-weeks multivitamin/mineral supplementation on functional brain activity during working memory

Authors: *D. J. WHITE[1], M. HUGHES[2], A. PIPINGAS[1], A. B. SCHOLEY[1]
[1]Ctr. for Human Psychopharmacology, [2]Brain and Psychological Sci. Res. Ctr., Swinburne Univ., Hawthorn, Australia

Abstract: There is growing evidence supporting positive effects of multivitamin/mineral (MV) supplementation on both mood and cognitive function. A double-blind, placebo-controlled study

examined, the impact of 4-weeks MV supplementation on functional brain activity using Steady State Topography (SST) and functional magnetic resonance imaging (fMRI) during completion of working memory tasks. A total of 40 healthy young adults (mean age 26.6 ± 5.27 years) consumed a daily dose of MV or placebo for 4-weeks using a balanced, parallel groups design. Assessment of neurocognitive function took place at pre-treatment baseline and after 28-days of supplementation. Brain electrical activity was assessed using SST during spatial working memory task completion, which explores changes in the Steady State Visually Evoked Potential (SSVEP) using a task-irrelevant visual flicker during periods of cognitive engagement. A subset of participants also underwent fMRI while completing a Rapid Visual Information Processing (RVIP) task. Changes in SSVEP response during the spatial working memory task showed significant latency reductions in centro-parietal regions after MV treatment, while no differences were observed in the placebo group. Analysis of fMRI activation during RVIP task performance showed significant treatment effects across task-related parietal lobe regions, whereby greater activation was seen following 4-week MV supplementation with respect to placebo. These findings suggest functional brain activity can be influenced by chronic MV supplementation, with patterns of activation following MV administration consistent with benefits to working memory systems.

Title: Cholinergic activity in human medial temporal lobe during active maintenance of configural information

Authors: *K. SHATTUCK[1], J. W. VANMETER[2]
[2]Ctr. for Functional and Mol. Imaging, [1]Georgetown Univ., Washington, DC

Abstract: Though short-term memory has traditionally been associated with neural processing in fronto-parietal networks, recent work emphasizes the importance of medial temporal lobe structures (MTL) for short-term memory of configural information. Increases in MTL neuronal activity during the active maintenance (AM) period between stimulus exposure and recognition test correlate with subsequent memory performance, indicating a role for MTL in transitioning current activity to long-term encoding. Importantly, cholinergic neurotransmission mediates AM processes as shown by systemic drug administration to human subjects: both MTL activity during AM and subsequent recall are increased by cholinesterase inhibitors and decreased by muscarinic acetylcholine receptor antagonists. Our current work addresses whether cholinergic activity during AM occurs locally in MTL. Human subjects complete a configural visual object recognition task that can be solved only by remembering feature arrangements rather than individual features themselves. BOLD-fMRI results confirm that neuronal activity increases in right MTL during AM between stimulus exposure and recognition test. Preliminary functional 1H-MR spectroscopy results show rises in signal peaks from unbound choline-containing metabolites in a 2x2x3cm voxel including right parahippocampal gyrus and hippocampus, suggesting short-timescale (60 second) increases in MTL cholinergic metabolism during AM of task information. No changes during task blocks are observed for other major MR spectroscopy peaks, in particular those associated with N-acetylaspartate or creatine.

Title: Direct recordings of sustained theta-band electrical activity in the human auditory cortex during working memory for tones

Authors: *P. E. GANDER[1], S. KUMAR[2,3], K. V. NOURSKI[1], H. OYA[1], H. KAWASAKI[1], M. A. HOWARD, III[1], T. D. GRIFFITHS[1,2,3]
[1]Dept. of Neurosurg., Univ. of Iowa Hosp. and Clinics, Iowa City, IA; [2]Inst. of Neurosci., Newcastle Univ., Newcastle upon Tyne, United Kingdom; [3]Wellcome Trust Ctr. for Neuroimaging, Univ. Col. London, London, United Kingdom

Abstract: Working memory is the capacity to hold and manipulate behaviourally relevant information in mind in the absence of ongoing sensory input. Here we tested the hypothesis that auditory working memory for tones requires ongoing activity in auditory cortex, and examined the form of such activity in neuronal ensembles. We recorded local field potentials from two human subjects undergoing invasive monitoring for pre-surgical localization of epileptic foci. The subjects were implanted with depth electrodes along the axis of Heschl's gyrus (HG) containing primary cortex in the medial part, and subdural grids over temporal and frontal cortex. Following a visual alert subjects were presented with a pair of tones (0.5 s duration, 1 s ISI) belonging to two different categories ('Low': 300-570 Hz; 'High': 2000 -2800 Hz). A visual cue (1.5 s) then informed the subjects which tone (first or second) to keep in mind. A 3 s retention period was followed by a tone which could be the same or different (frequency difference ±20%) from the tone held in mind. The subjects made a same/different decision by pressing a button. A total of 96 trials (48 each of 'Low' and 'High' tone retention) were presented. We measured average ERPs and carried out single-trial time-frequency analysis using a wavelet transform. Both the magnitude of ERPs (~100 ms after stimulus onset) and gamma-band (60-120 Hz) power in electrodes located in HG and lateral superior temporal gyrus (STG) showed category-specific responses during the perception of tones. High tones elicited stronger responses in medial HG and low tones in lateral HG. During the retention period, a sustained theta-band (2-6 Hz) activity was observed in all contacts that showed gamma-band responses during perception. Power in this band also showed a recency effect: a greater response in HG electrodes was observed for retention of the most recently presented (second) tone. On the STG, however, the opposite effect was observed: a greater 2-6 Hz power for retention of the first compared to the second tone. The data demonstrate: 1) theta-band correlates of tone retention in auditory cortex in the same neural ensembles that are active in the gamma band during perception 2) neural bases in the auditory cortex for interference effects within tonal working memory.

Title: Are default mode and task network activity anti-correlated?

Authors: *J. M. JANSMA[1], T. R. VAN RAALTEN[2], J. H. CALLICOTT[3], N. F. RAMSEY[1]
[1]Dept. of Neurol. and Neurosurg., UMC Utrecht, Rudolf Magnus Inst. of Neurosci., Utrecht, Netherlands; [2]Dept. of Neurol. and Neurosurg., UMC Utrecht, Brain Ctr. Rudolf Magnus, Utrecht, Netherlands; [3]Unit on Cognition and Psychosis Program, NIH, NIMH, Bethesda, MD

Abstract: Background. The default mode network (DMN) is defined as a set of brain regions that decrease their activity during goal oriented behavior. It has been hypothesized that the level of decrease in DMN is anti-correlated with the level of increase in the network of task specific regions that increase their activity during goal oriented behavior. However, there is yet little actual evidence to support this hypothesis. In this study we tested this hypothesis by measuring the change in activity in DMN and task specific activated regions before and after practice of a working memory task. As a control measurement, we measured and correlated the within network change in activity between regions in left and right hemisphere. Method. 46 healthy volunteers participated in the fMRI experiment, and performed a Sternberg task with novel and a shortly practiced target-set. Scan parameters: 3T GE Scanner; TE/TR = 30/2000, FA = 90, FOV = 24, voxel size = 3.75 x 3.75 x 5, matrix = 64 x 64 x 24, 192 reps. Scan preprocessing included movement correction, normalization into MNI space, spatially smoothing (FWHM: 8mm), voxel-wise high-pass filtering (0.0005 Hz), voxel-wise signal normalization. Individual subject analysis was performed according to a blocked design, with regressors for the novel and practiced condition. We identified regions of interest (ROIS) by clustering voxels that showed a significant effect of practice ($|t| > 5.1$) and divided these regions in two groups: regions that were activated in the novel condition (task network ('TN')) and regions that were deactivated in the novel condition (DMN). We calculated the correlation between the average activity change in DMN and TN, as well as in left and right ROIs is within DMN and within TN. Results. The within network correlation between left and right hemisphere appeared to be significant and very high for both the TN ($r = 0.78$; $p < 0.001$) and DMN ($r = 0.65$; $p < 0.001$). The correlation between the change in activity in TN and DMN appeared not to be not significant ($p = -0.24$; $p = 0.11$) Discussion. Our results indicate that on a network level, the change in activity in TN is not correlated with the change in activity in DMN, while our study was powerful enough to detect network correlations, as demonstrated by the observed strong correlation between left and right hemisphere in both TN and DMN. This result suggest that there is no strong functional connectivity between the DMN and TN. This result however does not imply that there are no subnetworks or single regions within the DMN and TN that do show anticorrelated activity.

Title: Attentional filtering and working memory storage in mild cognitive impairment and Parkinson's disease

Authors: ***N. G. MUELLER**, J. BLATT, A. VELLAGE
DZNE & Otto von Guericke Univ. Clin., Magdeburg, Germany

Abstract: Working memory (WM) involves the two subprocesses attentional selection (i.e. filtering out of irrelevant information) and information storage. These two processes have been proposed to be sustained by different neurotransmitters, namely acetylcholine for attentional selection and dopamine for memory storage. This hypothesis is challenged by the assumption that a dopaminergic deficit leads to filtering rather than storage deficits. We tested the these hypotheses in two patient cohorts which either served as models for a cholinergic or a dopaminergic deficit. The first group comprised 18 patients with amnestic mild cognitive impairment (aMCI), the second 22 patients with Parkinson's disease (PD). The two groups did not differ regarding their overall cognitive abilities. Both patient groups as well as a control group without neurological deficits (n=25) performed a visuo-spatial working memory task in which both the necessity to filter out irrelevant information and memory load, i.e. the number of items to be held in memory, were manipulated. In accordance with the primary hypothesis, aMCI patients displayed problems with filtering, i.e. were especially impaired when the task required ignoring distracting stimuli. PD patients on the other hand showed difficulties when memory load was increased suggesting that they mainly suffered from a storage deficit.

Title: rTMS/EEG of MT+ during STM for transparent motion

Authors: *A. D. SHELDON[1], J. SAMAHA[1], N. S. ROSE[2], A. C. RIGGALL[1], X. HUANG[3], B. R. POSTLE[1,2]
[1]Psychology, [2]Psychiatry, [3]Neurosci., Univ. of Wisconsin-Madison, Madison, WI

Abstract: Although the role for area MT/V5 in the perceptual processing of visual motion is well established, its role in the short-term retention of motion information, during tests of short-term memory (STM) and working memory, remains uncertain. Here, we applied repetitive transcranial magnetic stimulation (rTMS) to MT+ while simultaneously recording the electroencephalogram (EEG) in healthy human subjects performing STM for visual motion. Subjects fixated centrally while the sample stimuli ─ random-dots moving in two directions, giving rise to the percept of two superimposed transparent surfaces moving in different directions - were presented for 1000 msec in an aperture to the left of fixation. One sec after sample offset, a cue indicated which of the two remembered directions was to be recalled by aligning a radial vector with the cued direction. Precision of recall was estimated from the error between subjects' response and the cued direction. In a fully crossed within-subject design, a 10 Hz, 1 sec-long, train of rTMS was delivered (or not) concurrent with either sample presentation or the delay period, and with the stimulating coil positioned over right MT+ or right post-central gyrus (somatosensory cortex as the control). rTMS delivered during sample presentation had no effect on mnemonic precision. In contrast, delay-period rTMS produced large individual differences. In some, delay-period rTMS of MT+ produced a drop in recall precision, and in others it produced an improvement. (This pattern is consistent with previous findings using other types of stimuli and targeting other areas.) Inspection of the delay period EEG data for the electrode nearest MT+ (P8) revealed that each TMS pulse within the 10 Hz train evoked roughly 3 cycles in the ERP waveform. Consistent with this observation, the time-frequency spectrogram showed that 10 Hz rTMS produced elevated power at 30 Hz and higher harmonic frequencies.

However, the behavioral effects of rTMS on MT+ did not relate to these higher frequencies. Rather, they corresponded to rTMS-related changes in delay-period spectral power in the 10-15 Hz band. Further, the direction of these changes were predicted by individual differences in this frequency band that were observed during rTMS-absent trials, and that have been shown previously to reflect trait-like differences in the spectral pattern of delay-period activity (Kundu et al., 2014).

Title: Rinzai Zen meditators are superior to resolve semantic interference: An fMRI study based on a Stroop paradigm

Authors: *N. OSAKA[1], T. MINAMOTO[1], K. YAOI[1], M. AZUMA[2], M. OSAKA[2]
[1]Psychology, Kyoto Univ., Kyoto, Japan; [2]Human Sci., Osaka Univ., Suita, Japan

Abstract: Rinzai Zen is one of the traditional Japanese meditations, and the professional Zen monks are thought to accept the environmental world as it is, shedding their own bias that is often mediated by language. A color Stroop task is a suitable experimental paradigm to investigate such characteristic of the Zen monks, as the task requires to focus on the sensory information while ignoring higher order meaning. Given that the Zen monks are superior to avoid higher order semantic processing, the Stroop effect should disappear and neural regions related to the effect should be less activated. Nineteen Zen monks (M = 39.26, SD = 5.91) and eighteen age- and education-matched healthy male volunteers (M = 38.83, SD = 6.35) were participated in the present study. All the monks finished Zen training, which had lasted for at least four years, and mean training year was 7.53 (SD = 2.50). Participants in the matched group had not experienced meditation training. A standard color Stroop task was given in the MRI scanner, and brain regions related to the Stroop interference were measured. The Stroop task consisted of three types of block: congruent, incongruent, and neutral block. The behavioral

results of reaction time and accuracy showed a significant Stroop effect in the control group, while such interference was not observed in the meditators. As for the fMRI results, significant interactions were found in the anterior cingulate cortex, the dorsolateral prefrontal cortex, and the posterior parietal cortex, which are known to be involved in conflict resolution. Specifically, control subjects showed greater activation of the regions in the incongruent condition than the congruent condition, while meditators showed equivalent activation across conditions. Those results provide empirical evidence that Rinzai Zen monks, using cognitive control, focus on sensory processing with avoiding higher semantic processing.

Title: Changes in global brain connectivity predict behavioural performance across task difficulty

Authors: ***D. VATANSEVER**, D. K. MENON, A. MANKTELOW, E. A. STAMATAKIS
Div. of Anaesthetics, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Introduction: Resting state functional connectivity analysis has revealed a number of large-scale brain networks (LSNs) including default mode, fronto-parietal control, dorsal attention, somatomotor, vision, and audition. Despite the visual similarity of these LSNs to those obtained from task-based cognitive paradigms, their behavioural significance remains to be

elucidated. The aim of this study was to investigate the changes in whole-brain functional connectivity in a working memory paradigm and to relate these alterations to LSN connectivity and performance outcomes. **Methods:** A group of 22 healthy adults (19-57 years old, mean = 35.0, SD = 11.2) were scanned (Siemens Trio 3T MRI scanner) during a block designed N-Back (1,2,3-Back) paradigm. Behavioural analysis indicated a decrease in correct responses with increasing task difficulty. Subject-level, condition-specific intrinsic connectivity contrast (ICC) maps were calculated to measure global brain connectivity. Second level imaging analyses involved a one-way ANOVA to assess group level changes in ICC across the 1,2 and 3-Back blocks. The clusters with the highest ICC change were subsequently used as regions of interest (ROI) for seed-based functional connectivity analyses. Functional connectivity maps from these two ROIs were related to reaction times for correct responses. The reported clusters were corrected for multiple comparisons at the FWE 0.05 level of significance. **Results:** The greatest changes in ICC-based global connectivity across increasing task difficulty were centred on the left and right angular gyri. Seed-based functional connectivity from these two regions revealed connections to the default mode, fronto-parietal control, dorsal attention and visual networks. Increased connectivity between the left angular gyrus and posterior cingulate cortex (default mode network) predicted faster reaction times to correct responses. Increased connectivity between the right angular gyrus and the left calcarine sulcus (visual network) also predicted improved reaction times. **Conclusions:** Changes in ICC with increasing task difficulty reflected task-induced alterations in global brain connectivity. The bilateral angular gyri demonstrated the most significant ICC changes, suggesting a key role for these regions in facilitating communication between LSNs. Furthermore, functional connectivity between these two regions and both the default mode and visual networks predicted behavioural outcome, which indicates some relevance in task performance. Overall, the results suggest that LSN connectivity may contribute to working memory task execution.

Title: Ghost in the machine: Neural mechanisms of spatial working memory

Authors: *C. PAPADIMITRIOU[1], R. L. WHITE[2], L. H. SNYDER[1]
[1]Washington Univ. In St. Louis, Saint Louis, MO; [2]Univ. of California, Berkeley, Berkeley, CA

Abstract: In a previous study we found that spatial memory can be biased toward the memoranda of the previous trial. (Ferdoash, Papadimitriou, & Snyder, SFN 2011 Poster). In the current study we look for neural correlates of this behavior in frontal memory circuits. We find clear effects of the previous memoranda on neuronal activity, but these effects are not congruent with the behavior we observe in the animal. We recorded from frontal eye fields (FEF) while three macaques performed memory guided saccades. We found markedly different neural effects in trials when the previous trial and current trial targets were far apart, compared to trials when the previous and current targets were close to one another. When the previous and current targets were far apart, the neurons activated in the previous trial remained slightly active during the current trial. A vector sum readout of activity in these trials predicts an attractive bias towards the previous trial's target location. We observed an opposite effect in trials for which the previous and current targets were close to one another. On these trials, the neurons activated in the previous trial showed reduced activation in the current trial. A vector sum readout on these trials predicts that behavioral responses will be repulsed away from the previous trial's target location. Thus the previous target location had opposite effects on the frontal memory neurons depending on whether the current target activated the same or different neurons. We conclude that frontal memory circuits show two separate carryover effects from the target location on the previous trial, depending on the relative locations of the two targets. These results suggest that either other memory circuits are involved in producing the observed behavior, or that a different, more nuanced readout of these circuits is used by the brain to produce behavior.

Title: Adaptation to action-related changes in a volatile environment

Authors: *H. THÉRO, V. CHAMBON, E. KOECHLIN
ENS LNC, Paris, France

Abstract: Sense of agency refers to the feeling of controlling one's own actions and, through these actions, events in the outside world. A subjective experience of control implies the ability to discriminate the external events that are caused by our own actions from the events that are not. Ultimately, this processing of action-related changes is crucial to adapt to a volatile environment, structured with multiple informational levels. We hypothesized that such ability would depend on the active monitoring of three different types of statistics: 1) the mutual dependency between the action performed and the perceived event (i.e., action-outcome contingencies), 2) the rewarding value of the perceived event, and 3) its variability over time. In a modified reversal-learning task, human subjects played two slot machines simultaneously, and had to find out which machine was influenced by their choices. Critically, unpredictable reversals could occur so that subject's influence over one machine abruptly transferred to the other one. We found that subjects dynamically adjusted their response to these reversals, and quickly retrieved control over the relevant machine through active monitoring of 1) action-outcome contingencies, 2) the rewarding value of the machine's outcome, or 3) variability of this outcome across trials. These results showed that human subjects were influenced by these three classes of information to construct action outcomes from perceptual events. In order to further assess the respective contribution of these three factors to the feeling of control, we tested two contrasted families of models. Reinforcement-learning models make choices and guide behavior based on reward prediction errors, while Bayesian models dynamically compute optimal actions through performing inferences about states of the world, irrespective of the rewarding value associated with each alternative. The fitting of these two types of models suggests that the subjects' behavior was best explained by a reward-based heuristics of Bayesian inference. An fMRI experiment will be conducted to better understand the neural correlates of this sense of agency.

Title: The role of working memory in the Iowa Gambling Task

Authors: A. PIERCE, M. SAULS, R. TANK, *W. H. OVERMAN, Jr.
Psychology, Univ. North Carolina Wilmington, WILMINGTON, NC

Abstract: The Iowa Gambling Task (IGT) was designed to study decision-making deficits in patients with ventromedial prefrontal cortex (vmPFC) damage (Bechara et al., 1994). Based on their impaired IGT performance, the Somatic Marker Hypothesis (SMH) was developed (Bechara et al., 1997; Damasio, 1996). The SMH emphasized the contribution of emotion (as opposed to cognition) to decision-making. Subsequent studies found that IGT performance was also impaired after damage to the dorsolateral prefrontal cortex (dlPFC) (Fellows & Farrah, 2005). This raises the possibility that non-emotional, i.e., cognitive processes, contribute to decision-making in the IGT. One cognitive process that is implicated in dlPFC function is working memory (WM). Presently, there is a debate regarding the relative contribution of WM and emotion to IGT performance (Dunn et al., 2006). The present study investigated the role of WM on IGT performance in two experiments. Experiment 1 investigated the effects of increasing WM load during the IGT by having participants intermittently read and remember either a social or analytical scenario. Respectively, these scenarios putatively engage the Default Mode Network (DMN which involves vmPFC) and the Task Positive Network (TPN which involves dlPFC) (Jack et al., 2013). Results revealed that males' IGT performance did not differ with either scenario condition. However, females' IGT performance, as well as their conscious knowledge of the IGT rule increased with either scenario relative to a traditional IGT (no scenarios). Experiment 2 measured participants' working memory capacity (independent of the IGT) to determine if this was correlated with IGT performance or conscious knowledge of the rule of the IGT. Subjects performed the IGT and then their WM capacity was assessed using the Automated Operation Span (AOSPAN; Unsworth et al., 2005). Results showed that there was no significant correlation between WM span and IGT performance; however, there was a significant, positive correlation between WM span and the frequency of correctly stating which two decks were the good decks (i.e., conscious knowledge of the rule). In conclusion, this study found: (1) paradoxically, in females IGT performance and knowledge of the IGT rule improved when WM was loaded with social or analytical scenarios suggesting that the type task used to load working memory can differentially affect IGT performance. (2) WM capacity was correlated with stating the correct rule on the IGT, but not on performance on the IGT, indicating that participants may be aware of the correct decision, but that they do not always perform accordingly.

Title: EEG correlates of activity within salience, central executive and default-mode networks after errors

Authors: *A. NAVARRO-CEBRIAN[1], A. S. KAYSER[1], T. A. VEGA[2]
[1]UCSF, San Francisco, CA; [2]Univ. of California, Berkeley, Berkeley, CA

Abstract: fMRI research has revealed that activity in the 'salience network' (SN), involving medial prefrontal (MPFC) and anterior insular cortices, is thought to reflect a monitoring process engaged after salient events such as errors. This network has also been suggested to control switching between the default-mode network (DMN, more active during internally oriented mental activity), which includes posterior cingulate (PCC) and ventral medial prefrontal cortices (VMPFC), and the central executive network (CEN, more active during externally oriented activity), which includes dorsolateral prefrontal (DLPFC) and parietal cortices. Due to fMRI's limited time resolution and indirect measurement of brain activity, however, the interactions between these regions during task performance have yet to be investigated on a rapid timescale. We used EEG to analyze connectivity using seeds in three electrode sites that have previously been used to study error monitoring (FCz, MPFC), internally directed attention (Pz, PCC) and goal-directed mental activity (F5-F6, DLPFC). We sought to analyze whether time-frequency signals in these electrodes can be seen as an EEG index of the SN, DMN and CEN. We hypothesized that FCz, Pz and F5-F6 would show a stronger phase coherence with other areas attributed to the SN, DMN and CEN respectively, and that areas of the SN would correlate positively with the CEN and negatively with the DMN. In agreement with these hypotheses, our results indicated that phase coherence between the MPFC seed and all the other electrodes across the whole brain showed prominent connectivity with task-specific areas in the occipital region after errors. On the other hand, the PCC seed was significantly more connected with anterior prefrontal areas (VMPFC) while the DLPFC was more connected with parietal areas. Moreover, the time courses of these three electrodes revealed a positive correlation between the MPFC and the DLPFC ($p < 0.005$) and a negative correlation between these two and the PCC area ($p < 0.005$). These results agree with previous fMRI data that show a negative correlation of the DMN and a positive correlation of the CEN with the SN, respectively. Lastly, when compared to correct responses, our data show a stronger connectivity between the areas after errors,

supporting the idea that the SN may signal the need for enhanced cognitive control (CEN) and inhibition of non task-related activity (DMN) during situations of increased conflict. Ongoing work will further analyze the direction of the interactions between these areas and the correlations between this EEG connectivity and fMRI-derived networks.

Title: Dynamics of human anterior cingulate cortex responses during cognitive control

Authors: H. TANG[1], H.-Y. YU[2], C.-C. CHOU[2], J. MADSEN[3], W. S. ANDERSON[4], *G. KREIMAN[5]

Abstract: How the Anterior Cingulate Cortex (ACC) and Prefrontal Cortex (PFC) interact to orchestrate cognitive control is not known. Existing theories based on neuroimaging and single unit recordings in human dorsal ACC posit that the ACC is the source of conflict monitoring, which then triggers control processes in the PFC. Here we test this theory by recording intracranial field potentials from 1,728 electrodes implanted in 18 epilepsy patients for clinical purposes while patients performed a Stroop task. In both ACC and PFC, we find that power in the gamma band (70-100 Hz) is increased when incongruent stimuli are presented compared to congruent stimulus trials. This conflict-modulating activity arises with latencies of ~500ms after trial onset. By virtue of the high spatiotemporal resolution of the intracranial recordings, we present a characterization of the relative latencies between ACC and PFC during the Stroop task. We further describe the interactions between these two areas during cognitive control.

Title: Cortical activity reflecting a tactical thinking to follow a rule: An fNIRS study

Authors: ***N. MIURA**[1], N. SHIRASAWA[1], S. KANOH[2]
[1]Tohoku Inst. of Technol., Sendai, Japan; [2]Shibaura Inst. of Technol., Koto-ku, Japan

Abstract: Introduction A rule prescribes human's behavior in social relationships, and it is important to follow a rule when avoiding a risk of existing in society. In order to follow the rule, a tactical thinking is required to consider the appropriate behavior within the limitation of the rule, and that appropriate behavior may be different from optimal behavior in case the rule does not exist. And, it is expected that the tactical thinking is affected by the cognitive processing to determine the appropriate behavior independently from the difficulty of behavior. In this study, we investigated a cortical activity when performing an experimental task that is operated both existence of a rule which has a risk to violation and level of task difficulty is measured by using functional near-infrared spectroscopy (fNIRS). Methods Twenty healthy Japanese volunteers participated in this study. All participants provided written informed consent to an experimental protocol approved by the Ethical Committee of Tohoku Institute of Technology. The participants performed four conditions of experimental task like a video game to catch the balls falling down from the upper part of a screen. They were instructed to catch the ball by the object which is controlled by a computer mouse, and to acquire the high score. Four conditions were prepared by changing the task difficulty and existence of rule. The task difficulty was defined by the width of the playable space where the ball falls. And, on the conditions with the rule, a score of experimental task will be reduced greatly when the ball of a specific color cannot be caught. The fNIRS data were measured from a forehead region covering the frontal to temporal area. Two regions of interest (ROI) located on the bilateral prefrontal area were determined for this analysis. A three-way repeated-measures factorial ANOVA was performed using a condition-related signal change on each ROI. Each factor was determined by the difference of task

difficulty, existence of rule, and location of the ROI. Result and discussion The result showed that significant interaction effect between the factors of the existence of rule and the location of the ROI, that is, the left lateral prefrontal area showed significant signal increase when the rule existed in the task. When the rule exists, the subject has to catch the ball with the specific color to avoid a decline in his/her score. Then, it is necessary to take the tactics for catching more preferentially than the balls with different color in order to get higher score. Thus, increase of the left prefrontal activation reflects the cognitive processing underpinning that tactical thinking in consideration of the rule.

Title: Transcranial magnetic stimulation in human inferior frontal cortex alters voluntary action decisions

Authors: ***S. ANGSTMANN**[1], J. ZHANG[2], B. HALLSSON[1], K. H. MADSEN[1], J. B. ROWE[2], H. R. SIEBNER[1]
[1]714, Copenhagen Univ. Hosp. Hvidovre, DRCMR, Hvidovre, Denmark; [2]MRC Cognition and Brain Sci. Unit, Cambridge, United Kingdom

Abstract: Voluntary actions involve a special form of decision-making process that select between action alternatives. Our previous study proposed that during voluntary action decisions, the intentions of selecting different actions are accumulated over time and competed against each other until a response threshold is reached, and the right inferior frontal gyrus (rIFG) plays a crucial role in mediating people's tendency to inhibit the repetition of a previous action. Here, we set out to test whether voluntary actions showed altered characteristics when transiently perturbing rIFG by combining transcranial magnetic stimulation (TMS) and functional MRI. 15 healthy subjects performed a finger-tapping task in two fMRI sessions (active and inactive sham

TMS stimulation session, 80% and 30% resting motor threshold) on separate days. In each session, the subjects were instructed to voluntarily choose any one of three permitted buttons (480 trials) or to press with a specified button (240 trials). Before each session, the rIFG was localized on the basis of our previous published coordinates (x = 56, y = 14, z = -2) and stimulated using continuous theta-burst TMS (cTBS, 600 pulses). We found longer response times for choice than for specified trials. An interaction effect between trial type (choice vs. specified) and repetition characteristics indicated that response in the previous trial had different influences on the current trial. Active TMS shortened the response times both in the choice and in the specified condition, but irrespectively of response history ($p < .05$). This effect was observable in the first 30 to 35 minutes after stimulation which is consistent with previous reports of the duration of cTBS effects. The shortened response time after TMS suggests an unspecific pre-charging of all valid/specified neural accumulators via a rIFG pathway. This explains why the relative response pattern remains unchanged but results in a global response time decrease.

Title: Identification of context enables use of model-based learning strategies in value-based decision making

Authors: *M. BALCARRAS[1], O. ABID[1], T. WOMELSDORF[2]
[2]Ctr. for Vision Research, Dept. of Biol., [1]York Univ., Toronto, ON, Canada

Abstract: Decision-making strategies, such as using an internal model versus habitual model-free responses, provide advantages when used correctly, but deployment of an appropriate decision-making strategy requires correctly identifying the current context. Models of value-based decision-making often assume that the subject identifies the task context correctly (Wilson and Niv, 2011, Daw et al., 2005), however it is not clear that even well-informed subjects understand the experimental framework as assumed by the investigator (Shteingart and Loewenstein, 2014). We designed a task to test how behavioural adaptation to changing task conditions reflects latent identification of a decision-making context and utilization of a decision-making strategy. In our task subjects are required to learn stimulus values through trial and error, with discrete trials grouped into blocks by stimulus sets. In half the blocks, different reward probability is associated with a particular stimulus feature (i.e. just shape or colour), whereas in the other half of blocks, reward probability is associated with combinations of features that form an object. Importantly, blocks are organized into repeating pairs such that an object block precedes a feature block followed by a second pair using a new stimulus feature set but with the same relevant feature type as in the first feature block. Subjects can either use feedback to learn stimulus values and receive rewarding outcomes, a model-free strategy, or subjects can improve performance by learning the structure of block pairs, a model-based strategy. We analyzed subject choices across blocks and sessions to determine markers of model-free and model-based strategies. We observed that subjects (n=12, 2 sessions) reached a performance criterion of 80% average correct choices in 87.5% of all blocks (70% of subjects reached criterion in all blocks) indicating that they were able to use locally learned values to guide future choices. Subjects (86%) also took longer to reach criterion in feature blocks, reflecting the greater complexity of feature blocks. Importantly though, we observed 68% of subjects increased their learning rate and overall performance in the second feature block compared to the first session, and all of these subjects outperformed those subjects that don't show this increase. These results indicate that context identification and structure learning enable use of model-based strategies that improve performance in complex task environments. Developing markers of decision-making strategies is key for proper model development and improves the impact of fitting model components with neural activity.

Title: Cognitive mechanisms underlying instructed choice exploration of small city maps

Authors: *S. SAKELLARIDI[1], P. CHRISTOVA[2], J. PEPONIS[3], A. P. GEORGOPOULOS[1,2]
[1]Ctr. for Cognitive Sci., [2]Neurosci., Univ. of Minnesota, Minneapolis, MN; [3]Sch. of Architecture, Georgia Inst. of Technol., Atlanta, GA

Abstract: The ability to explore novel environments and make spatial decisions, such as selecting a place to live or choosing a landmark to visit, is a fundamental and highly evolved behavior that requires the coordination of cognitive functions. But how people explore novel environments to make spatial decisions is still poorly understood. To address this question, we conducted a psychophysical experiment in which subjects explored a set of real maps of various U.S. metropolitan cities, exemplifying different street network layouts, in order to place a hypothetical post office at one of two possible locations. Results suggest that people developed highly stereotyped strategies for evaluating and comparing the two potential options. Particularly, monitoring subjects' eye positions revealed restricted map exploration determined by the position of the two alternative options and the centers of the maps. We also found that subjects were continuously exploring the areas around the two options and the center of the map by repeatedly looking back and forth between them before deciding which option to choose, presumably implementing a comparison process. Another key finding is that the selection of an option was highly associated with the time spending exploring the area around that option, with subjects spending more time exploring the area around the option they finally selected than the option that was not selected at the end of the trial. Finally, we found that first and last fixation sets have an important role in influencing the value of the alternative options, and thus, biasing the decision. Overall, the initial fixations favored the location ultimately chosen. The first fixation bias occurred as early as 230 ms after the stimulus onset, whereas the final fixation bias appeared at about 345 ms prior to make a decision. All these findings suggest that human strategies are highly stereotyped in exploring novel environments for making spatial decisions, and these strategies share many common characteristics with the way that humans make economic choices.

Title: Identifying the relative influence of multiple prior events on predictions of a probabilistic future: An artificial neural network analysis

Authors: J. FREEDMAN[1], A. AMLIE-WOLF[2], R. WITTENBERG[1], O. SHOHAM[1], S. R. ARONSON[3], *M. D. LOOSE[1]
[1]Neurosci. Dept., Oberlin Col., Oberlin, OH; [2]Genomics and Computat. Biol., Univ. of Pennsylvania, Philadelphia, PA; [3]UC San Diego, La Jolla, CA

Abstract: When predicting future events most individuals tend to match their rate of predicting an outcome to the probability of that outcome occurring. We used an artificial neural network trained via back-propagation (ANN) to test the hypothesis that multiple types of information influence such predictions. The model used events of recent previous trials as inputs (14 input nodes) with two or five hidden nodes and two output nodes. The sign of the difference between the two output nodes determined the network's guess. Training sets were constructed (N=22) from behavioral data collected for an event-related potential study in which the probability ratio was 63:37 (Society for Neuroscience 2012, 101.22). Each training set contained a 50:50 ratio of high and low probability predictions while the test set retained the original choice ratio (range of high predictions: 54% - 82%). Ten networks, each initialized with random weight values, were trained for each of the 22 data sets. After training, the ANNs were more accurate compared to before training at predicting subjects' choices with the training set (mean improvement: 14.9 %, SD = 5.0%, $p < 0.001$), as well as with the test set (mean improvement: 9.5%, SD = 11.2%, $p < 0.001$). We compared 3 metrics for rank ordering the contributions of the various inputs to accuracy of the networks. We tested a new metric that used the magnitude of output node difference values (as a measure of network confidence) and two established metrics, a lesion method and a connection weight strength algorithm. We examined four types of input patterns that could have influenced each decision: Patterns that defied the expected probability, behavioral streaks, accuracy of the previous guess, and speed of the previous guess. The strongest correlations between input pattern metrics and actual behavior were achieved with the synaptic weight algorithm (mean r = .83) and the confidence metric (mean r = .81). Both metrics were more highly correlated ($p < 0.05$) than the lesion metric (mean r = .49). Each input pattern was found to be important for a subset of individuals. The interactions of two or more patterns

often were important to successful predictions by the ANN, and no one strategy was found to be strongly predictive for all participants. Our results suggest that for simple probabilistic predictions people vary their strategies depending upon recent events and their decisions are influenced simultaneously by multiple types of information. We infer that attempting to fit probabilistic decisions with a single strategy like the win-stay lose-shift or the expectation matching strategy will fail to capture significant components of the decision making process.

Title: Cue and outcome-based task retrieval in human

Authors: *M. E. EKOVICH, E. KOECHLIN
Ecole Normale Superieure, Paris, France

Abstract: Humans need to adapt to uncertain, changing, and open-ended environments. In such situations, decision-making involves exploring, adjusting and exploiting multiple task sets - defined as flexible sensorimotor mappings associating stimuli, actions, and expected outcomes. Collins and Kœchlin proposed a computational model that controls the creation, learning, storage, retrieval, and selection of such task sets for driving action (Collins & Kœchlin, 2012, PloS biology). The model monitors the reliability of a collection of concurrent task sets - i.e., the ability of alternative task sets to correctly predict action outcomes. Task set reliability is updated in a Bayesian manner according to outcomes and contextual information and arbitrates between exploiting the most reliable task set or exploring new ones to drive action. It has recently been shown that the reliability of alternative learned task sets is monitored in frontopolar cortex (Donoso, Collins & Kœchlin, submitted). However it remains unclear how task sets are actually retrieved for subsequent use. The goal of this study is to investigate the neural mechanisms that subserve the retrieval of stored task sets according to contextual cues or action outcomes. We designed an fMRI experiment requiring healthy human subjects to learn by trials and errors and

to switch between multiple task sets associated with various contextual cues. Experimental conditions varied unpredictably such that (i) previously learned task sets re-occurred with either the same or new contextual cues, (ii) new task sets that needed to be learned occurred with new cues or previously encountered ones. Behavioral results and model fits show that subjects learned, monitored and switched across an expanding repertoire of task sets as predicted by the computational model. More specifically: (i)Known contextual cues were used proactively to select the corresponding task set (ii)When previously learned task sets re-occurred with unknown contextual cues, subjects selected the stored task set based on action outcomes. Preliminary fMRI results revealed that lateral prefrontal cortex is engaged in the selection process in both cases. However distinct networks are involved depending on whether the retrieval is cue or outcome-based. On the one hand, cue-based retrieval relies on a ventral pathway including ventromedial prefrontal cortex, striatum and bilateral hippocampus. On the other hand, outcome-based retrieval relies on a frontal network including frontopolar cortex and dorsolateral frontal cortex. Overall these results suggest a possible dissociation between two types of task sets retrievals in humans.

Title: Electroencephalographic correlates of system two decision making

Authors: *O. E. KRIGOLSON, C. HASSALL
Dept. of Psychology, Dalhousie Univ., Halifax, NS, Canada

Abstract: Evidence suggests that human decision-making is the product of two distinct systems - a fast system that supplies well known or reflexive answers (System I) and a slow system that supplies more deliberative answers (System II)(Kahneman, 2011). Extending from this, decision making theory posits that early in learning System II is engaged as one works to link decision options to outcomes. However, with learning, and as the linking of decision options to outcomes becomes automated, there is a shift to rely on System I to provide intuitive responses. Here, we

hypothesized that early in learning decisions made by System II would be characterized by enhanced alpha activity in the human electroencephalogram over pre-frontal and medial-frontal cortex, and that with learning, a decrease in alpha activity would reflect a shift in reliance to System I. To test this, we had participants perform a perceptual learning task that required them to categorize "blobs" based on a subordinate level naming structure. Initially, participants had to classify the blobs into one of four families. In a key manipulation, at the midpoint of the experiment two new families of blobs were added while two were removed - thus, at this juncture in the experiment, there were "new" and "familiar" blobs. Our analysis of the EEG data revealed a decrease in alpha activity from the start of the experiment to the midpoint at the time of the blob classification decision. After the midpoint, enhanced alpha activity was observed over pre-frontal and medial-frontal cortex when classifying new blobs but the alpha activity associated for the classification of familiar blobs was still reduced. We suggest that the decrease in alpha activity with learning reflects a diminishment in the activation of the System II decision network and thus is reflective of a shift to the System I decision network. Importantly, our results provide novel electroencephalographic evidence for the two system model of decision making proposed by Kahneman and others.

Title: Is there overlapping neural activation from different sources of decision difficulty?

Authors: *B. E. KIM-VIECHNICKI, J. W. KABLE
Univ. of Pennsylvania, Dept of Psychology, Philadelphia, PA

Abstract: Objective: The subjective experience of difficulty can feel similar across many different decision situations, but it is unknown whether this similarity in experience is accompanied by a neural signal that is common to different forms of decision difficulty. Regions in a fronto-parietal network have been implicated in detecting subjective difficulty and responding to cognitive demand of many different forms. Previous studies have typically used a

single manipulation of cognitive demand, however. This study aims to address these limitations with a cognitive conjunctive design across multiple kinds of decision difficulty. Methods: We measured BOLD signal during a well-studied delay discounting task, with four different manipulations to induce increased difficulty: 1) time pressure, 2) more options, 3) disfluency, and 4) options close in subjective value. Easy control trials did not induce time pressure and involved only two options presented numerically that were far apart in subjective value. Trials were blocked and after each block subjects rated how difficult they thought the last set of decisions were. Results and Conclusions: All four of the manipulation blocks were rated as significantly more difficult than the easy control blocks. Subjects also spent significantly more time on hard trials than on control trials for the disfluency, 4-options, and close in value manipulations and spent significantly less time on hard trials than on control trials for the time pressure manipulation. Not surprisingly, unique activity was found in left inferior frontal regions for disfluency and early visual regions for increased number of options. We also found widespread activation in fronto-parietal regions for all manipulations. Surprisingly, however, we did not find a common frontal region of increased activation that was reliable across all four manipulations, and only found a small overlapping area in parietal cortex. These results suggest that, while all forms of decision difficulty are associated with greater activation in fronto-parietal regions generally, these activations in response to cognitive demand may not overlap at a more fine-grained level.

Title: Frequency-dependent feedback-related information exchange in the human medial and lateral prefrontal cortex

Authors: *S. A. SHETH[1], G. BANKS[1], M. K. MIAN[2], S. R. PATEL[2], E. N. ESKANDAR[2], E. H. SMITH[1]

Abstract: Rapid adaptation to a changing environment is integral for survival. Feedback, both internally and externally generated, plays a pivotal role in our ability to learn to survive in complex environments. Several salient feedback signals have been characterized in the human brain using scalp electroencephalography. One such signal, the feedback-related negativity (FRN), is a difference in the e¬¬voked potential between trials in which the subject receives positive and negative feedback. FRN is usually observed 100 to 200 milliseconds after a subject has registered a behavioral response, and is greatest on central EEG contacts. Source localization studies have implicated the dorsal anterior cingulate cortex as generating this potential. Recent studies in primates have provided evidence for an anatomical substrate for interactions among medial and lateral prefrontal regions, and physiological evidence for how medial and lateral prefrontal cortex may be interacting during environmental feedback. Here we show a frequency-dependent mechanism for information exchange between the human medial and lateral prefrontal cortices during feedback. This study examined intracranial electrocorticographic (ECoG) signals in 6 patients undergoing monitoring for medically refractory epilepsy. We examined local field potentials (LFP) recorded from the medial and lateral contacts on eight-contact depth electrodes implanted through the mediolateral extent of prefrontal cortex (12 left hemisphere and 8 right hemisphere). Recordings were acquired while patients performed the Multi-Source Interference Task, a Stroop-like cognitive task, with alternating feedback and non-feedback blocks. FRN was observed in the low frequency LFP on all contacts, though was significantly greater, relative to event-related potential size, on the medial contacts. FRN observed in high frequency LFP was also significantly greater on medial contacts, and in the left hemisphere. LFP coherence in theta and high gamma bands increased for feedback trials during the feedback period, compared with a baseline period. Conditional mutual information and Granger causality support medial prefrontal regions leading lateral prefrontal regions in processing feedback. These human ECoG recordings describe an oscillatory mechanism for propagation of feedback related information between medial and lateral prefrontal cortex. These results have implications for understanding cognitive control and reinforcement learning.

Title: Measuring and manipulating satisficing decision strategies in models, humans, and monkeys

Authors: H. OH, P. ZHU, K. RAFIE, S. FERRARI, J. BECK, T. EGNER, *M. A. SOMMER
Duke Univ., Durham, NC

Abstract: The study of rational decision-making assumes that decision-makers have perfect knowledge of possible choices and outcome probabilities, as well as ample time and computational resources to optimally integrate this information. In real life, however, some decision-relevant information is typically unknown or uncertain. Thus natural decision-making may be bounded by limited time and mental resources. Humans are thought to overcome such limitations through satisficing: fast but "good-enough" heuristic decision-making that prioritizes some sources of information while ignoring others. To start to elucidate the principles that govern satisficing, we developed a new protocol for measuring and manipulating decision strategies in a probabilistic classification task. The paradigm is suitable for testing computational models, humans, and non-human primates. Here we focus on human subjects. On each trial, participants were presented with compound cue stimuli consisting of multiple features, each of which could take multiple values, which can be treated as random variables associated with some implicit conditional distributions (reward probabilities) that must be learned via probabilistic feedback. We manipulated the amount of decision time available, and employed Bayesian inference to quantify subjects' decision-making strategies. We found that under low time pressure, participants performed comparable to an ideal observer, correctly weighting and integrating all available cues to arrive at near-optimal decisions using a Bayesian Network. With increasing time pressure, however, subjects gradually shifted their decision strategies by taking only a subset of the most predictive cues into account to arrive at fast, yet good-enough, decisions. Our data document adaptive re-weighting of cue values to compensate for limited decision time and thus support "bounded rationality" models of human decision-making.

Title: Exploration and exploitation in action selection in humans depends on striatal GABA

Authors: *A. S. ROKEM[1], G. S. TANG[1], T. LUCAS[2], A. THAMRONGRATTANARIT[3], L. BALTUSIS[1], R. F. DOUGHERTY[1], R. MATA[4], L. L. CARSTENSEN[1], G. R. SAMANEZ-LARKIN[5], S. M. MCCLURE[1]

Abstract: Balancing exploration of the environment with exploitation of known sources of reward is a ubiquitous behavioral challenge. Optimal performance requires exploring sufficiently to discover the best behaviors for each situation. Simultaneously, exploring too long runs the risk of deviating from known sources of reward only to sample novel, but inferior alternatives. Various strategies may be used to resolve exploration-exploitation trade-offs. One strategy that has received particular attention is to maintain estimates of uncertainty about behaviors and adaptively sample from unknown, but potentially valuable actions (Frank et al., 2009). An alternative strategy is simply to incorporate noise into the decision-making process so that choices do not always follow the option with the highest expected reward. In simple decision environments, such as multi-armed bandit tasks, this noise-based exploratory strategy best describes behavior (Daw et al., 2006). Our project had two goals. First, we wished to develop a multi-armed bandit task for which (1) the optimal exploration-exploitation trade-off varies in an adaptive manner, and for which (2) a noise-based exploration strategy accounts for behavior. To accomplish this, we took advantage of the fact that for longer time horizons, greater exploration increases total expected reward. We used a probabilistic learning task (multi-armed bandit) with two different task lengths. As predicted, behavior was well matched by a noise-based exploration model with greater exploration in the longer task condition. Second, we wished to test the hypothesis that noise-based exploration is related to the viability of the GABAergic inhibitory

network in the striatum. The basal ganglia are known to mediate action selection, and activity of striatal medium spiny neurons (MSNs) is believed to be critical to the selection process. Specifically, lateral inhibition among MSNs as well as from GABAergic interneurons is believed to underlie the competition among possible actions. We constructed a neural network model that accounts for action selection in terms of the inhibition applied by striatal MSNs. The model predicted that greater density of MSN processes (and hence greater total striatal GABA) would give rise to greater exploration. To test this prediction, we measured 1-H Magnetic Resonance Spectroscopy (MRS) and assessed *in vivo* concentrations of GABA in the striatum. In agreement with our model, we found that participants with larger striatal GABA concentrations had higher estimated exploration, suggesting that striatal GABA levels play an important role in mediating exploration.

Abstract: Background: The capacity to flexibly adapt behavior is crucial to negotiating the vicissitudes of daily life. Behavioural flexibility or compulsivity can be divided into subtypes orchestrated by overlapping yet distinct regions of fronto-striatal circuitry. These processes include habit formation, reversal learning (RL), and extradimensional set shifting (ED) and more basic processes of perseveration and shifting. We focus on the intrinsic functional connectivity of neural networks underlying habit formation (model-free learning) or the tendency to select a previously reinforced action, which co-exists in parallel with goal-directed behaviours (model-

based learning) involving forward planning of the task structure (Daw, Neuron, 2011; Voon, Mol Psychiatry, 2014). We compare these with RL and its counterpart, acquisition learning and ED. We further examine the influence of outcome valence on acquisition and RL. Methods: Resting-state fMRI was collected from 66 healthy volunteers. We used a novel multi-echo planar sequence allowing a more precise distinction between neuronal (BOLD-like) and non-neuronal (non-BOLD-like) components allowing for enhanced signal-to-noise ratio (Kundu, PNAS, 2013). Seed-based functional connectivity of distinct fronto-striatal circuits were mapped. Behavioural function was mapped onto fronto-striatal circuitry based on the compulsivity measures of habit formation using a two-step task, RL using a one-step task and a task testing ED shift. Acquisition learning and RL with both positive and negative outcomes were assessed. Results: We show a fine grained parcellation of motor, cognitive and limbic fronto-striatal connectivity maps. Goal-directed model-based learning using a two-step task was associated with enhanced mOFC-VS connectivity, and habitual model-free learning was associated with enhanced SMA-posterior putamen connectivity. Reward-related acquisition learning errors using a one-step task was associated with enhanced vmPFC-VS and reward reversal-learning errors were associated with enhanced mOFC-VS connectivity with loss errors associated with the opposite direction. ED shift errors were associated with lower dlPFC-VS connectivity. Conclusions: We map the functional substrate of parallel fronto-striatal circuits highlighting the distinct yet overlapping neural networks of subtypes of compulsivity.

Title: Electroencephalographic evidence for the sparsity heuristic

Authors: ***C. D. HASSALL**, P. C. CONNOR, T. P. TRAPPENBERG, O. E. KRIGOLSON
Dalhousie Univ., Halifax, NS, Canada

Abstract: Decision making in a complex world is aided by heuristics or “mental shortcuts”. One such heuristic, sparsity, guides our choices by focusing learning on only a small subset of available features. Alternative strategies, such as valuing specific combinations of features, have been shown to result in poorer performance when sparsity information is available (that is, when only certain dimensions are relevant). Here, we extended existing work suggesting that humans use sparsity when making complex choices, and found novel behavioral and electroencephalographic (EEG) evidence implicating selective attention in this process. In particular, we had participants choose between two complex stimuli that varied randomly along three dimensions: shape, color, and texture. Only one of these dimensions was relevant in each block, and reward probability was determined by a value map within the target dimension. Target dimensions and value maps were chosen randomly for each block, and unknown to participants. Thus, on each trial there was always a higher valued stimulus and a lower valued stimulus, as determined by the value map within the target dimension. We observed that participants were faster to respond to attentional probes that appeared unexpectedly within higher valued stimuli compared to probes within lower valued stimuli. Our EEG result supported our behavioural result: we observed a value-dependent change in the N2pc, a component of the human event-related potential (ERP) related to attention. Specifically, we observed an increase in the N2pc in response to higher valued stimuli compared to lower valued stimuli. Thus, our behavioral and ERP results suggest that selective attention may be one of the mechanisms behind the use of sparsity in decision making.

Title: Calibration of persistence based on delay-timing distribution is preserved in sleep deprivation

Authors: *S. A. MASSAR, M. W. L. CHEE
Ctr. for Cognitive Neurosci., Duke-Nus Grad. Med. Sch., Singapore, Singapore

Abstract: Persistence in waiting for a reward depends on the expectations of the statistical distribution of the possible delay durations (McGuire & Kable 2013). Under some distributions it can be appropriate to be completely persistent, whereas in other situations more optimal returns can be obtained if waiting is abandoned after a short delay. In a recent study it has been shown that human decision makers can accurately calibrate their persistence based on the statistical distribution of delays that they are exposed to (McGuire & Kable 2012). In the present study we sought to examine whether this ability is affected by sleep deprivation. Studies on the effects of insufficient sleep on intertemporal choice have yielded mixed findings. Traditional methods of delay discounting using delays ranging from days to months have shown no changes under sleep deprivation. However, some studies in which the delays, in the range of seconds, were actually experienced during the decision-making task show indications of decreased tolerance to delays during sleep deprivation. Whether this would affect the ability to discriminate different delay distributions and adjust behavior accordingly is not known. Here, participants performed a willingness-to-wait task once after a night of normal sleep, and once after a night of sleep deprivation. The task required subjects to make continuous decisions about whether to wait for a larger reward (15 ¢) or to abandon waiting in favor of a smaller reward (1¢). Crucially, the delay durations were drawn from either a uniform distribution (0-16 seconds) where being persistent is the optimal strategy, or alternatively from a heavy-tailed distribution where total persistence would lead to a suboptimal outcome since occasionally very long delays were presented (up to 90 seconds). In line with earlier findings participants showed stronger persistence under the uniform distribution compared to the heavy-tailed distribution. Interestingly, this ability to distinguish different delay distributions and adjust behavior accordingly was mostly preserved after sleep deprivation. Despite marked increases in subjective sleepiness and impairments of attentional performance in a psychomotor vigilance task, participants maintained sensitivity to delay distributions in the willingness-to-wait task.

Title: A general form for state-space representation in frontal and temporal cortex

Authors: *M. M. BOTVINICK[1], C. DIUK[2], D. YEE[3], J. CHEONG[1], A. WEINSTEIN[1], Y. NIV[1], A. BARTO[4]
[1]Princeton Univ., Princeton, NJ; [2]Facebook, Inc., Menlo Park, CA; [3]Washington Univ., St. Louis, MO; [4]Univ. of Massachusetts, Amherst, MA

Abstract: Data from frontal and temporal cortex convincingly show that the neural representation of particular stimuli can be strongly shaped by the tasks into which they fit. Although this has been demonstrated mainly in the context of simple classification tasks, it suggests something general, namely that the neural representations of state space — the set of stimuli or situations arising within a particular task — assume a form that facilitates the computations necessary for task performance. The present work takes this broad idea and translates it into a formally explicit account of how task structure influences state-space representation, culminating in an experimental test. Our computational theory starts from the assumption that any task can be understood as comprising a set of action-outcome contingencies and an objective function favoring reward-maximizing behaviors. Optimal control theory identifies a fundamental consistency constraint in this context, expressed in the famous Bellman equation (the foundation for well known reinforcement learning algorithms). Building on previous work in machine learning, we note that the Bellman equation implicitly embeds a particular kind of state-space representation, one that encodes individual states or stimuli in terms of what they predict about the future. On a theoretical level, this result is intriguing for its deep connections with a variety of other formal constructs, including slow feature analysis, spectral embedding, and principal components analysis. However, our focus in the present work is on implications for neuroscience. We hypothesize that the brain represents state space in precisely the format recommended by the Bellman equation. This gives rise to a specific, testable prediction, which is that task stimuli that are associated with overlapping predictions should give rise to similar neural representations. We tested for this effect in human subjects, using the Tower of Hanoi, a problem-solving task that has been used extensively in research on executive function and planning. Using fMRI and multi-voxel pattern analysis, looking within areas of inferior frontal and anterior and medial temporal cortex previously implicated in state-space encoding, we confirmed that the representation of state-space in these regions displays a similarity structure consistent with the predictions of the theoretical account. The results reported have direct implications not only for understanding state-space encoding and the function of the cortical regions involved, but also for understanding how the brain decomposes tasks into coherent subtasks, thereby facilitating planning in complex domains.

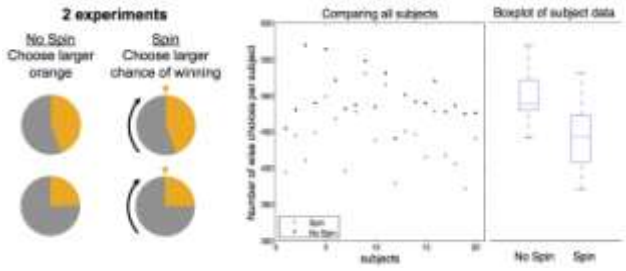
Title: Source of choice behavior variability in probabilistic events: Noise vs suboptimal inference

Authors: ***J. TEE**[1,2], L. T. MALONEY[1,2,3]
[1]Dept. of Psychology, [2]Inst. for the Interdisciplinary Study of Decision Making, [3]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: INTRODUCTION Choice behavior can vary from trial to trial, even with near-identical stimuli. This variability is often attributed to internal noise (i.e. the brain's sensory limitations). A recent work proposed the alternative idea that, in theory, variability could also arise from suboptimal inference [1]. It is, however, difficult to attribute the exact source of variability due to confoundment. We designed two complementary tasks in an attempt to isolate the sources. METHODS During each trial in Task 1 (i.e. No Spin), a subject was presented with two roulette wheels where a fraction of each wheel is colored orange. The subject was asked to choose the wheel that has the larger proportion of orange. Making the correct choice won a monetary prize. In Task 2 (i.e. Spin), a subject was presented with the same pair of wheels and was asked to choose the wheel that has the larger chance of winning. After choosing, the wheels were spun and the subject won a monetary prize if the chosen wheel stopped in the orange. A staircase procedure was used to vary one wheel while the other acted as the test condition. There were 20 test conditions, uniformly distributed between [0.025,0.975] with 30 trials/condition. 20 naïve subjects performed both tasks. RESULTS We compared the total number of wise (i.e. correct) choices made by each subject for both tasks. While the total number of wise choices differs across subjects, all subjects made more wise choices in the No Spin task than the Spin task. The former has a median of 489/600 while the latter's median is markedly lower at 444/600.



DISCUSSION Both tasks have the same optimal solution (i.e. the wheel with more orange). The No Spin task established a baseline for internal noise error while the Spin task measured the incremental error arising from suboptimal inference. The substantial difference in the results of both tasks supports the theory that suboptimal inference is an alternative source of behavioral variability. Title: A core brain network for mixed-strategy decision-making

Authors: *A. C. PARR[1], B. C. COE[1], M. C. DORRIS[2], D. P. MUNOZ[1]
[1]Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada; [2]Inst. of Neurosci., Shanghai Inst. for Biol. Sci., Shanghai, China

Abstract: During competitive social interactions, one's chosen actions and their associated outcomes change dynamically based on the actions of other agents. This often requires that one employ the use of mixed-strategies; that is, choosing among available actions unpredictably and stochastically, to avoid exploitation from opponents. The neural mechanisms that calculate abstract value representations and transform these into specific actions during human decision

making are currently not well understood. We have previously demonstrated that strategic decision-making is associated with the activation of a distributed corticostriatal network in humans; however, the contribution of motor structures to strategic action selection remains largely unknown. The current study used functional magnetic resonance imaging (fMRI) to dissociate the core elements of a strategic brain network from those brain structures involved in controlling specific motor effectors, in this case, the eye and the hand. A colour-based version of the strategic game, Matching Pennies, was played against a dynamic computer opponent that exploited biases in player's response patterns. Participants selected one of two different coloured visual targets, and were rewarded if their selection matched that of the opponent. We employed a block design, wherein participants indicated their choices with either the eye (saccade) or the hand (button-press). Brain activation during the saccade condition was contrasted with that observed during the button-press condition; any difference in response patterns should highlight processes related to controlling individual motor effectors. Strategic decision-making, *regardless of the particular effector used*, was associated with the activation of a highly distributed network including the head of the caudate nucleus, dorsolateral prefrontal, anterior cingulate, parietal, insular and orbitofrontal cortices. We propose that this network represents the key elements of a functional network underlying strategic forms of decisions. Conversely, we observed effector-specific activation of cortical motor structures, *depending on the particular effector used* to make choices. Activation of the supplementary motor area (SMA) and the pre-SMA was associated with choices made using a button press, while activation of the frontal eye fields was associated with choices made using a saccadic eye movement. These results suggest that strategic forms of decisions activate a common brain network, distinct from brain regions involved in controlling specific motor effectors.

Title: Dynamic normalization in cascaded decision circuits

Authors: *T. LOFARO[1], K. LOUIE[2], P. W. GLIMCHER[2]
[1]Mathematics and Computer Sci., Gustavus Adolphus Col., Saint Peter, MN; [2]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Decision-making is a complex cognitive function involving multiple processes including sensation, memory, reward processing, and option selection. Although the decision process likely involves multiple brain regions, neurophysiological studies primarily focus on the activity of neurons in a single brain area and little is known about how the decision process is coordinated across different neural circuits. Here, we use a dynamic network model of value coding to characterize neural activity in interconnected decision-related brain areas. In Louie et al (2011) a static normalization model was shown to explain neural activity in monkey lateral intraparietal area (LIP) under varying value conditions. Recently, we have shown that a differential equation model of normalization qualitatively predicts both the time-independent features of the original model as well as the temporal evolution of LIP firing rates. However, these previous models did not specify how value information reaches parietal circuits and did not incorporate other brain regions such as the orbitofrontal cortex (OFC), which is thought to store information about option values. We build on our previous work to model a cascaded network from OFC to LIP again using circuit-motivated normalization models. A key feature in the development of these models is the distinct time constants associated with OFC versus LIP neural activity, a feature that allows the model to capture the long timescale range-normalization empirically observed in OFC. Two distinct models are presented and analyzed for similarities and differences; in particular, we explore dynamical properties that might be used to experimentally distinguish between these two models.

Title: Investigation of the effect of different dopaminergic levels on the basal ganglia action selection properties using a biologically constrained computational model

Authors: J. BELLOT[1], J. LIÉNARD[3], M. KHAMASSI[1], *B. GIRARD[2]
[1]ISIR, [2]CNRS / UPMC, Paris Cedex, France; [3]Washington State Univ., Vancouver, WA

Abstract: The basal ganglia have been widely studied for their action selection properties [1] and their link with numerous pathologies involving dopamine dis-regulations such as Parkinson's disease. Numerous computational models of the basal ganglia have been developed for these purposes. However, many of the current models of the whole basal ganglia circuitry only reproduce the global network connectivity without much constraints over the strength of the connection weights, producing an output not comparable to the actual activity of the basal ganglia in living animals. [2] developed a biologically constrained mean field model of the primates basal ganglia that produces plausible activity for the different nuclei, while having action selection properties. We developed a reduced version of this model, based on the leaky integrator formalism, by replacing the dynamics of the post synaptic potentials with the corresponding integrated activity over time. We show that this simplification does not alter the ability of the model to (1) perform action selection, (2) produce plausible firing rates and (3) display beta oscillations with low levels of dopamine. This model has the specificity of not assuming the existence of the direct and indirect pathways associated with D1 and D2 dopamine receptors. If this dissociation seems to exist in mice, anatomical studies in primates revealed that these two pathways are, at best, marginally dissociated [3]. Consequently, changes in DA level have a different impact on the model than in the previous ones. We thus investigated these changes in two contexts: first, does the level of DA in the system regulate the exploration exploitation trade-off, as suggested by the work of [4]? Second, to what extent is the segregation in two different pathways necessary to reproduce the differences in reward and punishment sensitivity observed in Parkinsonian patients with or without medication [5]? Title: Divisive normalization and neurobiological constraints on decision-making

Authors: *R. WEBB[1], P. W. GLIMCHER[2], K. LOUIE[2]
[1]Rotman Sch. of Mgmt., Univ. of Toronto, Toronto, ON, Canada; [2]Ctr. for Neurosci., New York Univ., New York, NY

Abstract: Biology places constraints on the form of neural computations that ultimately characterize choice behaviour. Consistent with the result of a constrained optimization over evolutionary timescales, certain canonical computations occur widely and repeatedly in neural circuits. Recently, it was shown that value coding in decision-related circuits is implemented via divisive normalization, a computation extensively seen in sensory processing. However, the relationship between normalization, inherent constraints of biological information processing, and choice behavior are unknown. Here, we show that divisive normalization produces an efficient representation of value information under simple assumptions about neurobiological constraints. We further show that this optimization predicts specific context-dependent choice effects driven by the composition and size of the choice set. Evidence for such context-dependent choice behaviour is provided from two behavioural experiments, and these behavioral patterns are more accurately captured by a choice model incorporating normalization compared to common econometric specifications. These results emphasize both the positive advances offered by developing choice models grounded in neuroscience, and the normative role neurobiological constraints can play in the study of decision-making.

Title: Analogical mapping within and across modalities: Modular abilities or analo-g?

Authors: *G. ENGLISH[1], N. PARROTT[2], E. FEARON[2], N. LIU[2], N. GALLAGHER[2], A. GREEN[3]
[2]Psychology, [3]Psychology Department, Interdisciplinary Dept. in Neurosci., [1]Georgetown Univ., Washington, DC

Abstract: The ability to connect seemingly unlike things via analogical reasoning (mapping) underlies social, practical, and scholastic learning. To date, research on analogical mapping has focused on connecting items within a single information modality, especially verbal and visual analogies. The capacity to perform analogical mapping across (rather than within) a modality has remained unexplored. This project examined cross-modal analogical ability in young adults. 52 participants (56% male; M age=21.98, SD=2.91) underwent cognitive testing including WASI-II full-scale IQ and four blocked conditions of analogical reasoning. Analogical reasoning stimuli were 4-term proportional true or false analogies, interpreted as "A is to B as C is to D". In three conditions, the first two terms were line arrangements. The third and fourth terms varied by condition: line arrangements, words, or sounds. Each initial pair appeared in each of the three modalities. In addition to these Line-Line, Line-Word, and Line-Sound sets, 51 participants performed a fourth condition: 4-term true-false word-word analogy task. Participants exhibited good accuracy in all three conditions (Line-Line M Acc = 0.84, SD = 0.08; Line-Word M Acc = 0.82, SD = 0.06; Line-Sound M Acc = 0.92, SD = 0.07; Word-Word M Acc = 0.87, SD = 0.08). Word-Word accuracy had a significant positive correlation with Line-Word ($r=0.321$, $n=51$, $p=0.021$), but not Line-Line or Line-Sound. Line-Line and Line-Word accuracy were significantly positively correlated with Line-Sound accuracy ($r=0.348$, $n=52$, $p=0.012$; $r=0.464$, $n=52$, $p=0.001$). Line-Line and Line-Word accuracy correlated at a trend level ($r=0.264$, $n=51$, $p=0.058$). Verbal Comprehension, Perceptual Reasoning, and Full-Scale IQ all significantly positively correlated with Word-Word accuracy ($r=0.378$, $n=51$, $p = 0.006$; $r=0.329$, $n=51$, $p=0.018$; $r=0.438$, $n=51$, $p=0.001$), but none of the other modalities. High participant accuracy on the three nonstandard analogy conditions (Line-Line, Line-Word, and Line-Sound), as well as the Word-Word analogies, strongly supports the ability of individuals to reason both within and across modalities, expanding on current research. The positive correlations between participants' accuracy on the three nonstandard modalities indicate that these abilities access some of the same underlying mechanisms despite sensory input differences. However, the failure of Line-Line, Line-Word, and Line-Sound analogies to correlate significantly with IQ measures, as well as the significant correlation of Word-Word analogies only with Line-Word analogies, may imply some degree of verbal modularity in analogical reasoning ability.

Title: Sleep inspires temporal insight but not categorical insight

Authors: *L. CANNELLA, I. LERNER, D. OHIOMA, M. A. GLUCK
Rutgers Univ. Newark, Newark, NJ

Abstract: It is well documented that sleep has beneficial effects on memory and learning in humans. In particular, sleep has been shown to facilitate insight in associative-learning tasks that are known to depend on the hippocampus. However, tasks used to demonstrate sleep effects on hippocampal-dependent insight in humans were predominantly focused on the need to discover a hidden rule with a temporal structure. Whether such results can generalize to hippocampal tasks requiring non-temporal insight remains an open question. To investigate this issue, we developed two novel tasks, one requiring temporal insight and the other requiring insight that does not have temporal aspects. In each trial of the first task, subjects had to guide an avatar through five rooms. Each room had three different colored doors in different spatial locations. Perfect performance could be achieved by memorizing the correct sequence of doors or colors by trial and error; however, realizing that the sequences across all trials have a repetitive temporal structure, namely, that the location of some doors could be predicted by the location of other doors, could considerably improve performance. In the second task, subjects were instructed to sort visual objects that differed in shape, size, color, and pattern into category A or B based on trial and error. Optimal categorization could be achieved by either memorizing the features of individual objects, or by gaining the insight that a non-trivial systematic combination of features reliably determines the correct classification. We assessed if subjects discovered this hidden rule by testing them on new objects that complied with the same rule (‘generalization’). Subjects were assigned to either a ‘sleep’ group, in which they were tested in the evening and in the following morning with a 12-hour period of sleep in between; or to a ‘no-sleep’ group, in which they were tested twice on the same day with no intermediate sleep. In the temporal task, the sleep group showed a significantly reduced number of errors for predictable doors than the no-sleep group, and was also more able to explicitly point out the temporal rule, signifying that sleep

promoted insight. In the non-temporal task, whereas the sleep group showed increased performance in memorizing individual object categorization compared to the no-sleep group, generalization performance did not differ between the groups and no difference in explicit knowledge of the categorization rule emerged, indicating no improved insight. These results suggest that the facilitation of insight by sleep in hippocampal-dependent associative learning tasks is specific to those with a temporal structure.

Title: A neurocomputational model of how memory replay during slow-wave sleep inspires insight

Authors: *I. LERNER, M. GLUCK
Rutgers Univ., Newark, NJ

Abstract: In the current study, we present a neural network model with temporal-based learning mechanisms that accounts for how insight in humans is inspired by sleep. During the last decade, sleep has been shown to facilitate the sudden identification of hidden temporal structures within sequences of stimuli, a finding demonstrated using cognitive tasks such as the Number reduction Task (NRT) and the Serial Reaction Time Task (SRTT). Evidence suggests that this 'temporal insight' is related to hippocampal activation during Slow-Wave-Sleep (SWS). SWS, in turn, has been shown in rodent studies to express 'memory replay': hippocampal reactivations of previously encoded wake experiences in a time-compressed manner. Here, we suggest that compressed replay may in fact be responsible for the sleep-inspired insight by providing 'temporal scaffolding' to the process of memory consolidation. Specifically, we posit that extraction of unattended temporal structure contained within wake experiences is often beyond the reach of regular timescales of synaptic plasticity mechanisms; however, time-compressed reactivation of these experiences during SWS allows neurons to become sensitive to such structure. We demonstrate this mechanism using an integrate-and-fire neural network simulation.

Inputs to the network included sequences of stimuli that corresponded to those used by human experiments in the NRT and SRTT. These sequences could be presented to the network either in their original 'wake-time' pace, or in a compressed time-scale representing memory replay. The network attempted to learn economical representations of these sequences using unsupervised Hebbian-learning mechanisms based on spike-timing-dependent-plasticity; and to predict future desired responses by converting these representations to output signals using supervised temporal-learning mechanisms inspired by the Tempotron model. When stimuli were presented in regular 'wake' pace, no neural representations of the temporal structure were formed, preventing the network from successful prediction of future outputs. However, when accelerating the time-scale of stimuli presentation, the network became sensitive to the temporal structure of the tasks and yielded correct predictions. Thus, our model suggests a simple, biologically-driven mechanism, which accounts for the way sleep inspires temporal insight. In addition, it suggests a novel functional role for the time-compression characterizing memory replay in the hippocampus. We point to the entorhinal and prefrontal cortex as candidate brain regions in which these mechanisms may take place.

Title: Dissecting human cortical oscillations with surgical transections: White and grey matter contributions to independent oscillatory units

Authors: *A. H. HAWASLI[1,3], D. KIM[3], N. M. LEDBETTER[3], S. DAHIYA[2], D. L. BARBOUR[3], E. C. LEUTHARDT[1,3]

Abstract: Oscillating brain activity reflects changes in cortical potentials caused by activity in neuronal populations. Despite routine use of human cortical oscillations in neuroscience and medicine, the circuits and physiology underlying them remain largely unknown. The modulation of low-frequency oscillations tends to correlate across relatively large areas of cortex while the modulation of high-frequencies tends to be local. From this observation, we hypothesized that (1) low- and high-frequency oscillations preferentially reflect long- and short-range communications, respectively; and (2) synchronization between low-frequency phase with high-frequency amplitude (i.e. phase/amplitude coupling) represents a mechanism that enables large-scale distributed brain-networks to coordinate with local cortical processing. We tested these hypotheses by selectively disrupting white or grey matter connections (i.e., long- or short-range) to cortical sites in humans undergoing neurosurgical resection while recording surface field potentials. We found that selective disruption of white matter connections reduced oscillation power in low-frequencies more than high-frequencies, as expected. Contrary to our hypotheses, however, white matter transection increased functional connectivity with adjacent cortical sites (predominantly at low-frequencies) and did not alter phase/amplitude coupling. Disruption of surrounding grey matter connections did not significantly alter oscillatory power but increased functional connectivity in higher-frequencies and substantially increased cross-frequency phase/amplitude coupling at a synchronized phase. When the lesions were combined at the same site, endogenous oscillations and complex oscillatory relationships were maintained or enhanced. Oscillations persisted even after cortical tissue was completely removed from the brain. These findings suggest that cortex consists of independent oscillatory-units (IOUs) that maintain their own complex endogenous rhythm structure. IOUs are differentially modulated by their white and grey matter connections, where long-range connections maintain topographical heterogeneity (i.e. separable processing along the cortical surface) and short-range connections segregate cortical synchronization patterns (i.e. separable processing in time). Modulation of these distinct oscillatory modules allows for functional diversity necessary for complex signal processing in the human brain.

Title: Temporal coordination in human communications - Phase-oscillator analysis of a two-person alternate tapping task

Authors: Y. CHENG[1], M. KAWASAKI[2], K. KITAJO[3,4], *Y. YAMAGUCHI[5,1]
[1]Univ. of Tokyo, Tokyo, Japan; [2]Tsukuba Univ., Tsukuba, Japan; [3]RBIP Unit, RIKEN BSI-Toyota Collaboration Ctr., Wako, Japan; [4]ABSP Lab, RIKEN BSI, Wako. Saitama, Japan; [5]RIKEN BSI, Wako. Saitama, Japan

Abstract: Our conversation can be considered as a temporal evolution of alternate events between two (or more) speakers. In a two-person alternate speech task, common rhythms are known to emerge spontaneously between the speakers (Kawasaki et al. 2013). In this paper we aim to elucidate the principle of dynamical system in alternate communication events. We employed a two-person alternate finger-tapping task. Each pair of subjects participated in several alternate tapping tasks, in which they were required to make their inter-tapping-interval (ITI) as similar as possible to the ITI made by the partner's latest tapping. A visual signal was shown to both the subjects after each tap, where the color of the signal depended on who made the tap. We designed three types of alternate tapping tasks: human-human (HH), in which the two subjects played with each other; human/computer-follow (HC-F), in which each subject played with a computer program implemented to reply its ITI same as the preceding one plus the Gaussian noise; human/computer-step (HC-S), in which each subject played with a computer program changing its ITI stepwise after a certain number of taps. The change of partner from human to computer program was not notified in both HC-F and HC-S tasks. 19 pairs (38 subjects) participated in the experiment. We analyzed the time series data of ITIs based on phase-oscillator model coupled with phase response curves (PRC). Although the performance of HH task varied largely through pairs, the alternate tapping sequence of every pair was found to be the outcome of an attractor formed by phase locking. PRCs of all the subjects, obtained in HC-F task, were either the types 0 or 1. In HC-S task, on the other hand, three types of adaptation to the sudden step change of ITI were observed. In addition, after the behavioral tasks, the questionnaire for autism-spectrum quotient (AQ) known to be available for evaluation of communication ability of healthy subjects, was applied to the subjects. The performance in HC-F task was found to correlate with the score of AQ. Thus, our findings imply the importance of dynamical system theory in social communications.

Title: Temporal orienting of attention can be preserved in normal ageing

Authors: *J. CHAUVIN, C. GILLEBERT, G. ROHENKOHL, G. HUMPHREYS, A. NOBRE
Univ. of Oxford, Oxford, United Kingdom

Abstract: Studies using temporal orienting cues have discovered that it is possible to orient attention to moments in time, optimizing behavioural performance in young adults (Davranche et al., 2011; Nobre & Rohenkohl, 2013). It is generally accepted that older adults show deficiencies or impairments on timing tasks (Balci et al., 2009), though there have been few studies examining the effects of temporal orienting in elderly participants. Zanto and colleagues (2011) demonstrated that elderly participants exhibited what they called an 'expectation deficiency' on a temporal orienting task. To investigate the effects of temporal expectation in ageing further, two experiments in healthy young and old adults were conducted. For the first experiment, 18 younger (<30 years) and 18 older (>60 years) participants took part in blocked versions of two temporal orienting tasks: a speeded motor reaction timing task and a rapid search visual presentation (RSVP) task. In both tasks, two temporal cues in the form of a beep (high and low pitch) indicated the likelihood of a target item occurring after a short or longer period of time. In the motor reaction time task, participants were instructed to use the cues to help them respond as quickly as they could to seeing a green patch appear at the centre of the computer screen. In the RSVP task, participants used temporal cues to orient their attention in time in order to help them perceive a target letter in a stream of rapidly presented letters. In a second experiment, 18 younger (<30 years) and 19 older (>60 years) participants took part in a trial-by-trial version of these tasks. In both experiments, it was found that elderly participants were able to use temporal orienting cues to enhance RT performance and sensitivity to the target stimuli when validly cued for short foreperiod relative to invalid cues. Contrary to previous findings, our results suggest that the ability to allocate attention to moments in time can be preserved in normal ageing. Further research is needed to ascertain whether similar networks are used or whether compensatory mechanisms are at work.

Title: Integration of short-term and long-term temporal information in interval timing

Authors: ***S. W. EGGER**[1], M. JAZAYERI[1,2]
[1]McGovern Inst. for Brain Res., [2]Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Humans are sensitive to the passage of time and use temporal cues to coordinate their actions. However, tracking time is inherently noisy and is thus associated with significant behavioral variability. Humans employ various computational strategies to combat this variability. For example, the ability to measure or produce intervals is improved if the interval is presented within the context of a rhythm. This indicates that subjects utilize the short-term information available within a rhythm to mitigate interval timing variability. It has also been shown that subjects rely on the temporal statistics of the environment learned over longer time periods to improve estimates of time intervals (Jazayeri and Shadlen; 2010). It is not known, however, whether and how the information inferred from a rhythmic structure and the prior knowledge about temporal statistics are integrated to further improve timing behavior. Therefore, we developed a task in which subjects could rely on both prior expectations (based on previous trials) and the rhythmic structure (within a trial) to improve timing behavior. Subjects fixated a central spot and observed 2 to 5 visual spots in the periphery flashed successively. The number and position of flashes were known at the beginning of the trial. The interval between successive flashes (sample interval) was fixed within a trial creating a visual rhythm. Across trials, the sample interval was drawn from a uniform distribution (prior distribution) that ranged between 500 and 900 ms. Subjects had to measure the sample interval and reproduce it immediately after the last flash by a key press, continuing the rhythm for one beat beyond the last flash. We found that subjects' relied on both the long-term prior distribution and short-term rhythmic structure of

the stimulus to improve performance. With 1 sample interval, production intervals exhibited a trade off between bias and variance predicted by a Bayesian model. As the number of sample intervals increased, performance improved but the bias persisted to a greater degree than predicted by the model. The persistence of the bias despite additional sensory evidence suggests that the integration of multiple intervals within a rhythm is imperfect and that the internal estimate is subject to a diffusion process that over time relaxes to the mean of the prior. This observation indicates that subjects use their prior knowledge to compensate for the additional uncertainty due to an imperfect integration of short-term information.

Title: Mindfulness meditation alters subjective experience of time

Authors: *D. SMITH[1], A. CATE[1], M. KOFFARNUS[2]
[1]Virginia Tech., Blacksburg, VA; [2]Virginia Tech. Carilion Res. Inst., Roanoke, VA

Abstract: Evidence shows that mindfulness meditation reduces stimulus-independent thought or "mind-wandering," by focusing attention and awareness on the present moment through mediation of the default mode network. Despite the relatively limited knowledge of the cognitive mechanisms underlying the default mode network, recent literature suggests that perception of time and mental time-keeping strategies may play a key role in the attentional lapses that lead to mind-wandering. Given the increased focus of attention on moment-to-moment awareness, meditation may modify the way we attend to our subjective experience of time. However, few studies have examined the interaction between the meditative state and temporality. In the present experiment, we measured time perception on a verbal time estimation task before and after meditation or relaxation training. We found that meditation training improved performance on a verbal interval estimation task, whereas the relaxation training control group showed no

enhancement in duration estimates. Since experienced meditators report a sense of time slowing down both during meditative practice and everyday life, this experiment has important implications for how meditation alters perception of time and the resulting behavioral consequences of this contemplative practice.

Title: Neural substrate of omitted stimulus response: A simultaneous EEG-fMRI study

Authors: *I. B. SAMUEL, H. HUANG, A. RAJAN, M. DING
J. Crayton Pruitt Family Dept. of Biomed. Engin., Univ. of Florida, Gainesville, FL

Abstract: An expected but missing stimulus is often accompanied by an endogenously generated brain response called the omitted stimulus response (OSR). Neuronal mechanisms of OSR in humans have been mainly studied with EEG and MEG techniques. Given these techniques' limited spatial resolution the anatomical substrate of OSR remains not well understood. We addressed this problem by conducting a simultaneous EEG-fMRI experiment. Participants were presented with a rhythmic stimulus train of random duration in the visual domain (inter-stimulus interval=2s) and instructed to anticipate the onset of the next stimulus upon each visual stimulation. Since the number of stimuli in the train was random it was expected that the omitted stimulus response should occur 2s after the termination of the stimulus train. This prediction was confirmed by an ERP analysis. A GLM analysis of the fMRI data revealed the activation of the anterior cingulate cortex and the dorsal lateral prefrontal cortex. To further examine the relation between the ERP response and fMRI response to the omitted stimulus, omitted stimulus ERP was estimated on a trial by trial basis using the ASEO method (analysis of single-trial event-related potentials and ongoing-activity) and used as a regressor in the fMRI analysis.

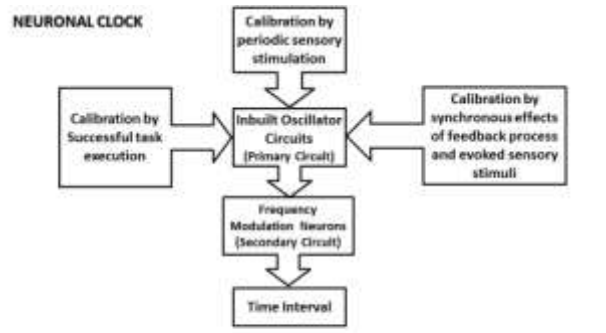
Title: Processing of sub- and supra-second intervals in primate brain results from the calibration of multiple neuronal oscillators via sensory/motor and feedback processes

Authors: *D. S. GUPTA
Biol., Camden County Col., Blackwood, NJ

Abstract: Processing of time intervals by brain is critical for our interaction with the surroundings. Conscious processing of time intervals predicts movements in a vehicular traffic or the temporal delay in finger movements while playing a musical instrument. Processing of time interval also occurs at a subconscious level, which helps to determine the speed of individual muscle contractions, coordinating our movements. To understand how brain processes various sub- and supra-second intervals, I have proposed inbuilt neuronal oscillators within various circuits in brain, which helps to form neuronal clock mechanisms. Proposed oscillators include pacemaker neurons, tonic inputs and, synchronized excitation and inhibition of inter-connected neurons. Time is represented within proposed neuronal clock mechanism by intervals, called 'sensory moment', between two spikes or spike bursts produced by oscillators. Outputs from oscillators are processed to generate changes in states of next level of circuits, represented by rates of changes in frequency and/or frequency of neuronal activity, which encode time intervals. Inbuilt oscillators are proposed to be calibrated by (a) feedback processes (b) input of time intervals resulting from rhythmic external sensory stimulation and (c) synchronous effects of feedback processes and evoked sensory activity. Proposed mechanism of calibration also imposes fluctuations on the regular activity of oscillators. Differences with the pacemaker/accumulator model are discussed, which proposes a separate oscillator with a stable frequency. Multiple calibration mechanisms account for redundancies in the timing mechanisms. Furthermore, abnormal feedback processes associated with motor symptoms could be responsible for the impairment of temporal processing, as seen in schizophrenics.



Above schematic shows the circuitry of the proposed neuronal clock. A neuronal clock is formed by an inbuilt oscillator circuit (one per circuit), which is calibrated by different mechanisms involved in the homeostasis of the primary or the main circuit. A calibrated oscillator circuit activates a second level of circuits, which contains frequency modulator (FM) neurons, exhibiting short term plasticity. Different states of second level of circuits, produced with the help of the modulation in the activity of FM neurons, encode various types of circuit or task specific sub- and supra-second intervals.

Title: Transcranial magnetic stimulation over the right dorsal premotor cortex increases dependence on prior information during tactile temporal order judgment

Authors: *M. MIYAZAKI[1], S. TAKEUCHI[2], H. SEKIGUCHI[2]
[1]Res. Inst. for Time Studies, Yamaguchi Univ., Yamaguchi, Japan; [2]Fac. of Business and Information Sci., Jobu Univ., Isesaki, Japan

Abstract: We can improve perceptual and behavioral accuracy using prior information. In the Bayesian estimation model (Körding & Wolpert, 2004), an optimal estimate for a sensorimotor task can be computed by combining prior information on the task statistics with the likelihood

obtained from sensory input. Psychophysical studies (Miyazaki et al., 2006; Yamamoto et al., 2012; Nagai et al., 2012) indicate that the brain implements Bayesian estimation during temporal order judgment (TOJ). Based on our preliminary study using electroencephalography (partially reported in Takeuchi et al., 2013), we hypothesized that the dorsal premotor cortex (PMd) is associated with Bayesian estimation during tactile TOJ. Here, we tested this hypothesis using disruptive transcranial magnetic stimulation (TMS). Twelve subjects performed TOJ with two tactile stimuli, one in each hand (detailed in Miyazaki et al., 2006). The stimulus onset asynchronies (SOAs) were sampled from the Gaussian distribution, biased to the right-hand side first (mean = 80 ms, SD = 80 ms; R1st-bias condition) or to the left-hand side first (mean = -80 ms, SD = 80 ms; L1st-bias condition). Each participant completed two sessions (1600 trials/session). TMS was applied over the right PMd in one session and over the left PMd in another session (3 cm anterior to hot spots for the motor evoked potentials of the abductor pollicis brevis; van der Berg et al., 2010). For each session, the TMS and no-TMS conditions were interleaved every 200 trials. Under the TMS condition, TMS was applied in 50% of the trials, with the SOA within -40 to 40 ms. We used a paired pulse (ISI = 10 ms) for TMS. The TMS intensity was 110% of the resting motor threshold. The TMS timing was 80 ms after the first tactile stimulus in each trial. Using the proportion of "right-hand side first" judgments as a function of the SOAs, we calculated the difference in the point of subjective simultaneity between the R1st-bias and L1st-bias conditions (ΔPSS). Positive ΔPSS values imply that the brain implements Bayesian estimation using the biased distributions as prior information. The results supported our hypothesis. TMS of the left PMd did not affect ΔPSS (mean ± SEM: no-TMS, 67.8 ± 17.2 ms; TMS, 82.3 ± 20.7 ms; $P = 0.51$, paired t-test with Holm correction), whereas TMS of the right PMd increased ΔPSS (no-TMS, 68.2 ± 17.8 ms; TMS, 91.3 ± 16.2 ms; $P = 0.02$). A greater ΔPSS implies increased dependence on prior information. That is, applying disruptive TMS to the right PMd led to overuse of prior information, suggesting that the right PMd is involved in processing of the likelihood.

Title: Electromagnetic signatures of mental travel in time and space

Authors: *B. GAUTHIER, K. PESTKE, V. VAN WASSENHOVE
Cea/dsv/i2bm/Neurospin Center/Cognitive Neuroimaging Unit, Gif-sur-Yvette, France

Abstract: The Human ability to navigate through space and time mentally has been widely explored with both psychophysics and fMRI and produced two major frameworks (ATOM: Walsh, 2009 and MTL theory: Bonato, 2012) that diverged on the functional relationship between time and space but critically converged on the involvement of parietal cortex in manipulation of these two dimensions. Linking serial stages of cognition and brain imaging demands to access to the finest temporal resolution of brain activity but surprisingly few M/EEG characterizations have been reported that would allow establishing the time course of these high level cognitive functions. In this context, we explored the M/EEG responses related to the temporal and spatial distance effects with a combined mental time and space travel paradigm. First, subjects memorized a set of events with their historical context, date and location. One day after, subjects performed a temporal or a spatial judgment task (TJ and SJ, respectively) while being recorded with MEEG. TJ and SJ conditions were randomly intermixed in a block-design. In a given trial, participants were asked to mentally place themselves in a given temporal and spatial position and asked a Before/After or East/West question with regards to an event presentation - e.g. Ouragan Katrina. Subjects responded in a 2-AFC by button press. The references that were tested were ego- and allo-centric, namely: Present, 9 years ago or after for TJ, and Paris, Cayenne or Dubaï for SJ. A significant decrease was found in both reaction times and accuracy as a function of temporal and spatial distance for both TJ and SJ respectively, replicating previous results interpreted as a psychological correlate of a mental mapping of time and space metrics. MEEG analyses were performed using event-related potentials (ERPs) and fields (ERFs). Contrasting TJ vs. SJ revealed a long-lasting frontal positivity 300 ms post-stimulus onset in both MEG and EEG. Psychological distance effects were indexed as 300 ms post-stimulus parietal differences between close and far conditions, followed by a late parietal negativity at ~700ms. These patterns were notably observed prior to the comparison stage differentially implicating frontal cortices. The neural latencies and topographies are globally congruent with previous results (Arzy et al, 2008). As predicted, we observed a shared parietal lobe response for time and space mapping but interestingly, with a specifically early implication of frontal region for TJ.

Title: The role of the supplementary motor area and the cerebellum in beat-based and non-beat-based timing

Authors: *L.-A. LEOW, J. A. GRAHN
Psychology, Brain and Mind Inst., London, ON, Canada

Abstract: Time intervals in a rhythm can be represented as absolute durations (non-beat-based timing) or relative to a recurrent beat (beat-based timing). Neuropsychological and neuroimaging work show that the supplementary motor area (SMA) and the cerebellum are involved in beat-based and non-beat-based timing (Grahn and Brett, 2007, Grube et al., 2010), however, the specific role of these structures remains unclear. Here, we assess their roles in beat- and non-beat-based timing by modulating excitability in each area using anodal and cathodal 2mA transcranial direct current stimulation. During stimulation, subjects performed a discrimination task with beat and non-beat rhythms to test beat-based and non-beat-based timing, respectively. Discrimination of beat rhythms was better when SMA excitability was increased and worse when SMA excitability was decreased. Discrimination of non-beat rhythms was worsened when SMA excitability was decreased. Conversely, discrimination of beat (but not non-beat) rhythms was worse when cerebellar excitability was increased and better when cerebellar excitability was decreased. Discrimination of non-beat rhythms was not significantly affected by altering cerebellar excitability. Overall, the data suggest both areas play a critical role in the timing of rhythmic sequences.

Title: Novel regimes in dynamic attractor networks account for timing and temporal warping

Authors: *N. HARDY, D. V. BUONOMANO
Neurobio., UCLA, Los Angeles, CA

Abstract: The ability to encode time and generate timed responses is essential to motor control. A general feature of motor control is the ability to produce motor patterns, such as reaching, typing, and speaking, at a range of different speeds ("temporal warping"). Though a number of models address how the brain produces complex spatiotemporal motor patterns, few have addressed how such patterns could undergo temporal warping. One general class of models ("population clocks") proposes that the timing necessary for motor activity arises from the temporally dynamic patterns of neural activity, or neural trajectories, of recurrent neural networks (RNNs). In order to reliably encode time and produce complex spatiotemporal motor patterns such networks must exhibit reproducible dynamics. However, the dynamics of most RNNs studied to date are highly-sensitive to noise and often formally chaotic. We have recently established that firing-rate based RNN models can exhibit highly stable and computationally powerful dynamic regimes by appropriately tuning the recurrent connections (Laje & Buonomano, 2013). In these dynamic attractor network models, triggered activity patterns follow a trained neural trajectory and will return to the ongoing neural trajectory if perturbed by an external stimulus or internal noise. Here, we show that these dynamic attractor networks can also account for temporal warping. Specifically, the network can be trained to complete the same arbitrary "innate" trajectory at different speeds (i.e., trajectory durations). This is accomplished by delivering a constant tonic input which signals the network to temporally scale the speed of its current trajectory. Once trained, the network can generalize its speed based on interpolated untrained velocity signals. While the RNN is trained to produce the same warped trajectory at different speeds, the network converges to states in which very similar "parallel" trajectories in neural space can be generated at different speeds. Because of the large dimensionality reduction of the RRN patterns at the level of the output units, the output patterns are virtually indistinguishable other than the fact that they are temporally warped. Our results describe a general computational framework that accounts not only for the generation of complex spatiotemporal patterns, but also the ability to rescale such patterns_thus capturing a heretofore unaddressed but fundamental feature of motor control. These findings have implications for the problem of temporal warping of motor patterns as well as the neural mechanisms underlying the generation of complex spatiotemporal motor patterns.

Title: Brain activity differences during rhythm discrimination in adults who stutter

Authors: *E. A. WIELAND[1], J. D. MCAULEY[2], D. ZHU[3], L. C. DILLEY[1], S.-E. CHANG[4]
[1]Communication Sci. & Disorders, [2]Psychology & Neurosci. Program, [3]Radiology, Michigan State Univ., East Lansing, MI; [4]Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: Stuttering affects the timing and rhythmic flow of speech production. Interestingly, when speech is synchronized with an external pacing signal (e.g., a metronome), stuttering can be markedly alleviated. This suggests that people who stutter may have difficulty generating an internal rhythm to pace their speech. We hypothesized that adults who stutter (AWS) would have different brain activity patterns relative to controls during a rhythm discrimination task, specifically in a network of regions that have been shown to support rhythm processing (i.e., putamen, supplementary motor area (SMA), auditory, and premotor regions; Grahn & Rowe, 2009). Eleven AWS (6 M) and 11 controls (5 M) (aged 18-46 years) participated in an fMRI experiment where on each trial, participants heard two successive presentations of a standard rhythm and then judged whether a third (comparison) rhythm was the same or different from the standard. Rhythms were either simple (accents at regular periodic intervals) or complex (accents at irregular intervals). Trials were presented using an event-related design divided into six

functional runs. Whole-brain EPI volumes were acquired (44 contiguous 3 mm axial interleaved slices, TR = 2.5s, TE = 27.7 ms, FOV = 22 cm) on a 3T GE Signa HDx scanner with an eight-channel head coil. Statistical inference was based on a whole-brain corrected $p < 0.05$. Consistent with previous research, simple rhythms were discriminated significantly better than complex rhythms. There was no overall significant effect of group, but there was a tendency for AWS to have more difficulty discriminating complex rhythms than controls. Although the behavioral results were comparable in both groups, fMRI results revealed that AWS had significantly greater brain activity than controls in right-hemisphere regions previously implicated in rhythm processing, regardless of rhythm type. AWS showed bilateral activity in the SMA and putamen, whereas controls showed lateralized left-sided activity in these areas. AWS also showed dispersed hyperactivity in the premotor and auditory regions in both hemispheres relative to controls. AWS seem to exhibit less efficient neural network activity patterns to support rhythm processing. This may underlie deficiencies in internal rhythm generation, in turn affecting timing of speech movements.

Title: Motor activity improves interval timing judgments

Authors: *E. THOMAS[1], L. FAUTRELLE[2], D. MARESCHAL[3], R. FRENCH[4]
[1]INSERMU1093, Univ. De Bourgogne, Dijon, France; [2]Univ. Paris Ouest, Paris, France; [3]Univ. of Birkbeck, London, United Kingdom; [4]CNRS, Dijon, France

Abstract: Interval timing involves the judgement of durations ranging from 0.5 seconds to some minutes. Some of the brain areas known to be involved in interval timing are also important in motor activity. These include the basal ganglia and the presupplementary and supplementary motor areas [1]. This raises the possibility that motor acts accompanying interval timing judgment might influence the latter process and especially its learning. In order to test this

hypothesis, we carried out interval timing tests following different types of training, some of which included motor acts. The pre and post training tasks consisted of a button press upon rhythmic presentation of a visual stimulus. Improvements in reaction times were taken as indicating improvements in interval judgment [2]. Training also consisted of asking the subjects to respond to visual presentations of the stimulus, but with a different response mode. Depending on the group to which the subject belonged, the individual was asked to either 1) point with a whole body movement 2) point with the arm from a sitting position 3) imagine a whole body pointing 4) simply watch the stimulus presentation. Subjects undergoing training in interval estimation using motor activity showed significant improvements on these judgments compared to individuals who had not. While the improvements were slightly less for the motor imagery group, this group also showed significantly lower response times than those without any motor training. Control tests were carried out in order to ensure that the improvements obtained with motor training could not simply be attributed to an improved attention or facilitation in sensory motor coordination for this group. In the latter case, this consisted of training with a whole body pointing movement in response to irregular stimuli. No significant improvements in response times were obtained with this group. Similar performances in a secondary task for all groups also indicated that there were no major differences in attention levels between the different training groups. Our results indicate that motor activity can improve interval timing judgments. [1] Coull JT, Cheng RK, Meck WH. (2011) Neuroanatomical and neurochemical substrates of timing. Title: Representation of elapsed time in the human posterior parietal cortex

Authors: *M. I. LEON, N. B. FLYNN, J. E. MEDINA
Cal State Univ, Bakersfield, BAKERSFIELD, CA

Abstract: We measured broadband (1-60 Hz) EEG power from scalp electrodes positioned over the posterior parietal cortex of human participants performing a time-discrimination task. Subjects were required to judge whether the duration of a tone (test cue) was longer or shorter than the duration of a remembered standard cue. Subjects indicated their decision after a delay period by making a left-arm or right-arm reach movement toward one of two choice buttons of a response box. Across all subjects, the probability of choosing "long" increased sigmoidally with the duration of the test cue. Using a short (1.5 sec) and long (3 sec) standard was found to affect participants' bisection point, the test cue duration at which short and long choices are equally likely. Throughout the presentation of the test cue, the signal power appeared to encode the participants' perception of elapsed time relative to the standard duration. During the test cue period, the signal power initially decreased, and then later increased with the passage of time. The test cue duration at which the signal power reversed its trajectory depended on the standard duration and correlated with the bisection point. This experiment lends novel insight into the neural representation of human time sense.

Title: The effects of energy drinks on cognitive performance on the Stroop test

Authors: *B. C. NOLAN, G. L. HUBER
Psychology, Quincy Univ., Quincy, IL

Abstract: The present study examines the cognitive effects of energy drinks. A computerized Stroop Test, which measures cognitive processing of color-word congruent and color-word incongruent conditions, was used to evaluate 4 conditions: Energy Drink, Decaffeinated Energy Drink, caffeine pills, and acetaminophen pills (placebo). Participants were college age volunteers randomly placed into 1 of the 4 conditions, and then administered the appropriated drug/drink. Participants filled out a screening questionnaire to assess recent caffeine (previous 4 hours) and typical caffeine consumption on an average day. Participant took the Stroop Test twice. A pre-test was given, and then again 40 minutes after consuming their drug. A 2x2x2 ANOVA and t-test were used for statistical analysis. The data suggest that caffeine leads to faster reaction

times regardless of condition, but showed the lowest accuracy in discrimination between congruent and non-congruent conditions. The Energy Drink conditions showed better discrimination between the congruent and non-congruent conditions. Taken together, this suggests that while caffeine speeds up processing, other ingredient of the energy drinks may help increase the accuracy of cognitive performance.

Title: Analysis of the trajectories of the neuronal population activity in the premotor cortex of Rhesus monkeys during a Synchronization-Continuation Task

Authors: J. GAMEZ, R. BARTOLO, *H. MERCHANT
Inst. de Neurobiologia UNAM, Queretaro, Mexico

Abstract: Time in the range of hundreds of milliseconds is the context in which different behavioral responses, such as target interception and speech recognition-production, are organized. The neural basis of temporal information processing is not well understood; although it has been proposed that time could be an emergent property of neural network dynamics. In the present work, we used Principal Component Analysis on the neuronal activity of extracellular recordings of the medial premotor cortex of monkeys performing a Synchronization-Continuation Task (SCT). In each trial of the task, the animals first synchronized their tapping with a metronome to produce 3 intervals, and then continued tapping for other 3 internally timed intervals, without the metronome. Five target intervals (450-1000 ms) were used. We found highly stereotyped trajectories that varied according to the target interval performed by the monkey. Moreover, the neural trajectories followed the scalar property increasing their variability for longer intervals. Using a neural-network based classifier; we found that

combinations of Principal Components contained information about the target interval, sequential order, and phase (synchronization or continuation) of the SCT task.

Title: Theta oscillations during processing of rapid frequency change differ between infants with a family history of Specific Language Impairment and controls

Authors: *N. A. CHOUDHURY[1,2], S. ORTIZ-MANTILLA[2], J. PARASCANDO[2], A. A. BENASICH[2]
[1]Ramapo Col., Mahwah, NJ; [2]Ctr. for Mol. and Behavioral Neurosci., Rutgers University, Newark, Newark, NJ

Abstract: The ability to perform fine-grained acoustic analysis in the tens of millisecond range during infancy is a robust predictor of language development and subsequent language disorders. However the basic neural mechanisms underlying infant processing of pre-linguistic auditory information remain unclear. In this study we examine the temporal dynamics of brain activity that may support rapid auditory processing abilities in a group of 6-month old infants at higher risk for language impairment as a function of family history of Specific Language Impairment (FH+, n=17) and control infants without such a history (FH-, n=20). An oddball paradigm to complex tone-pairs (standard:100-100 Hz, deviant:100-300 Hz [15%]) with 70ms between pair ISI was employed. Dense array EEG/ERP's were collected using a 62-channel EGI geodesic net. Co-registered, age-appropriate MRIs were used to model a two-dipole source solution for each individual at the largest positive peak representing sensory discrimination. Temporal-spectral analysis was conducted in source-space using a 2-50 Hz frequency band from -300 to 915 ms, with 1Hz wide frequency bins and time resolution of 50 ms. Changes in frequency band

amplitude as a function of time relative to stimulus presentation was evaluated using TSE (temporal spectral evolution). Permutation testing, in combination with data clustering analyses, confirmed that theta oscillations underlie evoked responses in the auditory cortices for both groups of infants and that there is a relative increase in power during processing of the deviant signal for both groups. However, there were significant group difference in theta power (5-8 Hz) between 300 and 550ms; infants in the FH+ group had attenuated theta oscillatory activity as compared to FH- infants, and showed atypical lateralization. While control infants showed enhanced theta activity in left cortical regions when processing rapid rate stimuli, FH+ infants showed attenuated activity in left as compared to right regions. Previous research has established the significance of left hemisphere activation to frequency change when processing rapid rate auditory stimuli, as well as highlighting the crucial role of processing rapid spectrotemporal change for efficient language acquisition. Thus, our findings confirm and extend differences reported in the neural substrates that underlie basic auditory detection and discrimination in infants at familial risk for language learning disorders when compared to infants without such risk.

Title: Saccadic eye movements during a bisection timing task

Authors: *A. TOSCANO ZAPIEN[1], D. DANIEL VELAZQUEZ-LOPEZ[2], D. VELAZQUEZ-MARTINEZ[1]
[1]Dept. de Psicofisiología, Facultad de Psicología., Univ. Nacional Autónoma De México, Mexico, D.F., Mexico; [2]Dept. de Matematicas, Facultad de Ciencias, Univ. Nacional Autónoma de México, Mexico, Mexico

Abstract: Timing refers to a wide range of behaviors that reveals the sensitivity of organisms to the duration of events on the range of seconds to minutes. Many species produced similar

behavioral patterns on a variety of timing procedures, revealing its adaptive significance. On a bisection task, first, subjects are trained to emit differential responses to a short or to a long stimulus; thereafter, subjects are confronted with intermediate durations. Several cognitive models assume that organisms uses a pacemaker to estimate durations and that the rate of the pacemaker is related to the bisection point (subjective equality between short and long stimuli), while the Weber Fraction and Limen is related to the sensitivity to the stimulus dimension and the attention paid to that dimension. In this study with human subjects, gaze variables (duration of fixations, pupil diameter, sequence of fixations, latency to fixation, latency of response, etc) were recorded while the subjects were trained in a bisection task (200 vs 800 msec) and then confronted intermediate durations of visual stimuli presented randomly at 5 locations on a screen. Data analysis included fixation to a stimulus by at least 100 msec and with a latency larger than 100 msec; with this criteria, two different populations emerged: subjects with a gaze that attempted to follow the location of the stimulus and a different population whose gaze remained in the center of the screen. Despite these differences, similar bisections point were obtained in the two populations but differences in Weber Fraction emerged; these differences may be related to the duration of fixations and to se sequence of fixations, revealing differences in the attentional mechanism used.

Abstract: Duration perception has been shown to be influenced by the sensory modality; for instance, for the same physical durations, auditory stimuli have often been reported to be perceived as longer and more accurately than visual stimuli (Penney, Gibbon, and Meck, 2000). This auditory dominance is even present when audio-visual durations are used (Burr, Banks, Morrone, 2009; Chen and Yeh, 2009). In the context of internal clock which integrates temporal pulses to provide an estimates of elapsed time, auditory dominance is believed to result from the enhanced pacemaker rate, something that could be reflected in a build up of sustained magnetic fields (Sieroka et al., 2003) . Alternatively, duration and accuracy of temporal performance could be reflected in a pre- and pos- interval neural dynamics (Mayo and Sommer, 2013). Given that the neural signatures of multisensory duration perception have been rarely investigated, we asked participants to discriminate subsecond intervals marked by Audio, Visual, and Audio-Visual stimuli. This study was also designed to address how expectancy of a certain modality can modulate duration perception and how this expectancy changes pre-interval dynamics. To this end, participants were cued with cues that were predictive of interval modality. We will demonstrate how interval modality and cue predicting interval modality impacts subjective timing. Moreover, the role of ramping activity (Wittman, 2013) and oscillatory dynamics in duration discrimination will be discussed (Kosem, Gramfort, and Van Wassenhove, 2014).

Title: Paced auditory stimuli with distinct characteristics affect differently the clock-like neural process?

Authors: *D. MINCIACCHI, E. QUARTA, E. J. COHEN, R. BRAVI
Dept. of Exptl. and Clin. Med., Univ. of Florence, Florence, Italy

Abstract: In millisecond timing research, two forms of timing are distinguished: event-based and emergent timing (Spencer and Ivry, Brain Cogn, 2005, 58, 84-93). The essential difference between the two timing modes is considered to be consisting in the involvement or noninvolment of a clock-like neural process, i.e., an abstract effector-independent representation of the time intervals to be produced (Wing and Kristofferson, Percept Psycholphys, 1973, 14: 5-12). The

character of movements in a rhythmic motor task is considered a key factor for eliciting a specific mode of timing. The class of discrete movements, defined as having a clear-cut beginning and end, shown to engage the involvement of clock-like neural process (Huys et al., 2008, PLoS Comput Biol, 4: e1000061.10.1371). Discrete movements are not the only ones favoring exploitation of the event-based timing. Recent studies have demonstrated that salient auditory markers, such as streams of clicks (Torre and Delignières, 2008, Biol Cyb, 99: 159-170) and tactile feedback (Studenka et al., 2012, Q J Exp Psychol 65, 1086-1100.10.1080), are also able to elicit the event-based timing. Here, we investigated whether simple and complex paced auditory stimuli, as streams of clicks and excerpts of music, influence differently the processes for temporal regulation. Particularly, we wanted to study if music, when compared with clicks, has a different power in encouraging the event-based timing. Also, since Zelaznik and Rosembaum (2010, J Exp Psychol H Percept Perfor, 36: 1565-1575) provided evidence that external auditory event representation of movement favors event-based timing, we decided to explore whether the recall of an auditory stimulus, where auditory imagery is involved and is simulating an internal auditory representation, might influence timing control processes. In order to answer to these questions, subjects have participated in a session in which sets of repeated isochronous wrist's flexion-extensions were performed under various auditory conditions and during their recall. Kinematics was recorded and temporal parameters were extracted and analyzed. Results indicate that streams of clicks and music do affect differently the timing processes, with music having only a minor role in provoking event-based timing, especially evident at high ranges of tempi. In addition, the auditory experience, constructed of components drawn from memory in the absence of direct sensory instigation of experience, favors the involvement of event-based timing.

Title: The role of perceptual and semantic processing on visually distracted time reproduction

Authors: *K. FOLTA
Univ. of Hildesheim, Hildesheim, Germany

Abstract: Question In humans, valence, temporal location and perceptual complexity of distracters have been demonstrated to modulate the perception and precise reproduction of physical time intervals in the seconds to minute range (interval timing). However, perceptually complex distracters might also be semantically more complex. This study aimed to further investigate whether perceptual and/or semantic complexity of distracters significantly contributed to the magnitude of distracter-induced temporal distortions. Methods Human participants were trained to a fixed target interval, before they reproduced the memorized duration in trials with and without presentation of distracting visual stimuli. Distracters varied according to their arousal, perceptual and semantic complexity, as well as their location within the to-be-timed interval. Possible effects of distracter-induced saccadic eye-movements were taken into account by complementing psychophysical measurements with high-speed eye-tracking recordings. Results In line with previous studies, we observed relatively large overproductions of the trained target duration, when distracters were presented near the end of the critical interval. In addition, a significant interaction between distracter characteristics of arousal and semantic complexity was observed. High arousing distracters induced longer time reproductions, when semantically complex (vs. less complex) distracters were presented, whereas low arousing distracters induced longer time reproductions in trials with presentation of semantically less complex distracters. However, no correlations between the number of saccades and the magnitude of temporal misperceptions had been observed. Conclusion Within an internal clock framework, our results can best be explained by a time- or resource-sharing mechanism that becomes modulated by the expectancy, arousal, and semantic complexity of visual distracters. The importance of our data will be discussed in the context of psychiatric disorders and involved symptoms of temporal misperceptions.

Abstract: Language acquisition relies on accurate neuronal representations of the rapid acoustic changes in the sounds we hear. Precise neuronal synchrony, and refinement of tonotopic and phonetic maps in the auditory system are fundamental to acquiring these representations. In support of this theory, previous data have shown that event-related potentials (ERPs) to rapid acoustic change can predict language outcomes from as early as 6 months-of-age. However, the hemispheric and temporal dynamics of development, and how auditory experience impacts the dynamic interplay are only beginning to be understood. To investigate this, we examined ERPs and source-localized brain activity to rapidly presented tone-pairs at 4 and 7 months in typically developing infants. Two groups were recruited: 1) The Active Experience (AEx) group received interactive auditory experience between 4 and 7 months, and 2) 7-month-olds who had no such experience (Naïves). EEG responses were recorded to frequency-invariant (STD) and frequency-variant (DEV) tone pairs in an oddball paradigm. Acoustic change in the tone-pair approximated formant transition timing in consonant-vowel phonemes during clear speech. Infants were fitted with an 128-sensor net, seated in the caregiver's lap, and entertained for the duration of the experiment. Individual ERPs were averaged offline (MATLAB) and submitted to mass univariate analyses in order to 1) compare current data to previous findings and 2) understand standard vs. deviant differences. ERPs showed no significant difference between STD and DEV responses at the first positive peak ("P1") and marked differences at the second negative peak ("N2*"). To investigate maturation and training effects, co-registered, age-appropriate brain templates were then used to model a two-dipole source solution (BESA, Inc.) for each individual ERP at P1 and N2* (N2 on the deviant wave). P1 and N2* peak values were submitted to significance testing with ANOVAS and t-tests (when appropriate). MATURATION: Shorter latencies and smaller amplitudes were seen bilaterally to sound onset (e.g. P1) and frequency change (N2*) as a function of age. TRAINING: AEx responses trended towards faster and more symmetric left/right activation to sound onset (P1). N2* latency was earlier than at 4 months and earlier on the right. AEx amplitude at N2* was smaller, compared to 4 months and to the Naïve 7-month counterparts. This implies a maturational increase in synchrony and decreased recruitment of neurons from 4-7 months and that auditory training at this age enhances neuronal synchrony to rapid frequency change, particularly in right auditory cortex.

Title: Effect of Transcranial Magnetic Stimulation on Long Range Temporal Correlations in the motor cortex of the human brain

Authors: *E. BLAGOVECHTCHENSKI[1], M. NAZAROVA[2], V. NIKULIN[2]
[1]Higher Sch. of Econ., Moscow, Russian Federation; [2]Natl. Res. Univ. "Higher Sch. of Economics", Moscow, Russian Federation

Abstract: Long Range Temporal Correlations (LRTC) is one of the methods for studying the processes associated with neurodynamics of the brain networks that is becoming more popular. As shown by the model , this method of analysis of electrical activity can show the ratio of excitation and inhibition in the study of neural populations. We applied this method of electroencephalogram (EEG) analysis in the primary motor cortex during and after TMS . TMS is not nature characteristic effects on the nervous system, so it is interesting to evaluate how such effects can shift the ratio of inhibition and excitation and how such changes permanent . Primary motor cortex was chosen because in this case we can compare the effects shown in LRTC and in evoked motor responses (EMR). Furthermore, we can estimate the duration of effects (LHTC and EMR). We applied different protocols of TMS : like single pulse and double pulse stimulation up to rTMS and theta TMS . We got significant differences in changes LRTC primary motor and premotor cortex. Depending on the protocol of TMS, we obtained various deviations. We have also discovered that the duration TMC effects not directly correlated with the effects evoked motor responses .

Title: Neural dynamics of perceptual narrowing for phonemes in infants

Authors: *S. C. ORTIZ-MANTILLA[1], J. A. HÄMÄLÄINEN[2], A. A. BENASICH[1]
[1]Rutgers The State Univ. of New Jersey, NEWARK, NJ; [2]Univ. of Jyväskylä, Jyväskylä, Finland

Abstract: During the first months of life, infants process phonemic elements from all languages similarly. This ability fades by 12 months-of-age as the brain constructs language-specific phonetic maps in acoustic cortex and as preference for the infant's native language increases. This ontogenetic process, known as perceptual narrowing, supports formation of specific neural representations and promotes more efficient processing of sensory information. To explore the oscillatory mechanisms underlying perceptual narrowing during early language acquisition, 6- and 12-month-old infants born into English monolingual families were presented with an oddball paradigm comprised of a native English and a non-native Spanish syllable contrast that varied in voice onset time. Dense array EEG/ERPs were collected with a 62-channel EGI sensor net and mapped onto age-appropriate brain templates. Source modeling placed dipoles for both conditions in right and left auditory and frontal cortices. Temporal-spectral analyses were conducted using a brain region montage consisting of 15 regional sources. The frequency range examined was 2-50 Hz at -300 to 930 ms, with 1Hz wide frequency bins and time resolution of 50 ms. Changes in frequency band amplitude, as a function of time relative to stimulus presentation, and consistency of phase alignment across trials were evaluated using TSE (temporal spectral evolution) and ITPL (inter-trial phase locking) measures. Permutation testing in combination with data clustering analyses followed by repeated measures ANOVA showed an age by stimulus interaction in the left posterior temporal region. At 6 months-of-age, a phase synchronization increase at 2-4Hz between 250 and 400 ms characterized infant's evoked responses to both, native and non-native syllable contrasts. In contrast, at 12 months-of-age, a decrease in ITPL was observed for non-native but not for native contrasts. It is assumed that phase synchronization would increase with age due to increasing myelination and more coherent neuronal connections (synaptogenesis and pruning). We found that in 12- as compared to 6-month-old infants, non-relevant sensory (phonemic) information does not induce increased phase synchronization in left auditory cortex. This suggests that changes in the magnitude of phase

synchronization may play a supporting role in the infant phonemic perceptual narrowing that favors processing of native over non-native syllable contrasts.

Title: Long-term recalibration of neural time lag in audiovisual temporal order judgment

Authors: ***S. YAMAMOTO**, K. MORI
AIST, Tsukuba, Japan

Abstract: The brain is able to determine the temporal order of multiple sensory signals; this is a key factor in reconstructing the external world. However, the existence of two types of time lag, physical (from the event to receptors) and neural (from receptors to a comparator, if any), makes temporal ordering theoretically indeterminate. One possible solution that may promote the adjustment of these time lags would be to take past experiences into account. When a single source of sound and light is located close to an individual, the final time lag at the comparator should be primarily due to neural lag. In this case, the final arrival time of the sound signal (relative to that of the light signal) should be earlier compared to the situation where the source is located far from the individual. Thus, we hypothesized that 1) the brain can adjust neural lag such that the final time lag at the comparator in the case that the arrival time of the sound signal (relative to that of light signal) would be the earliest is equal to the size of the neural lag, and that 2) this adjustment is slow and stable, because the neural lag is normally supposed to change only during development and aging. To test these hypotheses, we performed a multiple-day experiment in which subjects judged the temporal order of pairs of audiovisual stimuli (a white noise burst and a red light-emitting diode flash). Stimulus onset asynchronies (SOAs) were sampled from -220 (light-first) to +220 ms (sound-first) in 40 ms steps (mean = 0 ms). A single experimental session consisted of 72 trials; there were 12 sessions on each experimental day, and subjects were tested for a total of 8 days with an interval of less than 7 days. In the first session on the first day, the point of subjective simultaneity (PSS) was slightly biased towards the light-

first direction (mean: -13.3 ms), but it gradually shifted towards the sound-first direction within and across days. In the final session on the eighth day, the PSS was as large as 69.3 ms on average. Furthermore, when subjects attended 1-day sessions using the same protocol more than 1 month after the eighth day, the PSS remained as large as that on the eighth day. Taken together, these results support our hypotheses, that is, neural lag was adjusted by taking long-term past experiences into consideration. This slow change in subjective temporal order with retention was termed "zero-adjustment". The zero-adjustment may contribute to a reconstruction of the temporal structure of the external world together with another type of quick and flexible temporal recalibration (lag adaptation), which is considered to facilitate the adjustment of the physical lags.

Title: A comparison of the effects of different pharmacological stressor and restraint stress on effort-based decision-making

Authors: C. A. BRYCE[1], *S. B. FLORESCO[2]
[1]Psychology, [2]Univ. British Columbia, Vancouver, BC, Canada

Abstract: Decision-making involves choosing between several alternative possibilities after evaluation of the relative costs and benefits. Increasing the amount of effort required to obtain a reward is one type of cost that can diminish the subjective value of objectively larger rewards. Repeated episodes of stress can result in depressive symptoms including anergia, which may reduce the tendency to exert effort to obtain rewards. The goal of the present study was to compare the effects of restraint stress to different types of pharmacological stressors on effort-based decision-making. Using an operant chamber assay, rats were required to choose between a low effort/low reward lever (LR; 2 pellets), and a high effort/high reward lever (HR; 4 pellets), with the effort requirement increasing over trial blocks (2, 5, 10 and 20 presses). Acute restraint stress, but not injection of corticosterone, causes rats to choose the HR option less compared to

baseline performance. In a subsequent study, we assessed the effects of the alpha 2 adrenoreceptor antagonist yohimbine (1-3 mg/kg, IP), which mimics increased noradrenaline transmission induced by acute stress. Contrary to our expectation, yohimbine increased preference for the HR option compared to vehicle treatment. This suggests that yohimbine and restraint stress produce divergent effects on some decision-making tasks, highlighting the fact that different types of stressors can induce opposing effects on behavior. However, in a second experiment, we assessed how effort-related choice may be affected by increased corticotropin-releasing factor (CRF), a stress hormone and centrally acting excitatory neurotransmitter, as CRF is known to induce anxiolytic behavior in certain assays. Indeed, we found that microinfusions of CRF (3 ug/ul ICV) decreased HR choice and increased response latency, mimicking the behavioral profile of restraint stress on effort-related choice behavior. This identifies CRF as a potential mediator of restraint stress on decision-making ability. Whether blockade of CRF transmission will ameliorate the effects of restraint stress on effort discounting is a topic for future research.

Title: Prefrontal GABAA receptor regulation of working memory assessed with a delayed non-match to position task

Authors: *M. AUGER, S. B. FLORESCO
Dept Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Perturbations in prefrontal GABA function are thought to contribute to the cognitive symptomatology of schizophrenia. However, there has been surprisingly few studies assessing the role of GABA in cognitive functions carried out by the frontal lobes. Recent work from our group has shown that blockade of prefrontal GABA receptors leads to a constellation of cognitive abnormalities that resemble those observed in schizophrenia. However, intra-PFC infusions of a GABAA antagonist did not impair working memory accuracy assessed with a

delayed-response version of a radial arm maze task. Notably, performance on this task was self-paced, while cognitive tasks used with patients often present multiple trials in quick succession, placing higher demands on attention. As such, the goal of this study was to assess the contribution of prefrontal GABA signaling to working memory in these conditions. Male Long Evans rats were trained in a delayed non-match to position task. The task consists of a sample phase in which one of two levers is extended, and a choice phase that requires the selection of the opposite lever, separated by a variable delay (1-24 s). Well-trained rats received counter-balanced intra-medial PFC infusions of saline or the GABAA antagonist, bicuculline (50 ng). Prefrontal GABA receptor blockade induced a delay-independent impairment in performance. While this effect was significant, the magnitude of the impairment was relatively small in comparison to effects induced by prefrontal GABA blockade in forms of cognition, such as cognitive flexibility or spatial reference memory. As such we are currently assessing the contribution of other transmitter systems relevant to schizophrenia to the performance of the delayed non-match to position task, including NMDA GluN2B mediated glutamate transmission. These findings indicate that prefrontal GABA transmission plays a role in working memory processes executed by the frontal lobes, and diminished PFC GABA function can lead to cognitive abnormalities relevant to schizophrenia.

Title: Alterations in probabilistic learning, testosterone and the prefrontal cortex during aging

Authors: R. J. TOMM, C. Q. MA, M. T. TSE, M. M. GRIST, S. B. FLORESCO, *K. K. SOMA
Univ. British Columbia, Vancouver, BC, Canada

Abstract: During aging, changes in the mesocorticolimbic dopamine system may lead to impairments in decision making and executive function. In addition, circulating levels of testosterone (T) decrease during aging, and T regulates dopamine synthesis and/or action in the ventral tegmental area (VTA), nucleus accumbens (NAc) and prefrontal cortex (PFC). In the present study, we used a rat model and compared young adult (3-5 months) and aged (20-22 months) male rats (Fischer 344/Brown Norway hybrid). To measure cognitive flexibility, we used a probabilistic reversal task. Rats were trained to choose between a correct lever (80% probability of food reward) and an incorrect lever (20% probability of food reward). After 8 consecutive correct choices, the contingencies of the correct and incorrect levers were switched, and this continued over the 200 trials of a daily session. Rats were trained on the task for 16 days. Over the last 5 days of training, when performance was asymptotic, aged rats showed increased win-stay behavior, relative to young adults (i.e., selecting the correct lever after a rewarded correct choice on the previous trial). Aged rats also showed increased lose-shift behavior (i.e., selecting the incorrect lever after a non-rewarded correct choice). Thus, aged rats displayed an increased sensitivity to both rewards and negative feedback, and instead of using a longer-term representation of action-reward history, they were driven by more immediate feedback. The increase in reward sensitivity suggests impaired medial PFC functioning. Furthermore, there was a significant decrease in circulating T levels in aged rats. Testosterone may modulate the PFC via either dopaminergic projections from the VTA or androgen receptors in the PFC. Presently, we are measuring tyrosine hydroxylase immunoreactivity in the PFC and VTA of these subjects. These data will further our understanding of the neurochemical mechanisms that underlie cognitive changes during aging.

Title: Predictive validity of the neurokinin-1 knockout mouse model of ADHD

Authors: *K. PILLIDGE[1], A. PORTER[1], Y.-C. TSAI[1], T. VASILI[1], D. HEAL[2], C. STANFORD[1]
[1]Univ. Col. London, UCL, London, United Kingdom; [2]RenaSci Ltd, Nottingham, United Kingdom

Abstract: Attention Deficit Hyperactivity Disorder (ADHD) is a heterogeneous psychiatric disorder which presents as different subtypes according to the primary characteristic (i.e. predominantly hyperactive/impulsive or inattentive). The disorder is highly heritable; recent evidence suggests that four single-nucleotide polymorphisms within the tachykinin1 (TACR1) gene are associated with ADHD (Sharp et al., 2009, Neuropharmacology, 57:590-600). Mice with functional ablation of the murine equivalent of the TACR1 gene, neurokinin 1 (NK1R-/-), display locomotor hyperactivity, impulsivity and inattentiveness. Moreover, the psychostimulant treatments for ADHD (d amphetamine and methylphenidate) paradoxically alleviate the hyperactivity of this mouse. However, d amphetamine does not alleviate the inattention/impulsivity displayed by these mice in the 5 Choice Serial Reaction-Time Task (5 CSRTT). Our aim in these experiments was to further validate the NK1R-/- mouse in preclinical studies of ADHD-like behaviour. We tested non-stimulant treatments (atomoxetine; a preferential noradrenaline reuptake inhibitor and guanfacine; an alpha2A-adrenoceptor agonist) in wildtype and NK1R-/- mice in the 5-CSRTT. Wildtype and NK1R-/- mice were trained to perform the 5-CSRTT as previously described (Yan et al., 2011, PLoS One, 6, e17586). Separate cohorts of mice were tested with either atomoxetine (1, 3 and 10mg/kg) or guanfacine (0.1, 0.3 and 1mg/kg). Mice were tested once weekly, using a variable inter-trial interval (VITI) after reaching the criteria for a stable baseline of performance. Each treatment was given to each mouse once, 30 min before testing and treatments were assigned in counterbalanced order. Behaviour specific, and genotype dependent, effects were found: guanfacine (0.1mg/kg) improved attention in NK1R-/- mice only, but caused a non-specific blunting of behaviour, which reduced impulsivity, at a high dose (1mg/kg). This resembles the clinical profile of guanfacine in ADHD. Atomoxetine (10mg/kg) selectively reduced impulsivity in NK1R-/- mice only, without affecting attention, and thus may be a preferential treatment for the predominantly hyperactive/impulsive subtype of ADHD. The results further validate the use of NK1R-/- mice to study ADHD-like behaviour expressed by patients with TACR1 polymorphisms.

Title: The brain renin angiotensin system influences the locomotor hyperactivity and impulsivity of neurokinin-1 receptor 'knockout' mice

Authors: *A. J. PORTER[1], K. PILLIDGE[2], T. VASILI[2], C. STANFORD[2]
[1]Neuroscience, Physiol. and Pharmacol., [2]Univ. Col. London, London, United Kingdom

Abstract: Mice with functional ablation of the substance P-preferring neurokinin-1 receptor gene (NK1R-/-) display behavioural abnormalities that resemble Attention-Deficit Hyperactivity Disorder (ADHD), namely: hyperactivity, impulsivity and inattentiveness (Yan et al., 2011, PloS ONE, 6:e17586). The brain renin angiotensin system (BRAS) influences both motor activity and cognition (see: Wright et al., 2008, JRAAS, 9(4):226). Angiotensin converting enzyme (ACE) hydrolyzes substance P (Yokosawa et al. 1985, J Biochem, 98:1293), and there is a striking overlap between the distribution of substance P and angiotensin binding sites in the brain (Diz et al., 1986, J Hypertens Suppl., 4:S468). Here, we tested the effects of the ACE inhibitor, captopril, and the angiotensin receptor (ATR) antagonists, losartan (ATR1) and PD123319 (ATR2), on the locomotor hyperactivity, impulsivity, and inattentiveness of NK1R-/- mice using the light/dark exploration box (LDEB) and 5-Choice Serial Reaction Time Task (5-CSRTT). In the LDEB, following 90 min habituation to a 'dark zone', animals were transferred to a 'light zone' and their free movement across both zones recorded for 30 min. During habituation, animals received an i.p. injection of (dose; time before recording): vehicle (saline; 30 min), captopril (10 and 25 mg/kg; 30 min), losartan (10 and 25 mg/kg; 60 min), or PD123319 (1 and 3 mg/kg; 30 min). In the 5-CSRTT, a separate batch of animals was trained to baseline performance criteria and tested, once weekly, using both a variable intertrial interval (2, 5, 10 and 15 s) and a long intertrial interval (10 s). In both tests, animals received either no injection or an i.p. injection of vehicle or captopril (5, 10 and 25 mg/kg). Every animal experienced each drug treatment once for each test, in a counterbalanced sequence. Data were analysed using either single-measures (LDEB) or repeated measures (5-CSRTT) ANOVA, with post hoc (LSD) pairwise comparisons. Captopril reduced the locomotor hyperactivity of NK1R-/- mice in the LDEB (10 and 25 mg/kg: $P<0.05$ and $P<0.001$) and reduced their impulsivity in the 5-CSRTT (10 mg/kg: $P<0.05$), but did not affect the wildtypes in either test. By contrast, both ATR antagonists caused an apparent increase in locomotor activity in NK1R-/- mice. These findings point to an interaction between ACE activity in the BRAS and activation of NK1R that regulates motor activity and impulsivity. The possibility that ACE inhibitors provide a novel therapeutic treatment for ADHD (particularly the Predominantly Hyperactive/Impulsive subtype) warrants further investigation.

Title: Chemotherapy reduces locomotor activity, impairs working and spatial memory and decreases BDNF, but does not affect anxiety or visual memory

Authors: *D. WOO[1], C. RICHARDSON[2], C. STREET[3], K. URIBE[2], M. QADRI[3], N. TALUKDER[3], G. DEJESUS[3], S. PEREZ[4], T. AHLES[5], K. HUBBARD[2], K. Y. SALAS-RAMIREZ[3]

Abstract: Breast cancer is the most common cancer among women impacting over 100,000 women a year and has the second highest mortality rates among the cancers women suffer. A growing body of work has shown that chemotherapy can have profound cognitive effects on patients up to ten years after exposure, specifically on memory function and executive function. This study aimed to determine whether chemotherapeutic agents, commonly used in breast cancer, results in cognitive impairments. Forty Sprague Dawley female rats, half intact and half overiectomized (OVX), were treated intravenously with either saline or a combination of cyclophosphamide (40mg/kg) and doxorubicin (4 mg/kg) once a week for three weeks. One week after the last chemo treatment, all subjects were tested for anxiety (elevated plus maze), locomotor activity (open field), working (y-maze), visual (object recognition) and spatial (object placement) memory. After all behavioral assessments were performed, animals were decapitated and trunk blood was collected. Although anxiety and visual memory remained intact,

chemotherapy significantly decreased locomotor activity. More significantly, it decreased working memory and spatial memory in female rats, independent of their hormonal status. In addition, we determined that brain derived neurotrophic factor in the blood plasma was significantly decreased by treatment. The cognitive deficits observed are hippocampal dependent, hence confirming other findings that cyclophosphamide and doxorubicin impact synaptic plasticity molecules that regulate learning and memory function. Further studies will focus on understanding additional aspects of neural plasticity that can be affected by chemotherapy that could result in cognitive deficits. We hypothesize that chemotherapy reduces neurogenesis and synaptic communication of hippocampal neurons resulting in cognitive dysfunction.

Title: Amygdalar pathways target excitatory and distinct inhibitory mechanisms in mnemonic cortices of the primate medial temporal lobe

Authors: *J. G. BUNCE, H. BARBAS
Neural Systems Lab., Boston Univ., Boston, MA

Abstract: Signals of affective value from the amygdala play a prominent role in the neural processes underlying learning and memory. The recent confirmation that amnesic patient H.M. had severe damage to the amygdala while much of his hippocampus was spared, has refocused attention on the interaction between the amygdala and other mnemonic structures in the medial temporal lobe. Information flow to and from the hippocampus is gated by the rhinal cortices (areas 28 and 35) and is largely segregated by layers. The upper layers direct projections to the hippocampus while the deep layers receive hippocampal output. Signals arriving in the rhinal cortices must overcome the "wall of inhibition" to propagate to and from the hippocampus, though the anatomical substrate is unclear. Here we examined the organization and features of the amygdalar pathway to excitatory and inhibitory post-synaptic targets in entorhinal (area 28) and perirhinal (area 35) cortices in the rhesus monkey (N=5) using anterograde tracers and standard immunohistochemistry techniques. We mapped and measured the distribution of amygdalar bouton terminals and their interaction with neurochemical classes of inhibitory post-synaptic targets labeled for parvalbumin (PV), calbindin (CB), and calretinin (CR). Analysis using unbiased stereological techniques, showed that the amygdalar pathway to area 28 was most dense in the upper layers (68.6%) compared to the deep layers (31.4%). In contrast, amygdalar terminations in area 35 were more evenly distributed in the upper (51.8%) and deep (48.2%) layers. We measured the size of amygdalar bouton terminals in areas 28 and 35 and used a k-means cluster analysis to classify them into large and small populations based on a criterion threshold of 1.2 μm for area 28 and 1.1 μm for area 35. Amygdalar projections to both the upper and deep layers of areas 28 and 35 terminated in small and large boutons with a ratio that exceeded 3:2. Confocal analysis at the fluorescence microscope of neurochemically distinct inhibitory post-synaptic targets showed that the amygdalar pathway was preferentially in apposition with CR (5.5%) neurons in the upper layers and PV (3.8%) neurons in the deep layers of area 28. In area 35, amygdalar boutons were in apposition most frequently with PV (4.8%) inhibitory neurons in the upper layers and CR (3.8%) inhibitory neurons in the deep layers. These findings suggest that the amygdala is positioned to transfer affective information to memory related rhinal cortices that may overcome the rhinal "wall of inhibition" via interactions with mostly excitatory post-synaptic targets as well as CR inhibitory neurons which disinhibit the local network.

Title: Context and emotion: Computational modeling of interactions between hippocampus and amygdala

Authors: *Y. J. JOHN[1], D. BULLOCK[2], J. G. BUNCE[1], B. ZIKOPOULOS[1], H. BARBAS[1]
[1]Neural Systems Lab., [2]Psychological and Brain Sci., Boston Univ., Boston, MA

Abstract: An important function of cognitive-emotional interactions is to allow an organism to discern the affective values of perceived cues or contexts. The emotional value of recognized cues or contexts can then be used to adjust decisions and behavior. Contextual learning, which is distinct from focal cue learning, allows assignment of affective value to a context or a spatial location. For example, animals exposed to an aversive stimulus such as footshock in a particular context form an association which leads them to respond fearfully when reintroduced to that context. Experimental data indicate that the hippocampus is required for the spatial and contextual aspects of such learning, and that the amygdala is required for the affective associations as well as the expression of fearful behavior. Further evidence suggests that the role of the hippocampus in emotion extends beyond spatial processing: it has been implicated in stress, anxiety and depression. Uncovering the precise role of the hippocampus in emotion requires understanding its interactions with the amygdala. The network that links the hippocampus and the amygdala may serve as a basis for the formation of an “emotional space”. In such a space, external contextual information becomes labeled or “colored” according to affective significance. Our computational model of interactions between the hippocampal formation and amygdala explicates network features that enable learned associations of contexts with appetitive or aversive events. Simulations also distinguish mechanisms by which dysfunctions in the hippocampus-amygdala network can lead to mislabeling or overgeneralization of emotional contexts. This insensitivity or overgeneralization may become manifest as an emotional disorder. For instance, some forms of depression may involve an inability to distinguish between aversive, neutral and positive contexts. Similarly, post-traumatic stress disorder (PTSD) may involve a form of overgeneralization that leads to the conflation of a neutral or pleasant context with that of a previously experienced traumatic episode. Our computational model can help generate hypotheses regarding the origins of such disorders and may point to possible treatment strategies.

Title: Common architecture of subgenual anterior cingulate cortices and white matter pathways in human and non-human primates

Authors: *B. ZIKOPOULOS, M. Á. GARCÍA-CABEZAS, H. BARBAS
Boston Univ., Boston, MA

Abstract: Anterior cingulate cortices and in particular areas 25 and 32, ventral to the genu of the corpus callosum (referred to as sgACC), are consistently affected in various neuropsychiatric and neurodevelopmental disorders, including depression, schizophrenia, and autism. Diverse, but often discordant, findings correlate structural changes in the grey matter volume, cellular content, and integrity of underlying white matter pathways of sgACC with hyper- or hypo-activity of this frontal region in diverse diseases. This makes it hard to discern patterns of systematic variation in key anatomical/molecular substrates that can predict normal or abnormal connectivity and function. To address this issue, we examined and compared the laminar density and morphology of neurons, glia, and myelinated axons in the grey and white matter of sgACC from post-mortem normal adult human and rhesus monkey brains at very high resolution. Our goal was to establish a framework that can be used to integrate and correlate functional/neuropathological data from human studies with fine details of pathway connectivity from primate studies. The features and organization of the grey and white matter were similar in both primate species. Although both areas are dysgranular, individual layers in area 32 were overall better delineated than in area 25. The density of neurons was higher in area 25, especially

in the middle/deep layers, but the density of glia was similar throughout sgACC, with a tendency for fewer oligodendrocytes in area 25, leading to a significantly lower glia to neuron ratio. Levels of myelinated axons, which were mostly small and medium in diameter, were moderate in layer 1, dropped in the other layers, and got progressively higher through the transition from layers 5-6 to the white matter, where axons made up about 40% of the volume, with the rest of the space occupied by glia. Interestingly, area 25 had overall the lowest levels of myelin and myelinated axons within sgACC, especially in the middle/deep layers of the cortex and the superficial white matter. Our findings highlight key loci in the primary output layers (middle/deep) of sgACC, and the superficial white matter below, which contains mostly short/medium-range pathways, connecting these areas with their neighbors. In these loci, we pinpoint differences in: a) glia/neuron ratio and b) myelin content that may underlie, on one hand, the remarkable potential of these limbic cortices for plasticity and, on the other hand, their disproportionate vulnerability in disease.

Title: A novel pathway from the anterior cingulate to the premotor cortex may link cognitive control and movement

Authors: O. K. SWANSON, *M. GARCIA-CABEZAS, H. BARBAS
Hlth. Sci. (Neural Systems Lab), Sargent College, Boston Univ., Boston, MA

Abstract: The prefrontal cortex has a key role in flexible behavior and decision for purposeful movement, yet the circuits linking this cortex and effector motor areas are understudied. Within the prefrontal cortex, the anterior cingulate cortex (ACC) is a unique node for cognitive processing: the ACC has strong and widespread connections with other prefrontal areas, such as dorsolateral areas 9 and 46, and is activated during tasks involving high cognitive load, including

those that demand selective attention or elicit response conflict. To determine whether the ACC directly influences motor areas, we mapped pathways after injection of neural tracers into ACC area 32 in rhesus monkeys. We found a novel pathway from ACC area 32 that terminates across all layers of dorsorostral area 6 (6DR) of the premotor cortex. A majority of axon boutons from ACC area 32 formed synapses with spines of excitatory neurons in area 6DR; only approximately 10% of the total number of boutons formed synapses with neurochemically and functionally specialized classes of inhibitory interneurons. Area 6DR is distinguished from other premotor cortices by having fewer direct spinal projections and more widespread connections with lateral prefrontal areas associated with cognitive processes. We found that the same sites of area 32 that project to area 6DR also receive pathways from lateral prefrontal areas 46 and 9. This evidence suggests that serial pathways from the lateral prefrontal cortex influence ACC area 32, which has a role in attention and a direct output to the premotor cortex. These connections, together with projections to other motor cortices, place area 6DR in an ideal position to interface between areas associated with cognition and motor control. The novel pathway that links ACC area 32 and premotor area 6DR provides a circuit through which the prefrontal cortex may mediate decision for movement in goal-directed behavior.

Title: Effects of ventral medial-prefrontal-cortex NMDAR-NR1 subunit deletion on a spatial reference memory radial maze task in adult mice

Authors: R. M. WESTON[1], *M. J. MANA[1], A. M. SCHILLER[1], T. V. NGUYEN[1], M. M. GORHAM[1], R. F. KYDD[1], R. W. GREENE[2], J. M. FINLAY[1]

Abstract: Dysfunction of glutamate *N*-methyl-D-aspartate (NMDA) receptors may contribute to cognitive deficits in schizophrenia. In the present study, we examined the effects of chronic NMDA receptor dysfunction in the ventral medial prefrontal cortex (VmPFC) on acquisition of a spatial reference memory radial maze (SRM) task as employed by Niewoehner et al. (2007). Localized NR1 gene deletions were induced in the VmPFC of floxed NR1 mice (DEL, n=10) using an AAV-Cre vector; Control mice (CON, n=10) received sham deletions. In the SRM task, food was placed in 3 arms of a 6-arm radial maze at the start of each trial; the location of the food was consistent for each mouse across all trials, but randomly varied between mice. At the start of each trial, each mouse was placed in the central chamber of the maze and allowed to enter any of the 6 arms; once an arm was visited and a mouse returned to the central chamber, the entrance to each of the 6 arms was blocked for 10 sec. At the end of each 10 sec timeout, the arms that had not yet been visited during the trial were made accessible and a mouse could choose to enter one of the remaining unvisited arms. Thus, this task only assessed reference memory errors (RME); that is, entries to arms that were never baited. Mice were tested in 4 trials/each daily session. We found that NMDA receptor dysfunction in the VmPFC had no effect on acquisition of the SRM task. There were no differences in behavior observed in the first session (mean arms visited, DEL = 5.3 arms and CON = 5.2 arms; mean baited arms visited DEL and CON = 3.0; mean unbaited arms visited, DEL = 2.3 arms and CON = 2.2 arms). Mice in both the groups acquired the SRM task over 24 sessions (mean arms visited, DEL = 3.5 arms and CON = 3.6 arms; mean baited arms visited DEL and CON = 3.0; mean unbaited arms visited (that is, RME), DEL = 0.5 errors and CON = 0.6 errors). After the 24-session Acquisition Phase, we rotated the extra-maze spatial cues to confirm the use of such cues in SRM performance by both groups (mean RME during the Rotation session, DEL and CON = 1.8 errors). The lack of significant between-group differences in the SRM task in our study contrasts with recent reports that $Grin^{1DGCA1}$ mice with NMDA receptor deletions in the dentate and CA1 regions of the hippocampus show impaired acquisition in this task (Bannerman et al., 2013), reflecting different contributions of the VmPFC and hippocampus in the task. Given the well-known contribution of the PFC to working memory, we are currently assessing PFC NR1-deleted mice in a working memory variant of this task.

Title: Effects of ventral medial prefrontal cortex NMDAR-NR1 subunit deletion on attention and response inhibition in adult mice

Authors: H. G. MANNING[1], M. A. MAYNES[1], R. K. FLYNN[1], R. M. WESTON[1], R. W. GREENE[2], *J. M. FINLAY[1]
[1]Psychology Dept., Western Washington Univ., Bellingham, WA; [2]Psychiatry, UTSW & Dallas VAMC, Dallas, TX

Abstract: Dysfunction of prefrontal cortex (PFC) glutamate N-methyl-D-aspartate receptors (NMDARs) is implicated in cognitive impairments associated with schizophrenia. NMDAR antagonists administered directly into the medial PFC (mPFC) of adult rats have been found to impair cognitive processes involved in both attention and response inhibition. Recent work in our lab indicates that chronic NMDAR-NR1 subunit deletion in the mouse dorsal mPFC, while not affecting attention, results in deficits in response inhibition that are manifest as increased compulsive behavior. We have now extended this work to examine the effects of chronic NMDAR-NR1 deletion in the mouse ventral mPFC on attention and response inhibition. NMDAR-NR1 dysfunction was induced on postnatal day 70 by bilateral infusions of adeno-associated virus Cre-recombinase into the ventral mPFC of targeted knock-in mice with loxP sites flanking exons 11-22 of the NR1 gene. Attention and inhibitory response control were assessed using a 5-choice serial reaction time task (5CSRTT) in which mice exhibit a nosepoke in response to a brief, random illumination of one of five apertures. Premature responses, responses occurring during an intertrial interval (ITI), and perseverative responses, multiple responses to a single stimulus, were assessed as measures of inhibitory response control. Baseline conditions consisted of a 0.8 s stimulus duration (SD) and a 5.0 s ITI. On baseline trials, deleted and control mice exhibited comparable accuracy (all data are represented as mean ± SEM; 90 ± 1.6% and 88 ± 1.4%, respectively), premature responses (1.5 ± 0.4 and 1.6 ± 0.3), and perseverative responses (13.1 ± 1.7 and 11.8 ± 1.5). Upon acquisition of baseline responding, we examined whether differences between deleted and control mice would emerge under conditions of increased demand, achieved by testing under shorter and longer ITIs, reduced SD and stimulus intensity, and white noise. In a test session consisting of variable longer ITIs (randomly presented 5, 6, 7, and 8 s ITIs), control mice exhibited progressively more premature responding as the ITI increased such that premature responding increased from 0.3 ± 0.1 response during a 5 s ITI to 3.8 ± 0.9 responses during an 8 s ITI. This effect was exacerbated in deleted mice, with this group exhibiting premature responding of 0.4 ± 0.2 responses during a 5 s ITI and 5.1 ± 1.1 responses during an 8 s ITI. Together with our previous

study, these findings suggest that the NMDARs in the dorsal mPFC play a role in inhibition of compulsive behavior whereas those in the ventral mPFC play a role in inhibition of impulsive behavior.

Title: The neurosteroid pregnenolone sulfate interacts with the NMDA receptor antagonist MK-801 to impair cognitive flexibility and spatial working memory in a rat model of schizophrenia

Authors: *M. R. STEFANI, J. K. GEHRMANN, E. D. H. BARNARD, D. M. PRIOR
Psychology, Middlebury Col., MIDDLEBURY, VT

Abstract: Schizophrenia is a chronic disorder characterized by debilitating cognitive impairments. Most affected are the 'executive functions' crucial for the temporal organization of goal-directed behaviors. These cognitive abilities, which include working memory and cognitive flexibility, require brain networks that share as a common node the prefrontal cortex (PFC). Recent research has linked these cognitive deficits to reduced PFC inhibitory signaling by the neurotransmitter GABA, leading to the hypothesis that reduced inhibitory regulation of glutamatergic principle neurons results in disorganized information processing and cognitive impairments. We used male Sprague-Dawley rats to examine the cognitive effects of pregnenolone sulfate, a neurosteroid that modulates GABA-A receptors to reduce GABA-mediated inhibition, and MK-801, an NMDA glutamate receptor antagonist commonly used to induce schizophrenia-like cognitive deficits in rodents. MK-801 is believed to act, in part, through inhibitory actions on GABA neurons. Rats were tested for extradimensional (ED) set-shifting ability, a measure of cognitive flexibility, and spontaneous alternation behavior (SAB), a measure of spatial working memory. Rats received bilateral intra-medial PFC injections (0.5

uL/hemisphere) 20 min prior to the ED shift phase of the set-shift task or the single SAB session. Injections consisted of a vehicle solution, MK-801 (0.3 or 3 μg/hemisphere), or pregnenolone sulfate (0.05, 0.5 or 5.0 ng/hemisphere), alone or in select combinations. We observed that MK-801 alone at 3.0 ug but not 0.3 ug impaired cognitive performance relative to vehicle-injected controls, in the set-shift task by increasing the trials required to reach a learning criterion and increasing the amount of perseverative responding to the first discrimination rule learned, and in the SAB task by decreasing the percent alternation score. Pregnenolone sulfate also dose-dependently impaired task performance. In the set-shift task, the highest dose of pregnenolone sulfate produced significant impairments; in the SAB task, the intermediate dose significantly impaired. Co-administration of individually ineffective doses of MK-801 and pregnenolone sulfate impaired task performance relative to vehicle-injected controls in the set-shift task. This pattern of results, in which two neuromodulatory compounds known to act by decreasing GABA-mediated inhibitory tone interact to produce performance deficits on behavior tasks dependent on prefrontal function, provide further support for the hypothesis that aberrant GABAergic signaling underlies schizophrenia-associated cognitive deficits.

Title: Cerebellar pathology influences cerebellar-nucleus accumbens and striatum pathways in modulating dopamine release: Relevance to Autism-related behavioral disorders

Authors: E. MCKIMM[1], D. M. COOMES[1], M. A. CALTON[1], D. GOLDOWITZ[2], G. MITTLEMAN[1], *C. D. BLAHA[1]
[1]Dept. of Psychology, Univ. of Memphis, MEMPHIS, TN; [2]Dept. of Med. Genet., Ctr. for Mol. Med. and Therapeut., Vancouver, BC, Canada

Abstract: Autism is characterized by at least two neural abnormalities: cerebellar pathology that includes Purkinje cell loss or functional dysregulation as well as compensatory changes in

prefrontal cortex (PFC) dopamine (DA) transmission. The inter-relationship between these two abnormalities is unknown. However, we have previously shown that PFC DA release evoked by electrical stimulation of the deep cerebellar dentate nucleus (DN) is attenuated in Lurcher (Lc) mutant mice lacking Purkinje cells (Mittleman et al. 2008). A similar attenuation in DN stimulation-evoked PFC DA release was also observed in Fragile X (Fmr1) mutant mice showing cerebellar neuropathology involving Purkinje cells. Our previous research has also shown disruptions in both the cerebello-thalmocortical and cerebello-ventral tegmental pathways in Lc mutant mice mediating both PFC DA (Rogers et al. 2011) and glutamate (McKimm et al. 2013) release. Pastura et al. (2011) and Vaidya (2012), have also shown that decreased volume in the cerebellum influences the striatum and nucleus accumbens (NAc). Here we explore the potential influence that cerebellar neuropathological abnormalities have on DA release in both the NAc as well as the dorsal striatum, while stimulating the DN. We used fixed potential amperometry in combination with carbon fiber electrodes in urethane anesthetized (1.5g/kg i.p.) wildtype Fmr1 mice. We stimulated the DN (50 pulses; 50 Hz every 60 sec) and recorded NAc and striatal DA release. Results indicated that there were comparable levels of stimulation-evoked DA in both the NAc and striatum (60 and 40 nM), respectively. Further exploration of the current research is expected to show similar deficits in DA release in Lc and Fmr1 mutant mice compared to their corresponding wildtype strains, as seen in previous research involving strains with cerebellar neuropathological abnormalities. These studies indicate an influence of the cerebellum on NAc and striatal DA transmission. In addition to cognitive and social deficits, autism patients also show motor and reward deficits. Given the well-known involvement of the striatum and NAc in, respectively, motor function and reward, these results certainly suggest that developmental cerebellar neuropathology could also result in deficits in these abilities.

Title: Does lack of CaMKII autophosphorylation model a neuropsychiatric disorder?

Authors: *K. MIZUNO, K. GIESE
Kings Col. London, London, United Kingdom

Abstract: Neuropsychiatric disorders, such as autism and schizophrenia, are accompanied by spine abnormalities and behavioural abnormalities including deficits in social interaction, impaired communication abilities, and ritualistic-like repetitive behaviors. The alpha-isoform of Ca2+/calmodulin-dependent protein kinase II (CaMKIIα) is a major synaptic kinase, which is expressed exclusively in glutamatergic neurons. Upon activation via the NMDA receptor CaMKIIα autophosphorylates at T286, which prolongs CaMKII activity for about one minute after the Ca2+ stimulus has declined to baseline. Additionally, the T286 autophosphorylation may alter the interaction of CaMKIIα with other proteins in the post-synaptic density. The T286 autophosphorylation is fundamentally important for the induction of NMDA receptor-dependent synaptic potentiation (with the exception of LTP in dentate gyrus) and memory formation, as demonstrated with T286A mutant mice (targeted point mutants where T286 is changed to A286, which cannot be phosphorylated). T286A mutants also have aberrant dendritic branching and sensory inputs at least in spinal cord (Pattinson at al., MCN 33, 88-95, 2006). Therefore, T286A mutant line could be an animal model of neuropsychiatric disorders. Since mouse models of neuropsychiatric disorders are characterized by disruptions in social and repetitive behaviors, we studied behaviors of T286A mutants in such tasks. T286A mutants displayed significantly less repetitive digging behavior in the marble-burying test compared with wild-type littermate controls. The impairment was age- and sex-dependent. T286A males, but not females, were impaired at 6 months of age. However, T286A females were also impaired at 12 months of age. Sociability and preference for social novelty, using the three-chamber paradigm, did not differ between T286A mutants and wild-type littermates at 6 months of age. However, in the buried food test T286A mutants differed from wild-type littermates. The latency to find the food was longer in T286A mutants. Therefore, the mutants appeared less motivated than the wild-type mice. Taken together, our data are in support of the idea the loss of T286 autophosphorylation causes some neuropsychiatric endophenotypes.

[6]Interdepartmental Neurosci. Program, Yale Univ. Sch. of Med., New Haven, CT

Abstract: Tourette syndrome (TS) is a neurodevelopmental disorder that affects approximately 0.5% of the population, with a peak onset in preadolescence with symptoms ranging from mild to disabling. The underlying mechanisms of the disorder are incompletely understood. A better appreciation for the neurochemical substrates will set a path for developing new pharmacological treatment. Data from a recent genetic study found a connection between mutations in the slit and trk-like family member 1 (SLITRK1) gene and TS. Although some research into the family of SLITRK genes has found an association between these genes and neuronal growth, guidance, and branching, the exact function of this gene in a healthy population and after development is still being uncovered. We have developed a floxed SliTrk1 mouse, which permits global or regional inactivation of the gene; we produced global knockouts by crossing this mouse with actin-CRE transgenic mice. We assessed the phenotype of knockout, heterozygous, and control littermates in several behavioral experiments. The mice were examined for startle and prepulse inhibition, in an open field and rotarod for locomotion, in the elevated plus maze and light/dark box for anxiety, the forced swim test for helplessness, and spray-induced grooming and amphetamine-induced stereotypy for tic-like or compulsive behaviors. There was a significant effect of genotype on prepulse inhibition, with the knockout mice showing a deficit compared to the controls and the heterozygous mice in an intermediate position. The knockout mice also spent less time in the open arm of the plus maze. Further analyses are ongoing. A behavioral classification of the phenotypes involved in knocking out the SLITRK1 gene can further our general understanding of its role in development and more specially how mutations may contribute to the symptoms of Tourette syndrome.

Title: Familial hemiplegic migraine type 1 mutant mice show cognitive impairment in hippocampal memory tasks

Authors: *A. M. LENSELINK[1], T. HOUBEN[2], E. DILEKÖZ[3], C. AYATA[3], M. FERRARI[2], A. B. SMIT[1], A. M. J. M. VAN DEN MAAGDENBERG[2], S. SPIJKER[1]
[1]Mol. and Cell. Neurobio., VU Amsterdam, Amsterdam, Netherlands; [2]Dept. of Neurol., Leiden Univ. Med. Ctr., Leiden, Netherlands; [3]Neurovascular Res. Lab., Massachusetts Gen. Hospital, Harvard Med. Sch., Charlestown, MA

Abstract: Familial hemiplegic migraine (FHM) type 1 is a monogenic subtype of migraine with aura that is caused by mutations in the CACNA1A gene, which encodes the alpha1 subunit of voltage-gated CaV2.1 Ca2+ channels. Because transgenic knock-in mice that express gain-of-function FHM1 mutations (R192Q and S218L) in the Cacna1a gene exhibit a synaptic phenotype, including an increased cortical glutamatergic neurotransmission, we investigated whether these mutations would lead to hippocampal plasticity changes that are accompanied by cognitive and memory phenotypes. In learning and memory tests, FHM1 mice showed significantly impaired expression of the memory compared with controls, with S218L mice being more affected. This genotype difference fits with the notion that patients and mice with the S218L mutation have more pronounced clinical and neurobiological phenotypes than those with the R192Q mutation. Anxiety-related behavior appeared reduced in mutant mice , and was mildly confounded by increased locomotor activity, as observed in the open field. Furthermore, hippocampal LTP was augmented by two-fold in FHM1 knock-in mice, whereas LTD was unchanged compared with wild-type. Taken together, mutations causing a gain-of-function of CaV2.1 channels impair learning and memory, while enhancing hippocampal excitatory transmission and LTP. Our data suggest that abnormally enhanced hippocampal neuroplasticity can be as unfavorable to learning as reduced plasticity.

Title: Nicotine's effects on cognitive effort are dependent upon individual differences: acetylcholine manipulation on a rodent cost/benefit decision-making task

Authors: *J. G. HOSKING[1], F. C. W. LAM[2], C. A. WINSTANLEY[2]
[1]Dept. of Psychology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: All individuals are confronted with choices that require weighing potential benefits against their associated costs. Animal models of such cost/benefit decision making have typically focused on dopamine's contributions to choice. Acetylcholine is heavily interconnected with the dopaminergic system, and has also been demonstrated to be essential in many cognitive processes. Despite this, its role in cost/benefit decision making remains poorly understood, especially within the realm of effort. Here we utilize a rat Cognitive Effort Task (rCET) to probe acetylcholine's contribution to effortful decision making. In the rCET, animals can choose either an easy trial, where the visuospatial attentional demand is low but the potential reward (sugar) is small, or a difficult trial on which both the attentional demand and available reward are greater. Following the establishment of baseline behavior, four drug challenges were administered via intraperitoneal injection: nicotine, mecamylamine, scopolamine, and oxotremorine (saline plus three doses for each). As per previous rCET studies, animals were divided by their baseline preferences, with "workers" choosing high-effort/high-reward options significantly more than "slackers". Nicotine dose-dependently caused slackers to choose even fewer high-effort trials than at baseline, but had no effect on workers' choice, which was near ceiling. Despite slackers' decrease in willingness to expend effort, nicotine modestly improved all animals' ability to perform the task, by decreasing nosepoke omissions. Nicotine also increased measures of motor impulsivity in all animals. In contrast, scopolamine dose-dependently decreased all animals' choice of high-effort trials, while oxotremorine decreased motor impulsivity for all animals without affecting choice. In sum, it appears both nicotinic and muscarinic cholinergic systems contribute to decision making, and in part their contributions can be understood as a function of individual differences. While nicotine has been considered as a cognitive enhancer, these data suggest that its modest benefits to attention may be coupled with impulsiveness and decreased

willingness to work hard, especially in individuals who are particularly sensitive to effort costs (i.e. slackers).

Title: Noradrenergic regulation of optimal decision making

Authors: *E. M. VAZEY, G. ASTON-JONES
Dept Neurosciences Res., MUSC, Charleston, SC

Abstract: Decision making goes awry in many psychiatric disorders. Cortical function during decision processing is heavily influenced by several ascending monoamines, including norepinephrine (NE). Locus coeruleus (LC) provides the vast majority of NE to the cortex. Our lab and others have previously shown LC-NE neurons respond phasically during optimal decision processing in several cognitive tasks including two alternative forced choice (2AFC) tasks. NE release is posited to act as a temporal filter for integrating task relevant information and facilitating decision execution. We tested a range of pharmacological compounds to identify potential mechanisms of noradrenergic influence in optimal decision performance in a 2AFC task. We trained male Long-Evans rats to perform a 2AFC task in which one of two adjacent central cue lights (red/green) illuminated on every trial to indicate which of the two laterally-located levers would be rewarded. Rats self-initiated cue presentation by nose-poking in front of the cue lights, and performed 249 trials per session with each trial a 50% probability of either cue presentation. Correct responses were rewarded with 100µl of 15% sucrose. The α2-noradrenergic agonist guanfacine, or the noradrenergic reuptake inhibitor atomoxetine, both increased accuracy of 2AFC performance. However, this effect was restricted to animals that had <75% accuracy on vehicle, indicating a ceiling effect in the cognitive enhancement with these compounds. Guanfacine and atomoxetine also increased reaction times, possibly indicating an effect on the

response criterion (β in signal detection theory). The α2 antagonist atimpamezole produced no clear effects on either accuracy or reaction time. The α1 antagonist prazosin did not alter accuracy but caused significant increases in reaction time, indicating a possible arousal or motor effect. The β noradrenergic antagonist propranolol strongly reduced accuracy in all subjects; however, propranolol caused no change in reaction time, indicating a role for β noradrenergic signaling in cognitive processing. These results have implications for the development of cognitive enhancers and highlight intricacies of noradrenergic function during optimal decision processing that require further investigation.

Title: Locus coeruleus norepinephrine neurons are phasically activated during behavioral response inhibition

Authors: *M. D. RIEDY, G. ASTON-JONES
Neurosci., Med. Univ. of South Carolina, CHARLESTON, SC

Abstract: Response inhibition is a central element in the executive control of behavior. Humans suffering from attention deficit hyperactivity disorder (ADHD) and various cognitive pathologies show impaired performance on go/nogo (GNG) and stop-signal (SS) tasks, clinical measures of behavioral response-restraint and response-cancellation. Importantly, some behavioral impairment is recovered in humans by treatment with the selective norepinephrine (NE) reuptake inhibitor atomoxetine. As the locus coeruleus (LC) is a primary endogenous source of NE, these data bolster findings indicating an important role for LC-mediated regulation of behavioral response inhibition. We analyzed the activity of LC-NE neurons in rats performing GNG and SS tasks. Rats were rewarded with aqueous sucrose (15%), punished with a lights-off delay, and

instilled with a pre-potent go response via pseudorandom control of trial ratio (75:25; Go:NoGo/Stop). In our versions of these tasks, rats were trained to maintain a lever-hold. The shaped behavior then was cue-contingent and rapid lever-release (<600 msec), which constrained the execution of alternate behaviors and permits analysis of neural activity strictly associated with inhibition of the pre-potent response. Upon reaching performance criterion (≤15% premature releases; ≥80% correct trials; ≈300 msec mean reaction time), rats were unilaterally implanted with drivable stereotrode arrays in LC, static electrodes in orbitofrontal (OFC) and anterior cingulate cortices (ACC), skull surface electroencephalogram (EEG), and dorsal cervical electromyogram (EMG) electrodes. Putative LC single units were identified in awake rats by their long-duration waveforms (>1 msec), low tonic firing rate (1-3 Hz), and neutral tone-evoked phasic bursts. Anodal current (20 μA 10 sec) was passed through a single steel wire of the array, and rats were perfused and processed for histological validation of recording sites. Results to date demonstrate that LC neurons exhibit greater cue-elicited phasic activation associated with successful vs. failed response inhibition trials. These ongoing studies promise to reveal properties of LC function important for response inhibition behavior and the associated cognitive functions.

Title: Genetics and pharmacogenetics of simple vertebrate decision-making

Authors: ***R. JAIN**[1], K. MARSDEN[1], M. WOLMAN[2], H. BELL[1], K. HAYER[1], J. HOGENESCH[1], M. GRANATO[1]
[1]Univ. of Pennsylvania, PHILADELPHIA, PA; [2]Univ. of Wisconsin, Madison, WI

Abstract: The nervous system constantly integrates sensory information to select appropriate, context-dependent behavioral responses. Selecting one out of several potential responses to a given situation is called decision-making. While decision-making can involve complex cognitive processing, it has become clear that even simple reflexes are dynamically biased and modulated,

representing a more tractable system to study the mechanisms of decision-making. We have developed a simple decision-making paradigm in larval zebrafish using the evolutionarily conserved acoustic startle response. Larvae perform 2 kinematically and neuronally distinct forms of the startle response: a Short-Latency C-bend (SLC) initiated 4-15 ms post-stimulus, or a less vigorous Long-Latency C-bend (LLC) initiated 20-80 ms post-stimulus. Individual larvae can respond to acoustic stimuli with either behavior, yet bias their responses toward SLCs following intense (26dB) stimuli and toward LLCs following weak (13dB) stimuli. Importantly, individuals incorporate prior experience in selecting their behavioral output, shifting their response bias from SLCs to LLCs following repeated strong stimuli. Thus, the basic dynamic aspects of complex cognitive decision-making are present in the simple SLC/LLC decision-making paradigm. To identify genes and pathways critical for the development and function of startle decision circuits, we performed a small molecule screen and a forward genetic screen. The small molecule screen results demonstrate that as in more complex cognitive assays, serotonergic modulation is critical for decision-making. Through our forward genetic screen we identified 11 mutants with specific defects in SLC/LLC bias, the first vertebrate mutants specifically isolated based solely on decision-making deficits. Using whole-genome sequencing we have identified mutations in both the calcium-sensing receptor (CaSR) gene and a regulator of CaSR trafficking. We will present functional neural imaging data to elucidate how serotonergic signaling and CaSR gene function influence simple decision-making.

Title: Choice of strategies is influenced by emotionality in a repeated prisoner's dilemma in mice

Authors: *K. KIM[1], I. CHOE[2], I. KIM[1], S. PARK[1], H. SHIN[1]
[1]Ctr. for Cognition and Sociality, Inst. For Basic Sci., Seoul, Korea, Republic of; [2]Inst. for Basic Sci., Seoul, Korea, Republic of

Abstract: The repeated prisoner's dilemma (RPD) is an established paradigm to explore animal behaviors upon various strategies involved in consecutive economic decision-making. We investigated whether individuality affects the choice of strategies in the RPD in inbred mice. We developed a new system for robust operant training using a brain stimulation reward via wireless intra-cranial stimulation to the medial forebrain bundle, a pleasure center in the brain. This new system overcomes the disadvantages of using natural rewards which is known to induce unstable behavioral results dependent on the level of deprivation. Prior to the RPD game, we measured general locomotor behavior of each mouse in the open field test (OFT). A 3-day operant training test and a 5-day reversal learning test in a modified T-maze were used to screen for the mice with sufficient learning ability and flexibility. Subsequently, each mouse performed an RPD game against a virtual, tit-for-tat partner for 12 days. Two groups received two different 'reward' payoffs for the mutual cooperation choice. One group (A) received a 'reward' equal to the 'predicted' value, the same amount of reward used in the preceding operant trainings, whereas the other group (B) received a lower 'reward' than the 'predicted' value. We found that the choice frequency of certain strategies became heterogeneous among the mice in the Group B while it remained homogeneous in the Group A. Further analysis of the results of the Group B revealed a strong correlation between the choice frequency of a certain strategy and the level of anxiety-related emotion of an individual mouse, as measured in the OFT, and the choice of the strategy directly affected the level of benefit to the mouse. These findings suggest that an individual's emotionality is an important factor involved in the cognitive process of economic decision-making.

Title: Altered performance on a novel effortful maze task following methamphetamine in rats

Authors: *A. STOLYAROVA, A. DE LA TORRE, A. B. THOMPSON, A. IZQUIERDO
Brain Res. Institute, Dept. of Psychology, UCLA, Los Angeles, CA

Abstract: One of the fundamental components of adaptive decision making is an ability to assess the value of rewards in relation to the effortful costs required to obtain them, and to use this information to guide choices. Effort-based task performance is heavily modulated by distributed dopaminergic and glutamatergic signals, primarily in striatal and prefrontal cortical regions of the brain (Floresco et al., 2008; Assadi et al., 2009). Given that frontostriatal neurotransmission is vulnerable to the effects of methamphetamine (mAMPH) exposure and that psychostimulant abuse has been linked to alterations in cost/benefit decision making (Floresco and Whelan, 2009), we hypothesized that effortful reward magnitude choices would be altered in animals treated with mAMPH. Work-aversion on an effortful t-maze task following binge doses of mAMPH has been reported previously (Kosheleff et al., 2012), yet work-aversion was not observed following an escalating mAMPH dose regimen on the same task (unpublished). In the present experiment we employed a novel maze task procedure with three possible courses of action, each associated with different effort requirements and reward magnitudes. One arm of the maze was randomly designated as a low reward (LR), another as a medium reward (MR), and the third as a high reward (HR) arm. The LR arm was unimpeded by a barrier, but in order to obtain the medium or high reward, rats were required to climb a 20 cm or 30 cm barrier, respectively. The arm assignment was counterbalanced across animals, and held constant between sessions. Once baseline arm preference was established and stable across 3 subsequent sessions, rats were treated with 4 weeks of saline (SAL) or escalating mAMPH, followed by reassessment of effortful choice behavior after an acute withdrawal period (7 d). Following treatment, mAMPH-treated animals increased their choices of the MR option over the LR option compared to SAL, and were indistinguishable from SAL in their choice of the HR option. The shift away from the LR was present from the beginning of the post-treatment testing suggesting increased sensitivity to differences in reward magnitude following mAMPH. In contrast, MR choice preference developed with repeated training, possibly as a function of reward history for that arm. MAMPH animals did not take any more days than SAL to establish stable performance and treatment groups were not different in weight or food intake. These findings suggest that mAMPH exposure has long-lasting effects on effortful decision-making and reward choice preferences. Ongoing studies are aimed at determining the dopaminergic and glutamatergic changes that underlie these altered reward choices.

Title: Effects of nicotine exposure on probability discounting in rats

Authors: *C. REICH[1], J. BURK[2]
[1]Neurosci., [2]Psychology, The Col. of William & Mary, Williamsburg, VA

Abstract: Nicotine administration has been shown to affect impulsivity in multiple paradigms, including delay discounting. Probability discounting tasks are used as a measure of impulsive choice with aspects of risky behavior. We conducted two experiments to assess the effects of nicotine on probability discounting. First, we examined the effects of repeated exposure, abstinence, and re-exposure to nicotine on a probability-discounting task in rats. Rats received nicotine (0.4 mg/kg, ip) or saline twice per day for four days prior to probability discounting task performance. All rats then received challenge doses of 0.1 mg/kg or 0.4 mg/kg nicotine on Days 5, 8 and 12 and saline injections prior to task performance on all intervening days. The probability of receiving the large reward during the first block was 100% and then was decreased to 33% and then to 17% in subsequent blocks within each testing session. We observed a main effect of nicotine pre-exposure, but no interaction with administration day. Rats that were pre-exposed to nicotine continued to enter the port that allowed access to the larger, uncertain reward more frequently than the saline pre-exposed rats. In Experiment 2, we tested whether the α4β2 nicotinic acetylcholine receptors were necessary for the effects of nicotine on probability discounting. Rats were trained in the same probability discounting task as in Experiment 1. All rats then received nicotine (0.4mg/kg) and/or the α4β2 receptor antagonist, dihydro-β-erythroidine, along with appropriate vehicle control injections, prior to task performance. Similar to Experiment 1, nicotine-treated animals did not show a significant change in choice behavior when the probability of receiving the large reward was decreased. Blockade of α4β2 nicotinic receptors did not impact the effects of nicotine on probability discounting. We conclude that nicotine administration affects probability discounting performance. Nicotine may have increased perseverative behavior or decreased sensitivity to contingencies. The effects of nicotine on probability discounting do not appear to be solely mediated by α4β2 nicotinic receptors.

Title: Action-dependent state prediction in the parietal cortex of mouse during a virtual navigation task

Authors: *A. FUNAMIZU, B. KUHN, K. DOYA
Okinawa Inst. of Sci. and Technol., Okinawa, Japan

Abstract: Model-based decision making requires representation of predicted states that are updated by action-dependent state transition models. To investigate their neural implementation, we conducted a virtual sound navigation task with mice and recorded the neuronal activities of posterior parietal cortex (PPC) with 2-photon microscopy. A mouse was head restrained for 2-photon imaging and maneuvered a spherical treadmill. 12 speakers around the treadmill provided a virtual sound environment. The direction and the amplitude of sound pulses emulated the location of the sound source, which was moved according to the mouse's locomotion on the treadmill. When the mouse reached the sound source and licked a spout, it got a water reward. The task consisted of two conditions: continuous condition in which the guiding sound was presented continuously and intermittent condition in which the sound was presented intermittently. In both conditions, mice increased the licking as they approached the sound source. This indicates that (i) mice recognized the sound-source position in the virtual environment and (ii) they predicted the reward given at the sound source. In the intermittent condition, the anticipatory licking was increased even when the sound was omitted, suggesting that mice updated the predicted sound-source position without auditory feedback based on their own actions. We optically recorded calcium transients of layer 2/3 neurons in the PPC with the genetically encoded indicator GCaMP6f transfected by AAV. The neural activities during the task were recorded on 23 days (sessions) from 3 mice; each session targeted a different coordinate of PPC. The PPC contained neurons with ramping activities whose slopes correlated with the distance to the sound source rather than the licking frequency or locomotion. The sound-source distance was then decoded from the population activities of PPC by the least absolute shrinkage and selection operator (LASSO). The decoder trained with the data in continuous condition could successfully decode the sound-source distance during no-sound periods in intermittent condition. We also trained a decoder of time to reach the sound source and found that the PPC neurons better represented the distance than the timing in all the sessions (two-sided t-test, $p = 2.29E-13$ - $1.09E-172$). LASSO extracted the $39.9 \pm 2.7\%$ of all neurons for distance coding; the neurons were homogeneously distributed in the PPC. These results suggest that the

PPC neurons represent and update the distance of sound source not only from present auditory inputs but also by dynamic update of the estimate using an action-dependent state transition model.

Title: Emergence of abstract knowledge that guides decision making in rats

Authors: ***S. TERADA**[1,2,4], H. NAKAHARA[3], S. FUJISAWA[2]
[1]Kyto Univ., Saitama, Japan; [2]Lab. for Systems Neurophysiol., [3]Lab. for Integrated Theoretical Neurosci., RIKEN Brain Sci. Inst., Saitama, Japan; [4]Japan Society for the Promotion of Sci., Tokyo, Japan

Abstract: Decision making or selection of actions is often guided by prediction of outcome such as reward. Both reward prediction and action selection need to be acquired (learning by reinforcement) and generated (decision making process) on neuronal representation that reflects sensory inputs or information of the environment. Critically, the representation should not be merely a collection of sensory inputs but instead, should be organized to encode and abstract information required for prediction and selection. So far mostly using a simple sensory cue, the prediction and selection have been studied in the field of value-based decision making, however, surprisingly little is known about the neural representations for the abstraction of the required information during the acquisition and generation, For this purpose, we have newly developed a behavioral task for rats, called cue-combination task. Central for this task is that the correct choice of action (and possibly reward prediction) should be determined by a combination of two cues (sound and odor cues); they cannot be determined by either of cues alone. In each session, sound and odor cues will be presented simultaneously for a couple of seconds to the rat, followed by a choice period, i.e., right or left lever to pull for getting a reward. Here the correct choices

will be determined by the combination of the sound and odor cues. Once the rat pulls the correct lever, then a drop of water will be provided as a reward from the tip of the spout lever, otherwise a reward will be omitted. This is a simplest circumstance that requires abstracting appropriate information of the environment for value-based decision making. After four weeks training, the rats were able to perform up to 200 trials of this task per session with 80~90% correct answer ratios. Combining a large-scale extracellular recording techniques it will be a powerful paradigm for studying neuronal representations of abstract knowledge.

Title: Addition of numerical quantities in working memory by rhesus monkeys

Authors: ***B. MASSI**, H. SOHN, N. CENERI, D. LEE
Neurobio., Yale Univ., New Haven, CT

Abstract: Animals must often estimate and arithmetically combine quantities of various objects in the environment, even when direct sensory inputs from the objects are not available. For example, an animal preparing for an upcoming winter may estimate the total quantity of food previously stored in several caches to decide whether or not to continue foraging. In fact, previous studies have demonstrated that humans and non-human primates might share a similar cognitive mechanism for manipulating estimated quantities, such as the approximate set size of a visible collection of objects. However, despite its ecological importance, the behavioral characteristics and neural mechanisms of arithmetic operations remain poorly understood. As a first step to neurophysiological studies on arithmetic, we developed an oculomotor choice task that requires macaque monkeys to add two separate quantities. During each trial, the animal fixated a central target while three clusters of dots sequentially appeared perifoveally. After a short delay, each cluster entered one of the two peripheral target areas, which was followed by another delay before the presentation of the next cluster of dots. The first cluster of dots (the augend) remained hidden until the end of the trial after it entered the target area. The second

group of dots (the addend) appeared centrally and moved to the same target area containing the augend, but remained visible. Finally, the third group of dots (the singleton) appeared and moved to the other target area and also remained visible. After another delay, the animal was required to shift its gaze to one of the target areas and received a juice reward with a magnitude proportional to the number of dots at the chosen target. Thus, the animals were encouraged to add the remembered augend with the visible addend and then compare the resulting sum to the visible singleton to maximize reward. We found that two animals reliably performed this task with over 80% accuracy. The animals performed above chance level even in trials where the magnitude of the visible quantities did not determine the correct choice. Crucially, both animals exhibited similar performance on novel trials, suggesting that the animals might use a generalizable addition rule. Consistent with existing theories of internal number representation, we found that the animals' performance depended on the ratio of the sum and singleton. Our results provide evidence that macaque monkeys can add in working memory, and future work will characterize the underlying neurophysiology.

Title: Maternal rats use frontal cortex to discriminate between own and alien pups

Authors: *A. FRANSSEN[1], A. J. HAUVER[1], J. LAFEVRE[1], M. CLASEN[3], K. GAFFNEY[3], A. PARDES[3], R. PRUETT[3], H. UYGUNER[3], M. VASSALLO[3], C. L. FRANSSEN[2,3]

Abstract: One intriguing behavior of mother rats is the care and nurturing of pups that are not her own. Previous research has demonstrated that mother rats are able to identify their own pups (OWN) versus those from another mother (ALIEN) through olfactory and auditory cues (e.g.,

Smotherman, 1974); yet somewhat surprisingly, mother rats eventually care for ALIEN pups once her natural pups are attended to (Beach and Jaynes, 1956). However, the underlying neural basis for the responses of mothers to pups is unclear and may aid in understanding triggers of the maternal response more generally. Here, we attempt to elucidate the neurological underpinnings of the decision to care for both OWN and ALIEN pups. We compared three groups of female Sprague-Dawley rats (Rattus norvegicus): Mothers with OWN pups; Mothers with OWN and ALIEN pups (creating a MIXED group); and Mothers with ALIEN pups. Pup exposures were video-recorded for analysis of behaviors including latency to retrieve and grooming. Rats were then sacrificed and neural tissue examined through immunohistochemistry for differences in c-fos in several regions of the brain. Behavioral results indicate that mothers will care for both OWN and MIXED pup groups more quickly than a completely ALIEN group. Expression patterns of c-fos suggest that while identification may occur in sensory-associated areas, such as the insular cortex (highest fos expression in response to OWN, lowest to ALIEN), the decision to care for pups may involve the prefrontal cortex (highest c-fos expression in response to MIXED). Data from additional brain regions will be discussed in the context of a maternal recognition circuit.

Title: Low level lead exposure differentially impairs performance of an attentional set shifting task depending on developmental period of exposure

Authors: *L. S. NEUWIRTH, D. W. ANDERSON, J. S. SCHNEIDER
Pathology, Anat. and Cell Biol. Med., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Exposure to low levels of lead (Pb) impairs a variety of cognitive processes. Although children exposed to lead developmentally present with a variety of cognitive impairments that

include deficits in learning, memory, language, and executive functioning, experimental work on Pb toxicity in rats has focused mostly on learning and memory deficits and less on executive functions. However, detrimental effects on executive functioning could lead to or even underlie a variety of other cognitive problems attributed to Pb exposure. In this study, we examined the ability of Long Evans rats (control and Pb-exposed: 150ppm Pb-acetate in food given perinatally (gestation through weaning) or early postnatally (EPN, birth through weaning)) to acquire and perform an attention set shifting test (ASST) that requires animals to locate a food reward based on discriminating between digging materials and odors. The task consisted of simple (SD) and compound (CD) discriminations and reversals and intra-dimensional (ID) and extra-dimensional (ED) shifts followed by reversals. Pb-exposed animals performed the task different than controls. Rats with EPN Pb exposure were unable to learn an odor-based SD. Perinatally exposed rats learned the odor SD but had significant numbers of errors at most task levels with particular difficulty in performing the ID shift. Perinatally exposed rats also exhibited very short response latencies suggesting impulsive responding. Additionally, the more complex the stimuli presented during testing the greater the number of trials needed to reach criterion and the greater the numbers of errors made, suggesting that Pb exposure disrupted cognitive information processing when animals attempted to associate reinforcement with odor and/or digging material. These data suggest that low level Pb exposure results in significant executive dysfunction and in particular, may impair the ability to form, maintain, and shift response sets and may result in impulsivity and problems with cognitive flexibility.

Title: Ipsilateral ventral striatal lesions disrupt reward prediction error signals in rat dopamine neurons

Authors: *Y. K. TAKAHASHI[1], G. SCHOENBAUM[2]
[1]NIDA/NIH, BALTIMORE, MD; [2]NIDA/NIH, Baltimore, MD

Abstract: Midbrain dopamine neurons have been shown repeatedly to signal errors in reward prediction. The ventral striatum has been proposed as a major source of the predictions upon

which these errors are based, even serving the role of "Critic" in some accounts. Here we tested this hypothesis by recording from putative dopamine neurons in ventral tegmental area in rats with sham or neurotoxic lesions of ipsilateral ventral striatum. Recordings were made in a simple odor-guided choice task, which we have used previously to demonstrate prediction error signals in rat dopamine neurons. In this task, different odor cues signal that a sucrose reward is available in one of two nearby fluid wells. During recording, we independently manipulate the timing or size of reward across blocks of trials to induce both positive and negative reward prediction errors. Consistent with our prior work in this task, dopamine neurons in sham rats exhibited robust error signals; activity in both single units and across the population showed a phasic increase to unexpected reward and this firing declined with learning. After learning, the same neurons also showed phasic activity to the predictive cues that differed according to their value and suppressed firing upon omission of the expected reward. By contrast, although the ipsilateral ventral striatal lesions had no apparent effect on learning or performance in the task, dopamine neurons recorded in the lesioned hemisphere failed to show this pattern. In preliminary analyses, these neurons appear to still fired strongly to unexpected rewards, however this activity does not change with learning, nor is there any evidence of suppression on omission or transfer to the reward-predicting cues after learning. These results are consistent with the proposal that that input from ventral striatum is an important source of the predictions that midbrain dopamine neurons use to calculate reward prediction errors.

Title: Neuronal activity-dependent BDNF alterations in corticostriatal circuits during flexible decision-making

Authors: *R. COLE, P. J. PATEL, P. N. OSUAGWU, V. PARIKH
Psychology and Neurosci., Temple Univ., Philadelphia, PA

Abstract: Brain-derived neurotrophic factor (BDNF) exerts neuromodulatory effects on synaptic transmission, and is essential for actively regulating learning, memory, and motivational processes. Recent evidence suggests that exogenous BDNF administration into the dorsal striatum regulate cognitive flexibility by altering cortiostriatal glutamatergic transmission (D'Amore et al., 2013). However, the role of endogenous BDNF signaling in flexible decision-making remains unknown. Activity-dependent alterations in BDNF expression is considered to be a key event in synaptic plasticity and cognition. As frontostriatal circuits involving discrete regions of the prefrontal cortex (PFC) and orbitofrontal cortex (OFC), and striatum, are critical in maintaining different forms of cognitive flexibility such as extradimensional shifting and reversal learning, we hypothesized that shifting to new strategies would produce neuronal activity-dependent alterations in BDNF expression in these circuits. Male C57BL/6J mice were trained in an operant task that required the animals to shift a visual cue-based strategy to an egocentric spatial response-based strategy. Another cohort of mice were trained on reversal learning where they initially acquired a response-based discrimination and then required to flexibly adapt to the reversal of stimulus-response contingencies. Brains were removed either during the initial learning phase or after complete acquisition of the new strategy to conduct quantitative immunohistochemical examination of BDNF and c-fos (a marker of neuronal activation) expression in the regions of interest. During the early learning phase, the counts of BDNF-positive cells and BDNF-c-fos co-labelled cells were elevated in the OFC and prelimbic/infralimbic areas of the PFC irrespective of the shift-type compared to discrimination control groups. However, the dissociation between region-specific changes in BDNF expression became apparent only after acquisition of specific task type. Acquisition of reversal learning was only associated with increased BDNF expression in the OFC while higher c-fos-BDNF colabelled neurons were restricted to PFC after attainment of strategy shifting. Increased neuronal activation in the dorsal striatum occurred regardless of the task type. Collectively, these data suggests that flexible decision-making produces temporal alterations in corticostriatal BDNF expression that depend upon region-specific neuronal activity. Moreover, cortical BDNF plays a critical role in modulating striatal activity to maintain shifts in strategies with changing environmental contingencies.

Title: The role of temporal variability during time-constrained motor sequences: A computational study

Authors: *I. COS-AGUILERA[1], P. RUEDA-OROZCO[2], D. ROBBE[2], B. GIRARD[1]
[1]ISIR, Univ. Pierre et Marie Curie, Paris, France; [2]Inst. de Neurobiologie de la Mediterranee (INMED), Marseille, France

Abstract: The study of decision-making of motor actions with rodents is mainly based on tasks in which animals perform specific action sequences to attain reward [1]. Here we were interested in understanding the behavioural organization of rats during time-constrained, reward driven, locomotion tasks. Experimental evidence suggests that whenever the motor responses are time-constrained to obtain reward, the resulting strategy reflects a compromise between the motor factors relevant to the task and the timely requirements to attain the goal. To investigate this, we took advantage of a novel behavioural protocol in which rats running on a treadmill were required to estimate a fixed-temporal interval to obtain reward [2]. Interestingly, rats became proficient by developing stereotyped running sequences through a trial and error learning process that extended 2-3 months, attaining success rates of ~70-80% per session. We hypothesized that the behaviour was habitual [4] and consistent with a principle of reward maximization that traded-off effort and temporal discount. Moreover, because of the motor and temporal constraints of the task, this had to be equally constrained by the ability of the CNS to estimate time intervals [6]. Two complementary methods were used to estimate this hypothesis: our first analyses showed of the habitual motor strategy was consistent with an optimization process of each behavioural phases as a function of effort and discount, but also of the temporal variability associated to each phase of their behaviour. For example, the rat's behaviour was less variable at constant acceleration than at constant speed, and the duration of their phases of movement was consistent with an overall strategy to minimize temporal variability over the entire movement. Second, we built a continuous time and space RL model that could accommodate the statistics of Weber's law for time estimation [5], as well as learn locomotion sequences by optimizing reward. This model yielded behaviours that reproduced the statistics of the rat's by optimizing the trade-off between discounted reward and effort. Remarkably, the optimal behaviour also yielded the motor sequences with least overall temporal variability, therefore suggesting that the estimates of time intervals and the trade-off between reward and effort are intrinsically related.

Abstract: INTRODUCTION: Damage to the medial prefrontal cortex (mPFC) often leads to problems characteristic of addiction, such as impulsivity and insensitivity to future consequences. To learn more about the role of this region, we studied the effects of mPFC lesions in rats on decision making processes related to behavioral addiction. We hypothesized that rodents with mPFC lesions would be less flexible when faced with changing task contingencies resulting in a diminished ability to obtain as much reward over time compared to control animals. METHODS: 23 male Long Evans rats (10 lesion; 13 sham) were tested on a novel version of the N-arm Bandit Task. Each rat was given a choice between 3 food ports which delivered a different amount of liquid Ensure (i.e. high, medium or low reward). Each port maintained this amount of food for a given amount of trials at which time the amounts associated with each port changed abruptly. The rats then had to disengage from the port that was previously highly rewarding and searched for the new high reward port. RESULTS: We found that damage to the mPFC made rats much more likely to perseverate on ports that were previously rewarding and were much less sensitive to outcomes. Lesioned animals achieved less net reward and were slower to adjust to changes in reward contingency. CONCLUSIONS:

Rodents with mPFC damage display less flexible goal-directed behaviour. These data support a role for the mPFC in behavioural addictions. In humans, this effect may contribute to some of the difficulties individuals experience when trying to disengage from activities related to substance or behavioural addictions. This region may be a useful target for research relating to the treatment of addictions.

Title: The nematode *C. elegans*: A new model organism for economic decision making

Authors: *A. W. KATZEN[1], W. T. HARBAUGH[2], S. R. LOCKERY[3]
[2]Econ., [3]Biol., [1]Univ. of Oregon, Eugene, OR

Abstract: Investigation of the neuronal basis of economic decisions would be accelerated by establishing decision making paradigms in simple, genetically tractable organisms, such as the nematode *Caenorhabditis elegans.* For an organism to be a valid model of economic decision making, it must satisfy two conditions: (i) the organism must be capable of distinguishing between high and low quality goods, and (ii) its decision must be sensitive to the prices of those goods. Previous work has shown that the nematode worm *C. elegans* quickly learns to prefer those foods (species of bacteria) that promote higher rates of growth and reproduction. Preference is manifested by the amount of time the worm spends foraging in patches of good bacteria (high worm growth rate) versus mediocre bacteria (moderate growth rate) when equally abundant. Until now, however, it has not been possible to precisely manipulate both the quality and cost of food during choice presentation We have developed an electro-microfluidic device in which a semi-restrained worm forages between contiguous yet discrete fluid streams containing good and mediocre quality food. Electrodes inserted into the device monitor muscular impulses associated with individual swallowing events. Relative consumption of good and mediocre food is measured by counting the number of swallowing events in the respective fluid streams. The

fraction of total swallowing events in good vs mediocre food serves as an index of food preference. Importantly, we can alter the effective prices of the two foods by adjusting the concentration of the bacteria, with price being inversely related to concentration. We find that worms exposed to the two species of bacteria at equal prices prefer good bacteria, indicating that feeding preferences are normal in the device. However, when mediocre food is made much less expensive than good food, worms prefer mediocre food. We conclude that *C. elegans* is sensitive to both quality and cost when deciding where to forage in the microfluidic device. Thus, the new device enables investigation of the neuronal and genetic basis of economic decisions in *C. elegans*. Because of the extensive genetic and neurochemical similarities between the nervous system of *C. elegans* and its mammalian counterparts, the present approach is well positioned to provide novel insights into how economic decisions are generated in a range of medically relevant nervous systems.

Title: Variability of perceptual decision-related activity differs between the frontal eye field and caudate nucleus

Authors: J. A. CABALLERO, J. I. GOLD, *L. DING
Dept of Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Variability in neuronal activity is widely observed in the brain. Although it is often treated as a nuisance, neuronal variability can be modulated by task context (e.g., in songbirds) and provide clues about a given neuron's computations (e.g., [1, 2]). Previously we reported that neurons in the frontal eye field (FEF) and caudate nucleus (CD) show different patterns of mean

firing rate in a random-dot visual motion discrimination saccade task, in which macaques report their choices with saccades to fixed target locations [3, 4]. In this study, we compared several measurements of firing-rate variability in the same samples to provide a more complete characterization of the decision-related activity patterns in the two brain regions. We focused on the task period from stimulus onset to saccade onset and included only neurons with choice- and motion strength-dependent activity (n = 34 and 48 for FEF and CD, respectively). We estimated several variability-related quantities using a sliding window (100 ms) and tested for choice and/or coherence (motion strength) dependence using a combination of linear regression analyses and t-tests (criterion: p = 0.05). Our three main findings are as follows. First, firing-rate variance followed choice-, motion strength- and time-dependent trajectories akin to those of mean firing rates in both CD and FEF. Second, the average Fano factor was largely unmodulated in CD. In contrast, in FEF it decreased gradually for both choices after stimulus onset and more rapidly and in a choice-dependent manner prior to saccade onset. This pre-saccadic decrease was earlier and deeper for saccades toward the neurons' response field (IN) than for opposite saccades (OUT). Third, the average coefficient of variation squared (CV2) was larger for OUT than IN saccade trials in both CD and FEF. During early motion viewing, coherence modulation of CV2 was observed for both IN and OUT trials in CD neurons, but only for IN trials in FEF neurons. Closer to saccade onset, coherence modulation of CV2 was observed only for OUT trials in FEF, but not for either choice in CD. These differences in neuronal variability may support different computational roles of FEF and CD in perceptual decision making. Title: Dorsomedial striatum lesions disrupt the balance between model-free and model-based learning in a multi-stage decision-making task in rats

Authors: *S. M. GROMAN[1], L. CHEN[1], N. J. SMITH[1], D. LEE[2], J. R. TAYLOR[1]
[1]Psychiatry, [2]Neurobio., Yale Univ., New Haven, CT

Abstract: Reinforcement learning processes are impaired in individuals with psychiatric disorders, such as addiction and schizophrenia. Although a large body of work indicates that model-free (MF) learning is altered in psychiatric disorders, emerging evidence suggests that model-based (MB) learning strategies may also be impaired. However, the neural mechanisms mediating MF and MB learning processes are not well understood. Here, we developed a rodent version of a multi-stage decision-making (MSDM) task to determine the role of the dorsomedial (DMS) striatum in MF and MB learning strategies. Rats received either bilateral lesions of the DMS striatum or sham surgery and were trained on a MSDM task analogous to that used in humans (Daw et al., 2011). In this task, rats made decisions between two options in two successive trial stages. In the first stage, rats are presented with two levers. Rats respond on a single lever to probabilistically illuminate two noseports (NPs): responses on one lever result in the presentation of noseports A and B 70% (common) of the time and noseports C and D 30% (rare) of the time; responses on the other lever resulted in the opposite configuration. In the second stage, rats chose between the two illuminated noseports that were differentially reinforced. MF and MB learning models posit that reinforcement in the second stage should differentially impact first-stage choices. To examine the contributions of MF and MB learning strategies, we calculated the probability that rats would stay on the first-stage option based on the trial outcome (win/lose) and trial type (common/rare). Similar to humans, rats use both MF and MB learning strategies (main effect of trial outcome: $p=0.001$; trial outcome by trial type interaction: $p<0.001$). Furthermore, there was a significant interaction with lesion type ($p=0.04$): although sham rats displayed evidence of both MF and MB learning (main effect of trial outcome: $p=0.04$; trial outcome by trial type interaction: $p<0.001$), lesion rats only displayed evidence of MF learning (main effect of trial outcome: $p=0.006$; trial outcome by trial type interaction: $p=0.27$). These data indicate that rats, similar to humans, use both MF and MB learning strategies to guide their decision-making processes and that the DMS striatum plays a critical role in MB learning. By using a MSDM task with high translation value, our ongoing studies will disentangle the neural mechanisms mediating MF and MB learning strategies to provide insight into the neuroanatomical basis of decision-making impairments in psychiatric disorders.

Title: Neural correlates of risk/reward decision making in nucleus accumbens neurons

Authors: *J. D. LARKIN, S. B. FLORESCO
Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Many of the choices we make in everyday life have ambiguous or uncertain outcomes. Choosing the most appropriate course of action to optimizing potential outcomes is mediated by distributed neural circuits incorporating the prefrontal cortex, amygdala and in particular, the nucleus accumbens (NAc). The NAc is thought to play a critical role in determining how an animal prioritizes responses, particularly *in situ*ations where reward contingencies may vary. Inactivation of this nucleus reduces preference for larger, uncertain rewards, most prominently when riskier options have greater long-term utility. To further clarify how NAc neurons encode different types of choices during risk/reward decision making, the present study used moveable tetrode arrays to obtain extracellular electrophysiological recordings from NAc neurons of rats performing a probabilistic discounting task conducted in an operant chamber. Rats were well trained on a task where they choose between a 'risky' lever that delivered a larger, 3-pellet reward at varying probabilities, and a 'certain' lever that always delivered a smaller, 1 pellet reward. For the first 40 trials of a session (20 forced/20 free-choice) the risky option delivered the large reward 70% of trials and during a subsequent 40 trial block, the odds of obtaining the larger reward decreased to 10%. Our analyses focused primarily on differential patterns of activity occurring prior to choices of the risky versus certain option. Preliminary analyses revealed that pre-choice activity of some NAc neurons appear to encode choice relative to utility of the two options. We have found that NAc neurons fire differentially to 'risky' and 'safe' options depending on the probability of large reward. Specifically, some cells displayed differential changes in firing prior to risky versus certain choice when the odds of obtaining the larger reward were high, but this differential encoding was not apparent when reward probabilities were low. In some cells, this effect was dependent on whether animals were forced to choose an option or free to choose between them. Other cells differentially encoded the outcome of choices (eg; firing more or less after a non-rewarded vs rewarded choice). Collectively, these data suggest that NAc neurons integrate information about actions, outcomes

and reward expectation during risk/reward decision making, which in turn may enable a decision maker to update choice behavior *in situ*ations where reward probabilities are volatile.

Title: Distinct mechanisms of reward that underlie decision-making in mice

Authors: *C. F. ROBLES, J. ROTONDO, A. GRANT, A. W. JOHNSON
Neurosci., Michigan State Univ., East Lansing, MI

Abstract: Intact decision-making results in the ability to choose appropriately between distinct courses of action. To characterize mechanisms of decision-making in rodents, we developed a task in which CD1 mice were trained to respond separately on two distinct levers ('high' and 'low') for the delivery of different reinforcers and auditory stimuli. Responses on the 'high' lever led to the delivery of 20% sucrose and contemporaneous presentation of an auditory cue (e.g., noise), whereas 'low' lever responses led to 2% sucrose and presentation of a second discriminable cue (e.g., tone). Subsequently mice received a choice test with access to both levers. The results revealed significant variability across mice in preferences for the 'high' lever. To examine whether lever preferences may be accounted for by differences in value attributed to the sucrose reinforcers or the auditory cues, we conducted tests of licking microstructure and conditioned reinforcement, respectively. Analyses of licking microstructure revealed that high (but not low) palatability responses for 20% sucrose was predictive of responding on the 'high' lever. By comparison, high levels of conditioned incentive value to the cue associated with 2% sucrose was predictive of responding on the 'low' lever. Finally, to evaluate this behavioral difference neurobiologically, prior to a second choice test, mice were treated with the D2 receptor antagonist, Haloperidol. This influenced responding to a greater extent in mice where conditioned reinforcement performance predicted responding on the 'low' lever. These results suggest dissociable mechanisms of reward that may influence (and predict) decision-making performance.

Title: Reward timing in primary sensory cortex during multi-modal intertemporal decision-making

Authors: *J. M. LEVY[1], M. G. SHULER[2]
[1]Johns Hopkins, Baltimore, MD; [2]Johns Hopkins Univ., Baltimore, MD

Abstract: Primary visual cortex (V1) has traditionally been thought to exclusively represent low-level, physical attributes of visual stimuli. This canonical view has been challenged by the discovery that V1 can represent an interval between a stimulus and a predicted reward, a phenomenon known as reward timing. The discovery of reward timing in V1 suggests that, beyond merely sensing the visual world, primary visual cortex may relay expectation signals--vital components of reinforcement learning models--and, thereby, contribute to prospective decision-making. To test this hypothesis, we have trained wild type and ChAT-ChR2 mice on an intertemporal decision-making task in which they are required to lick at one of two reward ports, each yielding water after the same delay, depending on whether a visual or auditory cue is presented. After performing this task with high accuracy, mice are exposed to choice trials in which both cues are presented simultaneously and the animal is allowed to choose whichever port he prefers. Recordings from V1 during this task reveal that temporal expectation signals are only present following the visual, but not auditory, cue. Furthermore, this expectation signal does not modulate with the animal's choice on free choice trials. When an earlier water reward is introduced following the visual stimulus, this reward time also comes to be represented in V1, and the animal's choice behavior comes to be biased toward this port. We attempt to manipulate choice behavior of the transgenic mice by introducing an earlier, fictive reward representation in V1 following the visual stimulus through optogenetic hijacking of basal forebrain inputs. This manipulation has a similar effect in V1 as introducing an earlier water reward and preliminary evidence suggests that it may bias an animal's choice behavior in this intertemporal decision-making task.

Title: Optical dissection of cortical circuits underlying short-term memory

Authors: *M. GOARD, G. PHO, M. SUR
MIT, Cambridge, MA

Abstract: Short-term memory, the ability to hold information in mind over short timescales, is a fundamental cognitive process underlying an array of complex abilities. Short-term memory is associated with sustained neural activity in cortical (and subcortical) structures, but it is not established how mnemonic information is maintained within distributed cortical regions. Here we developed a memory-guided visual discrimination task (with stimulus, delay, and choice epochs) for head-fixed mice, enabling large-scale 2-photon calcium imaging and targeted optogenetic perturbation of sensory, association, and motor cortices during STM. High-speed volume scanning was used to simultaneously image the neural activity of large populations (hundreds to thousands of cells) of GCaMP6s-expressing cortical neurons in visual, parietal, and frontal motor cortices. Visual cortex (V1) neurons primarily responded during the stimulus epoch whereas posterior parietal (PPC) and frontal motor cortical (fMC) neurons exhibited complex responses across all task epochs, including steady-state delay-period activity. To test the functional role of each region during task performance, we used VGAT-ChR2-EYFP mice (expressing channelrhodopsin in inhibitory interneuron types) to inactivate defined regions of cortex in a spatially and temporally restricted manner. Optogenetic inhibition of bilateral V1 or PPC disrupted behavioral performance only during the stimulus epoch, revealing that PPC was not necessary for STM maintenance despite exhibiting prominent delay-period activity. Surprisingly, photoinhibition of fMC disrupted performance not only during choice, but also during stimulus and delay epochs. These results indicate that in a memory-guided behavior, task-relevant information can be rapidly transmitted from sensory to association to frontal motor cortices, where steady-state activity is essential for STM maintenance.

Title: Dysfunctional learning: what happens in the dentate nucleus when one gets the answer to an acoustically cued question wrong?

Authors: *C. D. WOODY
UCLA Med. Cntr. NPI 58-258, Los Angeles, CA

Abstract: Can patterns of neuronal response in subcerebellar nuclei distinguish correct from incorrect learned motor responses to acoustic stimuli? To examine this spike activity was recorded from 204 single units of the dentate nuclei of awake cats trained to perform discriminatively conditioned blink responses (CRs) to a 70 dB click CS versus a 70 dB hiss DS. Concurrent bipolar recordings of EMG activity from the orbicularis oculi muscles during each trial of CS presentation allowed objective assessment of the presence or absence of CRs while remaining blind to the associated spike activity. The trials were separated into those with absent CRs (failed to exceed 3 sd of baseline activity and no apparent CR-like increase >2 sd), weak CRs (exceeded 2 but not 3 sd of baseline), and strong CRs (exceeded 3 sd of baseline activity). Averages were then made of PSTHs of spike activity associated with each classification and the concurrent EMG activity. The overall averages of EMG activity showed a peak response 12 Z above baseline in the trials with strong CRs, a response 8 Z above baseline in the trials with weak CRs, and a response 3 Z below baseline in the trials with putatively absent CRs. There was a separate group of cells in which each trial showed a strong CR (EMG mean peak response 157 Z above baseline). The PSTHs of corresponding CS-evoked spike activity showed peak discharges 25 Z above baseline in the cells with each trial showing a strong CR, 21 Z in the group with strong CRs, discharges 13 Z in the group with weak CRs, and discharges 12 Z in the group with putatively absent CRs. Baseline spike activity was highest in the group with putatively absent CRs. The results demonstrate that the signal:noise ratio of spike activity

elicited by the CS in dentate nucleus is reduced when performance of the CR is deficient and that the coding matters. Early latency (4-12 ms) spike responses were less well correlated with changes in EMG activity than slightly later (12-24 ms) responses, illustrating the dual functions of the dentate (see refs.). Apparently the dentate nucleus is involved directly or indirectly with production of dysfunctional learned motor responses to an acoustic CS, and enhancement of spike activity plus reduction of baseline noise may help reduce such errors. Title: Adaptive interpretation of sounds without the auditory cortex

Authors: T. L. GIMENEZ[1], M. LORENC[2], *S. JARAMILLO[1]
[1]Univ. of Oregon, Eugene, OR; [2]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: A defining feature of adaptive behavior is our ability to change the way we interpret sensory stimuli depending on context. We designed a two-alternative choice sound-categorization task for rats to study the neuronal mechanisms underlying this flexibility in behavior. Animals were required to associate low frequency sounds with a left reward port, and high-frequency sounds with a reward port on the right. Each behavioral session was divided into blocks of 200 trials, and the boundary that separated the two acoustic categories changed from one block to the next. These shifts in the boundary resulted in changes in the rewarded action for a subset of stimuli. Rapid adaptation in behavior has usually been attributed to cortical circuits. In this study we tested if the auditory cortex was necessary for succesful performance of the

flexible categorization task. We found that extensive lesions of the auditory cortex did not impair the ability of rats to switch between categorization contingencies, and sound discrimination was minimally impaired as measured by psychometric curves under each contingency. Similar results were obtained after reversible inactivation of the auditory cortex with muscimol. In contrast, lesions of the auditory thalamus largely impaired discrimination performance, and as a result, the ability to modify behavior across contingencies. Thalamic lesions did not impair performance of a visual discrimination task, indicating that the effects were specific to audition and not to motor preparation or execution. These results suggest that subcortical outputs of the auditory thalamus can mediate adaptive interpretation of sounds.

Title: Early termination of drift diffusion trajectories in decision making in monkeys

Authors: *S. CHANDRA, M. A. G. ELDRIDGE, B. RICHMOND
NIMH, Lab. of Neuropsychology, NIH, Bethesda, MD

Abstract: Monkeys can learn to classify whether images morphed from cat to dog, i.e., images of cats and dogs that are blended in different proportions, are more cat-like or dog-like. In the experiments that we are modeling here, monkeys were required to identify whether the morph being presented is closer to a cat or a dog in a sequential two-alternative forced choice task. The monkeys were trained to touch a bar to initiate a trial, and release the bar during one of two intervals; early (during the presence of a red central target) if they identified the stimulus as more cat-like, or late (following the transition of the central target to green) if the stimulus was more dog-like. Rewards were only delivered for correctly identifying a dog. In summary, if cat, release on red to skip the trial and move on to the next, if dog, release on green to get a reward. We measured the percentage of trials and reaction times when the monkey correctly indicated cat. As the morph level changes from pure cat towards dog, the number of times the monkey indicated a cat decreased sigmoidally. The sigmoid was also shifted toward dog, indicating a bias toward

choosing dog - when very unsure, guessing dog prevents missing a potential reward, with a penalty of having to wait through the whole trial for nothing if the stimulus should have been identified as cat. As the morph progresses from all cat to equal cat/dog, the monkeys take longer to make a decision, i.e., the reaction times become longer. We model this behavior as a drift diffusion process. A point starts midway between 2 boundaries, and takes a random walk until it hits a boundary, which represents a decision of cat or dog. The drift velocity depends on the morph level presented. The model has an analytical solution. Here we use the experimentally measured frequency with which the monkey identifies a given morph as dog to determine the drift velocity, which is then used to predict the mean reaction time. We find that for morph levels close to a pure cat the experimental mean reaction times are similar to the theoretical ones. When the morph level is close to a 50:50 mixture, the experimental mean reaction times are faster than the theoretical predictions. It appears that for the easy morph levels the monkey reaches the boundary quickly and decides. For more ambiguous morphs the monkey takes more time to accumulate evidence. If reaching a bound takes too long, the monkey stops accumulating evidence and indicates dog - not wanting to miss a potential reward. The question now is whether there is another process apart from drift diffusion, also stochastic, governing how long the monkey will wait to accumulate evidence before simply terminating the trial by guessing dog.

Title: VTA neurons exhibit associative activity to cues based on inferred value

Authors: *B. F. SADACCA, G. SCHOENBAUM
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: In recent years, the application of reinforcement learning models to neuroscientific data has led to an understanding that multiple decision making systems do, in fact, coexist in the brain, with two of these described in terms of ‘model-free’ and ‘modal based’ decision making.

Dopamine (DA) released from the ventral tegmental area (VTA) has often been related to model-free learning; actions that occur just prior to increases in DA release are more likely to occur again, and cues that occur just prior to increases in DA release are more likely to be sought. However, it is unclear if dopamine neurons of the VTA have access to information about cues whose relationship to reward is inferred. To test if VTA neurons can predict this value, rats were run in a sensory pre-conditioning task, while the activity of VTA neurons was recorded extracellularly. In this task, rats first learn a timing relationship within two pairs of cues in the absence of reward (A before B, and C before D). Rats then learn that one of the cues (B+) predicts the availability of reward while another (D-) predicts the absence of reward. In a final phase, rat behavior is monitored while cues A and C occur; here rats infer the learned relationship between cues A and B, and try to access reward in the presence of cue A alone. In the test, neurons showed early phasic responses to cues with inferred value mimicking the responses to cues explicitly paired with reward, clearly demonstrating that the VTA can access values beyond the model-free systems of the brain. Further, beyond this reward-related activity, during initial pre-conditioning VTA neurons show a diverse array of evoked responses to cues not yet paired with reward. Taken together, these finding demonstrate a role for the VTA beyond simply driving learning based on immediate experiences, and suggests that there may be further effects of drug-induced plasticity in VTA beyond changes to simple cue-reward learning.

Abstract: Since the finding that midbrain dopamine neurons signal the difference between actual and predicted outcomes (reward prediction error), dopamine has been postulated to play an essential role in updating values according to reward prediction error as postulated by reinforcement learning theory. However, the extent and nature of dopamine roles in reward-based learning are still under debate. Also unknown are specific roles of different dopamine receptor subtypes in this process. In order to investigate roles of dopamine D1 and D2 receptor subtypes in reward-based learning, we examined choice behavior of dopamine D1 and D2 receptor-knockout (D1R-KO and D2R-KO, respectively) mice in an instrumental learning task with progressively increasing reversal frequency and a dynamic foraging task. Performance of D2R-KO mice was progressively impaired in the reversal task as the frequency of reversal increased and severely impaired in the dynamic foraging task even with prolonged training. By contrast, D1R-KO mice showed only minor performance deficits in these tasks. The animal's choice behavior was well explained by a hybrid model including win-stay-lose-switch and simple reinforcement learning terms. A model-based analysis revealed increased win-stay, but impaired value updating and decreased value-dependent action selection in D2R-KO mice, which would be detrimental to making optimal choices based on the history of past rewards in the dynamic foraging task. Our results indicate an important role of dopamine D2 receptors in learning from the history of past choices and their outcomes for optimizing choice strategy in a dynamic and uncertain environment.

Title: Information processing in temporal lobe area TE and in rhinal cortex during a visual categorization task

Authors: *K. LOWE, M. A. G. ELDRIDGE, R. C. SAUNDERS, B. J. RICHMOND
Lab. of Neuropsychology, NIH, Bethesda, MD

Abstract: Single unit recordings in regions of inferior temporal cortex--specifically area TE and rhinal cortex (Rh)--have implicated these regions in late-stage visual processes, such as categorization and stimulus-reward association, respectively. We have previously reported (SFN, 2012) that TE-lesioned monkeys are only mildly impaired in a perceptually difficult test of visual categorization (employing dog-cat morphs), and that the performance of Rh-lesioned monkeys is indistinguishable from that of controls. Now, we asked whether decreasing the information available by shortening the stimulus duration would affect any of our study groups: controls, or monkeys with either TE or rhinal removals. We trained the monkeys to touch a bar to initiate a trial, and release the bar during one of two intervals; early (during the presence of a red central target) if they identified the stimulus as more cat-like, or late (following the transition of the central target to green) if the stimulus was more dog-like. A correct response resulted in the delivery of a fixed-size liquid reward, an incorrect response led to a punishment time-out. We presented the morphed stimuli for durations of 25, 50, 100, 250 or 500 ms in an interleaved design. The stimuli appeared on a background of black and white noise. When the stimuli were removed, the background immediately reappeared; the reappearance of the visual noise appeared to mask the after-image. The accuracy with which control monkeys categorized the stimuli decreased as the stimulus presentation became shorter. The reaction times of control monkeys were indistinguishable across the different stimulus durations. Bilateral TE and Rh cortex removals had different effects: TE-lesioned monkeys made more incorrect categorization judgments, but made their decisions as quickly as controls. Rh-lesioned monkeys categorized as accurately as controls, but took longer to respond, that is, their reaction times were longer. The mild impairment in the performance of TE-lesioned monkeys is consistent with our previous results, and may reflect compromised perceptual or associative processes. The slower reaction times of the Rh-lesioned monkeys could be related to the decision process in some as yet undefined manner.

Title: Optogenetic induction of fast-gamma and sharp-wave ripples *in vivo*

Authors: *D. C. KLORIG[1], G. ALBERTO[2], M. MASICAMPO[3], D. W. GODWIN[3]
[1]Neurosci. Program, Wake Forest Hlth. Sci., Winston-Salem, NC; [2]Neurosci., [3]Neurobio. and Anat., Wake Forest Univ. Hlth. Sci., Winston-salem, NC

Abstract: Sharp-wave ripples (SWRs) are naturally occurring high-frequency (140-200 Hz) oscillations thought to be involved in memory reconsolidation. SWRs are found in the pyramidal cell layer of hippocampal area CA1 during quiescent and sleep states, associated with strong depolarizing inputs from CA3. Weaker depolarizing inputs to CA1 produce similar but distinct oscillatory activity in the fast-gamma range (90-150 Hz). Optogenetic light-ramp stimuli have been demonstrated to induce gamma oscillations in cortex and CA3, despite conveying no oscillatory content themselves. Using chronically implanted transgenic mice expressing Channelrhodopsin 2, we found that depolarization of CA1 pyramidal neurons using light ramp stimuli was sufficient to induce high-frequency oscillations (HFOs) in the fast-gamma to ripple range (80-200 Hz) (n = 5). We also observed that the frequency of the evoked oscillation was tightly correlated with the amplitude, but not the slope, of the depolarizing input and was reduced by potentiation of GABAa receptors. Evoked oscillation frequency and magnitude did not vary with behavioral state and could be held for the longest duration tested (10 sec). These results support the hypotheses that: 1) HFOs in the fast-gamma and ripple ranges are a robust intrinsic property of the CA1 local circuit; 2) SWRs and fast-gamma are paced by GABAergic interneurons and share similar mechanisms; and 3) CA1 functions as a voltage controlled oscillator.

Title: Role of astrocyte connexins in the regulation of sleep oscillatory patterns

Authors: *M. M. LACROIX[1], L. ROUX[2], C. GIAUME[3], K. BENCHENANE[4]
[1]CNRS UMR7637, Paris, France; [2]Neurosci. Inst., New-York Univ., New-York, NY; [3]CNRS UMR 7241 / INSERM U1050, Collège de France, CIRB 7241, Paris, France; [4]CNRS UMR 8249 Brain Plasticity Unit, ESPCI Paris Tech., Paris, France

Abstract: Coordination across brain structures is thought to be crucial for the appropriate consolidation of memory trace. Cortical slow oscillations orchestrate the timing of hippocampal ripples (supporting neuronal reactivations), cortical delta waves and cortical spindles. Our project aims at challenging the classical "neurocentric" view of brain rhythms regulation during sleep. Indeed, recent evidences showed that astrocytes regulate cortical slow oscillations during sleep and are involved in brain processes related to memory deficits induced by sleep deprivation (Halassa et al. 2009). We therefore investigated the role of astrocytic connexins (main constituent of gap junctions and hemichannels) in the regulation of network oscillations, by multi-site recordings in mice double knock-out for astrocytic connexins Cx43 and Cx30 (dKO) (Wallraff et al. 2006). Our results show that sleep slow oscillations are decreased in cortical structures and that the coordination between spindles and ripples are impaired in this dKO model. Moreover, we found that the slow rhythm associated to breathing was also impaired in the olfactory bulb of dKO mice, confirming the results obtained *in vitro* by Lisa Roux. Olfactory bulb slices indeed exhibit spontaneous oscillations very similar to the slow oscillations recorded during sleep in cortical cells, and those oscillations are impaired in dKO mice. Therefore here we suggest that astrocytes could be involved in the fine regulation of sleep oscillatory patterns.

Title: Sleep-scoring in mice using gamma frequency in the olfactory bulb

Authors: *S. BAGUR[1], M. LACROIX[2], K. BENCHENANE[2]
[1]ESPCI, Paris, France; [2]Brain Plasticity Unit (UMR 8249 CNRS), ESPCI - ParisTech, Paris, France

Abstract: The growing interest in the physiology of various behavioral states demands reliable and systematic methods of wake and sleep stage scoring. Traditional methods identify sleep by monitoring movement or muscular activity, however if sleep and wake are truly different brain states the two should be identifiable using information on neuronal activity alone. It has been shown that gamma oscillations in the olfactory bulb (OB) of the mouse are strongly reduced during sleep (Manabe et al. 2013). Here, we show that low gamma power in the 50-70Hz band recorded from the OB shows a bimodal distribution that allows to separate sleep and waking states. Moreover rapid-eye-movement (REM) and non-REM (NREM) sleep can be distinguished using theta-band power (6-10Hz) recorded in the hippocampus (HPC). We therefore present a method of constructing a two-dimensional phase space allowing to distinguish between waking, REM and NREM sleep that relies exclusively on LFP recordings from the HPC and the OB and can be automatically calibrated. This technique allows for identification of brief periods of arousal and dozing and is therefore a promising tool for the fine study of sleep microstructure.

Title: Explicit memory creation during sleep: The causal role of place cell on navigation

Authors: *G. DE LAVILLEON[1,2], M. M. LACROIX[1], L. RONDI-REIG[2], K. BENCHENANE[1,2]
[1]MOBs Team, Brain Plasticity Unit, UMR 8249 CNRS ESPCI, Paris, France; [2]CeZaMe Team, Neurosciences Paris Seine, CNRS UMR 8246, INSERM UMR-S 1130, Paris, France

Abstract: It is now widely accepted that sleep is important for the consolidation of preexisting memory traces, and hippocampus is thought to be a critical player is this process. Here we show that a place preference task can be learned during sleep without prior waking experience, using spontaneous neuronal reactivations. We design a protocol to trigger during sleep, intracranial rewarding stimulations by the action potentials of a unique hippocampal place cell. At waking, animals went and stayed within the associated place field. These results show that it is possible to create an artificial explicit memory during sleep and that this memory trace is used during subsequent waking period to drive a goal directed behavior. Moreover, it demonstrates that place cells activity is functionally significant for navigation, and that place cells still conveys spatial information during sleep.

Title: Sleep and memory consolidation of auditory classification learning in European starlings

Authors: *T. P. BRAWN, H. C. NUSBAUM, D. MARGOLIASH
Univ. of Chicago, Chicago, IL

Abstract: Memory consolidation strengthens newly encoded memory traces and stabilizes them against interference, a process widely believed to benefit from sleep. Behavioral evidence of sleep-dependent memory consolidation is well established in human memory tasks but is limited in adult animals. We previously demonstrated sleep-dependent memory benefits in European starlings that were trained on a Go/No-Go task to classify pairs of 5-second segments of novel starling songs. Classification accuracy improved after retention intervals that included sleep but not after waking retention (Brawn et al., *Journal of Neuroscience*, 2010). Furthermore, learning two similar classification tasks (tasks A and B) interfered with each other during the day, resulting in performance impairments for both tasks after waking retention. Yet, performance on both tasks improved after sleep (Brawn et al., *Psychological Science*, 2013). Here we aim to characterize patterns of sleep in starlings and to correlate post-training changes in sleep structure with post-sleep memory improvements on an auditory classification task. In an initial behavioral experiment, starlings in three conditions were trained on classification task A and received an immediate post-training test followed by posttests in the evening and next morning. The Control (no interference) condition only learned task A. The New-Interference condition learned classification task B (with novel stimuli) after task A. The Old-Interference condition also completed task B but with a previously learned stimulus set. Whereas performance in the Control and Old-Interference conditions remained stable across wakefulness, the New-Interference condition expressed significant performance impairments after waking retention, suggesting that the formation of interference requires the learning of a new classification task. Nonetheless, classification accuracy in each condition improved after sleep. In the current study, new starlings implanted with 4 EEG electrodes in each hemisphere complete the same three conditions while undergoing 56 hours of chronic EEG and video recording. Additionally, each bird will undergo 48 hours of chronic baseline EEG and video recordings prior to and after the completion of the three behavioral conditions. Though data analysis of sleep states has not begun, the behavioral results demonstrate a robust system of sleep-dependent memory consolidation in European starlings. We are currently attempting to use EEG recordings to connect the behavioral benefits of sleep to changes in slow wave sleep, intermediate (or transition) sleep, and rapid-eye movement sleep.

Title: Selective intervention in hippocampal and cortical consolidation: Impact of novelty and sleep

Authors: *L. GENZEL, J. ROSSATO, R. FITZPATRICK, R. G. M. MORRIS
Morris Lab., Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: BACKGROUND: For memory traces to be successfully recalled, they need to be consolidated. Different factors are thought to influence this process including (1) novelty exposure that enhances the persistence of a hippocampal trace via neuromodulation; and (2) sleep that aids systems consolidation and thus a cortically based memory. Do such hippocampal and cortical and traces differ qualitatively with respect to their behavioural expression, or their persistence over time? To investigate this, in Expts 1 and 2 rats were trained on two competing memories with training to one followed by sleep deprivation plus novelty (hippocampal) and the other by sleep (cortical). Further, in Expt 3, we compare IEG expression in the hippocampus and prefrontal cortex in association with retrieval between animals given each of the conditions. METHODS: In Expts. 1 and 2, rats were trained to learn two opposite escape locations in a watermaze over 2 sessions, with novelty + sleep deprivation, or sleep following session 1 and the alternative intervention after session 2 (counterbalanced). Probe trials without any platform present were conducted at varying times afterwards (Expt 1: 24h, 7d and 21d (within-subjects); Expt 2: 7d and 21d). In Expt. 3, rats were taught only one escape location and were then divided into two groups with novelty + sleep deprivation, or sleep, following the encoding session. Probe trials were performed for Expt 3a at 24h, 7d and for Expt 3b at 7d. 30 min after the 7d probe the animals were sacrificed for qPCR analysis. RESULTS: In probe tests at 24h, the rats remembered both escape locations in the watermaze, but displayed a preference for the location whose encoding was followed by novelty (hippocampal trace dominating). This hippocampal memory trace did not survive to 7d at which time the cortical trace dominated. In Expt 2 without the 24h probe, the novelty-enhanced memory trace did survive, suggesting the expression of a hippocampal trace can contribute to its demise. Performance was at chance in all conditions by 21d. Expt. 3 confirmed this pattern of results in the between subject design, but further showed that cortical memory at 7d can paradoxically benefit from the 24h probe trial without feedback,

i.e. under conditions where there is no competition between the hippocampal and cortical trace. qPCR analysis of IEG is underway. CONCLUSION: These data contribute to other findings suggesting a dynamic interplay of hippocampal and cortical memory. They indicate that cortical memory is more resistant to interference, but at the cost of being less exact and vivid, while hippocampal memory can enable a stronger behavioural response soon after memory encoding.

Title: The neural basis of complex associative memory in tone-light compound fear conditioning in mice

Authors: *O. I. IVASHKINA[1], M. ROSHCHINA[1], K. TOROPOVA[1], K. ANOKHIN[1,2,3,4]
[1]Dept. of Neurosci., NRC Kurchatov Institute, NBICS-Center, Moscow, Russian Federation; [2]Dept. of Systemogenesis, Anokhin Inst. of Normal Physiol. RAMS, Moscow, Russian Federation; [3]Inst. of Higher Nervous Activity and Physiol. RAS, Moscow, Russian Federation; [4]Lab. of Brain Stem Cells, Moscow Inst. of Physics and Technol., Moscow, Russian Federation

Abstract: Cellular mechanisms of associative memory are commonly studied in Pavlovian fear conditioning to a single discrete stimulus. Much less is known about neuronal mechanisms engaged in formation and retrieval of complex associative memories composed of stimuli from several modalities. In the present study we used mouse fear conditioning to a compound cue consisted of auditory (tone, T) and visual (blinking light, L) stimuli. First, we showed that mice could successfully establish fear learning to compound T+L stimulus, along with discrete T or L stimuli. In retrieval session 7 days after the training mice, conditioned to compound cue were presented either with the entire compound cue, or with its discrete T or L components. Mice, that were conditioned to one of cues (T or L) were presented with the relevant cue in the retrieval

session. Active control animals were presented with T+L compound stimulus, without footshock during training session and with T+L, T or L stimuli during retrieval session. To evaluate patterns of brain regions involved into memory formation and retrieval by entire compound cue or its discrete components we performed c-Fos mapping in associative and sensory cortices (frontal, prelimbic, cingular, retrosplenial, parietal, primary and secondary visual, primary and secondary auditory), hippocampal areas (CA1, CA3, dentate gyrus) and amygdala nuclei (basolateral, lateral and central). First, we showed the specific involvement of prelimbic and frontal associative cortices along with amygdala nuclei in associative memory formation, both to compound or single cues. Next, we compared patterns of c-Fos expression after memory retrieval by the entire compound cue or by its discrete components in compound cue conditioned-mice and by relevant cue in single cue-conditioned animals. Retrieval of complex memory by light or tone component was accompanied by specific activation of the prelimbic, parietal, primary visual, mediolateral area of the secondary visual cortex and amygdala nuclei. Hippocampus was specifically involved neither in formation nor in the retrieval of associative memory. Taken together our data suggests that complex associative memory is supported by distinct cortical mechanisms that affect both sensory and associative cortical areas. Moreover, brain regions that shape neural basis of complex associative memory formation and its retrieval are different.

Title: Erasure of recent and remote hippocampus-dependent fear memory by enhancing memory forgetting through increase in adult hippocampal neurogenesis

Authors: *R. ISHIKAWA[1], P. FRANKLAND[2], S. KIDA[1,3]
[1]Biosci., Tokyo Univ. of Agr., Tokyo, Japan; [2]Univ. of Toronto, Toronto, ON, Canada; [3]CREST, JST, Saitama, Japan

Abstract: Erasure of fear memory is thought to be a therapeutic target for emotional disorders such as post-traumatic stress disorders (PTSD). Memantine (MEM) is a noncompetitive N-methyl-D-aspartate (NMDA) glutamate receptor antagonist and has known to enable to increase in adult hippocampal neurogenesis. Previous study has shown that increasing adult hippocampal neurogenesis enhanced forgetting of hippocampus-dependent memory formed recently. In this study, we tried to examine effects of MEM treatment on forgetting of hippocampus-dependent fear memory. Mice were contextual fear-conditioned with an electrical footshock and then received systemic injections of MEM (50 mg/kg body weight) once a week for 4 weeks. We found that MEM-treated group displayed disruption of contextual fear memory following the MEM treatment, while control group treated with saline displayed normal contextual fear memory. Importantly, MEM-treated group did not show spontaneous recovery of fear memory even a month after the MEM treatment. Moreover, we observed similar effects of MEM treatment on inhibitory avoidance memory, another type of hippocampus-dependent fear memory. In contrast, MEM-treated group showed normal amygdala-dependent cued fear memory. We next examined the relationship between erasure of hippocampus-dependent memory and enhancement of adult hippocampal neurogenesis by MEM. Mice received an injection of MEM followed by injections of 5-bromo-2-deoxyuridine (BrdU; 50 mg/kg body weight) 2 days later, and then were contextual fear-conditioned. Interestingly, there was a significant negative correlation between the number of BrdU-positive cells increased by MEM and differences of freezing scores before and after the MEM treatment. These observations suggest that MEM treatment enables to erase hippocampus-dependent fear memory by enhancing memory forgetting through the increase in adult hippocampal neurogenesis. Thus our findings suggest a possible therapeutic treatment to weaken traumatic memory. We are now examining effects of the MEM treatment on remote fear memory.

Title: Up-regulation of CREB activity in forebrain enhances working-like memory and increases spine density in the hippocampus

Authors: *T. SERITA[1], H. FUKUSHIMA[1,2], S. KIDA[1,2]
[1]Tokyo Univ.Of Agr., Tokyo, Setagaya, Japan; [2]JST, CREST, Saitama, Japan

Abstract: Transcription factor cAMP response element-binding protein (CREB) plays essential roles in memory formation through activation of gene expression. Our previous study indicated that loss-of-CREB function leads to an impairment of long-term memory (LTM), but not short-term memory (STM). To further understand roles of CREB in learning and memory, we have examined effects of gain-of-CREB function on memory formation by generating transgenic mice expressing a constitutively active CREB mutant (CREB DIEDML) in the forebrain. Interestingly, these transgenic mice displayed enhancement of not only LTM but also STM, suggesting that CREB positively regulates both LTM and STM. These findings raise the possibility that CREB plays critical roles in learning processes. To ask this, we first examined the ability of temporal association learning and spatial working memory in DIEDML mice. In the trace fear conditioning task, mice learn an association between the conditioned stimulus (CS; tone) and the unconditioned stimulus (US; footshock) separated by the trace interval. During the training that consists of 8 CS-trace-US-intertrial interval, mice were assessed freezing responses during each trace interval. DIEDML mice learned trace fear conditioning significantly faster and better compared to wild-type (WT) mice. We next performed working memory version of Morris water maze task in which mice were given training with 4 trials (trial 1-4) per day and the position of platform was changed every day. DIEDML mice showed significantly more decreases in escape latencies to the platform at the trial 2-4 compared to WT mice although these mutant mice displayed normal escape latency at the trial 1. These results indicated that DIEDML mice showed enhancement of working memory. Thus our results suggest that up-regulation of CREB activity improves working-like memories. Furthermore, morphological analysis of dendritic spine of hippocampus revealed that DIEDML mice showed significant increase in dendritic spine density compared to WT mice. These changes in dendritic spine density or morphology of neurons observed in DIEDML mice may contribute to improvement of learning process.

Title: Poly ADP-ribosylation is required for reconsolidation and extinction of contextual fear memory

Authors: *H. INABA[1], A. TSUKAGOSHI[1], S. KIDA[1,2]
[1]Dept. of Biosci, Tokyo Univ. of Agr., Tokyo, Japan; [2]CREST, JST, Saitama, Japan

Abstract: Retrieval of contextual fear memory by re-exposure to conditioned stimulus (CS; context) initiates new gene expression-dependent processes; reconsolidation and extinction. Our previous study showed that short (3 min) re-exposure to the CS (context) inducing memory reconsolidation activated new gene expression in the hippocampus and amygdala, while long (30 min) re-exposure inducing memory extinction activated it in the medial prefrontal cortex and amygdala (Mamiya et al., 2009). Poly (ADP-ribose) polymerase-1 (PARP-1) has been known to covalently modify nuclear proteins including histones and transcription factors through poly ADP-ribosylation. Interestingly, recent studies have suggested that poly ADP-ribosylation by PARP-1 plays critical roles in long-term neuronal plasticity and formation of long-term memory in *Aplysia* and mammals (Cohen-Armon et al., 2004; Hernandez et al., 2009; Fontan-Lozano et al., 2010). To understand roles of poly ADP-ribosylation in the regulation of contextual fear memory after retrieval, we have examined effects of inhibition of poly ADP-ribosylation in the hippocampus and medial prefrontal cortex in reconsolidation and extinction in mice. Mice were micro-infused a PARP-1 inhibitor (3-aminobenzamide (3AB) or PJ34) into the hippocampus or medial prefrontal cortex 5 min before or immediately after the re-exposure for 3 or 30 min. This inhibition of poly ADP-ribosylation in the hippocampus impaired reactivated contextual fear memory when tested 24 hrs, but not 2 hrs, after the re-exposure for 3 min, suggesting that poly ADP-ribosylation in the hippocampus is required for reconsolidation of contextual fear memory. Additionally, the inhibition of poly ADP-ribosylation in the medial prefrontal cortex, but not the hippocampus, blocked long-term extinction of contextual fear memory, suggesting that poly ADP-ribosylation in the medial prefrontal cortex is required for consolidation of extinction memory. Our findings suggest that poly ADP-ribosylation in the hippocampus and medial prefrontal cortex plays essential roles in reconsolidation and extinction, respectively, of contextual fear memory.

Title: Posttraining optogenetic control of basolateral amygdala projections to the ventral hippocampus modulates the consolidation of emotional, but not contextual, learning in rats

Authors: *M. L. HUFF, R. T. LALUMIERE
Psychology, Univ. of Iowa, Iowa City, IA

Abstract: The basolateral amygdala (BLA) modulates memory consolidation for multiple types of learning, including contextual fear conditioning (CFC), whereas other brain regions appear to play more specific roles in different kinds of learning. However, whether BLA projections to such regions influence memory consolidation in a learning-specific manner has never been directly investigated. One of the BLA's efferent targets, the ventral hippocampus (vHPC), has previously been suggested to selectively process emotion-related aspects of learning, yet whether the BLA->vHPC pathway modulates memory consolidation, and does so in a manner specific to the type of information being learned, is unknown. Therefore, the present study used an optogenetic approach to modulate activity in the BLA->vHPC pathway during the consolidation period immediately following training in a modified CFC task that permits separation of the context and footshock learning. Male Sprague-Dawley rats received intra-BLA injections of an adeno-associated virus that produced expression of either the light-sensitive membrane-bound cation channel channelrhodopsin-2 [ChR2(E123A); to permit high-frequency stimulation] or the outward proton pump archaerhodopsin (eArchT3.0; to permit inhibition). After allowing ~5 weeks for opsin expression, fiber optic probes were implanted immediately dorsal to the vHPC to provide later illumination of the BLA axonal fibers innervating this region. For the CFC task, rats received 3 min of pre-exposure to the apparatus on day 1. On day 2, rats were placed into the apparatus, received an immediate footshock, and were then quickly removed. Retention was tested on day 4. Results indicate that optical stimulation of the BLA->vHPC pathway following context pre-exposure had no effect on retention regardless of the stimulation frequency. In contrast, optical stimulation of the BLA->vHPC pathway following footshock training, using trains of 40, but not 20 or 80, Hz light pulses, enhanced retention. Similar light pulses given to eYFP-control rats following footshock training had no effect on retention. In rats that did not receive context pre-exposure, optical stimulation of this pathway did not affect retention.

Preliminary work also suggests 15 min of optical inhibition of this pathway following footshock training impairs retention. These findings provide direct evidence that BLA projections to other brain regions modulate memory consolidation differently depending on separable components of a task. Specifically, BLA->vHPC projections influence the consolidation for the footshock, but not context, learning for a modified CFC task.

Title: Retrieval of contextual fear memory enhances the post-burst afterhyperpolarization in burst-spiking cells in the subiculum

Authors: *K. A. HOPE, S. M. NEUNER, L. A. WILMOTT, C. C. KACZOROWSKI
UTHSC, Memphis, TN

Abstract: Changes in intrinsic neuronal excitability following a learning task have been demonstrated in many brain regions, especially the hippocampus. The subiculum is the major output pathway of the hippocampus and contains two distinct pyramidal cell types: burst-spiking and regular-spiking neurons (also referred to as early-bursting and late-bursting neurons, respectively). It is generally thought that burst-spiking neurons convey spatial information, while regular-spiking neurons convey non-spatial information. Despite the importance of the subiculum for hippocampal output, learning related changes have remained largely unexplored in this key brain region. Here we used a hippocampus-dependent contextual fear conditioning task to examine changes of intrinsic excitability in burst-spiking and regular-spiking neurons of the subiculum in the mouse. We found that the medium component of the afterhyperpolarization (mAHP) was significantly enhanced in burst-spiking neurons after fear conditioning and retrieval of contextual fear memory (-3.75±0.21 mV) compared to mice that either underwent fear conditioning without retrieval (-2.61±0.36 mV), context exposure without shock (-3.07±0.39 mV), or home cage controls (-2.16±0.45 mV). Interestingly, regular-spiking neurons showed no change in AHPs in any treatment group. Moreover, the slow component of the AHP was

unaffected relative to conditioning groups and across cell types. We hypothesize that the cell-type specific enhancement of the mAHP in burst-spiking neurons following retrieval of fear memory may facilitate extinction of conditioned contextual fear memory. Ongoing studies in our laboratory aim to identify the molecular mediators of AHP plasticity in burst-spiking neurons during the retrieval process and assess their role in the extinction process. Mechanisms underlying this plasticity may be particularly relevant to understanding dysfunction of fear-related disorders including post-traumatic stress disorder.

Title: Acute effects of exposure to space radiation on CNS function and cognitive performance

Authors: *B. M. RABIN[1], B. SHUKITT-HALE[2], K. L. CARRIHILL-KNOLL[1], D. F. BIELINSKI[2], S. M. POULOSE[2], N. A. HEROUX[1], C. BAXTER[1]
[1]Univ. Maryland Baltimore County, Baltimore, MD; [2]Human Nutr. Res. Ctr. on Aging, USDA-ARS, Boston, MA

Abstract: On exploratory class missions, such as a mission to Mars, astronauts will be exposed to types and doses of radiation (cosmic rays) that are not experienced in low earth orbit where the Space Shuttle and International Space Station operate. Exposure to cosmic rays produces changes in neuronal function and in cognitive performance. While the changes in neuronal function are observed as shortly as 36 hr following irradiation, it is not known whether or not there are similar acute effects of exposure on cognitive performance and how the behavioral changes may relate to the changes in neuronal function. The present experiment was designed to determine the acute effects of exposure to space radiation on cognitive performance (novel object recognition) and the relationship to radiation-induced changes in neuronal function. Conditioning occurred either 3-6 hr before (memory) or 18 hr after (learning) exposure to 56Fe or 16O particles (600 MeV/n). Exposure to either particle disrupted the recall of a previously

acquired task (memory), but did not affect the acquisition (learning) of the task. Following behavioral testing rats were euthanized; their brains removed and selected areas analyzed for oxidative stress. Increases in the levels of NOX2 were observed in several brain regions including hippocampus, frontal cortex, cortex, striatum and cerebellum following irradiation. Changes in oxidative status varied as a function of whether or not there was an effect of irradiation on cognitive performance, as NOX2 levels were different between the rats exposed using the memory design and those exposed using the learning design. These results suggest that exposure to the types of radiation encountered in space may affect the recall of recently acquired material (memory) but may not have immediate effects on the acquisition of new material (learning). The results also suggest that exposure to space radiation has widespread effects on neuronal function throughout the brain, and some of these changes in neuronal function may be related to the radiation-induced changes in cognitive function.

Title: Layer specific inputs to layer V primary motor cortex exhibit different profiles of training-induced synaptic plasticity

Authors: *Q. LI[1], H. KO[1], C. W. CHAN[1], G. ARBUTHNOTT[2], Y. KE[1], W. H. YUNG[1]
[1]Sch. of Biomed. Sci., The Chinese Univ. of Hong Kong, Hong Kong, China; [2]Okinawa Inst. of Sci. and Technol. Grad. Univ., Okinawa, Japan

Abstract: Functionally distinct streams of information are conveyed by synapses that terminate at different dendritic sites of cortical pyramidal neurons. As the major output neuron of neocortex, how layer V pyramidal neurons integrate widespread synaptic inputs to both proximal

basal dendrites and distal apical tuft dendrites and shape the learning-related cortical plasticity in intact brain is an important but unanswered question. As a first step to address this issue, in the present study, we examined the properties of physiologically induced plasticity in these layer-specific synaptic inputs by chronic field potential recordings from the primary motor cortex of rats undergoing forelimb-reaching task. A 16-channel microwire recording array and 2 pairs of monopolar stimulating electrodes were implanted into MI forelimb territory, with recoding site at layer V and stimulating sites at both layer V and layer I. Different synaptic inputs targeting basal and apical dendrites were induced by stimulating the layer V local circuit and superficial layer I respectively, which were further confirmed with the aid of current source density analysis. The potentiation level of synaptic plasticity was evaluated by the increment of the stimulation evoked field potential amplitude. In the initial learning phase (day1 to day3), rats exhibited rapid improvement in single success rate (baseline in naïve subjects: 8.74± 3.0%; end of day1: 31.3±3.1%; end of day3: 42.9±1.1%; n=6). This fast, motor skill acquisition stage was accompanied by substantial learning-related synaptic potentiation on both local basal dendrites (day1: 26.2±5.3%; day3: 35.4±3.2%, n=4) and distal apical tuft dendrites (day1: 28.2±4.1%; day3:27.7±4.8%, n=5). As training continued, motor skill was consolidated gradually, and the single success rate reached a plateau (day7: 44.4±2.4%, n=6). Intriguingly, only the potentiated synaptic input targeting the basal dendrites could be sustained till day 7 (34.2±5.6%, n=4), but not those targeting the apical tufts dendrites (7.2±3.2%, n=5). The consolidated synaptic potentiation on local basal dendrites could be impaired by locally depleting the mesocortical dopaminergic innervation, which also compromised overnight retention of newly learned skill. Our results suggest that motor learning-related synaptic potentiation in basal and apical dendrites of layer V pyramidal neuron exhibit different coupling profiles, implying different functions in motor memory formation. Dopamine appears to be essential for long-term consolidation of synaptic plasticity mediated by local basal dendritic circuit.

Title: The effect of subhypnotic doses of propofol on spatial memory retrieval and the phosphorylation of glycogen synthase kinase-3β in the hippocampus

Authors: H. LIU[1], *X. LIU[2], Y. LI[1]
[1]1st Affiliated Hosp. of Anhui Med. University, Anhui, China, He fei, China; [2]Dept. of Anesthesiol., 1st Affiliated Hosp. of Anhui Med. Univ., Anhui, China

Abstract: Objective: Propofol administration affects multiple stages of memory processes in both humans and animals. Many researches focused their attention on the influence of propofol on memory encoding and consolidation while leaving the unexplored area of propofol's effect on memory retrieval. Glycogen synthase kinase 3β (GSK3β) is a serine/threonine protein kinase and GSK3β has been suggest to implicate in synaptic plasticity and memory formation. Inhibition of GSK-3β induced by SB216763 was recently shown to weaken memory retrieval. The current experiments were designed to examine the effects of subhypnotic doses of propofol on memory retrieval in rats, and, more precisely, whether the glycogen synthase kinase GSK3β signaling pathway was involved in mediating the effects of pre-testing propofol administration on Morris water maze retention. Methods: Adult male Sprague-Dawley rats were trained on a water maze task in which they subjected eight trials during a single acquisition session. After 24 hours a probe test was processed to examine the memory retrieval effects of subhypnotic doses of propofol(10 or 25 mg/kg) administered intraperitoneally 5 minutes before test. Animal' hippocampi were isolated to measure the levels of different forms of GSK-3β. In addition, the behavior of 25mg/kg propofol in the open filed was observed to excluding the probable effects on spontaneous locomotor. Results: Subhypnotic doses of propofol (25mg/kg) administered 5 minutes before test significant decreased the time percentage spent in the target quadrant(24.6±2.3%,mean ± SEM) compared with the vehicle group(37.3±4.0%).Meanwhile, the impairment of memory retrieval by propofol is not due to the alteration of locomotor activity. On GSK- 3β assessment: memory retrieval is accompanied with inhibition of the Serine-9 residue phosphorylation of GSK-3β rather than the activation of Tyrosine- 216 residue, and propofol could reverse the increasing activity of GSK-3β induced by retrieval. Conclusion: A subhypnotic doses of propofol (25mg/kg) injected 5 minutes before Morris water maze test impaired memory retrieval. In addition, our results suggest that the amnestic effects of propofol might be mediated by weaken GSK-3β signaling in the hippocampus. [Key words] Propofol; Memory retrieval; hippocampus; glycogen synthase

Title: Neural mechanisms of strategy change during conditioned learning

Authors: R. KOZMA[1], *M. H. MYERS[2], W. J. FREEMAN[3]
[1]Mathematics, Univ. of Memphis, Memphis, TN; [2]Univ. of Memphis, Germantown, TN; [3]Mol. and Cell Biol., Univ. of California, Berkeley, CA

Abstract: Aim: Analyze neural dynamics underlying conditioned learning in gerbils using multichannel recordings in the auditory cortex and ventral striatum. Introduction: Conditioned learning is usually described as a monotonic optimization processes that can be well described in reinforcement learning framework. Experimental evidence, however, points to the existence of clearly defined moments of sudden changes in neural processes underlying learning [1, 2]. We hypothesize that the moments of abrupt changes indicate that the system gives up its existing behavioral strategy and transitions to the next state of cognition. Methods: We describe phase transitions in distributed systems to provide a suitable theoretical framework to model neuronal processes underlying behavioral strategy changes. We analyze multichannel recordings in the auditory cortex and ventral striatum in gerbils making the transition from naïve to avoidance behavior. Phase transitions in neuropercolation models [3] are used to interpret experimental findings. Results: We developed statistical tools to discriminate spatiotemporal activity patterns in cortical structures during the different phases of learning. We described the emergence of the attractor landscape of brain states, as well as state transitions in each action-perception-cycle that were analyzed in already trained animals. Conclusions: Cognitive abstraction from learned stimulus enables rodents to categorize previously unknown stimuli. The abstraction is described through the emergence of classifiable metastable spatiotemporal patterns. These patterns can be viewed as dynamically enacting symbols executing brain commands, rather than passive representational symbols [3]. 1. Title: Median raphe nucleus regulates hippocampal ripple oscillation and memory consolidation

Authors: *D. V. WANG, H.-J. YAU, C. J. BROKER, J.-H. TSOU, A. BONCI, S. IKEMOTO
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: Sleep promotes memory consolidation, a process known as reorganization and progressive integration of newly acquired information into pre-existing neural networks for long-term storage. Hippocampal sharp-wave ripples that occur primarily during slow-wave sleep are believed to play an essential role in the memory consolidation process. Ripples are thought to reactivate newly-formed hippocampal-neocortical neural ensembles and gradually transform them into neocortical memory traces. However, as ripples are intrinsically generated in the hippocampus, little is known about how they are regulated by other brain regions. Here we provide the first direct evidence that the median raphe nucleus, a midbrain structure, plays a key role in regulating hippocampal ripple activity and memory consolidation. We performed *in vivo* simultaneous recordings in the median raphe nucleus and hippocampus, and found that when a group of raphe neurons were active, ripples were absent. To determine a causal relationship, we employed an optogenetic approach and found that photostimulation of raphe neurons strongly suppressed hippocampal ripple activity. Conversely, photoinhibition of raphe neurons increased hippocampal ripple activity. We then examined whether such manipulation of raphe neurons would interfere with memory consolidation using a fear conditioning procedure, and found that photostimulation during subsequent sleep/ rest significantly reduced freezing behavior when mice were tested 24 hours later. Our results demonstrate an unprecedented role of the median raphe nucleus in regulating hippocampal ripple activity and memory consolidation processes. We anticipate that our study is a beginning to understand how subcortical and cortical regions interact to regulate memory processes and to provide insights for the treatment of affective/anxiety disorders arising from dysregulated memory processes.

Title: Rapid encoding of novel spatial information requires LTD

Authors: *D. M. ASHBY[1], Y. WANG[1,2]
[1]Brain Res. Ctr., [2]Med., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The exploration and encoding of a novel environment is a fundamental learning process that occurs on a short time scale, and is a useful model for studying how the hippocampus encodes and represents complex and arbitrary associations, as is required for episodic memory. Novelty exploration has been demonstrated to promote LTD induction in area CA1 of the hippocampus, but it is unclear what role this LTD plays as the novel space is represented and encoded in the hippocampus. Here we show that novelty exploration produces AMPAR endocytosis-dependent LTD in CA1 in the absence of a paired LTD induction protocol, and that blockade of AMPAR endocytosis/LTD produces a prolonged exploration period in a novel environment. Male Sprague-dawley rats were chronically implanted with recording arrays in CA1, while afferent pathways were stimulated with bipolar stimulation electrodes. After recovery from surgery, baseline fEPSP responses were measured in a familiar environment, after which rats were allowed to explore a highly novel environment. A decrease in evoked potentials consistent with LTD was observed upon novelty exploration, which was blocked by IV administration of an interference peptide (Tat-GluA2-3Y) that blocks regulated AMPA receptor endocytosis. To assess the effects of this LTD on the acquisition of novel spatial information, the GluA2-3Y peptide was administered prior to a spatial recognition memory test in which rats are allowed to spontaneously explore both a familiar and novel spatial location. While vehicle administered rats showed a transient preference for the novel location, inhibition of AMPA receptor endocytosis produced a prolonged exploratory preference for the novel spatial location, indicating that behavioral habituation to the novel location was impaired when LTD processes were blocked. These results demonstrate a behaviorally relevant role for a rapid LTD-like process in the acquisition of novel spatial information, with important implications for the mechanisms of information processing in the hippocampus.

Title: Inflammation as a potential mediator of decreased NMDA receptor function and the onset of age-related cognitive decline: A test for the effectiveness of anti-inflammatory drugs

Authors: *A. KUMAR, A. RANI, T. C. FOSTER
Dept Neuroscience, McKnight Brain Inst., Univ. of Florida, Gainesville, FL

Abstract: A redox mediated decrease in N-methyl-D-aspartate (NMDA) receptor function in the hippocampus is associated with the emergence of impaired episodic spatial memory. However, the source of reactive oxygen species that contributes to impaired NMDA receptor function is unclear. Inflammation provides one potential source for reactive oxygen species suggesting a possible mechanism through which inflammation could compromises neurons leading to the onset and progression of cognitive decline. Therefore, the current studies tested the hypothesis that treatments to reduce inflammation would enhance NMDA receptor function in older animals. For these studies, young (5-6 mo, n = 20) and aged (18-20 mo, n = 22) male F344 rats were first tested on a one day version of the water maze which is sensitive to spatial episodic memory. Young rats and aged rats that exhibited impaired learning were included for treatment. Animals were treated with the nonsteroidal anti-inflammatory drug, indomethacin (Indo, 2.5 mg/kg; young-Indo = 11; aged-Indo = 7), delivered in a frozen treat (orally, twice per day, 3 weeks) and compared to vehicle controls (young-Veh = 9; aged-Veh = 9). Following 3 weeks of treatment with indomethacin, subsequent re-testing on the water maze indicated superior learning associated with indomethacin ($p<0.001$) treatment and post hoc test indicated a drug effect in young and aged rats ($p<0.05$). Hippocampal slices were prepared and input-output curves of CA3-CA1 NMDA receptor-mediated synaptic responses were generated. Examination of synaptic NMDA receptor input-output curves indicated a tendency ($p=0.06$) for an interaction of treatment and stimulation intensity mainly due to an increased response for Indo treated animals. Indeed, no aged difference was observed for Indo groups and a tendency ($p=0.09$) for an interaction of age and stimulation intensity was observed only for the vehicle treated animals due to a reduced response in aged animals. NMDA receptors are critical for long-term potentiation (LTP). LTP was induced by theta burst stimulation consisting of 4 sets of 5 bursts of 4 pulses at 100 Hz with 200 ms intervals between bursts and the 4 sets separated by a 10-second interval. An ANOVA indicated an interaction of age and treatment ($p<0.05$) due to increased LTP for

aged-Indo relative to aged-Veh ($p<0.05$). The results suggest that inflammation may act through NMDA receptors to contribute to the onset and progression of age-related cognitive decline.

Title: Coordinated increase of excitatory and Purkinje cell somatic synapses on eyeblink projection neurons of the anterior interpositus after eyeblink conditioning

Authors: *J. GONZALEZ-JOEKES, B. G. SCHREURS
WVU, Morgantown, WV

Abstract: The effect of eyeblink conditioning on excitatory and inhibitory somatic synapses on eyeblink projection neurons of the anterior interpositus nucleus (AIN) was examined. Rabbits were divided into three groups that received different behavioral procedures. The experimental group received paired delay training with a tone conditioned stimulus and an airpuff unconditioned stimulus. There were two control groups, one received unpaired stimulus presentations, and the other did not receive any stimuli. After behavioral procedures, eyeblink projection neurons of the AIN were identified using a retrograde transneuronal tracer. A coordinated increase in the number of excitatory and inhibitory Purkinje cell somatic synapses was observed in subjects that acquired eyeblink conditioned responses. These results support a parallel and correlated mechanism of cerebellar learning mediated by excitatory (presumably from mossy fibers) and inhibitory Purkinje cells. In contrast, control subjects that received unpaired stimulus presentations showed an increase in the number of inhibitory somatic synapses from local interneurons, suggesting a possible role of feedback inhibition that may also explain the retardation effect in learning observed after unpaired stimulus preexposure. Another important finding was that the somatic surface area of eyeblink projection neurons was highly correlated with the number of somatic synapses; suggesting that synaptic remodeling is a bilateral process that entails proportional structural alterations on the postsynaptic neuron.

Title: The role of dopamine 1 and 5 receptors in hippocampal dependent learning and memory

Authors: *J. SARINANA[1], T. KITAMURA[1], P. KÜNZLER[2], L. SULTZMAN[3], S. TONEGAWA[3]
[1]RIKEN–MIT Ctr. for Neural Circuit Genet., Massachusetts Inst. of Technology, The Picower Inst. for Learning and Me, CAMBRIDGE, MA; [2]Inno-Motion Ltd., Zürich, Switzerland; [3]MIT, Cambridge, MA

Abstract: Mounting evidence supports the role of midbrain dopaminergic neurons in aversive Pavlovian conditioning. Activation of the hippocampal dopamine 1-class receptors (D1R and D5R) are implicated in Pavlovian conditioning, such as contextual fear conditioning (CFC). However, the specific role of the D1R versus D5R in hippocampal dependent CFC has not been investigated. Generation of D1R- and D5R-specific *in situ* hybridization probes showed that D1R and D5R mRNA expression was greatest in the dentate gyrus (DG) of the hippocampus. To identify the role of each receptor in CFC we generated spatially restricted KO mice that lack either the D1R or D5R in DG granule cells. DG D1R KOs displayed significant fear memory deficits while DG D5R KOs did not. Furthermore, D1R KOs but not D5R KOs, exhibited generalized fear between two similar but different contexts. Home cage c-Fos expression was relatively low in the DG of control mice, but significantly increased when mice were exposed to the training context or when they were fear-conditioned. In contrast, c-Fos expression was elevated in the DG of D1R KOs, in the home cage as compared to the ¬control mice, which did not further increase when the KOs were exposed to the training context or when they were fear-conditioned. DG D5R KOs did not exhibit any differences in c-Fos expression under these conditions, compared to the control mice. Overall our results suggest that DG D1Rs, but not D5Rs, contribute to the formation of distinction contextual representations of novel

environments by keeping DG baseline activity low in familiar contexts (i.e., the home cage environment) and promoting DG activity upon an exposure to novel contexts.

Title: Muscarinic receptor-mediated destabilization of object memories is blocked by proteasome inhibition

Authors: *M. L. STIVER, D. L. JACKLIN, N. VICIC, J. CARLIN, M. O'HARA, B. D. WINTERS
Dept. of Psychology and Collaborative Neurosci. Program, Univ. of Guelph, Guelph, ON, Canada

Abstract: Consolidated memories can become destabilized and susceptible to updating and modification upon retrieval, requiring a post-reactivation reconsolidation process in order to persist in long-term memory. Destabilization is most reliably prompted when novel information is present during memory reactivation. We hypothesized that the neurotransmitter acetylcholine (ACh) plays an important role in novelty-induced memory destabilization due to its established involvement in cognitive functions related to new learning. Accordingly, we investigated the effects of cholinergic manipulations in rats using an object recognition paradigm that requires reactivation novelty to destabilize object memories. The muscarinic receptor antagonist scopolamine, delivered pre-reactivation either systemically (0.3 mg/kg) or infused directly into the perirhinal cortex (PRh)(10 μg/μl), a brain region strongly implicated in object memory, blocked this novelty-induced memory destabilization. Conversely, systemic injection (0.1 mg/kg oxotremorine) or intra-PRh microinfusion (0.25 μg/μl carbachol) of muscarinic receptor agonists mimicked the destabilizing effect of novel information presented during reactivation. Furthermore, preliminary data suggest that the destabilization seen with muscarinic receptor agonism requires proteasome-regulated protein degradation within the PRh. The destabilizing

effects of carbachol delivered directly into the PRh were blocked with pre-reactivation microinfusion of the proteasome inhibitor β-lactone (32 ng/μl). The bidirectional cholinergic effects reported here suggest a crucial influence of ACh on memory destabilization and the updating functions of reconsolidation. This is a hitherto unappreciated mnemonic role for ACh with implications for its potential involvement in cognitive flexibility and the dynamic process of long-term memory storage. A connection between muscarinic receptor activation and proteasome activity provides a basis for investigation of the intracellular pathways involved in ACh-mediated object memory destabilization. This research has the potential to expand our understanding of how memories are returned to a labile state in order to be modified.

Title: Aging is associated with altered intrinsic neural dynamics in the basolateral complex of the amygdala

Authors: *R. D. SAMSON[1,2], A. W. LESTER[1,2], P. LIPA[1,2], C. A. BARNES[1,2,3]
[1]Evelyn F. McKnight Brain Inst., [2]ARL Div. of Neural Systems, Memory & Aging, [3]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: Emotion regulation is thought to be preserved, if not improved with aging. That is, older adults show a "positivity effect", as shown by a greater attention to and memory for positive items or events as compared to young adults. Currently, two competing theories argue that the positivity effect is as result of either a decline in amygdala function, or decreased prefrontal cortical control over the amygdala (Nashiro et al., 2012). To further our understanding of how aging impacts the function of the amygdala, we recorded from the amygdala of 19 rats

(10 young and 9 old) and have analyzed both intrinsic neuronal properties of its cells as well as their short time-scale interactions. In line with the idea that amygdala networks are altered with aging, we found neurons of this structure to be disinhibited in aged rats. Indeed, we found that the average firing frequency of neurons of the basolateral complex of the amygdala (BLA) in aged rats (4.6 Hz) to be greater than that of young rats (3.7 Hz). In contrast, neurons recorded in the cortical area ventral to the BLA did not differ across age. The age difference in firing frequency of BLA cells could in part be explained by the finding that a larger proportion of neurons fired at less than 2 Hz in young rats, whereas a greater proportion of cells fired above 5 Hz in aged rats. To further investigate the cellular properties of BLA neurons, spike waveform characteristics (peak-to- trough width, half-amplitude width) and spike dynamics (autocorrelation functions) were assessed; only the peak-to-trough width was different in aged rats and was found to be shorter (average over all BLA neurons). To further dissect whether the effects of aging are heterogeneous across different cell types, cross-correlation analysis will be performed to identify excitatory and inhibitory neuron types based on their short-latency interactions. Thus far, our results suggest that amygdala networks in rats do change with aging, and may actually be overactive. It remains to be determined, however, whether this change is detrimental to amygdala function or serves as a compensatory mechanism to maintain activity in downstream targets in aged rats.

Title: Behavior of normal aged rats mimics the pattern of task performance of rats with hippocampal lesions on a W-track continuous spatial alternation task

Authors: *A. R. UPRETY[1,2], A. I. ESPINOZA[1,2], A. RICHARDS[1,2], A. C. SMITH[1], C. A. BARNES[1,2,3]

Abstract: The aged population and life expectancy has been steadily increasing as significant progress has been made in medical treatment, making it vital to understand the physiological and cognitive changes that may occur during the aging process. The hippocampus is clearly an important contributor to the formation and storage of episodic memories that are known to be affected during aging in humans and in animal models of normal aging. Critical to uncovering the neurobiological mechanisms that underlie memory deficits in aging is the application of cognitive tests that have been validated through the use of lesion methodologies. A particularly interesting apparatus in this regard is the W-track continuous spatial alternation task developed by Kim and Frank (2009) in which hippocampal lesions were shown to disrupt animal performance. Among the error types that can be detected in the task include outbound, inbound or exaggerated side-to-side errors, as well as an overall learning rate of the task. Compared to non-lesion sham controls, hippocampal lesioned animals make many more errors, and are slower to improve on the task. We compared the performance of old rats on the W-track continuous spatial alternation task to young controls using a state-space algorithm to allow accurate characterization of learning performance (Smith et al., 2004). While both young and old rats take longer to learn the outbound compared to the inbound routes on the track, the old rats tend to learn the task rules for outbound and inbound choices more slowly than do the younger animals, and make several times more side-to-side errors than the younger animals. The pattern of results from older animals is reminiscent of the pattern of performance in hippocampus-lesioned rats, although less severe. These data suggest that this task will be sensitive to age-related neurobiological changes within the hippocampus and may provide a means to better understand defects in communication between the hippocampus and prefrontal cortical circuits.

Title: Age-related changes in high-frequency local field activity in the rodent hippocampus during ripple and inter-ripple periods

Authors: *J.-P. WIEGAND[1,2], D. T. GRAY[1,2], L. A. SCHIMANSKI[1,2], P. LIPA[1,2], C. A. BARNES[1,2,3,4], S. L. COWEN[1,2,3]
[1]Evelyn F. McKnight Brain Inst., [2]ARL Div. of Neural Systems, Memory & Aging, [3]Dept. of Psychology, [4]Departments of Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: Ripples are brief (50-150 ms), high-frequency (80-200 Hz) oscillations in the local field potential in the hippocampus (Buzsaki et al., 1992). Given the hypothesized association between ripples, memory consolidation, and homeostatic plasticity, we explored whether there might be age-associated changes in ripple characteristics that contribute to age-related memory loss. To investigate this, local field potentials were recorded from CA1 during rest sessions before and after rats performed a place-dependent eyeblink conditioning task. High-frequency (80-500 Hz) oscillatory activity in the hippocampus of old (n=6) and young (n=6) male F344 rats during ripple events (50-150 ms in duration) and during inter-ripple periods was recorded. Two features of these local field potentials were found to differ between the young and old animals. Specifically, during hippocampal ripple periods the mean frequency in old rats was 6 Hz lower than that observed in young rats (174 Hz old, 180 Hz young, unpaired t-test, $p<0.05$). Additionally, during the inter-ripple periods, old rats showed greater local field power in high frequency bands (150 to 500 Hz; unpaired t-test, $p<0.05$). The increased power during inter-ripple periods in old rats reduced the signal-to-noise ratio between ripple and inter-ripple intervals compared to the young animals. The combination of reduced frequency during the ripple periods and the reduction in the contrast between ripple and inter-ripple periods in old animals could conceivably result in impaired spike timing and altered ripple-associated functions such as the transfer of information from the hippocampus to extra-hippocampal targets during memory consolidation.

Title: Age-associated changes in spike-timing of hippocampal principal cells and interneurons during ripple oscillations

Authors: *S. L. COWEN[1,2,3], J.-P. WIEGAND[2,3], D. T. GRAY[2,3], L. A. SCHIMANSKI[2,3], P. LIPA[2,3], C. A. BARNES[1,2,3,4]
[1]Dept. of Psychology, [2]Evelyn F. McKnight Brain Inst., [3]ARL Div. of Neural Systems, Memory & Aging, [4]Departments of Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: Ripples are brief (50-150 msec), high-frequency (80-200 Hz) local-field oscillations generated in the hippocampus and associated with memory consolidation and homeostatic plasticity. We explored the hypothesis that normal aging alters the timing of the spiking response of individual neurons during the ripple oscillation. To investigate this hypothesis, we measured single-unit and high-frequency local-field activity in CA1 in aged (n=6) and young (n=6) rats during rest sessions that preceded and followed performance on a place-dependent eyeblink conditioning task. We observed that neurons with excitatory firing responses during the ripple oscillation exhibited notably similar mean firing responses in aged and young rats; however, putative interneurons that exhibited suppressed activity during ripple oscillations remained suppressed 40 msec longer in aged animals. Furthermore, although the mean firing response of principal cells during ripple oscillations was similar in aged and young animals, principal cells in aged rats responded to a narrower range of phases of the ripple oscillation (span of 21 degrees) relative to principal cells in young animals (span of 28 degrees). Taken together, these results suggest that aging results in alterations in the timing of spiking activity relative to local-field oscillations with the specific form of the alteration depending on the cell type. Such changes could disrupt ripple-associated processes in aged animals such as memory consolidation.

Abstract: Current imaging techniques for whole-brain visualization such as confocal or electron microscopy are costly, time consuming and labor intensive. Furthermore, using such techniques for the identification of cell types and markers of neuronal activity typically require thin (~40 uM) slices of brain tissue in conjunction with slow and costly techniques such as immunohistochemistry. Recent advances in non-linear optics by the College of Optical Sciences at the University of Arizona have allowed harmonic frequency and resonance changes by Raman amplification to be used to image thick (1 mm) brain slices (cortex and hippocampus) with sub-micron resolution. Ongoing analyses of these images suggest that the technique may also produce non-linear optical signatures corresponding to specific cell types (e.g., interneurons or glial cells). To investigate this possibility, we are combining this technique with standard immunohistochemistry and signal co-registration analysis to identify recently-activated neurons using the immediate early gene *Arc*. In addition, we are using other markers such as parvalbumin, GFAP and tyrosine hydroxylase to determine whether this imaging technique produces signatures that correspond to specific cell-types. If effective, this imaging method could open up the possibility of rapidly identifying patterns of neuronal activation and cell type distributions in entire brains (rodent and primate) at sub-cellular resolution.

Title: Novel method for behavior-driven molecular and structural investigation in rodent whole brain

Authors: *M. K. CHAWLA[1,2], D. T. GRAY[1,2], A. E. COMRIE[1,2], B. K. BAGGETT[3], U. UTZINGER[3], C. A. BARNES[1,2,4]
[1]Evelyn F. McKnight Brain Inst., [2]ARL Div. of Neural Systems, Memory & Aging, [3]Biomed. Engin., [4]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: Methods for identifying the regional distribution of neuronal activity within the brain during specific behaviors are labor intensive, time consuming and suffer from the necessity to prepare thin (20 micron) sections when *in situ* hybridization methods are employed. To circumvent these limitations, we are currently developing a novel method that allows behavior-induced activity markers to be imaged in intact brain tissue. This involves combining a recently developed whole brain clarification method (CLARITY; Chung et al., 2013) that provides the capacity to image deep into intact brain tissue, with a gene expression, cellular activity marker method (catFISH; Guzowski et al., 1999) that labels only those cells active in a given behavioral experience. Prior to using spatial exploration behavior we used a rat that was given maximal electro-convulsive shock treatment (that enables rapid transcription of immediate early genes) to maximize *Arc* expression. Current experiments are being done using exploratory behavior. Brain was quick frozen in isopentane that was cooled in a dry-ice ethanol slurry. The frozen brain was then placed in a 50 ml centrifuge tube containing hydrogel solution for post-fixation which allows cross linkage with formaldehyde in the presence of hydrogel monomers, covalently linking tissue elements to monomers that are then polymerized into a hydrogel mesh via thermal initiation. An electric field (25 volts) was applied across the sample in ionic detergent in an electrophoretic chamber which actively transports micelles through the tissue, which removes brain lipids, leaving the fine structure and cross linked biomolecules in place. The cleared brain tissue (~2 mm slab) was then processed for *in situ* hybridization using full length *Arc* digoxigenin tagged *cRNA* probe (Chawla et al., 2005) followed by CY3 TSA amplification. Tissue was counterstained with DAPI and submerged in 85% glycerol for imaging. Images were collected using an advanced intravital multi-photon microscope and a 3-D rendering of the collected images was performed. Cell nuclei with *Arc* transcription foci and cytoplasmic *Arc* were clearly visible up to ~300 μm deep in the tissue. These results provide evidence for the first time that we can combine *Arc in situ* hybridization with CLARITY methods in a slab of cleared brain. Future experiments will be carried out to increase signal penetration, imaging depth, and

eventually be applied in whole brains of animals that have undergone exploratory behaviors to visualize the activity of entire circuits.

Abstract: Hippocampal neurons have been shown to encode features of episodic memory in multiple animal models. These representations rely on complex neural codes, and basic electrophysiological characteristics of neurons in the hippocampus have been suggested to underlie the ability of these networks to encode and retrieve information. In rodent models, activity of neurons in specific subregions of the hippocampus increases with age, and this hyperexcitability correlates with performance deficits in various medial temporal lobe-dependent behaviors. While the origins of this increased neural output remain poorly understood, several studies suggest that inhibitory circuits in select hippocampal regions change with age. No study to date has examined the relationship between the behavioral, electrophysiological, and molecular components of these deficits in the same animals. Furthermore, it is unknown whether similar age-related alterations occur in non-human primates. To address these questions, ensemble single unit electrophysiological recordings and counts of parvalbumin- and

somatostatin-expressing GABAergic interneurons were obtained from various subregions of the temporal lobe in three middle aged and two aged rhesus macaques which were behaviorally characterized in a delayed nonmatching-to-sample task. Age-related behavioral deficits were significantly correlated with both neural hyperexcitability and decreases in the number of somatostatin-containing interneurons in CA3, but not CA1 or the perirhinal cortex. Together, these findings are consistent with data suggesting that age-related declines in episodic memory are due, at least in part, to network dysfunction in specific regions of the medial temporal lobe which arise from losses in a specific class of interneuron. Furthermore, the selective impairment of CA3 suggests that this region may be a hub of neural dysfunction in the natural aging process that gives rise to behavioral deficits observed near the end of the lifespan of primates.

Title: PACAP expression is downregulated in aged nonhuman primates

Authors: *P. HAN[1], M. R. PERMENTER[2], J. A. VOGT[2], J. R. ENGLE[2,3], C. A. BARNES[2,3,4,5], J. SHI[1]

McKnight Brain Inst., [4]ARL Div. of Neural Systems, Memory & Aging, [5]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: Pituitary adenylate cyclase activating polypeptide (PACAP) is considered to be a potent neurotrophic and neuroprotective peptide. PACAP exists in two forms. The 38-amino acid form (PACAP-38) is the major form in the brain and peripheral organs such as pancreas and

respiratory tract. The shorter 27-amino acids form corresponds to the N-terminal of PACAP-38 (PACAP-27) that contains the biological active region and is preserved during evolution. Both forms of PACAP bind to and activate G protein-coupled receptors (PAC1, VPAC1, and VPAC2). We characterized changes in PACAP in human Alzheimer's disease cortex and in AD transgenic mice and found significant decreases in PACAP protein and mRNA levels (Han et al., 2014, Neurobiol Aging). As aging has been identified as the most significant risk factor for AD, it is essential to understand how PACAP changes during the aging process. Because postmortem brain tissue from young humans is rarely available, in this pilot study we examined PACAP expression in four nonhuman primates (*Macaca mulatta*) from mature adult to aged (12 to 30 years, equivalent to 36 to 90 human years). For the immunohistochemistry, the tissues were mounted on glass slides and treated with 3% H2O2 in methanol. After blocking with goat serum, the primary PACAP antibody was added to incubate in a humid chamber overnight at 4ºC. The slides were washed and incubated with a secondary antibody for 1 hour at room temperature, followed by DAB chromogen imaging. We used the size exclusion method in Image J software to select neuronal populations, measure the immunodensity and quantify the PACAP (+) cells. We analyzed the neurons from the visual cortex, the parietal cortex, the post-cingulate gyrus, the hippocampal formation, and the temporal cortex. PACAP expression was high in the temporal cortex particularly in younger monkeys, very low in parietal cortex and not detectable in hippocampus or postcingulate gyrus. While larger numbers of animals will be needed to confirm our preliminary results, it appears that PACAP expression in temporal cortex is inversely related to aging in nonhuman primates.

Title: Unique contributions of medial and lateral entorhinal cortices to episodic memory in a context-guided object-association task

Authors: *C. S. KEENE, J. H. BLADON, S. MCKENZIE, H. EICHENBAUM
Boston Univ., Boston, MA

Abstract: The entorhinal cortex is critically positioned to impact memory and the hippocampus. Specifically, evidence suggesting roles in spatial navigation and processing of objects in space suggest entorhinal cortex may be particularly situated to integrate items and space to impact episodic memory. However, it remains to be seen how medial entorhinal cortex (MEC) and lateral entorhinal cortex (LEC) contribute to learning and memory in the presence of task-relevant objects and contexts. To address this, single unit recordings from MEC or LEC were collected from rats trained in a task designed to distinguish neural activity associated with object, place, and spatial-contextual stimuli. In this task, rats were required to select one of two objects within each of two distinctive spatial contexts differing in multiple features. Specifically, object X was rewarded when it appeared within either of two positions within spatial context A, whereas object Y was rewarded when it appeared within either of two positions within spatial context B. In addition, rats foraged in an open field environment following testing in the context-guided object-association task in order to identify spatial properties of the cells (e.g., grid cells). Single unit and ensemble analysis of these recordings indicate a striking degree of overlap in function between MEC and LEC, while also highlighting complementary, but unique, contributions to episodic memory. In particular, preliminary analysis of ensemble recordings in LEC and MEC indicate that LEC population representations more strongly distinguish the item-place combinations within contexts, whereas MEC population representations more strongly distinguish item-position combinations within contexts. One interpretation of this finding is that LEC may be specialized for pattern separation of item-place information within a context, while MEC may be specialized for pattern separation across contexts. Additional analyses are underway to determine how these representations develop while learning novel object-context associations. Title: Investigating the role of the medial entorhinal cortex in the hippocampal encoding of time and space for memory function

Authors: *N. T. ROBINSON[1], J. W. RUECKEMANN[1], J. B. PRIESTLEY[1], A. D. GARCIA[1], V. A. SMEGLIN[1], A. CHUONG[2], E. BOYDEN[2], H. B. EICHENBAUM[1]

Abstract: The hippocampus and entorhinal cortex generate the neural activity patterns that enable the formation of spaitotemporally organized episodic memories. It is thought that the lateral entorhinal cortex provides object/event information that is integrated onto a spatiotemporal contextual framework within the hippocampus. The mechanisms that underlie the creation of hippocampal spatiotemporal firing fields and their characteristics remain largely unknown. We report that transient inactivation of the medial entorhinal cortex (MEC) during a mnemonic temporal delay or spatial experience disrupts the existing spatiotemporal firing fields. The red-shifted inhibitory opsin JAWS was expressed in MEC through adeno-associated viral injection. Rats were implanted stereotaxically with bilateral 3-fiber optic arrays in MEC and recording tetrodes were lowered into CA1. Animals performed an object-delay-response association task in which they ran on a treadmill during the delay period. On each trial, one of two distinct objects was encountered before each 8s treadmill run, after which the animal was required to match the object identity to either digging or withholding digging in order to receive reward. During the treadmill run, many CA1 neurons fired at successive brief moments, the sequence of "time cell" firings filled the entire delay, and time cell sequences differed depending on the object that began the trial. Transient MEC inactivation during the delay disrupted temporal firing fields in CA1 both during and following the inactivation period. Neurons with firing fields prior to the inactivation timing remained relatively stable. The disruption of time cell sequences was accompanied by a behavioral deficit implicating MEC activity and hippocampal time cell sequences in effective task performance. Inactivation of MEC during track running had a variety of time locked affects, with place fields being disrupted, remapping or created. Our results support a crucial role for MEC in the stable expression of spatiotemporal coding that supports memory function.

Title: Single cell and ensemble odor-place representations in the dentate gyrus and CA1 of the hippocampus

Authors: *L. M. RANGEL[1], P. D. RIVIÈRE[2], C. H. BUDLONG[3], I. HEIMBUCH[2], B. S. PORTER[4], H. EICHENBAUM[3]

Abstract: The traditional hypothesized role of the dentate gyrus (DG) of the hippocampus is to provide distinct representations of events at the population level for similar experiences, thus providing an orthogonalizing code within the hippocampal circuit. We examined how the DG and CA1 subregions of the hippocampus represent multiple features of repeated experiences in its single cell and ensemble activity during an odor-place conditional learning paradigm. We found that in addition to exhibiting activity selective for distinct spatial locations irrespective of changing task conditions (place cells), DG and CA1 cells were also selective for individual odor cues that informed subsequent behavior in the task. The firing rates of these cells were often additionally modulated by odor-position conjunctions, or the combined presentation of a given odor cue in a specific location. We examined the extent to which DG and CA1 activity contained information for each of these parameters. Both DG and CA1 ensembles demonstrated decreases in the similarity of their firing rates across trial types in which there were different task conditions, such as changes in the spatial contexts in which odor cues were presented. The degree to which different task conditions elicit changes in DG versus CA1 ensembles was evaluated. Lastly, during cue presentation we observed large increases in the power of beta (15-30Hz) frequency oscillations during cue presentation. We then assessed differences in how beta coherent cells in DG and CA1 represent multi-dimensional task features compared to non-beta coherent cells. This study highlights the potential importance of dentate gyrus activity in the formation of odor-place associations.

Title: Bidirectional hippocampal-prefrontal interactions support context guided memory

Authors: *R. J. PLACE[1], A. FAROVIK[2], H. EICHENBAUM[3]
[1]Boston Univ., Cambridge, MA; [3]Psychology, [2]Boston Univ., Boston, MA

Abstract: The medial prefrontal cortex (mPFC) and hippocampus (HPC) are both necessary for contextual-guided memory retrieval. Here we pursed predictions of a model of the flow of information between the mPFC and HPC consistent with known anatomical connectivity. According to this model, ventral CA1 (vHPC) may send meaningfully distinct contextual information directly to mPFC (Komorowski et al., 2013). Subsequently, mPFC may employ this contextual information to generate decision rules and apply them to bias object representations in perirhinal and lateral entorhinal cortex, and thence to the hippocampus, thereby guiding the retrieval of the contextually appropriate object associations in dorsal CA1 (dHPC) (Navawongse et al., 2013). To test this model, we recorded local field potentials (LFPs) from dHPC, vHPC, and mPFC simultaneously in rats as they learned to use different spatial contexts to guide the selection of conflicting object-reward associations. On each trial, rats first explored one of the contexts, then were allowed to sample two objects and select the one associated with reward in that context. Cross-correlations of systematically time-shifted theta-filtered amplitude-envelopes (Adhikari et al., 2010) were used to characterize the directionality of mPFC-HPC information flow during the separate context exploration and object sampling periods. During context exploration, dHPC theta leads that in vHPC, suggesting that vHPC integrates specific spatial information from dHPC. Then, vHPC theta leads that in mPFC, consistent with the prediction that vHPC sends contextual information to mPFC. During subsequent object sampling, the direction of information flow is reversed, with mPFC theta leading dHPC, consistent with the prediction that mPFC biases HPC representations in order to retrieve specific task-relevant

experiences that guide decision making. These results suggest bidirectional dynamics within a circuit of mPFC-HPC interactions that support context guided memory.

Title: Name-calling in the hippocampus (and beyond): Coming to terms with neuron types and properties

Authors: *D. J. HAMILTON, D. W. WHEELER, C. WHITE, C. L. REES, A. O. KOMENDANTOV, S. VENKADESH, G. A. ASCOLI

Abstract: “What's in a name? That which we call a [neuron] by any other name would [fire] as [frequently].” Widely spread naming inconsistencies in neuroscience pose a vexing obstacle to effective communication within and across areas of expertise. Hippocampome.org is a web-accessible neuroinformatics resource that organizes existing data about essential properties of all known neuron types in the rodent hippocampal formation. In this context, a neuron type is identified by its (putative) neurotransmitter and the presence of axons and dendrites across the distinct layers of dentate gyrus, CA3, CA2, CA1, subiculum, and entorhinal cortex. Each type is further characterized by any available information on biomarker expression and electrophysiological features. Hippocampome.org links the evidence supporting assignment of a property to a type to relevant literature sources with direct pointers to text quotes or figures. Mining this knowledge from peer-reviewed reports reveals the troubling extent of terminological ambiguity and lack of definitions. Examples span simple cases of using multiple synonyms and

acronyms for the same molecular biomarkers (or other property) to more complex cases of neuronal naming. New publications use different terms without mapping them to previous terms. As a result, neurons of the same type are often assigned different names while neurons of different types are bestowed the same name. Furthermore, non-unique properties are frequently used as names, and several neuron types are not named at all. One of the benefits of Hippocampome.org is to recognize and clarify this nomenclature confusion by mapping all encountered synonyms and homonyms. Moreover, all key properties are defined in the Neuron Term Portal, a curated catalog of human- and machine-readable definitions also encompassing other brain regions (e.g. neocortex). Based on these resources, we developed a robust approach to provide each neuron type with an informative name and unique identifier.

Title: Firing pattern classification of hippocampal neurons

Authors: *A. O. KOMENDANTOV, D. W. WHEELER, C. L. REES, C. WHITE, D. J. HAMILTON, S. VENKADESH, G. A. ASCOLI
Krasnow Inst. for Advanced Study, George Mason Univ., Fairfax, VA

Abstract: Collecting knowledge on the structural and physiological properties of hippocampal neurons is important for understanding the computational function of the hippocampus. The Hippocampome.org knowledge base identifies more than 100 neuron types in the rodent hippocampal formation (dentate gyrus, CA3, CA2, CA1, subiculum, and entorhinal cortex) based

on the locations of their axons and dendrites, putative excitatory/inhibitory outputs, and molecular marker expressions. For every hippocampal neuron type, electrophysiological data are also collected, quantified, and analyzed from available published experiments, including firing responses to depolarizing current injections. We have developed and implemented protocols to classify firing responses based on the analysis of transient and steady-state activity (e.g. spiking, bursting, stuttering, and silence) as well as their regularity/irregularity. Leveraging this automated classification approach, we characterized the set of all known firing responses exhibited by each neuron type, which defines its firing pattern phenotype. These results guide, constrain, and validate the design of simple neuronal models with different dynamics, which are suitable for large-scale network simulations. At the same time, this work reveals several statistical associations of firing responses, firing pattern phenotypes, and other electrophysiological properties with morphological features and molecular marker expression.

Title: Using Hippocampome.org to unravel the circuitry of the hippocampal connectome

Authors: *C. L. REES, D. W. WHEELER, C. WHITE, A. O. KOMENDANTOV, D. J. HAMILTON, S. VENKADESH, G. A. ASCOLI
Krasnow Inst. for Advanced Study, George Mason Univ., Fairfax, VA

Abstract: Hippocampome.org is a knowledge base of neuron types in the hippocampal formation (dentate gyrus, CA3, CA2, CA1, subiculum, and entorhinal cortex), with evidence culled from the information-rich rodent literature. We collate morphological, molecular expression, and electrophysiological data to describe a set of more than 100 neuron types.

Amassing this information into a centralized resource yields numerous benefits, including a platform for data sharing, the opportunity to establish community-wide interpretation and nomenclature standards, and, notably, comprehensive knowledge of type-based circuitry. Information on network connectivity is compiled in two stages: by (1) literature mining for experimentally-verified data on synapses (or lack thereof) between types and (2) determining the binary (and later, weighted) potential for synapsing that arises from a spatial overlap of axons and dendrites of any two types. Our analyses of these connectomic data employ graph theory metrics, including degree distribution, betweenness centrality, rich club coefficient, and motif composition, to unveil the fundamental architectural principles of the network. Furthermore, using measures like absorption and driftness, we investigate the relationship between network topology and the dynamic behaviors of information flow, which may foster intuition on hippocampal operation. Consequently, by gathering data and performing analyses at the mesoscopic level of neuron types, we circumvent the time and data requirements of projects aimed at mapping the circuitry of every individual neuron. This strategy provides immediate traction toward the ultimate goal of obtaining and comprehending the full hippocampal connectome.

Title: Parameter optimization in a CA3 network model by evolutionary algorithms

Authors: *S. VENKADESH, A. O. KOMENDANTOV, D. W. WHEELER, C. L. REES, C. WHITE, D. J. HAMILTON, G. A. ASCOLI
Krasnow Inst. for Advanced Study, George Mason Univ., Fairfax, VA

Abstract: Modeling biologically realistic large-scale spiking neural networks (SNN) is essential for understanding cognition and behavior. Izhikevich neurons are widely used in large-scale SNN simulations, due to their computational efficiency and ability to reproduce the variety of spiking patterns observed in real neurons. However, the parameters of a large-scale network of Izhikevich neurons create a massive search space, making it computationally challenging to constrain the model based on experimental evidence. We aim to build a real-scale model of the rodent hippocampus using information available from Hippocampome.org. To help constrain the model, we leverage the optimization capabilities of evolutionary algorithms. As an initial proof of principle, we designed a simple CA3 network model with pyramidal cells and two interneuron types (one perisomatic and one dendrite-targeting). First, we identify the ranges of Izhikevich model parameters that reproduce the firing patterns experimentally exhibited by these three neuron types. The quantitative features used to compare simulated and observed firing patterns include average inter-spike interval, spike frequency adaptation, and latency to first spike. Next, we optimize the network parameters, such as connection probabilities and strengths, to obtain desired network activity and target firing rate for each neuron type. While this pilot phase in its limited scope runs on a CPU architecture, our implementation is compatible with Graphical Processing Unit (GPU) based systems, thus allowing for scalability.

Title: Hippocampome.org: a knowledge base of neuron type properties for the rodent hippocampus

Authors: *D. W. WHEELER[1], C. WHITE[1], A. O. KOMENDANTOV[1], F. FAGHIHI[1], C. L. REES[1], D. J. HAMILTON[1], S. VENKADESH[1], B. HOLMES[2], G. A. ASCOLI[1]
[1]Krasnow Inst. for Advanced Study, George Mason Univ., Fairfax, VA; [2]Bioinformatics Res. Group, Wright State Univ., Dayton, OH

Abstract: Hippocampome.org is an open-access knowledge base of neuron types in the rodent hippocampal formation. Our extensive literature mining and curation protocols have identified over 100 neuron types to date based on their main neurotransmitter and neurite morphology. We focus on the presence or absence of axons and dendrites in twenty-six neuroanatomical parcels corresponding to widely agreed upon subregions (dentate gyrus, CA3, CA2, CA1, subiculum, and entorhinal cortex) and their respective layers (e.g. CA1 oriens, radiatum, etc.). We integrate these morphological characteristics with information on electrophysiological features and molecular marker expression. Each property is directly linked to the specific supporting evidence in the relevant publication. In addition, we assign each neuron type a unique identifier to unambiguously connect all references to their appropriate content. This collation of knowledge into a centralized online repository enables (1) data mining for novel correlations among types and properties, (2) inferring potential connectivity between neuron types, (3) characterizing neuronal dynamics for use in computational models, (4) analytics via user-friendly browsing and searching capabilities, and (5) inter-relating newly acquired neuronal information with the existing content of the knowledge base.

Title: Memory-guided visual search reveals behavioral and autonomic markers of aging and Alzheimer's disease

Authors: *M. DRAGAN[1,4,2], T. K. LEONARD[4,3], A. M. LOZANO[5,6], M. MCANDREWS[5,6], K. NG[6], J. D. RYAN[5,7], D. F. TANG-WAI[5,6], J. WYNN[7,5], K. L. HOFFMAN[3,4,2]
[1]York Univ., Mississauga, ON, Canada; [2]Biol., [3]Psychology, York Univ., Toronto, ON, Canada; [4]Ctr. for Vision Res., Toronto, ON, Canada; [5]Univ. of Toronto, Toronto, ON, Canada; [6]Toronto Western Hosp., Toronto, ON, Canada; [7]Rotman Res. Institute, Baycrest., Toronto, ON, Canada

Abstract: Prodromal and typical Alzheimer's Disease (AD) is characterized by episodic memory deficits that are thought to correspond to disease progression in the hippocampal formation. AD therapies targeting hippocampal function may be best evaluated through the use of specific and selective hippocampal tasks. We used a hippocampal-dependent episodic target-in-scene detection task (Chau et al., 2011) to determine if task performance shows age-related decline, and if performance of the AD group is further impaired relative to an age-matched cohort. AD patients (N=7) were selected based on their participation in an ongoing clinical trial, using deep-brain stimulation targeting the fornix. To enroll in the clinical trial, patients must have scored between 12-24 on the Alzheimer's Disease Assessment Scale -cognitive test 11 (ADAS-cog11), and either 0.5 or 1 on the Clinical Dementia Rating. Testing described here was conducted before the treatment conditions were applied. Older adults (N=20) were divided into healthy (N=10; Montreal Cognitive Assessment: MoCA score >=26) and at-risk for developing mild cognitive impairment (N=7; MoCA score <=24); three participants fell in between these cutoffs. Younger Adults (N=17) were university students tested on the same task. Participants were asked to find items ('targets') that appeared/disappeared in alternation within flickering images of natural scenes. Previously, we observed that faster search times on repeated trials was due to explicit recall of the targets-in-scenes (Chau et al., 2011). . In this study, older adults from healthy, at-risk, and AD groups had longer search times and required more fixations compared to younger adults on repeated trials. Individuals with AD were significantly worse on both measures relative to any other population ($p<0.001$). Autonomic engagement was evaluated by measuring pupillary responses, revealing increasingly slower responses in aged and AD populations. Furthermore, memory effects on pupillary responses were only seen in younger adults and healthy older adults, not in the at-risk or AD groups. Our results suggest that this nonverbal memory-guided visual search task can be used to detect age-related impairments, to differentiate age-related impairments from those associated with AD, and to act as a possible early diagnostic aid, specifically by discriminating the pupillary responses of unimpaired groups from those at-risk for or affected by Alzheimer's Disease.

Hospital, Boston, Boston, MA

Abstract: Hippocampal neurons replay activity from previous experiences during sharp-wave ripples (SWRs). In rodents, SWRs have been associated with learning during quiescent and waking states. In many of these studies, analysis of waking activity is restricted to periods of immobility, but SWR-associated replay also occurs during exploration and it appears to play a

specific role in rapid learning through experience. Exploration in the task environments is operationalized as walking speed, leaving open the question of whether ambulatory movement is necessary and sufficient for generating eSWRs. In primates, SWRs have only been described during inactive states such as sleep, quiescent wakefulness, and under anesthesia ; their prevalence in waking exploration is unknown. Finally, the detection of SWRs during exploration is complicated by non-SWR activity that occurs in overlapping 'epsilon' oscillatory bands ('high gamma', 'high-frequency oscillations' or HFOs). Here, we describe SWRs in the macaque during visual exploratory behaviors that were found to be distinct from high gamma events or HFOs. During visual exploration eSWR events do occur in non-human primates. Furthermore, for visual search, eSWRs occurred more often during spatially constrained sequences of saccades than during periods of spatially diffuseness . These results suggest that in primates eSWRs may similarly contribute to learning from visual experiences.

Title: State- and frequency-dependent changes in medial temporal lobe activity after Deep Brain Stimulation in the macaque

Authors: *A. GÓMEZ PALACIO SCHJETNAN, T. K. LEONARD, K. HOFFMAN
Dept. of Psychology, Ctr. for Vision Res., York Univ., Toronto, ON, Canada

Abstract: Deep brain stimulation (DBS) has been applied to various brain structures and pathways in an attempt to selectively alter neural activity associated with disease states. The optimal frequency of stimulation for specific targeted regions and the effectiveness of a given stimulation protocol across differing ongoing brain states is less well understood, but has widespread implications for DBS-treatment strategies. To determine the influence of different stimulation protocols, and their possible dependence on brain state, we tested frequency- and behavioral state-dependence of neural activity in the medial temporal lobe in response to stimulation of the anterior portions of the extended circuit, including the fornix and connected structures of the basal forebrain and anterior thalamus. We delivered unilateral, bipolar stimulation trains of 10 bursts, where each burst contained 8 biphasic pulses of 100μs duration at a rate of 500 Hz. Each train of 10 bursts was delivered at intervals corresponding to 1.25, 2.5, 4, 9, and 11 Hz. During stimulation experiments, a chronically-implanted multi-electrode/tetrode array sampled local field potentials from different sites in the medial temporal lobe of a rhesus macaque, while the animal was: 1) performing a goal-direct memory task 2) during rest periods where the animal sat in the darkened booth and occasionally slept. Our preliminary results show an interaction between inter-burst frequency and behavioral state. The higher frequencies, i.e. shorter inter-burst intervals, evoked stronger theta/alpha-band power than lower-frequency bursts. This effect occurred in resting states rather than during attentive, goal-seeking states. Our preliminary results suggest that 1) changes in stimulation patterning - here, burst frequency - lead to different responses in targeted pathways, and 2) behavioral state during stimulation can determine the effects of stimulation, presumably as a consequence of underlying brain states. These state-dependent modifications support further investigation of closed-loop, state-contingent stimulation including stimulation during sleep. Title: Theta-gamma cross-frequency coupling in the macaque hippocampus during learning and recollection

Authors: *J. M. MIKKILA[1,2,3], T. K. LEONARD[1,2,3], R. MONTEFUSCO-SIEGMUND[1,2], K. L. HOFFMAN[1,2,4]
[1]Psychology, [2]Ctr. for Vision Res., [3]Neurosci. Grad. Diploma Program, [4]Biol., York Univ., Toronto, ON, Canada

Abstract: One of the best-characterized examples of cross-frequency rhythmic interactions in the brain is the modulation of gamma oscillations by the theta rhythm in the hippocampus [1]. The functional correlates of this phenomenon, however, are only beginning to be understood. Hippocampal theta-gamma cross-frequency coupling (CFC) has been implicated in object-location associative learning in rats [2] and working memory in humans [3]. Here we ask whether or not theta-gamma coupling in primate hippocampus changes as a function of associative learning and recall. We conducted multi-electrode recordings in the hippocampus of two macaques as they performed a goal-directed visual search task to locate an object embedded in a natural scene [4]. Animals saw each scene twice, providing an opportunity to locate the object faster on the second trial, indicating memory for the location of the object in the scene. After identifying theta bouts (4-12 Hz) in the local field potentials, we calculated the modulation index [2] between theta phase and higher-frequency amplitudes. We observed bouts of theta (4-12 Hz) oscillatory activity during trial and after in the inter-trial interval. Identified bouts during search lasted on average 1.74 seconds (SD +/- 1.52 s) ; when average search time per trial was 15.53 seconds. The strength of the phase-amplitude coupling between theta and gamma (30-90 Hz) oscillations and the power of the coupled frequencies differed by memory condition. Repeated trials in which the object location was forgotten, and novel trials that lead to subsequent forgetting show stronger coupling than their 'remembered-object' counterparts. In line with previous reports [5], there was more theta power in novel trials that were subsequently remembered. This demonstrates that cross-frequency effects may not be directly related to the strength of the constituent oscillations. Prima facie, these results may be counterintuitive: stronger coupling is associated with worse performance; however, other tasks describing CFC effects include well-learned examples whereby early in learning the coupling is weakest. Further

examination of various behavioral correlates and of extended learning are required to better understand the significance of the cross-frequency effects we observed. [1] Lisman J & Jensen O. (2013). Title: Characterization of the rapid transcriptional response to long-term sensitization training in *Aplysia* californica

Authors: S. HERDEGEN[1], G. HOLMES[1], *R. CALIN-JAGEMAN[2], I. E. CALIN-JAGEMAN[1]
[1]Neurosci., [2]Psychology, Dominican Univ., River Forest, IL

Abstract: We used a custom-designed microarray and qPCR to characterize the rapid transcriptional response to long-term sensitization training in the marine mollusk *Aplysia californica*. *Aplysia* were exposed to repeated noxious shocks to one side of the body (4 ten-second shocks at 90mA, 30 min ISI), a procedure known to induce a transcription-dependent and long-lasting increase in reflex responsiveness that is restricted to the side of training. One hour after training, pleural ganglia from the trained and untrained sides of the body were harvested; these ganglia contain the sensory nociceptors which help mediate the expression of long-term sensitization memory. Microarray analysis on 8 animals suggests that long-term sensitization training strongly and rapidly regulates at least 102 transcripts. We used qPCR to test a subset of these transcripts and found that 86% were confirmed in the same samples, and 83% of these were again confirmed in an independent sample (n = 9 animals). Thus, our new microarray design shows very strong predictive and convergent validity for analyzing the transcriptional

correlates of memory in *Aplysia*. Fully validated transcripts include some previously identified as regulated in this paradigm (apC/EBP and apEgr) but also include novel findings. Specifically, we show that long-term sensitization training rapidly up-regulates the expression of transcripts which seem to encode a C/EBP gamma, a glycine transporter, and a vacuolar protein-sorting-associated protein.

Title: Distinct growth factor families engage spatially and temporally unique molecular cascades during two-trial long-term memory formation in *Aplysia*

Authors: *A. M. KOPEC, T. J. CAREW
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: In adult animals growth factors (GFs) signaling via TrkB and TGFβr-II receptors are required for long-term memory (LTM). However, the unique contribution of each GF family to memory formation is unknown. *Aplysia* californica is a powerful model system for examining molecular cascades during LTM formation. In *Aplysia*, repeated sensitizing stimuli (e.g. tail shocks) induce MAPK activation (P-MAPK) and gene expression in tail sensory neurons. Both P-MAPK and gene expression are required for LTM formation and are downstream of TrkB and TGFβr-II signaling. Thus, assaying P-MAPK and gene expression as a proxy for LTM formation provides the opportunity to assess the regulation of signaling pathways common to both GF families. We previously analyzed trial-specific GF regulation of P-MAPK in two-trial LTM analog training using tail nerve shocks (TNSs; Philips et al 2007; 2013). We found that Trial 1 induces synaptic TrkB signaling for an early phase of P-MAPK, and Trial 2 induces somatic TGFβr-II signaling for a late phase of P-MAPK (Kopec & Carew, 2013a). Here we examined the

GF-dependency of genes regulated during learning in *Aplysia*: ApC/EBP, ApUCH, and ApKHC1. We found that both Trial 1 and Trial 2 induce ApC/EBP expression (during the training interval and after training, respectively), while ApUCH and ApKHC1 were not modulated. Next, TNSs were given in the presence of either a TrkB-Fc or a TGFβr-II-Fc chimera, which sequesters endogenous TrkB or TGFβr-II ligands, respectively. We found that Trial 1 TrkB signaling is required for Trial 1-dependent ApC/EBP expression, and Trial 2 TGFβr-II signaling is required for Trial 2-dependent ApC/EBP expression. Furthermore, blocking Trial 1 TrkB signaling disrupts Trial 2-dependent ApC/EBP expression, suggesting that Trial 2 TGFβr-II signaling interacts with Trial 1 TrkB signaling to prolong ApC/EBP expression. Taken with our earlier data, these results show that both TrkB and TGFβr-II signaling are engaged during two-trial LTM to regulate MAPK activation and transcription, but with unique spatial, temporal, and mechanistic profiles. These data are consistent with the view (Kopec and Carew, 2013b) that signaling by individual GFs should be considered as a component of a complex and interactive molecular network involving multiple GF families.

Title: Taste avoidance conditioning with electrical shock as unconditional stimulus in Lymnaea stagnalis

Authors: *M. SAKAKIBARA, S. TAKIGAMI
Tokai Univ., Numazu 410-0321, Japan

Abstract: New taste avoidance conditioning paradigm has developed with an electrical shock as an unconditional stimuli (US) paired with sucrose application as a conditional stimuli (CS). Our previous study demonstrated that Lymnaea stagnalis can be conditioned with 20 paired presentations of sucrose as CS and gentle tactile stimulus as US. In this study we examined whether snails are capable to be conditioned with 100 mM sucrose application as CS paired with brief electrical stimulus (1000 V, 80 micro-A, 0.2 s) application in place of mechanical tapping to animal's head as US. Snails were evaluated with the feeding score, i.e., the number of mouth openings per minute in response to sole CS application examined at 10 min and/or 24 h

following the conditioning paradigm. We defined that a 10 min post-test characterized as a short term memory (STM) whereas a 24 h post-test characterized as a long term memory (LTM). In this study we evaluated the number of CS-US pairings from 5 to 20 whether snails acquired STM/LTM. As a result animals showed significant reduced feeding scores to sucrose application after 15 paired presentations of CS-US pairings leading to both STM and LTM, furthermore their memory persisted for at last one week. We next made intracellular recordings from right pedal dorsal 11 (RPeD11) neuron, which is known to process invasive stimulus such as mechanical tactile and/or chemical stimulus to control the whole-body-withdrawal response which is the only available escape behavior to this animal. Excitatory post synaptic potential was recorded in response to US application thus the electrical voltage stimulus was recognized as the invasive stimulus as same as the mechanical tactile stimulus we previously employed as US. With this new methodology we do not require the skill for the experimenter to give a tactile stimulus.

Title: Nitric oxide synthase is involved in maintenance but not in induction of activity-dependent LTP in the vertical lobe of the octopus

Authors: *A. TURCHETTI-MAIA[1,2], T. SHOMRAT[1,3], B. HOCHNER[1,4]
[1]Dept. Neurobiology, Silberman Inst. of Life Sciences, The Hebrew Univ., Jerusalem, Israel; [2]The Edmond and Lily Safra Ctr. for Brain Sci., Jerusalem, Israel; [3]The Ruppin Academic

Center, Sch. of Marine Sci., Michmoret, Israel; [4]Interdisciplinary Ctr. for Neural Computation, Jerusalem, Israel

Abstract: The vertical lobe (VL) of Octopus vulgaris, an area known to be involved in learning and memory, shows a robust activity-dependent LTP. This LTP, which occurs at the 'fan-out' glutamatergic synaptic input to the VL, seems to be non-NMDA dependent and presynaptically expressed; therefore it seems that the associative mechanism that mediates the Hebbian property of octopus LTP has not converged to vertebrate like mechanisms. Nitric oxide (NO), produced by nitric oxide synthase (NOS), has been associated with a variety of learning modalities in vertebrates and invertebrates. Here we examined the effect of NOS inhibitors on plasticity in slices of octopus VL. We observed that NOS inhibitors showed an inhibitory effect on LTP expression without affecting LTP induction by high frequency (50Hz) stimulation, as full LTP could be induced in the presence of NOS inhibitors (revealed after drugs washout). Once NOS inhibitors were applied to already induced LTP, they inhibited the synaptic field potential (fPSP), but did not depotentiate it. It is likely that NOS inhibitors negate the presynaptic effect of NO, as they both reduced the fPSP amplitude and reversed the effect of LTP on twin pulse facilitation to pre-tetanization level. In contrast, slowly developed LTP, induced by 0.1Hz stimulation, was attenuated by NOS inhibitors possibly because of an indirect effect via blockage of NO induced synaptic facilitation. We are checking the possibility that the tonic activation of NOS is mediated by PKC or PKD, because phorbol ester (5μM PDBu) activates full LTP even when synaptic transmission is blocked in zero Ca++ EGTA solution and/or AMPA-like glutamatergic transmission is also blocked. These results suggest that LTP expression occurs through synaptic facilitation induced by elevation of NO tonic concentration, which is likely to be generated by activity dependent NOS long-term activation. We conclude that molluscan NO/NOS system is conserved in the octopus VL, though the mechanism of involvement is adapted to mediate LTP maintenance rather than the conservative mechanism of LTP induction.

Title: The role of lrn-2/scd-2 in sensory integration and learning in Caenorhabditis elegans

Authors: *G. S. WOLFE[1], D. VAN DER KOOY[2]
[1]Inst. of Med. Sci., [2]Mol. Genet., Univ. of Toronto, Toronto, ON, Canada

Abstract: The cellular and molecular mechanisms of learning and memory can be studied in detail by taking advantage of the nematode, Caenorhabditis elegans. With a fully mapped connectome and genetic tractability, *C. elegans* has a wide variety of behaviours controlled by comparatively few neurons. We have characterized an EMS derived mutant strain, lrn-2, which shows deficits in both sensory integration and a wide variety of associative learning paradigms. Having deficits in these two established processes suggests that this gene is either a key component of separate sensory integration and associative learning pathways, or it is evidence that sensory integration and learning are the same psychological process. Snip-SNP mapping and genome sequencing suggested that the locus of the lrn-2 mutation was the gene scd-2, which is homologous to human anaplastic lymphoma kinase. This was supported by lrn-2 and scd-2 failing to complement each other after a cross, and by a wild type scd-2 containing fosmid successfully rescuing associative learning in a lrn-2 background. The primary test of associative learning used in this project involved learning about pathogenic bacteria. The N2 control strain learns to associate the pathogenicity of PA14, a strain of P. aeruginosa, with the odor of the bacteria after 4 hour exposure. This results in N2 worms leaving the PA14, and migrating to a safe E. coli lawn on the other side of the plate. The lrn-2 mutants do not learn this association and remain on the pathogenic bacteria. The sensory integration deficit is demonstrated by the mutant's inability to integrate two cues by crossing an aversive copper barrier to reach an attractive diacetyl odorant. Both learning and sensory integration involve processing of multiple sensory cues leading to altered behavioral output. While sensory integration does not require these changes to persist, learned behaviors do, as memories. Since lrn-2/scd-2 plays a role in both sensory integration and associative learning, they may be part of the same psychological process. The gene fsn-1 has been shown to have an upstream suppressive effect on scd-2 sensory integration; however, we have found that in an associative learning assay, fsn-1 may have act differently, downstream of scd-2. Furthermore, preliminary tests suggest that there is no measurable learned memory in the sensory integration assay, supporting the idea that they may be separate processes with some shared machinery. In order to further investigate the relationship between these processes, cell specific rescues of scd-2 in a mutant background will be performed to find where it must be expressed for both sensory integration as well as learning and memory.

Title: BK SLO-1 channel mediates specific aspects of locomotion, posture, and habituation learning on and off alcohol in *C. elegans*

Authors: C. H. C. LIN[1], S. KHAN[1], D. HSIAO[1], A. HUNG[1], S. SA[1], B. MENON[1], F. PSOLTANI[1], D. CHAIM[1], *C. H. RANKIN[2]
[1]Brain Res. Ctr., [2]Univ. British Columbia, Vancouver, BC, Canada

Abstract: Alcohol intoxication impairs locomotion, posture, and learning, but the underlying mechanism is not well understood. We use the model system Caenorhabditis elegans to investigate the mechanisms by which alcohol affects behavior. Previous research on *C. elegans* showed that a calcium-activated, voltage-gated potassium (BK) channel (SLO-1) plays a critical role in alcohol-induced behavior (Davies et al, 2003). In this study we investigated the role BK channels in different aspects of locomotion, posture, and learning using a high throughput tracking system "Multi-Worm Tracker". To investigate the role of SLO-1 on locomotion and body posture, we tracked worms on alcohol (400mM ethanol (v/v) plates; ~ 0.08-0.1% BAC) or off alcohol (0mM) for 60mins. Exposure to ethanol led to a depression is body curve (posture) in wild-type worms compared to unexposed worms; mutants missing a functional slo-1 gene had the same body curve (posture) on and off alcohol. Worms with a mutation missing the SLO-1 calcium-sensing region showed less body curve depression on alcohol compared to wildtype on alcohol. This suggests alcohol's depressive effect on body curve/posture requires a functional SLO-1 channel and missing the calcium-sensing region reduces the effect. To study the role of BK channel in learning under normal and intoxicated conditions, we focused on a non-associative type of learning, habituation. We induced habituation by giving repeated mechanical stimuli at 10s, 15s, 30s, or 60s interstimulus- intervals (ISI); habituation was analyzed as decrements in response probability, magnitude or speed. Unexposed slo-1 mutants habituated slower than wild-type worms for response speed, suggesting a role of SLO-1 in slowing down speed responses to repeated stimuli. We also found that SLO-1 became increasingly more important role as stimulus ISIs increased specifically in habituation of response probability. Wildtype worms on alcohol habituated faster in response probability (unrelated to fatigue), and this alcohol habituation phenotype was not present in slo-1 mutants. Our genetic rescue studies suggest that SLO-1 in neurons was responsible for the alcohol habituation phenotype. Interestingly, rescues only in muscles showed an opposite phenotype to alcohol habituation.

Title: A single gustatory sensory neuron of caenorhabditis elegans generates memory-dependent behaviors in nacl chemotaxis

Authors: *L. WANG[1], M. TOMIOKA[2], H. KUNITOMO[1], Y. IINO[1,2]
[1]Dept. of Biol. Sci., [2]Mol. Genet. Res. Lab., The Univ. of Tokyo, Tokyo, Japan

Abstract: Animals show various behaviors in response to environmental conditions, which are often plastic according to previous experiences. *C. elegans*, sensing chemicals with a limited number of sensory neurons, is an ideal model for analyzing the role of each neuron in innate and learned behaviors. ASE neurons (ASE-Left neuron and ASE-Right neuron) play major roles for salt chemotaxis but have lateralized functions: ASER neuron is stimulated by decreases in NaCl concentration and ASEL neuron is stimulated by increases in NaCl concentration. Until now, our lab has focused on the roles of ASER and its signaling pathways in salt chemotaxis and other behaviors, but whether and how ASEL regulates the behaviors in salt chemotaxis remains unknown. In this study, chemotaxis assays and optogenetics combined with behavioral quantification with worm tracking system were used to investigate the ASEL's roles in worm behaviors. By using transgenic worms in which channelrhodopsin (ChR2) was expressed in the ASEL neuron, the neuron was activated by blue-light illumination and the behavioral response was recorded. The result indicated that worms showed behavioral responses to ASEL activation after cultivation with NaCl, but no or small responses after cultivation in NO NaCl conditions. After cultivation in the presence of NaCl, the worms' turning rate decreased during ASEL stimulation and increased immediately after termination of ASEL stimulation. The behavior of ASER-ablated mutants was tested in chemotaxis assays. The chemotaxis index was almost zero for worms that had been cultured in NO NaCl conditions, which was consistent with the result of optogenetics and was possibly because activation of ASEL does not generate behavioral responses. On the other hand, when worms were cultured in the presence of NaCl, worms migrated to higher concentrations, which was also identified with above optogenetics' result and

our lab's former data, and it was possibly explained by the behavior that worms cultivated with NaCl went forward when NaCl concentration increased, but turned when NaCl concentration decreased, both contributing to migration to higher concentrations.

Title: Cellular and molecular mechanisms of short-term associative memory in *C. elegans*

Authors: *A. SYLVAIN, G. STEIN, M. RAHIMI, C. T. MURPHY
Princeton Univ., Princeton, NJ

Abstract: An important challenge is to understand how associations are formed and maintained in order to alter behavioral responses. Acquiring an in-depth understanding of memory formation on both the molecular and circuit level is important not only to gain an understanding of normal brain function, but can also lead to an understanding of disease states such as age-related cognitive decline and Alzheimer's disease. The simplicity of the *C. elegans* nervous system makes it a practical model organism to study memory encoding. Our lab has developed a short-term associative memory (STAM) assay in *C. elegans*, in which worms learn to associate food with an odor and can remember this association for over one hour. Here we use this assay to identify regulators of *C. elegans* short-term memory processes, by testing genetic mutants and assessing deficits in associative memory formation. We find that, as in higher organisms, *C. elegans* STAM requires calcium and cAMP signaling and is dependent on translation, but independent of transcription and the transcription factor CREB. Using GCaMP imaging, we found that STAM conditioning induces increased odor-evoked Ca^{2+} responses in the sensory neuron AWC^{on}, and that the number of animals responsive to the odor decreases with increased time post-conditioning. Our tests suggest that several neurons post-synaptic to the sensory neuron AWC^{on} are not required for normal STAM. Our data confirm that STAM in *C. elegans* is

a distinct behavioral paradigm controlled by a small neural circuit that requires canonical memory pathways. Study of short-term associative memory in *C. elegans* could lead to the rapid discovery of novel conserved short-term memory regulators.

Title: Transcriptional profiling of dissociated adult *C. elegans* neurons reveals short-term memory components of Insulin/FOXO signaling

Authors: *R. AREY, R. KALETSKY, A. WILLIAMS, V. LAKHINA, J. LANDIS, C. MURPHY
Lewis Sigler Inst. for Integrative Genomics, Princeton Univ., Princeton, NJ

Abstract: The ability to form associative memories is one of the most important functions of an organism's nervous system. However, the molecular mechanisms underlying learning and associative memory formation have yet to be fully elucidated. Identifying molecules involved in these processes is important not only to gain an understanding of normal brain function, but can also lead to an understanding of disease states such as age-related cognitive decline and Alzheimer's disease. We have developed a novel positive olfactory assay to study learning and memory in the nematode *C. elegans* (Kauffman et al., 2010), providing the opportunity to identify molecules that are most essential for learning and memory. We previously found that worms with a mutant form of the insulin/IGF-1 receptor daf-2, which have an extended lifespan, have increased short-term and long term memory (Kauffman et al., 2010). The molecular components that contribute to daf-2's threefold increased short-term memory are unknown, except that it is dependent on the FOXO transcription factor daf-16. We recently developed a technique for lysis of adult worms followed by Fluorescence-activated cell sorting (FACS) to isolate individual tissues, such as neurons. Using this technique in daf-2 and daf-2;daf-16

mutants, we have identified Insulin/IGF-1-like signaling (IIS) neuronal target genes. We have used RNAi to test whether the IIS-regulated neuronal genes enable daf-2's enhanced short-term associative memory (STAM). We have found that some of these neuron-specific IIS targets are required for daf-2's extended STAM. Ongoing studies are examining the roles of these IIS targets in wild-type short term memory and how daf-2 affects the expression of these genes. These studies will allow for the identification of genes that were not previously known to play a role in memory function, and may uncover novel genes involved in associative memory formation in higher organisms.

Title: Interneuronal mechanism for Tinbergen's hierarchical model of behavioral choice

Authors: M. CROSSLEY, Z. PIRGER, S. NASKAR, Z. LASZLO, G. KEMENES, M. O'SHEA, *P. R. BENJAMIN, I. KEMENES
Sussex Ctr. Neurosci, Univ. Sussex, Brighton, United Kingdom

Abstract: Recent studies of behavioral choice support the notion that the decision to carry out one behavior rather than another depends on the reconfiguration of shared interneuronal networks. We investigated another decision-making strategy, derived from the classical ethological literature which proposes that behavioral choice depends on competition between autonomous networks. According to this model, behavioral choice depends on inhibitory interactions between incompatible hierarchically-organized behaviors. We provide evidence for this by investigating the interneuronal mechanisms mediating behavioral choice between two autonomous circuits that underlie whole-body withdrawal and feeding in the pond snail Lymnaea,. Whole-body withdrawal is a defensive reflex that is initiated by tactile contact with predators. As predicted by the hierarchical model, tactile stimuli that evoke whole-body withdrawal responses also inhibit on-going feeding, even in the presence of feeding stimulus. By

recording neurons from the feeding and withdrawal networks we found no direct synaptic connections between the interneuronal and motoneuronal elements that generate the two behaviors. Instead, we discovered that behavioral choice depends on the interaction between two unique types of interneurons with asymmetrical synaptic connectivity that allows withdrawal to override feeding. One type of interneuron, the PlB (Pleuro-Buccal), is an extrinsic modulatory neuron of the feeding network that completely inhibits feeding when excited by touch-induced monosynaptic input from the second type of interneuron, PeD12 (Pedal-Dorsal 12). PeD12 plays a critical role in behavioral choice by providing a synaptic pathway joining the two behavioral networks that underlies the competitive dominance of whole-body withdrawal over feeding.

Title: Memory lapses are a general feature of consolidation after both reward and aversive classical conditioning

Authors: F. LORENZETTI, M. CROSSLEY, S. NASKAR, M. O'SHEA, P. R. BENJAMIN, *I. KEMENES
Sch. of Life Sci., Univ. of Sussex, Brighton, United Kingdom

Abstract: Memory consolidation is generally conceived as a process whereby new information sequentially moves to successively longer-term stores. In invertebrates and vertebrates, including humans, there are short periods of memory lapses during consolidation. Formerly these have been seen simply as moments of vulnerability in memory formation. Our recent work on the snail Lymnaea however suggests that they are adaptive, allowing consolidation to be regulated so that acquisition and storage are effectively modified by new information after initial learning. Recently, we found that one-trial appetitive classical conditioning using sucrose as the unconditioned stimulus (US) and amyl acetate (AA) as the conditioned stimulus (CS), was accompanied by memory lapses at 30 min and 2h after acquisition. Now we show that lapses at

similar time points also occur following either reward training with a novel appetitive stimulus (pairing AA with serine) or aversive conditioning using the same CS paired with quinine. This suggests that memory lapses could be a general feature of consolidation. The vulnerability of memory consolidation to disturbances during lapses was tested by application of either aversive or appetitive stimuli following classical reward conditioning (pairing amyl acetate with sucrose). Both quinine and serine were found to disrupt memory formation, but only when applied as a disturbance during periods of lapses. Interestingly, memory formation following appetitive classical conditioning can be disrupted by the presentation of an alternative appetitive stimulus at a lapse point. Lapses in memory formation have now been demonstrated at similar time points after conditioning with the aversive US quinine and the appetitive US serine, as well as sucrose. Thus, these lapses in memory formation appear to be a general feature of consolidation after classical conditioning. There is also generalization among the stimuli that can act as a disturbance when applied at a lapse point, as quinine, serine, and mechanical stimulation all successfully disrupt memory formation.

Title: Doxorubicin attenuates serotonin-induced long-term synaptic facilitation by phosphorylation of p38 MAPK in *Aplysia*

Authors: ***R.-Y. LIU**, Y. ZHANG, B. L. COUGHLIN, L. J. CLEARY, J. H. BYRNE
Univ. Texas Med. Sch. Houston, HOUSTON, TX

Abstract: A substantial proportion of cancer patients report significant impairments in cognitive function after chemotherapy, often referred to as "chemobrain." Although the major chemotherapeutic effects of doxorubicin (DOX) are due to oxidative damage of cellular membranes and interference with DNA replication and RNA synthesis, DOX also affects multiple isoforms of MAPK, such as extracellular signal-regulated kinase (ERK) and p38

mitogen-activated protein kinase (p38 MAPK), two kinases important for long-term memory (LTM) formation. Consequently, we examined the hypothesis that a component of chemobrain may be due to altered kinase signaling in memory circuits. In the adjacent poster, Zhang et al. demonstrated that DOX can activate both ERK and p38 MAPK in *Aplysia* sensory neurons. In this study, we evaluated the impact of DOX on long-term enhanced excitability (LTEE) and long-term synaptic facilitation (LTF), both of which are cellular correlates of LTM. In isolated *Aplysia* sensory neurons, DOX alone produced a significant increase in cell excitability 24 h after treatment ($p < 0.05$), as did 5-HT ($p < 0.05$). The two effects were not summative, however, as 5-HT-induced LTEE appeared to be attenuated by DOX, although this effect was not statistically significant. In sensorimotor neuron co-cultures, DOX alone appeared to produce a small synaptic facilitation, but this effect was not statistically significant. 5-HT-induced LTF was significantly reduced by DOX ($p < 0.05$). To determine whether activation of p38 MAPK was responsible for the impairment of 5-HT-induced LTF by DOX, we assessed LTF in the presence of SB203580 (SB), a specific inhibitor of p38 MAPK. Interestingly, the increase in magnitude of EPSPs produced in the 5-HT + DOX + SB group was significantly greater than in the 5-HT + DOX group ($p < 0.001$), suggesting that inhibition of p38 MAPK rescued the deficit in LTF induced by DOX. Moreover, no significant difference was observed in LTF between the 5-HT and 5-HT + DOX + SB groups, suggesting that the rescue is complete. Therefore, our results suggest that the deleterious effects of DOX on memory are due, at least in part, to activation of the p38 MAPK pathway.

Title: Doxorubicin enhances phosphorylation of ERK and p38 MAPK in *Aplysia* sensory

Authors: ***Y. ZHANG**, R.-Y. LIU, L. J. CLEARY, J. H. BYRNE
Neurobio. & Anat., Univ. Texas, HOUSTON, TX

Abstract: Doxorubicin (DOX) is an anthracycline widely used for cancer chemotherapy. Its antitumor actions include oxidative damage to cellular membranes and interference with DNA replication and RNA synthesis. However, DOX also affects the extracellular signal-regulated kinase (ERK) and p38 mitogen-activated protein kinase (p38 MAPK) isoforms of MAPK (Poizat et al., 2005; Small et al., 2003). Because these two MAPK isoforms play antagonistic roles in long-term memory (LTM) formation, their activation by DOX in neurons, if present, could have secondary effects on cognitive functions such as learning and memory. Here, we used cultured sensory neurons from *Aplysia* to examine the effects of DOX on levels of phosphorylated ERK (pERK) and p38 MAPK (phospho-p38 MAPK) as well as its effects on MAPK phosphatase MKP1. As a first step, immunofluorescence techniques were used to measure pERK levels at different concentrations and at different exposure times. A 30-min treatment with 10 μM DOX led to a 113 ± 29% ($n = 5$, $t_4 = 4.23$, $p < 0.05$) increase in pERK compared to controls. Treatments with lower concentrations (2.5 μM and 5 μM) were without effect. However, treatment with 2.5 μM DOX for a longer period (2 h) led to a 41 ± 14% increase in pERK ($n = 4$, $t_3 = 4.63$, $p < 0.05$). These results indicate that DOX is an effective activator of the ERK cascade in neurons and the magnitude of the effects are time and concentration dependent. Immunofluorescence techniques were also used to examine whether DOX affects levels of phospho-p38 MAPK after 2 h treatment with 2.5 μM DOX, a treatment duration and concentration used in the physiological studies in the accompanying abstract by Liu et al. DOX treatment led to a 73 ± 12% increase in phospho-p38 MAPK compared to controls ($n = 4$, $t_3 = 3.813$, $p < 0.05$). These results indicate that in SNs, DOX is an effective activator of both p38 MAPK and ERK. In breast epithelial and breast carcinoma cells, DOX increases pERK by decreasing the expression of MAPK phosphatase MKP1. To determine protein levels of MKP1 in neurons after DOX treatment, SNs were exposed to 10 μM DOX for 30 min or 2.5 μM DOX for 2 h, treatments that significantly enhanced ERK phosphorylation (see above). The 30 min treatment with 10 μM DOX produced a 9 ± 7% ($n = 4$) increase in MKP1, but this change was not statistically significant ($t_3 = 1.316$, $p = 0.3$), whereas the 2 h treatment of 2.5 μM DOX induced a modest (-13 ± 9%) but significant decrease in MKP1 levels ($n = 8$, $t_7 = 2.658$, $p < 0.05$). Therefore, down regulation of MKP1 expression may contribute, at least in part, to the prolonged (2 h) DOX-induced activation of ERK. The effects of DOX on excitability and synaptic plasticity are described in a separate abstract (Liu et al, 2014).

Title: Evidence for attention in a non-visual invertebrate, *Aplysia*

Authors: K. PEARCE, *T. W. ABRAMS
Pharmacol., U of Maryland Med. Sch., Baltimore, MD

Abstract: Attention is typically associated with animals with highly evolved visual systems, such as primates and owls. Attention-like processes with visual cues have also been demonstrated in fruit flies. Wan et el. (2012, Nat Neurosci 15:1144-52) suggested that a molecular switch that shifts afferent synapses between active and silent states may function in an attention-like process in *Aplysia*. We now asked whether this more primitive invertebrate, which lacks an image-forming visual system, exhibits attention. Attention is a limited resource and is degraded by multiple competing stimuli. Distraction is only possible if a subject attends to a stimulus. We tested whether *Aplysia* could be distracted from a stimulus that had gained importance through training with a fear conditioning paradigm adapted from Walters et al. (1981, Science 211:504-6), in which a neutral chemosensory CS is paired repeatedly with tail shock. For fear conditioning, animals were exposed to a dilute carrot juice CS for 90 sec; a tail shock was delivered during the final 15 sec of CS exposure. Sensitized control animals received the same CS and tail shock during training, but with the two stimuli separated by 15 min. After a series of a series of 6 training trials over 2 days, siphon withdrawal responses were tested on day 3, in the presence or absence of the CS. Fear conditioned animals showed a much more dramatically enhanced withdrawal response when tested in the presence of the CS, than did sensitized animals. Interestingly, fear conditioned animals tested in the absence of the CS showed <50% of the response as sensitized animals, suggesting that they had less general, non-specific fear. To test for attention to the CS, animals were tested with a very weak vibration stimulus as a distractor presented 5 sec before the CS. The distractor had no effect on the responses of sensitized animals tested with or without the CS. In contrast, when tested with the vibration distractor in the presence of the CS, fear conditioned animals showed little or no enhanced response to the test stimulus compared with pretests responses. We obtained similar effects of a distractor on responses to a fear conditioning CS that had been paired with tail shock when weak vibration was the CS, and either carrot juice or light flashes served as the distractor. Thus, the effect of the distractor was not due to inhibition of the behavioral response, as the same vibration distractor from the first protocol evoked an enhanced defensive response when used as the fear conditioning CS. In summary, these results suggest that *Aplysia* can only enhance their defensive responses when exposed to a fear conditioned CS if they are “paying attention” to this stimulus.

Title: Genomic dissection of the *Aplysia* californica siphon-withdrawal reflex circuit: One neuron at a time

Authors: *C. BOSTWICK[1], Q. YANG[3], T. P. MOROZ[1], A. B. KOHN[2], R. D. HAWKINS[3,4], L. L. MOROZ[1]
[1]Neurosci., [2]Whitney Lab. for Marine Biosci., Univ. of Florida, Whitney Marine Lab., Saint Augustine, FL; [3]Neurosci., Columbia Univ., New York, NY; [4]New York State Psychiatric Inst., New York, NY

Abstract: Analyzing single neurons is critical as studies have indicated that there is high variability in gene expression even within supposedly homogeneous cell populations. Here, we examined the transcriptome of single neurons that control the siphon-withdrawal reflex in the marine sea hare, *Aplysia californica*. The siphon and gill withdrawal reflex of *A. californica* has been studied for decades as a model circuit for understanding the molecular processes underpinning learning and memory that occurs when the animal undergoes sensitization training or classical conditioning. Three cell types were considered: the LE sensory neurons, LFs motor neurons, and L29 interneurons, which modulate the circuit. Unbiased transcriptome profiling of these single neurons (RNA-Seq) allowed us to explore the diversity of molecular components present in the circuit. It appears that each neuron has a unique expression profile with several hundred to thousands of differentially expressed transcripts. Interestingly, we discovered the CCAAT-enhancer-binding protein (ApC/EBP) was enriched in L29 interneurons compared to LE and LFs neurons. We also found expression of both isoforms of protein kinase C (PKC) and HCN channels to be relatively higher in LFs motor neurons. Also of interest is the set of novel uncharacterized neuropeptide candidates found to be differentially expressed in each of the neuronal types investigated. We suggest that small signal peptide molecules can act as both anterograde and retrograde messengers within the circuit. Comprehensive neuron-specific expression profiles could provide unique molecular resources and novel molecular targets which

might play essential roles in synaptic transmission and neural plasticity within this important model learning and memory circuit.

Title: Hyperpolarization-activated, cyclic nucleotide-gated cation (HCN) channels contribute to classical conditioning of the *Aplysia* siphon-withdrawal reflex

Authors: *R. D. HAWKINS[1,2], P. KUZYK[3], I. ANTONOV[1], Q. YANG[1], C. BOSTWICK[3,4], A. KOHN[3], L. L. MOROZ[3,4]
[1]Neurosci., Columbia Univ., New York, NY; [2]New York State Psychiatric Inst., New York, NY; [3]Whitney Lab., Univ. of Florida, St. Augustine, FL; [4]Neurosci., Univ. of Florida, Gainesville, FL

Abstract: Hyperpolarization-activated, cyclic nucleotide-gated cation (HCN) channels are critical regulators of neuronal excitability and have been implicated in different forms of neuroplasticity. Here, we examined their distribution, properties, and possible involvement in simple forms of learning in *Aplysia*. First, we cloned and characterized the expression (RNA-seq) and distribution (*in situ* hybridization) of HCN channel in the CNS of *Aplysia* californica. acHCN shares many canonical regions with other HCN channels. It is predominantly expressed in motor neurons of *Aplysia*, although we also observed moderate expression in other neuronal types. To characterize the biophysical and pharmacological properties of the channel we expressed acHCN construct in Xenopus laevis oocytes. The expressed channel exhibits all the major properties of HCN channels, including activation by both hyperpolarization and cyclic nucleotides, permeability to potassium and sodium ions, and inhibition by Cs+ and ZD7288. ZD7288 also suppressed spiking in buccal and pedal motoneurons, suggesting a role of HCN in *Aplysia* feeding and locomotor circuits respectively. Next, we used ZD7288 to test whether HCN channels are involved in two simple forms of learning in the semi-intact siphon-withdrawal preparation. We first gave a train of 4 shocks to the tail, which produces behavioral sensitization

of the siphon withdrawal reflex that lasts approximately 1 hr. However, bathing the abdominal ganglion in ZD7288 (100 μM) had no significant effect on the sensitization. We then examined classical conditioning. We compared changes in the withdrawal reflex in groups that received either paired or unpaired training with a siphon tap CS and a tail shock US while the abdominal ganglion was bathed in either normal seawater (control) or ZD7288. In the control group, paired training produced an increase in the response to the CS compared to either the pretest or unpaired training, demonstrating classical conditioning. ZD7288 (100 μM) significantly reduced the conditioning. As controls, it did not have significant effects on the amplitude of the initial response to either the CS or US. These results suggest that HCN channels contribute to associative learning (conditioning) but not nonassociative learning (sensitization) of the withdrawal reflex. Furthermore, the pattern of results with ZD7288 during conditioning (a partial blockade that becomes larger with additional training) is similar to the pattern with injection of the NO scavenger oxymyoglobin into the motor neuron (Antonov et al, 2007), suggesting that NO may act through cGMP to activate HCN channels in the motor neuron during conditioning.

Title: *Aplysia* neurotrophin and its Trk receptor play an essential role during the transition from short-term to intermediate-term facilitation produced by 5HT at *Aplysia* sensory-motor neuron synapses

Authors: *I. JIN[1], S. KASSABOV[1], H. UDO[2], R. NICHOLLS[1], E. R. KANDEL[1], R. D. HAWKINS[1]
[1]Columbia Univ., NEW YORK, NY; [2]Biol., Kyushu Univ., Fukuoka, Japan

Abstract: We have previously found that spontaneous neurotransmitter release from the presynaptic neuron during short-term facilitation (STF) acts as an anterograde signal to recruit postsynaptic mechanisms of intermediate-term facilitation (ITF), an early step in a cascade

leading to long-term facilitation (LTF) and synaptic growth at *Aplysia* sensory-motor neuron synapses in culture (Jin et al., 2012a,b). In addition, we found that an endogenous neurotrophin (ApNT) and its receptor (ApTrk) are important for LTF (Kassabov et al., 2013). We report here that presynaptic ApNT/ApTrk signaling also plays a major role in the transition from STF to ITF by enhancing spontaneous transmitter release. 2 X 5 min or a 10 minute bath application of 5HT produces ITF and an increase in mEPSC (mini) frequency, with little change in amplitude. 10 min application of mature ApNT also increased mini frequency, and blocking ApTrk by bath application of Fc fragments reduced the increase produced by 10 min 5HT. These results suggest that ApNT/ApTrk signaling is involved in the enhancement of spontaneous release produced by 5HT during the induction of ITF. Injection of siRNAi against ApNT into the SN reduced the increase in mini frequency produced by 5HT, implicating a presynaptic role for ApNT. Injection of ApTrk antisense into the SN similarly reduced the increase in mini frequency produced by 5HT. Conversely, activation of presynaptic ApTrk receptors with a hybrid system (Knight et al., 2000) increased mini frequency. These results suggest an autocrine feedback, in which presynaptic ApTrk is also involved. 10 min activation of heterologous octopamine (OA) receptors which are linked to the production of cAMP and activation of PKA in the SN also produces an increase in mini frequency, and that increase was reduced by injection of ApTrk antisense in the SN, suggesting that ApTrk is downstream of PKA. Conversely, injection of a peptide inhibitor of PKA into the SN blocked the increase in mini frequency produced by 5-HT, OA, or mature ApNT, suggesting that PKA is downstream of ApNT. Collectively, these results suggest that activation of presynaptic 5HT (or OA) receptors stimulates cAMP, PKA, and the release of ApNT, which binds to presynaptic ApTrk autoreceptors and acts back through PKA to enhance spontaneous release of glutamate from the SN. Thus, ApNT has a critical role as a presynaptic autocrine signal involved in the enhancement of spontaneous release and subsequent recruitment of postsynaptic mechanisms of ITF and LTF. In addition, presynaptic ApNT, ApTrk, and PKA apparently form a self-amplifying feedback loop that could increase activation of PKA and recruit presynaptic mechanisms of LTF.

Title: High-yawning rats are more anxious than low-yawning in elevated plus-maze and in the light-dark box: Effects of diazepam

Authors: *M. PALACIOS, C. URIBE, M. CORTES, J. EGUIBAR
Inst. of Physiol. Benemérita Univ. Autónoma De Puebla, Puebla, Mexico

Abstract: High-yawning (HY) subline of Sprague-Dawley rats none only yawned more than the low-yawning (LY), but they also show other changes more ambulation and less fecal boluses in the open-field test. In a novel environment HY rats showed more grooming bouts and time spent in grooming behavior suggesting that HY rats are more anxious than LY subline. The aim of this study is to study diazepam in the HY and LY rats exposed to behavioral standardized test to measure anxiety, the elevated plus-maze (EPM) and in the light-dark box (LDB). All subjects were maintained under standard conditions with a light-dark cycle 12/12 with lights on at 0700 with free access to rodent pellets and water. At 100 days old, male subjects were tested in the EPM and in the LDB. All experiments did between 1100 to 1300h. We also analyzed the effects the diazepam a well-known benzodiazepine. We used 0.25, 0.50 and 1 mg/kg doses administered by intraperitoneal (i.p.) injections. The behavior in the EPM and LDB was measured after 15 min of injection. The behavioral display were recorded using video camera by 5 min in each test and analyzed off-line by a blind observer using The Observer XT software. Data analyzed through ANOVA followed by Tukey test. The results showed that male HY rats are more anxious because they showed less entries and less the time spent in the open arms of the EPM respect to that showed by LY sublines ($P<0.05$). Similar results were obtained in the LDB with less entrances in the illuminated compartment and the time spent on it by the HY rats ($P<0.05$). Importantly, HY subline showed in both tests vicarious trial and error (VTE) behavior. However, both sublines are sensible to the action of diazepam being higher the effects with the 1 mg/kg dose ($P<0.05$). In conclusion, HY rats are more anxious in the EPM and LDB tests. Importantly, HY subjects showed more VTE behavior suggesting obsessive-compulsive disorder (OCD). Importantly, the benzodiazepine reduced VTE display and increased the time spent in the open arms in the EPM and light compartment in the LDB. So, HY subline is an adequate model for perseverance and OCD.

Title: A DA-SP-ENK interface promotes the translocation of the δ-opioid receptor on cholinergic interneurons in the striatum

Authors: *E. M. HEATH[1], B. CHIENG[1], V. LAURENT[1], J. BERTRAN-GONZALEZ[3], M. CHRISTIE[2], B. BALLEINE[1]
[1]Brain & Mind Res. Inst., [2]Discipline of Pharmacol., The Univ. of Sydney, Sydney, Australia; [3]Clem Jones Ctr. for Ageing Dementia Research, Queensland Brain Inst., The Univ. of Queensland, Brisbane, Australia

Abstract: The ∂-opioid receptor (DOR) is a heavily expressed in the striatum, particularly on cholinergic interneurons (CINs). Under baseline conditions these neurons contain large amounts of receptor sequestered in intracellular pools. During Pavlovian conditioning, DOR in the nucleus accumbens shell (NACsh) of DOR-eGFP mice translocates from the cytoplasm to the somatic membrane of CINs. The molecular mechanism that triggers this event is unknown. This study investigates the role of dopamine (DA) and substance P (SP) in this insertion. SP (300nm) was administered unilaterally to the striatum of DOR-eGFP mice *in vivo* and to slices *in vitro* for 30 minutes. In a separate experiment, the D1-receptor agonist chloro-APB (100μM) was infused into the striatum of DOR-eGFP mice either alone or with the D2-receptor agonist quinpirole (10μM) for 45 minutes. DOR-eGFP distribution was visualised with immunofluorescence and its levels at the membrane of CINs quantified with ImageJ. *In vivo,* SP produced a significant increase in the membrane levels of DOR-eGFP in both the dorsal medial striatum (DMS) and NACsh. This was blocked by administration of n-acetyltryptophan (NAT) (1μM), an NK1R antagonist. *In vitro*, SP treatment significantly increased the levels of membrane DOR-eGFP in the nucleus accumbens core (NACco) and the NACsh. Infusion of chloro-APB into the striatum significantly lowered levels of DOR-eGFP at the somatic membrane of CINs whereas co-treatment with quinpirole significantly increased membrane levels of DOR-eGFP. In conclusion, SP signalling triggers the translocation of DOR on CINs in the striatum. Concurrent D1- and D2-receptor activation also triggers the translocation of DOR, possibly by stimulating the release of SP from D1-positive striatonigral medium spiny neurons (MSNs) while simultaneously inhibiting the release of enkephalin from D2-positive striatopallidal MSNs. These data suggest that a DA-SP-ENK interface may drive DOR translocation in the striatum.

Title: Pharmacological fingerprints of contextual uncertainty

Authors: *L. MARSHALL[1], D. RUGE[1], C. MATHYS[2], K. E. STEPHAN[3,2], P. DAYAN[4], S. BESTMANN[1]
[1]Sobell Dept. of Motor Neurosci., [2]Wellcome Trust Ctr. for Neuroimaging, UCL Inst. of Neurol., London, United Kingdom; [3]Translational Neuromodeling Unit, Univ. of Zurich & ETH Zurich, Zurich, Switzerland; [4]Gatsby Computat. Neurosci. Unit, UCL, London, United Kingdom

Abstract: Adapting to environmental dynamics requires us to distinguish truly significant changes from chance fluctuations. This presents the brain with several forms of uncertainty and prediction errors (Yu & Dayan, 2005): 1) expected uncertainty (EU) arises from a combination of ignorance and known but irreducible variability in a given environment; 2) this determines the surprise that arises when prevailing expectations are dashed; 3) unexpected uncertainty (UU) occurs when one encounters a new environment governed by novel rules. Theoretical, and indirect behavioural and neuroimaging evidence (Iglesias et al, 2013; Payzan-LeNestour et al., 2013; Galea et al., 2012) has proposed distinct neuropharmacological underpinnings for these types of uncertainty, with EU linked to acetylcholine (ACh), UU to norepinephrine (NE), and aspects of surprise to dopamine (DA). Here we manipulated these neuromodulators pharmacologically to assess their causal impact on these forms of uncertainty. In a double-blind between-subjects design (n=128), human subjects received biperiden (ACh muscarinic antagonist), prazosin (NE antagonist), haloperidol (DA antagonist) or placebo before performing a probabilistic choice reaction time (RT) task, in which the underlying probabilistic rule controlling the trial-by-trial occurrence of one of four imperative stimuli switched every 50 trials. We modelled individual learning and contextual uncertainty within a Bayesian framework

(Mathys et al., 2011; Yu & Dayan, 2005). After estimating the parameters of subject-specific choice trajectories, we established the relative contributions of EU, UU and surprise on observed RTs. Our preliminary results indicate dissociable roles for ACh, NE and DA in signalling contextual uncertainty, which were not due to group differences in baseline impulsivity, risk-taking or distractibility. Subjects with reduced ACh signalling were slower to learn novel contextual rules. Ongoing analyses are probing the exact nature of the changes elicited by NE and DA signal suppression, but indicate separable impairments in contextual learning and processing of surprise. Collectively, our current results suggest dissociable neuromodulatory fingerprints for the control of our adaptive responses to dynamic and unexpected changes in the environment.

Title: Animal models of effort-related decision making: Reversal of the effects of tetrabenazine with the MAO-B inhibitor deprenyl (selegiline)

Authors: *H. M. CONTRERAS[1], M. A. ROWLAND[1], S. E. YOHN[1], M. W. JONES[1], M. CORREA[2,1], J. D. SALAMONE[1]
[1]Psychology, Univ. of Connecticut, Storrs, CT; [2]Psychobiology, Univ. Jaume I, Castello, Spain

Abstract: Considerable evidence indicates that nucleus accumbens dopamine (DA) is a critical component of the neural circuitry that regulates behavioral activation and effort-related processes. Motivated behaviors often are characterized by a high degree of behavioral activation and work output, and organisms frequently make effort-related decisions based upon cost/benefit analyses. Moreover, people with depression and other disorders often show effort-related motivational symptoms, such as anergia, psychomotor retardation, and fatigue. It has been

suggested that tasks measuring effort-related choice behavior could be used as animal models of these motivational symptoms, and in the present studies the effort-related effects of the vesicular monoamine transport (VMAT-2) inhibitor tetrabenazine (TBZ) were investigated. TBZ produces depressive symptoms in humans, and because of its selective inhibition of VMAT-2, it preferentially depletes DA. Effort-based decision making is studied with tasks offering choices between high effort options leading to highly valued reinforcers vs. low effort/low reward options. Several recent studies have shown that TBZ can alter effort-related choice in rats, and bias animals towards low effort alternatives. These effects are seen at doses that reduce extracellular DA in nucleus accumbens, and alter expression of DARPP-32 in accumbens medium spiny neurons in a pattern indicative of reduced transmission at both D1 and D2 DA receptors. In addition, these behavioral effects can be reversed by the adenosine A2A antagonist MSX-3 and the catecholamine uptake inhibitor/antidepressant bupropion. The present studies characterized the ability of the monoamine oxidase -B (MAO-B) inhibitor deprenyl (selegiline) to reverse the effort-related effects of TBZ. Originally developed as an antiparkinsonian drug, deprenyl has been shown to have antidepressant effects in humans, and to induce antidepressant-like effects in traditional rodent models of depression. Rats were assessed using a concurrent fixed-ratio 5/chow feeding choice task. Tetrabenazine shifted response choice in rats, producing a decrease in lever pressing and a concomitant increase in chow intake. Co-administration of the MAO-B inhibitor deprenyl (2.5 mg/kg) reversed the effects of 0.75 mg/kg TBZ, increasing lever pressing and decreasing chow intake in TBZ-treated rats. Future research will characterize the effects of MAO-A selective drugs for their effects on effort-related choice. These studies have implications for the potential use of MAO inhibitors as treatments for the motivational symptoms of depression and related disorders.

Title: Orally ingested curcumin attenuates shifts in effort-related choice behavior induced by the vmat-2 inhibitor tetrabenazine: Implications for depression

Authors: *S. E. YOHN[1], A. MISTRY[1], S. COLLINS[1], L. XIE[2], A. MANCHANDA[3], B. BOLLING[2], R. BOGNER[3], M. CORREA[4,1], J. D. SALAMONE[1]
[1]Psychology, [2]Dept. of Nutritional Sci., [3]Sch. of Pharm., Univ. of Connecticut, Storrs, CT; [4]Psychology, Univ. Jaume I, Castello, Spain

Abstract: Nucleus accumbens (NAc) dopamine (DA) is involved in behavioral activation and effort-related motivational processes. Behavioral paradigms have been developed to assess effort-related choice in rodents, including maze procedures and operant tasks. Administration of the vesicular monoamine transport-2 (VMAT-2) inhibitor tetrabenazine (TBZ) produces an alteration of response allocation in the FR5/chow procedure, biasing animals toward the lower effort alternative (i.e. consumption of freely available chow rather than lever pressing for a preferred food). The effects of TBZ are consistent with those of accumbens DA depletions and DA D1 or D2 family antagonists. It has been suggested that tasks assessing effort-related choice in rodents can model motivational symptoms such as psychomotor retardation, anergia, and fatigue, which can be seen in depression and other disorders. Previous studies have shown the effort-related effects of TBZ can be attenuated through co-administration of the monoamine-oxidase (MAO)-B inhibitor, deprenyl, as well as the antidepressant bupropion. Curcumin, a naturally occurring compound found in turmeric, has proven to be successful in traditional rodent models of depression. Curcumin acts as an MAO-A/B inhibitor, but it has low bioavailability due to poor absorption, rapid metabolism, and fast elimination. Prior studies have enhanced bioavailability through addition of excipients, and have generally employed gavage feeding. Although highly effective, this method can cause esophageal injury as well as restraint-associated distress, particularly with repeated use. Moreover, it does not mimic human ingestion. The current studies involved two experiments. The first experiment assessed the ability of rats to ingest food pellets formulated with curcumin and the excipient neusilin, while the second was undertaken to determine if ingested curcumin could reverse the effort-related effects of TBZ. Two different formulations of curcumin were tested to observe consumption; the crystalline (CRYS) and coground (CGR) formulations differed in the way that they were milled. Rats readily consumed CRYS curcumin pellets, but did not consume the CGR pellets. Thus, CRYS pellets were administered in the FR5/chow procedure at two different time points prior to testing. When administered three hours before testing, ingestion of 160 mg/kg CRYS curcumin significantly reversed the effort-related effects of TBZ. These studies demonstrate that orally ingested curcumin in rats can exert effort-related motivational effects. These results have implications for the clinical use of curcumin to treat motivational symptoms in humans.

Abstract: Motivated behaviors can be characterized by a high degree of behavioral activation and work output, and animals often make effort-related decisions based upon cost/benefit analyses. Moreover, people with depression and other disorders show effort-related motivational symptoms, such as anergia, psychomotor retardation, lassitude and fatigue. Nucleus accumbens dopamine (DA) is a critical component of the neural circuitry that regulates behavioral activation and effort-related processes. Effort-based decision making is studied with tasks offering choices between high effort options leading to highly valued reinforcers vs. low effort/low reward options, and it has been suggested that such tasks could be used as animal models of motivational symptoms. In the present studies the effort-related effects of the vesicular monoamine transport (VMAT-2) inhibitor tetrabenazine (TBZ) were investigated. TBZ inhibits

VMAT-2 and thereby blocks vesicular storage, preferentially depleting DA in the striatal complex. TBZ also produces depressive symptoms in humans. Recent studies have shown that TBZ alters effort-based choice in rats, and biases animals towards low effort alternatives across multiple behavioral tasks (operant lever pressing and T-maze choice tasks). These effects are seen at doses that reduce extracellular and tissue levels of DA in nucleus accumbens, and alter expression of DARPP-32 in accumbens medium spiny neurons in a manner consistent with reduced D1 and D2 receptor transmission. Because tasks involving effort-related choice may be useful for drug development, additional studies investigated the ability of various drugs that are putative or established antidepressants to reverse the effects of TBZ. The effort-related behavioral effects of TBZ were reversed by the adenosine A2A antagonist MSX-3, the MAO-B inhibitor deprenyl (selegiline), and the catecholamine uptake inhibitor/antidepressant bupropion. The 5-HT uptake inhibitor fluoxetine and the norepinephrine (NE) uptake inhibitor desipramine failed to reverse the effects of TBZ, and higher doses of fluoxetine and desipramine in combination with TBZ led to further behavioral impairments. This pattern of effects indicates that drugs acting on DA transmission are relatively effective at reversing the effort-related effects of TBZ. Moreover, adenosine A2A antagonism may be effective because of interactions between adenosine A2A and dopamine D2 receptors in nucleus accumbens. These results are consistent with the hypothesis that drugs acting directly or indirectly to enhance DA transmission may be effective at treating effort-related psychiatric symptoms in humans.

Title: Animal models of effort-related decision making: The antidepressant fluoxetine potentiates effort-related effects of the dopamine depleting agent tetrabenazine

Authors: *M. A. ROWLAND[1], H. M. CONTERAS[1], M. W. JONES[1], S. E. YOHN[1], M. CORREA[2,1], J. D. SALAMONE[1]
[1]Psychology, Univ. of Connecticut, Storrs, CT; [2]Psychobiology, Univ. of Jaume I, Castelló, Spain

Abstract: Impairments in behavioral activation and effort-related motivational function are often seen in depression and other disorders. Symptoms such as psychomotor retardation, anergia, apathy, avolition, and fatigue are common in psychiatric patients, and are highly resistant to treatment. Dopamine (DA), particularly in the nucleus accumbens, is involved in effort-related functions. DA antagonism and accumbens DA depletions make animals more sensitive to work-related response costs, and bias them towards low effort choices in decision making tasks. Thus, tasks that assess effort-related decision making can be useful for the development of animal models of motivational dysfunction. In the present studies, the vesicular monoamine transporter (VMAT-2) inhibitor tetrabenazine (TBZ) was used to induce effort-related dysfunctions in rats. TBZ induces depressive symptoms in humans, and low doses preferentially deplete DA. Several recent studies have shown that TBZ can alter effort-related choice in rats, and bias animals towards low effort alternatives. These effects are seen at doses that reduce both extracellular and tissue levels of DA in nucleus accumbens. In addition, these behavioral effects can be reversed by the adenosine A2A antagonist MSX-3, the catecholamine uptake inhibitor/antidepressant bupropion, and the MAO-B inhibitor deprenyl. The present studies characterized the ability of the selective serotonin reuptake inhibitor (SSRI) fluoxetine to reverse the effort-related effects of TBZ. SSRIs inhibit the uptake of serotonin into nerve terminals; fluoxetine (Prozac) is a commonly prescribed antidepressant that selectively inhibits uptake at the 5-HT transporter. Rats were assessed using a concurrent fixed-ratio 5/chow feeding choice task. TBZ (0.75 mg/kg) shifted response choice in rats, decreasing lever pressing while increasing intake of the freely available chow. When administered without TBZ, 10.0 mg/kg of fluoxetine decreased lever pressing in rats, but did not increase chow consumption as is seen in the TBZ condition. Co-administration of fluoxetine (2.5-10.0 mg/kg) with TBZ failed to reverse the effects of TBZ. In fact, co-administration of fluoxetine with TBZ produced further effort-related impairments, decreasing lever pressing at all doses of fluoxetine tested. These effects are consistent with human clinical studies showing that SSRIs are not highly effective at treating motivational dysfunction in depressed patients, and can induce symptoms such as fatigue and apathy. These studies have implications for the potential use of SSRIs as treatments for the motivational symptoms of depression and related disorders.

Title: Dopamine depletion reduces preference for physical effort in animals with low but not high experience of exercise: Shift to sedentary sources of reinforcement

Authors: *L. LOPEZ-CRUZ[1], N. SAN MIGUEL[1], P. BAYARRI[1], J. MEDRANO[1], C. CARRATALÁ[1], L. MONFERRER[1], J. D. SALAMONE[2], M. CORREA[1,2]
[1]Dept. of Psychobiology, Univ. Jaume I, Castellon, Spain; [2]Dept. of Psychology, Univ. of Connecticut, Storrs, CT

Abstract: Organisms frequently make cost/benefit analyses in which they weigh the value of rewards vs. the costs involved in procuring them. These decision-making processes include assessments of effort-related costs and other factors, and can involve cognitive as well as physical effort. The mesolimbic dopamine (DA) system plays a critical role in behavioral activation, exertion of effort, and effort-based decision-making, and DA antagonism and depletion in this system has been shown to induce anergia in effort-based decision tasks. Exercise has been demonstrated to have protective effects in animal models of pathologies characterized by motor disturbances such as Parkinson's disease, which involves DA loss in the nigrostriatal system. However, the beneficial effects of physical activity on symptoms such as mental fatigue or anergia, present in many psychiatric and neurological pathologies, also need to be explored. To assess DAergic involvement in the activational component of motivation and in effort based decision-making when multiple reinforcers are available, mice received injections of tetrabenazine (TBZ), a VMAT-2 inhibitor that produces a reversible DA depletion. These animals were tested with a mouse T-maze task developed for the assessment of preference between physical activity (wheel running) in one arm vs. sedentary reinforcers such as a freely available sucrose pellets in another arm, as well as a non-social (neutral) odor in the third arm. Additionally, to study the protective effects of physical exercise, different groups of animals were exposed to different regiments of exercise (i.e. forced versus voluntary by environmental enrichment). Under standard conditions, mice spent more time running and less consuming sucrose or sniffing. TBZ produced a shift in the relative preference; it reduced the choice of the

reinforcer that involved vigorous activity, but increased consumption of a reinforcer that required little effort (sucrose). None of these doses of TBZ reduced RW performance or sucrose consumption when animals could not choose between them. Finally, mice that were extensively exposed to exercise (forced or by environmental enrichment) did not show TBZ-induced shifts in preference towards low-effort reinforcers such as sucrose or olfactory stimuli. These results suggest that exercise could act as a preventive therapy for the anergia-inducing effects of DA depletion. Thus, DA depletion produced effects indicative of anergia (lack of energy), but did not impair the primary rewarding effects of sucrose.

Title: Low dopamine D2/D3 receptor availability is associated with steep discounting of delayed rewards in methamphetamine dependence

Authors: *M. E. BALLARD[1,5], M. A. MANDELKERN[5,6], J. R. MONTEROSSO[7], E. HSU[7], C. L. ROBERTSON[2,5], K. ISHIBASHI[3,5], A. C. DEAN[3], E. D. LONDON[3,2,4,5]
[2]Mol. and Med. Pharmacol., [3]Psychiatry and Biobehavioral Sci., [4]Brain Res. Inst., [1]UCLA, Los Angeles, CA; [5]Veterans Affairs Greater Los Angeles Healthcare Syst., Los Angeles, CA; [6]Physics, Univ. of California, Irvine, Irvine, CA; [7]Psychology, USC, Los Angeles, CA

Abstract: Background: Steep temporal discounting, or a tendency to undervalue delayed outcomes, is commonly exhibited by individuals with psychiatric disorders that are associated with aberrant dopaminergic neurotransmission. Studies of substance use disorders have indicated

that steeper temporal discounting is predictive of a lower probability of achieving protracted abstinence, and that interventions that reduce temporal discounting can improve treatment response. Dopamine signaling influences intertemporal choice, and indirect evidence suggests that low dopamine D_2-type receptor availability in the striatum may contribute to a propensity to sacrifice long-term goals for short-term gain; however, this possibility has not been tested directly. Methods: We investigated whether striatal D_2/D_3 receptor availability is negatively associated with preference for smaller, more immediate rewards over larger, delayed alternatives among research participants who met DSM-IV criteria for methamphetamine (MA) dependence. Fifty-eight adults (n = 27 MA-dependent, n = 31 control) completed the Kirby Monetary Choice Questionnaire, and underwent positron emission tomography scanning with [^{18}F]fallypride. Results: MA users displayed steeper temporal discounting and lower striatal D_2/D_3 receptor availability than controls. Discount rate was significantly negatively correlated with striatal D_2/D_3 receptor availability among MA users (r = -.342, p = 0.041) and in the combined sample (r = -.246, p = 0.032), but not among controls (r = -.121, p = 0.258). Conclusions: These results provide the first direct evidence of a link between deficient D_2/D_3 receptor availability and steep temporal discounting. This finding fits with reports that low striatal D_2/D_3 receptor availability is associated with a higher risk of relapse among stimulant users, and may help to explain why some individuals chose to continue using drugs despite knowledge of their future negative consequences.

Title: The effects of cocaine on oral sucrose self-administration by 6-hydroxydopamine lesioned male and female rats

Authors: *H. M. BARROS[1], K. M. BISOGNIN[2], L. S. UMPIERREZ[2], T. B. LOS SANTOS[2], L. FREESE[2], M. F. SOUZA[2]
[1]Ciencias Basicas da Saude, UFCSPA, Porto Alegre, Brazil; [2]UFCSPA, Porto Alegre, Brazil

Abstract: The attention deficit hyperactivity disorder (ADHD) is one of the most common psychiatric disorders of childhood and it can persist into adulthood. In adults, the most common comorbidity of ADHD is Substance Use Disorder. Cocaine abuse and dependence are more precocious in ADHD patients. Because females are more vulnerable to the effects of cocaine, our objective was to evaluate the self-administration of cocaine in male and female rats in a model to ADHD. Male (M) and female (F) Wistar rats, PN 4, were randomized to intrathecal 6-OHDA (100µg free base) or SHAM 10µL (0.1% ascorbic acid). When 30 days old the rats were placed daily in operant conditioning sessions (3 hours, FR1) for oral sucrose self-administration added or not with cocaine (0, 0.2, 0.3, 0.4 mg/ml), for 28 days. Horizontal activity was estimated on PN 21 and post cocaine 0,2 mg, 0,3 mg and 0,4 mg. For analysis of reinforcement and of locomotion a Two Way ANOVA was used, considering lesion and sex as factors. Tukey test was used for post hoc comparisons when appropriate. As expected, females showed more active lever presses than males and lesioned animals present less sucrose self-administration. When considering cumulative responses in the active lever, the lesioned animals presented less lever presses than the non-lesioned animals for oral sucrose self-administration when given cocaine (F/SHAM - 1415.23 ± 32.86; M/SHAM -1180.84 ± 32.86; F/6OHDA- 917.33 ± 28.17; M/6OHDA - 538.12 ± 28.12; $p < 0.001$). The mean number of daily reinforcements showed that cocaine decreased sucrose self-administration, dose-dependently, in males. Higher dose-dependent effect was seen in M/6OHDA. F/SHAM showed more sucrose consumption in the presence of cocaine and in F/6OHDA cocaine did not retain its dose-dependent effect towards sucrose self-administration. These results show that 6-OHDA lesion decrease sucre self-administration, as expected and that cocaine behaviuoral effects on sucrose reinforcement is sensitized in 6-OHDA lesioned males. Cocaine effects on sucrose self-administration are less intense in females, irrespective of previous dopaminergic lesion or not. Further studies should elucidate the participation of the pre-synaptic dopaminergic neurons in sucrose consumption in female rats. **Support:** CNPq 1C Researcher Grant; CAPES 059573/2010

Title: The effects of acute fluoxetine administration on functional abnormalities during temporal discounting in children with ADHD

Authors: *C. O. CARLISI, L. J. NORMAN, K. CHANTILUKE, A. CHRISTAKOU, M. J. BRAMMER, V. GIAMPIETRO, K. RUBIA
Inst. of Psychiatry, King's Col. London, London, United Kingdom

Abstract: The use of temporal foresight is critical in successful decision making. Temporal discounting is the rate at which a subjective value of reward decreases with increasing time delay and is a validated measure of temporal foresight and impulsivity. Patients with Attention Deficit Hyperactivity Disorder (ADHD) are impulsive and exhibit behavioural and neural deficits in temporal discounting and decision making because of this phenotype. The role of the selective serotonin reuptake inhibitor (SSRI) fluoxetine in ADHD is relatively unexplored, but evidence supports an involvement of serotonin in impulsivity, temporal discounting and in ADHD. Therefore, we wanted to examine whether acute fluoxetine administration would ameliorate atypical behavioural and brain response in ADHD on a temporal discounting task. 12 adolescent boys with ADHD and 20 controls (15.09+/-1.76y) completed a temporal discounting task which required participants to choose between receiving a certain amount of hypothetical money now or receiving £100 in either one week, month or year in an fMRI scanner. ADHD patients were scanned twice in a placebo-controlled randomised design under either Fluoxetine or placebo. Controls were scanned once, off medication. Activations to delayed vs immediate reward choices were modelled, with the modulatory effects of medication on the ADHD group's activations to delayed choices as the primary effect of interest. Repeated measures whole brain analysis for delayed vs immediate choices ($p<0.005$) revealed a significant medication effect in the right inferior frontal/superior temporal cortex, which was enhanced in activation with fluoxetine relative to placebo. Placebo, on the other hand, enhanced activation in the left cerebellum and left precentral gyrus relative to fluoxetine. Comparisons between healthy controls and patients under either drug condition to test for normalisation effects will be presented at the conference. Inferior frontal dysfunction is consistently implicated in ADHD during several cognitive functions including temporal foresight (Rubia et al., 2009, Chantiluke et al., 2014). Our recent meta-analysis showed that psychostimulants most consistently upregulate activation in this region during neurocognitive tasks in ADHD (Rubia et al., 2014). The present findings show that serotonin agonists may have a similar effect of upregulating the inferior frontal cortex in ADHD in the context of an impulsiveness measure of temporal discounting.

Title: Effects of mixed-function serotonergic compounds in a novel rodent cost/benefit decision-making task

Authors: *A. L. PERSONS, S. E. TEDFORD, T. NAPIER
Pharmacol., Rush Univ. Med. Ctr., Chicago, IL

Abstract: Preclinical and clinical studies suggest that drug and behavioral addictions (e.g., gambling) have overlapping features, and may involve the serotonergic (5-HT) system. Our preclinical studies indicate that mixed-function compounds that act on multiple 5-HT receptors can attenuate the behavioral and neurobiological effects of methamphetamine. Mirtazapine (an FDA-approved atypical antidepressant that acts on 5-HT2A/2C, 5-HT3 and adrenergic α2 receptors) decreases methamphetamine-induced behaviors such as drug-seeking (Graves & Napier. Biol. Psychiatry. 69:275,2011) and conditioned place preference (Herrold et al. Drug Alcohol Depend. 99:231,2009, Voigt et al. Behav. Brain Res. 225:91,2011; Voigt & Napier. Front. Behav. Neurosci. 5:92,2011). Additionally, we revealed that mirtazapine can reduce preference for larger, albeit costlier, reinforcement options and promote more advantageous decision-making in a cost/benefit decision-making task (Persons et al. Program No. 635.12. Neuroscience Meeting Planner. San Diego, CA: Society for Neuroscience. Online). Here we extend this work to determine if other mixed-function serotonergic compounds can alter decision-making. We implemented a novel rat model of cost/benefit decision-making that uses intracranial self-stimulation (ICSS) as the positive reinforcer in a lever-pressing operant task. Two options of cost/benefit decision-making included the choice between (i) the unpredictable occurrence of a high effort/large reinforcer (HE/LR) option, and (ii) the predictable occurrence of a low effort/small reinforcer (LE/SR) option. In this paradigm, the response cost placed on

obtaining the large reinforcer is the exertion of greater physical effort (i.e., increased lever pressing) necessary to obtain the reward. Increasing the effort required for the large reinforcer reduces the rats' tendency to select the HE/LR lever, and their preference switches to the LE/SR lever. The task allows the rats to demonstrate their well-documented tendency to prefer some level of risk when effort is relatively low. Results to date show the following: (i) Pretreatment with mianserin (5mg/kg) had no effect on preference for the HE/LR lever compared to baseline preference (76% vs. 62%). (ii) Pretreatment with ketanserin (5mg/kg) decreased preference for the HE/LR lever by ~30% (79% vs. 49%), suggesting that ketanserin was able to reduce gambling-like behavior. (iii) Treatment with vehicle for either test compound had no effect on baseline preference for the HE/LR lever. Further assessments of low-dose (1mg/kg) mianserin and ketanserin are ongoing.

Title: Nicotinic receptors in the ventral tegmental area mediates uncertainty-driven exploration in mice

Authors: J. NAUDÉ[1], S. TOLU[1], M. DONGELMANS[1], N. TORQUET[1], U. MASKOS[2], *P. FAURE[3]
[1]Univ. Pierre et Marie Curie / CNRS, Paris, France; [2]Inst. Pasteur, Paris, France; [3]CNRS UMR8246, INSERM U1130, Paris, France

Abstract: Smoking alters evaluative and decision processes: smokers are more impulsive, less sensitive to adverse consequences and exhibit less exploratory behaviors. Exploration is an important adaptive process that may help discovering more advantageous alternatives. In particular, exploration can be directed towards uncertain options, as reducing uncertainty has an informational value. However, the neural basis of uncertainty-driven exploration remains unclear and how nicotine can interact with these processes is unknown. In studies with non human animals, food commonly serves as the reward, often requiring food deprivation which can affect response to uncertainty itself. Using a behavioral paradigm that can be considered as a gambling task, where animals make a continuous series of choices between probabilistic brain stimulation

rewards (ICSS), we deciphered the role of nicotinic control of dopamine activity in uncertainty-driven exploration. Acute nicotine injection (n=10) increases exploration of uncertain options compared to saline control (n = 10). Compared to wild-type mice (n = 12), mice lacking nAChR β2-subunit (n=11) have an altered balance between exploitation of known rewards and exploration of uncertain options. Targeted re-expression of functional β2-containing nAChRs in the VTA (n = 11) restored this balance. Hence, our findings show that cholinergic modulation of the VTA is a neural basis for uncertainty-driven exploration. We also demonstrate a decrease in exploration following chronic nicotine exposure (n = 10), which modifies the dopaminergic system by acting on nicotinic acetylcholine receptors (nAChRs). Thus, by acting on VTA nAChRs, chronic nicotine not only exerts its reinforcing properties, but also favors the tendency to focus on known rewards, encompassing smoking itself and decisions unrelated to drugs.

Title: The forebrain circuitry underlying fear behavior: Connections between the mediodorsal thalamus, frontal cortices and basolateral amygdala in mice

Authors: *F. MATYAS[1], J. LEE[2], H.-S. SHIN[2], L. ACSÁDY[1]
[1]Inst. of Exptl. Med. of the Hungarian Acad. of Sci., Budapest, Hungary; [2]Ctr. for Cognition and Sociality, Inst. for Basic Sci., Daejeon, Korea, Republic of

Abstract: A large forebrain circuit, including the thalamus, amygdala and frontal cortical regions, is responsible for the establishment and extinction of fear-related memories. Understanding interactions among these three regions is critical to decipher the basic mechanisms of fear. With the advancement of molecular technology and optogenetics, mouse has become the main species to study fear-related behaviours. However, the basic connectivity pattern of the forebrain circuits involved in processing fear has not been described in this species. In this study we mapped - using single and double, anterograde and retrograde tracings - the connectivity between three key nodes of the circuit, the basolateral nucleus of the amygdala (BLA), the mediodorsal nucleus of the thalamus (MD) and the medial prefrontal cortex, which were shown to have closed triangular connectivity in rats. In contrast to rat, we found no evidence for this closed loop in mouse. There was no major input from BLA to MD and little overlap between medial prefrontal regions connected with both BLA and MD. The common nodes in the frontal cortex, which displayed reciprocal connection with both BLA and MD were the agranular insular cortex and the border zone of cingulate/M2 cortex. In addition BLA can indirectly affect MD via the orbital cortex. We attribute the difference between our results and earlier rat studies to methodological problems rather than to genuine species difference. Our data demonstrate that BLA and MD communicate via cortical sectors whose roles in fear-related behavior have not been extensively studied. In general, our study provides the morphological framework for the studies of murine fear related behaviors.

Title: The role of amygdala in human aggression disorders

Authors: ***F. V. GOUVEIA**[1], C. C. OLIVEIRA[1], L. T. C. SANTOS[1], M. D. J. SENO[1], E. T. FONOFF[2], E. ALHO[2], S. P. RIGONATTI[2], J. P. OTOCH[3], M. J. TEIXEIRA[2], *. C. R. MARTINEZ[1]

[1]Intituto Sirio Libanes De Ensino E Pesquisa, Sao Paulo, Brazil; [2]Dept. de Neurologia, Divisão de Neurocirurgia Funcional, [3]Dept. de Cirurgia, Faculdade de Medicina da Univ. de São Paulo, São Paulo, Brazil

Abstract: Aggression is a heterogeneous behavior that has multiple ways and it is related to violence, impulsiveness, irritability and hostility. Drug treatment with antipsychotic and anticonvulsant drugs are most commonly used for aggressive disorders. However, there is a small population of patients that displays extremely high levels of aggression, has drug-refractory symptoms and remain under maximum restrain measures. Some hormones, like testosterone and cortisol are implicated in the modulation of aggression. The amygdala is an important structure in the neurocircuitry of aggressive behavior and previous studies using lesions of the amygdala showed improvement in patient condition. Nevertheless, those studies had many limitations as follow-up, criteria for selecting patients and the surgery techniques were obsolete. As an attempt to reintegrate extremely aggressive patients into society, a judicial law proposed amygdala lesion in three adult men. In order of that and to have a better understanding of the neurobiology of human aggression, we analyzed the levels of different hormones - thyroid-stimulating hormone (TSH), T4, T3, Cortisol, Luteinizing Hormone (LH), Estradiol, Prolactin, Progesterone, testosterone, and sex hormone-binding globulin (SHBG) - before, 1 and 6 months after surgery. Our results showed an average lesion of 59.68% of the amygdala nuclei. There was a positive correlation between the ratio testosterone/cortisol and aggressive behavior ($r2=0.13$, $F(1,7)=1.04$, $p>0.05$). There were no statistical differences in all other hormones studied TSH ($F(4,10)=0.83$, $p>0.05$), T4 ($F(4,10)=0.14$, $p>0.05$), T3 ($F(4,10)=0.22$, $p>0.05$), LH ($F(4,10)=0.14$, $p>0.05$), FSH ($F(4,10)=0.07$, $p>0.05$), Estradiol ($F(4,10)=1.10$, $p>0.05$), Prolactin ($F(4,10)=0.13$, $p>0.05$), Progesterone ($F(4,10)=0.68$, $p>0.05$), SHBG ($F(4,10)=1.23$, $p>0.05$). The Overt Aggression Scale showed a significant reduction in aggression in one month in comparison with before and 6 months after the procedure ($F(4,10)=5.29$, $p<0.05$). Our results showed that partial amygdala lesion reduced aggression after surgery but this is not a long lasting effect and this decreased was accompanied by a reduction in the ratio testosterone/cortisol with no alteration in other hormones.

Title: Amygdala lesions compromise reinforcement learning to impact behavioral flexibility

Authors: *D. R. LUCAS, III, V. D. COSTA, O. DAL MONTE, P. H. RUDEBECK, E. A. MURRAY, B. B. AVERBECK
NIH, Bethesda, MD

Abstract: The primate amygdala is implicated in reward-guided behavior, including the ability to flexibly alter stimulus-reward associations. Despite this understanding, lesions of the amygdala are not reported to cause deficits in reversal learning. Past studies often assessed the performance of monkeys when they first experienced reversals as opposed to when performance had asymptoted, and exclusively used deterministic rewards. As such, it is not clear how the amygdala contributes to reversal learning when behavioral strategies are stable and feedback is stochastic. To address these issues, we examined the role of the amygdala in reversal learning when rhesus macaques were trained to expect a reversal in the stimulus-reward contingencies of the task. The performance of macaques with bilateral excitotoxic amygdala lesions (n = 4) and intact controls (n = 3) was assessed on two different versions of a two-arm bandit reversal-learning task. In the first version, macaques initially learned to choose between two novel, deterministically rewarded options and task progression was tied to reaching a criterion level of performance after each reversal. In each daily session, macaques completed a total of 8 serial reversals. In a second version of the task the animals learned to choose between two choice options, but the reversal of stimulus-reward contingencies did not depend on the monkeys' performance. Instead, reversals randomly occurred between trials 30 and 50 in a fixed block of 80 trials. In each daily session, macaques completed up to 36 blocks, with choices rewarded deterministically or probabilistically. To analyze choices across tasks we developed a formal, Bayesian model of reversal behavior and used it to guide fitting of reinforcement learning models. Results indicated that amygdala lesions compromise the ability to reverse stimulus-reward associations by disrupting reinforcement learning. In both tasks, across the acquisition and reversal phases, macaques with amygdala lesions exhibited less consistent choice behavior, as indicated by a smaller inverse temperature parameter compared to controls. Monkeys with amygdala lesions also showed heightened sensitivity to negative vs. positive feedback, compared to controls. These effects were not due to adoption of a win-stay/lose-shift strategy. Thus, monkeys with amygdala lesions were slower to reverse their choice behavior-especially when feedback was stochastic. In summary, amygdala lesions cause noisy choice behavior and heightened sensitivity to negative feedback that enhances or impairs behavioral flexibility based on unexpected or expected choice uncertainty.

Title: The control of social and self-directed behaviors

Authors: ***W. HONG**, D.-W. KIM, D. J. ANDERSON
Div. of Biol., Caltech, Pasadena, CA

Abstract: Animals exhibit a broad range of innate behaviors that are essential for their survival and reproduction. These include responses to predators or prey, social behaviors among conspecifics such as mating, aggressive and communicative behaviors, as well as self-directed behaviors such as grooming and feeding. The regulation and maintenance of a proper balance between social and self-directed behaviors is of importance in social species such as humans. Abnormalities in this balance are associated with several psychiatric disorders such as autism. Several subcortical limbic nuclei in the hypothalamus and amygdala have been implicated in playing an important role in regulating social behaviors. In this poster, I will present our work on investigating the circuits that control the choice between innate social and self-directed behaviors in these subcortical limbic circuits. A better understanding of how social vs. self directed behaviors are regulated may provide insights into human psychiatric disorders involving social behaviors.

Title: Ambiguous social threat perception and the role of the basolateral amygdala - Evidence from fMRI

Authors: *R. HORTENSIUS[1], D. TERBURG[2,3], B. MORGAN[4], D. J. STEIN[3], J. VAN HONK[2,3,5], B. DE GELDER[6,1,7]
[1]Tilburg Univ., Tilburg, Netherlands; [2]Exptl. Psychology, Utrecht Univ., Utrecht, Netherlands; [3]Dept. of Psychiatry and Mental Hlth., [4]fMRC Med. Imaging Res. Unit, Dept. of Human Biol., Univ. of Cape Town, Cape Town, South Africa; [5]Univ. of Cape Town, Institute of Infectious Diseases and Molecular Med, South Africa; [6]Dept. of Psychology and Neurosci., Maastricht Univ., Maastricht, Netherlands; [7]Dept. of Neurosciences, Leuven Univ., Leuven, Belgium

Abstract: Resolving ambiguity of social threat is important for adaptive reactions to face and body expressions. The amygdalae (AMG) play an important role in the processing of social signals but it has so far been difficult in human studies to investigate the contribution from the different amygdalae nuclei. Previously, we have shown that bilateral damage of the basolateral amygdala (BLA) in subjects with Urbach-Wiethe disease (UWD), a genetic disorder that results in bilateral calcification of the AMG, show a deficit in ignoring bodily threat signals that render the facial expression ambiguous. The current study investigated the neural signature of this face-body incongruence effect. Six subjects with UWD and twelve matched controls viewed facial and bodily expressions presented in isolation (happy, fear, and control), and in congruent and incongruent face-body compounds with their attention always directed at the facial expression. Given the importance of the BLA and the frontal cortex in regulation of the central-medial amygdalae (CMA) and subsequent attention and reactions to ambiguous social emotional cues,

differences in activation between UWD and control subject were predicted to emerge in frontal regions and in the CMA when viewing incongruent face-body compounds. Results show that UWD subjects compared to the control group show an increase in activity in the lingual gyrus and inferior occipital gyrus, but a decrease in activity in the inferior parietal lobule and precuneus, when observing emotional facial and bodily expressions. Importantly, UWD but not control subjects show an increase in activity in the CMA and superficial AMG for incongruent compared to congruent compounds. Furthermore, a decrease in activity in the inferior frontal gyrus for incongruent relative to congruent compounds was found in UWD subjects compared to the control subjects. These results suggest that in the absence of a functional BLA processing of ambiguous social threat is sustained by increased CMA activation together with decreased activation in the inferior frontal gyrus. The present study extends previous findings on the role of the AMG in ambiguous threat processing and throws new light on the role of its subnuclei.

Title: Long range amygdalar inputs to cortico-PAG neurons in infralimbic cortex

Authors: M. K. KAUSHIK[1], A. N. FERREIRA[2], H. YOUSUF[1], M. T. DINH[2], *P. L. SHEETS[1]
[1]Dept. of Pharmacol. and Toxicology, Indiana Univ. Sch. of Medicine-South Bend, South Bend, IN; [2]Biol. Sci., Univ. of Notre Dame, Notre Dame, IN

Abstract: Layer 5 (L5) pyramidal neurons are the primary subcerebral output pathway of the infralimbic cortex (IL) which is a cortical area that plays an important role in the extinction of fear memories. There is strong reciprocal circuitry between the IL and amygdala, a structure pivotal in fear and emotion processing. However, specific targeting of amygdalar inputs to

defined populations of L5 IL neurons is unknown but is important for understanding the dynamics of neural circuitry that regulates fear behavior. Our lab has identified a large subset of L5 pyramidal neurons in IL that send projections to the ventral periaqueductal grey (vPAG), a midbrain structure important for autonomic components of fear behavior. We have also identified a non-overlapping subset of L5 IL neurons that project to the amygdala. Using the mouse as a model system and applying anatomical labeling strategies, whole-cell recordings, and adenoviral optogenetics, we aimed to elucidate the organization and strength of amygdalar input to L5 cortico-vPAG (CvP) and L5 corticoamygdalar (CA) neurons in IL. CvP and CA neurons were identified via *in vivo* injection of fluorescent retrograde tracers into the vPAG and amygdala, respectively. Concurrently, adeno-associated virus (AAV1.CAG-ChR2-Venus.W.SV40) was injected into the amygdala for anterograde infection of channelrhodopsin-2 (ChR2) into amygdalar axons in IL. While performing whole-cell recordings of retrogradely labeled CvP and CA neurons in IL of coronal brain slices, we optogenetically stimulated AAV-ChR2 infected amygdalar axons to test for long-range input from the amygdala. We detected excitatory monosynaptic amygdalar inputs in both L5 CvP and L5 CA neurons following optogenetic stimulation. Recorded inputs were stronger in L5 CvP and L5 CA neurons compared to labeled L2 CA neurons in IL. Additionally, activation of amygdalar axons caused robust disynaptic inhibition in both L5 CvP and L5 CA neurons. Our current experiments are focused on determining preferential connectivity of amygdalar inputs to CvP and CA neurons. These results suggest that amygdala inputs can modulate or shape IL output to subcortical structures important in fear.

Title: Dissection of neural circuitry underlying trauma-induced enhancements in fear and aggression

Authors: *M. ZELIKOWSKY, D. J. ANDERSON
California Tech. Inst., Pasadena, CA

Abstract: Fear organizes and orchestrates a host of species-specific defense reactions that enable an animal to adaptively respond to threat. However, fear can be maladaptive when elicited in non-threatening situations or in excess, and the persistence of such inappropriate fears is thought to contribute to the formation of anxiety disorders and phobias. One poignant example of this is post-traumatic stress disorder (PTSD), wherein following an extremely traumatic event, animals display a host of maladaptive behaviors. Thus far, scientific research has largely focused on PTSD symptoms such as the propensity to acquire new fears, exaggerated fear responses to mild stressors, increased substance abuse, depression, and anxiety, while relatively fewer studies have examined the effects of trauma on social behaviors such as sex and aggression. Moreover, most rodent models of PTSD that have examined aggression report that trauma produces an overall reduction in aggression. Thus, current rodent PTSD models fail to capture the increases in aggressiveness, violence, and anger that often characterize humans with PTSD. Using mice, we adapted a model of PTSD in which mice received a single traumatic event comprised of multiple unsignaled, unpredictable footshocks in a novel environment. We found that following trauma, mice showed enhanced fear learning, increased aggression and alterations in adaptive mating behavior. Importantly, we found that these disruptions in adaptive behavior persisted despite extensive extinction of the context in which the trauma occurred. Lastly, using behavioral, pharmacogenetic, optogenetic and pharmacological techniques, we investigated and characterized the neural circuitry involved in trauma-enhanced fear and aggression.

Title: Dissecting a central amygdala neural circuitry for feeding behavior

Authors: *H. CAI[1], D. J. ANDERSON[2]
[1]Biol. & Biol. Engin., Caltech, PASADENA, CA; [2]Biol. and Biol. Engin., California Inst. of Technology, HHMI, Pasadena, CA

Abstract: Central amygdala (CEA) has long been indicated to play a role in regulating feeding behavior. However, due to its cellular complexity, previous lesion studies have yielded conflicting results, reporting positive, negative or no effect of CEA neurons in regulating feeding and body weight. Thus a clear view of the role of CEA in regulating feeding behavior has yet to emerge. Using novel genetic methods, we have identified a specific subpopulation of neurons in CEA. Here we show that optogenetic manipulations of the neural activity of these neurons directly regulate feeding behaviors. We further dissected the underlying neural circuitry through which these neurons regulate feeding behavior. An understanding of this neural pathway will yield new insight into the neural circuitry mechanism of eating disorders.

Title: Rapid control over food intake by accumbal to hypothalamic projection neurons

Authors: *E. C. O'CONNOR, S. LEFORT, V. PASCOLI, C. LUSCHER
Dept. of Basic Neurosciences, Univ. of Geneva, Geneva, Switzerland

Abstract: When feeding, animals must be able to rapidly switch away from food intake in response to sensory and external stimuli, like taste or predator threat. Projections from the nucleus accumbens (NAc) to the lateral hypothalamus (LH) are particularly important for conveying feeding relevant information. However, the identity of cells involved in this circuit and how they control moment-to-moment food intake is not known. Here we characterize the functional anatomy of NAc to LH projections in feeding. First, we establish a free-feeding paradigm in mice whereby analysis of licking microstructure provides precise temporal

information on food intake. Experiments using pharmacological and optogenetic inhibition of NAc neurons *in vivo* confirms the NAc as a key regulator of feeding. Next, we use a combination of neural tracing, *ex vivo* electrophysiology and optogenetic assisted circuit mapping to identify a specific population NAc neurons that project to the LH. Cell type and projection specific optogenetics in freely behaving mice is used to demonstrate causality between the activity of these NAc to LH projection neurons and rapid control over food intake. In summary, we find that a specific population of NAc neurons that project to LH control moment-to-moment food intake, providing a neural basis for the rapid switching of feeding behavior in response to sensory and external stimuli.

Title: Control of stress-induced persistent anxiety by an extra-amygdala septohypothalamic circuit

Authors: *T. E. ANTHONY[1], N. DEE[2], A. BERNARD[2], W. LERCHNER[1,3], N. HEINTZ[4], D. J. ANDERSON[1]
[1]Biol., Caltech, Pasadena, CA; [2]Allen Inst. for Brain Sci., Seattle, WA; [3]NIH, Bethesda, MD; [4]The Rockefeller Univ., New York, NY

Abstract: Traumatic stress induces persistent increases in anxiety, but the neural substrates underlying this effect are poorly defined. Classical ablation experiments have suggested that the septum suppresses emotional responses to stress, but its circuitry has not previously been dissected using modern genetic tools. We have used optogenetic approaches to investigate the function of a subpopulation of lateral septal (LS) neurons marked by expression of the type 2 CRF receptor (Crfr2). Crfr2+ cells include GABAergic projection neurons that connect with the

anterior hypothalamus. Surprisingly, we find that these LS outputs enhance stress-induced behavioral measures of anxiety. Moreover, transient activation of Crfr2+ neurons promotes, while inhibition suppresses, persistent anxious behaviors. LS Crfr2+ outputs also positively regulate circulating corticosteroid levels. These data identify a subset of LS projection neurons that promote, rather than suppress, stress-induced behavioral and endocrinological dimensions of persistent anxiety states, and provide a cellular point-of-entry to LS circuitry.

Title: *In vivo* calcium imaging of nucleus accumbens neurons in freely feeding mice

Authors: *S. LEFORT, E. C. O'CONNOR, C. LÜSCHER
Dept. Basic Neurosciences, CMU - Univ. of Geneva, Geneva, Switzerland

Abstract: Calcium imaging techniques in awake animals have been extensively used in the past decade to monitor neuronal activity within superficial cortical areas. However, imaging of subcortical brain structures has been limited due to optical limitations. Recent developments in microscopy, and more specifically in microendoscopy, have extended the possibilities for deep brain imaging of neuronal activity in freely behaving animals. Here we took advantage of different Cre mouse lines, combined with the improved genetically encoded calcium indicator GCaMP6s and deep brain calcium imaging techniques, to study neuronal activity in the nucleus accumbens (NAc) of mice engaged in a simple free-feeding task. After infecting GCaMP6s in specific NAc cell types and implanting a lens targeting the NAc, mice were first habituated to the weight of the microendoscope prior to being introduced to a feeding chamber. Imaging of NAc neurons expressing GCAMP6s was then performed while animals were given free access to a palatable fat solution. Analysis of licking microstructure provided precise temporal information on food intake that could be used to correlate with recorded calcium activity in specific NAc neuron populations. These data support the use of microendoscopy to study population activity of identified neurons in deep brain structures of freely behaving mice.

Title: Modulation of the amygdala-dorsal periaqueductal grey pathway by long-range inputs from the infralimbic cortex and ventral periaqueductal grey

Authors: *A. FERREIRA[1], P. L. SHEETS[2]
[1]Dept. of Biol. Sci., Univ. of Notre Dame, South Bend, IN; [2]Pharmacol. and Toxicology, Indiana Univ. Sch. of Medicine-South Bend, South Bend, IN

Abstract: A major focus of fear research involves understanding communication between the medial prefrontal cortex (mPFC) and the amygdala. However, another critical structure in fear is the midbrain periaqueductal grey (PAG). The dorsal and ventral columns of the PAG contribute to opposing behaviors related to fear expression and fear extinction, respectively. How specific input-output pathways of the PAG connect to the mPFC-amygdala network is poorly understood. Here, we used anatomical labeling techniques, acute brain slice recordings, and adenoviral optogenetics (AAV1.CAG-ChR2-Venus.W.SV40) to investigate long-range connectivity of the PAG and infralimbic cortex (IL) in the amygdala. Retrograde tracer injection into the dorsal PAG (dPAG) labeled neurons in the central amygdala (CeA) showing a direct pathway from the amygdala to the PAG. Following injection of AAV-ChR2 into the ventral PAG (vPAG) and layer 5 of infralimbic cortex (IL), optogenetically activated inputs were detected in the intercalated nucleus of the amygdala (ITC) and the CeA, respectively. Optogenetic activation of vPAG-ITC axons resulted in disynaptic activation and inhibition of CeA-dPAG neurons. Therefore, there is an indirect vPAG to dPAG pathway that is routed through amygdala circuits. Preliminary data also suggests that descending IL input excites CeA-dPAG neurons. Our results suggest that the amygdala serves as an important node for vPAG and IL input to indirectly influence dPAG activity. Further dissection of this circuit will provide insight into the mechanism of fear extinction as it relates to the mPFC-PAG-amygdala network.

Title: Characterization of amino acid neurotransmitter release in the prelimbic cortex of anxiety vulnerable rats in response to basolateral amygdala stimulation

Authors: *J. E. CATUZZI[1,2], D. M. GREGOR[2], K. C. H. PANG[1,2,3], K. D. BECK[1,2,3]

Abstract: Avoidance is a symptom common to all anxiety disorders and can be modeled in rodents using an active lever-press avoidance paradigm. During this task, an animal learns to actively avoid shock by pressing a lever. Extinction-resistance of this avoidant behavior is believed to signify the pathological avoidance characteristic of anxiety disorders. The Wistar Kyoto (WKY) rat serves as a model of anxiety vulnerability as this strain rapidly acquires and is resistant to extinguish this avoidant behavior. Interestingly, previous research from our laboratory has shown WKY rats lack NMDA-dependent synaptic plasticity in two brain regions known to mediate avoidant behavior: the amygdala and prefrontal cortex. Specifically, WKY rats lack long-term potentiation (LTP) within the basolateral amygdala (BLA) to prelimbic cortex (PL) projection using stimulation parameters known to induce NMDA-dependent LTP in outbred Sprague Dawley (SD) rats. In an attempt to determine the mechanism by which WKY rats lack LTP in the BLA to PL projection, we sought to characterize amino acid neurotransmitter release in the PL in response to BLA stimulation in WKY and outbred control SD rats under urethane anesthesia. We focused our assessment on glutamate, the endogenous ligand of the NMDA

receptor, and the NMDA receptor co-agonists d-serine and glycine. In this study, a microdialysis probe was implanted into the PL, and a stimulating electrode was implanted into the BLA. Dialysate samples were collected in 20-minute intervals and amino acid neurotransmitters were assessed using high-performance liquid chromatography (HPLC). Glycine release was significantly lower in WKY rats compared to SD rats. No effect of stimulation was observed on neurotransmitter release in WKY or SD rats. The reduction in extracellular glycine observed in the PL of WKY rats may represent a mechanism by which this strain fails to maintain LTP within the BLA to PL projection. Moreover, the reduction in extracellular glycine may underlie the avoidance susceptibility expressed by this strain.

Title: Excitation/inhibition balance in the nucleus accumbens microcircuit underlies stress resilience or susceptibility

Authors: *M. HESHMATI[1], S. A. GOLDEN[1], H. ALEYASIN[1], D. J. CHRISTOFFEL[1], M. L. PFAU[1], I. MAZE[3], P. H. GOFF[2], G. E. HODES[1], L. A. KHIBNIK[1], N. REBUSI[1], J. L. ABLES[3], S. J. RUSSO[1]

Abstract: Dysregulation of the mesolimbic reward circuit is a cardinal feature of mood and stress disorders. We are investigating shifts in excitation/inhibition balance on nucleus accumbens (NAc) medium spiny neurons (MSNs) following repeated social defeat stress, a mouse model of depression. Previously, we observed an increase in excitatory synapses in the NAc of mice that are susceptible to stress. Now, we show a concurrent decrease in spontaneous inhibitory postsynaptic currents restricted to the indirect pathway in susceptible mice, with an

overall elevation of excitation to inhibition ratio in dopamine receptor D2-expressing MSNs compared to control and stress resilient mice. On the other hand, we observe increased inhibition of direct pathway MSNs in resilient mice after stress. Susceptible mice have an overall decrease in vesicular GABA transporter (vGAT) protein, which is not due to decreased inhibition by parvalbumin-positive interneurons but may be caused by changes to other interneuron subtypes within the NAc. We are currently using Cre-dependent miRNA-mediated knockdown of neuroligin-2 *in vivo* to manipulate inhibitory synapses within the NAc microcircuit and test their contribution to stress susceptibility or resilience in a cell-type specific manner.

Title: Normalising high trait anxiety in monkeys; the role of hippocampal-medial prefrontal circuitry

Authors: J. ZEREDO[1,3], Y. SHIBA[1,2], *A. ROBERTS[1,2], H. F. CLARKE[1,2]
[1]Physiology, Develop. and Neurosci., [2]Behavioural and Clin. Neurosci. Inst., Univ. of Cambridge, Cambridge, United Kingdom; [3]Univ. of Brasilia, Brasilia, Brazil

Abstract: Depression and anxiety are highly prevalent, debilitating conditions, which are only partially alleviated by current treatments. There are many theories of depression and anxiety, and two of the most prominent implicate a smaller, overactive, anterior hippocampus (antHipp) with reduced glutamate (Yüksel and Öngür 2010, Biol Psychiatry,68(9):785-94), and altered activity in medial prefrontal cortex (PFC) including Brodmanns areas 32 and 25 (Hamilton et al. 2011, Mol Psychiatry, 16, 763-772). The antHipp sends direct projections to the medial PFC yet there has been no attempt to integrate these hypotheses and investigate how the antHIpp might modulate the medial prefrontal cortex in the regulation of anxiety related behaviour. To test the hypothesis that increasing glutamate within the antHipp alleviates anxiety (both autonomic and

behavioural indices) via the mPFC, high trait anxious marmosets received bilateral intracerebral cannulae targeting the antHipp, area 32 and area 25, and had telemetry probes inserted into their descending aorta for remote measurement of cardiovascular activity. Marmosets were then trained in a context of unpredictable threat (pseudoconditioning, 5 days of unpaired CS and aversive US; 12 each), a known trigger for anxiety. The anxiety elicited by this context results in an increased response to a novel neutral CS when presented in the same context, despite the absence of the aversive US. Marmosets show a strong anxiety response: decreased heart rate and very low vigilant scanning, possibly indicative of disengagement from the environment. Compared to saline, these effects were alleviated peripheral anxiolytic treatment (0.25mg/kg diazepam), and also by antHipp activation (100pg/µl LY341495 & 10ng/µl CGP52432 infused at 0.5µl /min). However, the anxiolytic effects of antHipp activation were blocked by concomitant inactivation (0.1mM muscimol & 1.0mM baclofen; 0.5 µl infused at 0.25µl/min) of area 25, but not area 32. Thus, the antHipp acts to modulate anxiety related behaviour via its connectivity with distinct regions of the medial PFC. In particular, the anxiolytic effects of antHipp activation are dependent upon an intact area 25 and not area 32.

Title: Activation of noradrenergic locus coeruleus neurons promotes anxiety-like and aversive behaviors

Authors: *J. G. MCCALL[1], R. AL-HASANI[1], E. R. SIUDA[1], D. Y. HONG[1], C. P. FORD[2], M. R. BRUCHAS[1]
[1]Anesthesiol., Washington Univ., Saint Louis, MO; [2]Physiol. & Biophysics, Case Western Reserve Univ., Cleveland, OH

Abstract: The locus coeruleus (LC) and its projections are the primary source of norepinephrine for the mammalian forebrain. The LC is a target for corticotropin-releasing factor (CRF), opioid neuropeptide containing neurons, and is highly enriched with all four opioid receptor types. LC tonic firing increases during stress and this increase is thought to be controlled by opioid and CRF activity. Therefore, we hypothesized that specific modulation of LC neuronal firing could lead to anxiety-like and aversive behaviors. We used optogenetic stimulation to specifically increase LC-NE neuronal activity. Consistent with previous reports, we demonstrate increased LC firing rate in response to stress *in vivo*. We investigated the role of this increase in LC-NE activity in negative affective behaviors. We report consistent firing of LC-NE neurons following repeated 5hz light stimulation *in vitro* and *in vivo*. We examined the effect of increasing tonic LC-NE firing on anxiety- and aversion-like behaviors using both conditioned place aversion and a real-time aversion paradigm. We found that increasing tonic firing of LC-NE neurons, consistent with CRF release in the LC, induces a subsequent aversion to the stimulated context. This same stimulation is aversive in real-time and scales linearly with frequency, with animals choosing to avoid increased activation of these neurons. Increased LC-NE firing also results in decreased open arm time in the elevated zero maze, and time in the center of the open field test, both assays for anxiety-like behavior. Furthermore, the same stimulation that drives aversion and anxiety-like behavior is sufficient to reinstate a cocaine place preference. We next used viral tracing to determine key sites of afferent innervation to the LC. These studies identified the central amygdala (CeA) as a structure with robust projections to the LC. We then investigated the CRF-containing CeA inputs into the LC that regulate its firing in these behaviors. We found that stimulation of these CRF terminals in the LC increases the firing rate of a subset of LC neurons and is sufficient to recapitulate the behaviors seen by directly increasing the firing rate of LC neurons. These data suggest that increasing the firing rate of LC-NE neurons is sufficient to produce negative affective behaviors including aversion and anxiety. Together these results suggest that noradrenergic locus coeruleus tone is important for anxiety and aversive behavioral states as well as reinstatement to drug seeking.

Title: Is it safe? Brain areas involved in the the processing of safety signals

Authors: *F. S. ERTHAL[1], I. MOCAIBER[2], L. OLIVEIRA[3], M. PEREIRA[3], V. ROCHA-REGO[1], I. FIGUEIRA[1], E. VOLCHAN[1]
[1]Federal Univ. of Rio de Janeiro, Rio de Janeiro, Brazil; [2]Federal Fluminense Univ., Rio das Ostras - RJ, Brazil; [3]Federal Fluminense Univ., Niterói - RJ, Brazil

Abstract: For survival it is crucial to continuously evaluate the presence or absence of risk in the environment, identifying signals of danger or security. An important internal factor that modulates safety detection mechanisms is a trait disposition favoring positive affect. Positive affect trait was shown to enhance the engagement in safety contexts, capturing contextual cues of security and transforming them more efficiently into implicit modulations of the balance between the circuits underpinning predispositions to deal with threat and safe situations. Interestingly, trauma-exposed victims with post traumatic stress disorder, compared to trauma-exposed controls, fail to learn safety signals besides presenting low levels of positive affect. Further, patients with post traumatic stress disorder present volumetric reduction in the pregenual anterior cingulate cortex, a region which is associated with positive affect and may be involved in the processing of safety signals. The aim of this study was to search for putative brain areas tuned to safety cues processing in healthy subjects . We focused in the pregenual anterior cingulate, specifically the region which showed reduced volume in patients with post traumatic stress disorder.. Highly unpleasant pictures were shown in two contexts in which a prior description presented them as taken from movie scenes (fictitious/safe) or real scenes (control). In whole brain analysis, the comparison between unpleasant pictures in safe vs control contexts revealed activations in the pregenual anterior cingulate cortex and in the anterior insula ($p<0.001$ uncorrected). Beta values (task versus baseline), extracted from an unbiased region-of-interest in the pregenual anterior cingulate cortex (coordinates taken from the very same region which is reduced in volume in post traumatic stress disorder), were significantly higher in the “safe” compared to the “control” context (T-test, $p<0,05$). Additionally, we found a significant correlation between an index of engagement of the pregenual anterior cingulate cortex (beta of the safe context minus beta of the control context) and the scores on positive affect trait. These results suggest that the anterior insula and the pregenual anterior cingulate cortex are involved in the processing of safety signals. Involvement of the latter seems more conspicuous in individuals with higher positive affect. A rupture in the normal functioning of the pregenual anterior cingulate cortex in traumatized victims with PTSD may account for the failure in the processing of safety cues contributing to their emotional deficits.

Title: Sexually dimorphic neurons control levels of aggressiveness in male *Drosophila* through the neuropeptide Tachykinin

Authors: *K. ASAHINA[1,3], K. WATANABE[1,3], B. J. DUISTERMARS[1,3], E. HOOPFER[1,3,4], C. ROBERTO GONZÁLEZ[2], E. A. EYJÓLFSDÓTTIR[2], P. PERONA[2], D. J. ANDERSON[1]
[1]Biol. and Biol. Engin., [2]Engin. and Applied Sci., Caltech, Pasadena, CA; [3]Howard Hughes Med. Inst., Pasadena, CA; [4]HHMI Janelia Farm Res. Campus, Ashburn, VA

Abstract: Males of most species are more aggressive than females, but the neural mechanisms underlying this dimorphism are not clear. Here we identify a neuron and a gene that control the higher level of aggression characteristic of *Drosophila* melanogaster males. Males but not females contain a small cluster of FruM+ neurons that express the neuropeptide tachykinin (Tk). Activation and silencing of these neurons increased and decreased, respectively, inter-male aggression without affecting male-female courtship behavior. Mutations in both Tk and a candidate receptor, Takr86C, suppressed, while over-expression of Tk potentiated, the effect of neuronal activation. Tk neuron activation overcame reduced aggressiveness caused by

eliminating a variety of sensory or contextual cues, suggesting that it promotes aggressive arousal or motivation. Tachykinin/Substance P has been implicated in aggression in mammals, including humans. Thus, the higher aggressiveness of *Drosophila* males reflects the sexually dimorphic expression of a neuropeptide that controls agonistic behaviors across phylogeny.

Title: The anatomical connections of the interpeduncular nucleus: Another interface between the habenula and the mesopontine tegmentum

Authors: L. LIMA[1], L. GONÇALVES[2], F. LEITE[1], *M. METZGER[1]
[1]Dept. of Physiol. & Biophysics, Univ. of Sao Paulo, Sao Paulo, Brazil; [2]Dept. of Human Anat., Federal Univ. of the Triangulo Mineiro, Uberaba, Brazil

Abstract: The medial habenula (MHb) and its major terminal field the interpeduncular nucleus (IP) make part of the dorsal diencephalic conduction (DDC) system that links the limbic forebrain with monoaminergic and cholinergic cell groups in the mid- and hindbrain. Interestingly, two other components of the DCC, the lateral habenula (LHb) and its major target the rostromedial tegmental nucleus, have recently been shown to be central structures of an anti-reward system that encodes aversive conditions and inhibits dopamine and serotonin neurons. Both the MHb and IP contain several subnuclei, with a dorsal group of MHb subnuclei mainly projecting to dorsal parts of the IP, whereas the ventral group of MHb subnuclei massively innervates subnuclei in the ventral IP. Interest in the MHb-IP axis resurged when it was recently discovered that, MHB and IP, as well as probably structures downstream to the IP, are critically involved in mediating the aversive effects of nicotine and the somatic symptoms of withdrawal.

The afferent and efferent connections of the IP have hitherto not been systematically investigated with modern sensitive tracers. Thus, we placed small topic injections of the retrograde tracer cholera toxin subunit b (CTb) or the anterograde tracer Phaseolus vulgaris leucoagglutinin (PHA-L) into different IP subdivisions of male Wistar rats. We found massive reciprocal connections between the IP, the median raphe nucleus, dorsomedial tegmental area, and laterodorsal tegmental nucleus. Moreover, the IP was robustly interconnected with all parts of the supramammillary nucleus. Beside a dominant input from the MHb, the IP received minor inputs from the ventromedial prefrontal cortex, rostral parts of the cingulate cortex, nucleus of the diagonal band, medial and lateral preoptic area, lateral hypothalamus, and medial division of the LHb (LHbM). Dense focal IP outputs were directed to the ventrolateral septum, ventral CA1 hippocampal field, caudal part of the dorsal raphe nucleus, nucleus incertus, and interestingly, LHbM. Regarding a possible topography of IP outputs, we observed that all IP subnuclei have descending projections, whereas dorsocaudal parts of the IP specifically gave rise to most of its ascending projections. In all, our findings indicate that the IP might serve as another relay signaling aversive information from the habenula to serotonergic and cholinergic cell groups in the mesopontine tegmentum, and also as a missing link between the MHb and LHb.

Title: Ventral striatal projections to the lateral habenula modulate the motivational component of aggressive behavior

Authors: ***S. GOLDEN**[1], D. J. CHRISTOFFEL[3], M. HESHMATI[1], K. GUISE[1], M. PFAU[1], H. ALEYASIN[1], G. E. HODES[1], M. FLANIGAN[1], D. BREGMAN[1], L. KHIBNIK[1], J. TAI[1], B. KRAWITZ[1], D. CHAUDHURY[2], J. WALSH[3], M.-H. HAN[2], M. SHAPIRO[1], S. J. RUSSO[1]
[1]Neurosci., [2]Pharmacol. and Systems Therapeut., Mount Sinai Sch. of Med., New York, NY; [3]Dept. of Psychiatry and Behavioral Sci., Stanford Univ. Med. Ctr., Palo Alto, CA

Abstract: Aggressive behavior is commonly associated with a number of neuropsychiatric disorders and is thought to result, in part, from inappropriate reward circuit activation. However, little is known about the neural circuits that modulate the motivational or rewarding components of aggressive behavior. Here we establish a novel behavioral model for investigating the rewarding component of aggression, using aggressive social interaction with an intruder mouse as a reinforcer for the development of conditioned place preference (CPP). In this model, aggressor mice develop a CPP, while non-aggressive mice develop a conditioned place aversion (CPA) to the intruder-paired environment. Further, we identify an inhibitory GABAergic projection from the ventral striatum (vStr) to the lateral habenula (lHb) that acts as a critical modulator of the rewarding component of aggressive behavior. Circuit-specific optogenetic silencing of inhibitory ventral striatal afferents with halorhodopsin (NpHR) in the lHb of aggressive mice abolishes the rewarding properties of aggression. Conversely, activation of these terminals with channelrhodopsin (ChR2) in non-aggressive mice enhances the rewarding properties of the intruder context. Lastly, directly stimulating or inhibiting the lHb cell bodies of aggressive and non-aggressive mice with ChR2 and NpHR, respectively, recapitulates the ventral striatal circuit-specific behavioral phenotypes. These results demonstrate that the vStr-lHb circuit plays a critical role in regulating the rewarding component of aggressive behavior and provides novel mechanistic insight into the neural circuits mediating aggression.

Title: Anatomical connections subserving the default mode network in monkeys

Authors: *S. R. HEILBRONNER[1], S. N. HABER[2]
[1]Pharmacol. and Physiol., [2]Univ. of Rochester, Rochester, NY

Abstract: The default mode network (DMN) is a set of brain regions consistently activated at rest and deactivated during task performance. DMN activity is abnormal in many neurological and psychiatric disorders, including major depressive disorder and drug addiction. The two main parts of the DMN are the medial prefrontal cortex (mPFC) and posteromedial cortex (PMC), two areas that are spatially distant and with distinct canonical functions. Functional connectivity within the DMN may result from direct anatomical links, indirect ones, or some combination of both. While there is some evidence of direct connections between these general cortical areas, little is known about their specifics and how they link the network together as a whole. In this study, we delineate how anatomical connections and pathways between mPFC and PMC allow them to operate as a network. Defining these specific DMN connections will establish the circuitry subserving neuroimaging results that demonstrate changes under normal and psychiatric conditions. We used bidirectional and anterograde injections to analyze connections between the PMC and frontal cortex. These connections are substantial. Preliminary stereological analyses and 3-D models indicate that the PMC connects both more strongly (greater density of labeled cells) and to a greater area within the dorsal prefrontal cortex than the ventral prefrontal cortex. That is, anterograde and retrograde connections between the PMC and the dorsolateral prefrontal cortex, anterior cingulate cortex, and dorsomedial prefrontal cortex are more pronounced than the connections between the PMC and the ventromedial prefrontal cortex, subgenual cingulate, orbitofrontal cortex, and ventrolateral prefrontal cortex. In addition, the prefrontal cortex connects to specific nodes within the PMC--defined as overlapping terminal fields and cell patches from multiple DMN regions. These nodes may integrate the multiple streams of information necessary for DMN functions. Interestingly, while this specific pattern of anatomical connections does not closely fit the canonical human DMN, it does roughly match the monkey DMN identified by Mantini and colleagues (2011, Journal of Neuroscience). These results raise interesting questions about the relationship between functional and anatomical connectivity, and possible species divergence in the DMN.

Title: Diffusion tensor imaging of extraordinary altruists: Differences in fractional anisotropy in non-directed living kidney donors

Authors: *K. M. BRETHEL-HAURWITZ[1], E. M. CARDINALE[1], S. A. STOYCOS[1], J. W. VANMETER[2], A. A. MARSH[1]
[1]Psychology, Georgetown Univ., Washington, DC; [2]Neurol., Georgetown Univ. Med. Ctr., Washington, DC

Abstract: Altruistic kidney donors volunteer to undergo surgery so that one of their own kidneys can be transplanted into a stranger, an act often described as "extraordinary altruism." The neural basis of this form of extraordinary altruism is not yet well understood. In the present study, we recruited altruistic living kidney donors and healthy controls matched on age, gender, and IQ. Group comparisons of white matter structure were made through analyses of data collected during diffusion tensor imaging (DTI). In particular, it was hypothesized that altruists would have greater fractional anisotropy (FA), a measure of axonal integrity and coherence, in the uncinate fasciculus, a bidirectional white matter tract spanning the frontal and temporal lobes that connects structures of the limbic system, including the amygdala, to the orbitofrontal cortex and temporal poles (Ebeling & Von Cramon, 1992). The amygdala, orbitofrontal/ventromedial prefrontal cortices, and connections between them have been implicated in empathy (Parkinson & Wheatley, 2012) and moral decision-making (e.g., Luo et al., 2006). Further, lower FA in the uncinate fasciculus has been observed in highly antisocial populations (Craig et al., 2009). Voxelwise statistical analysis of the FA data was carried out using Tract-Based Spatial Statistics (TBSS; Smith, 2006), part of FMRIB's software library (FSL; Smith, 2004). TBSS projects all subjects' FA data onto a mean FA tract skeleton, before applying voxelwise cross-subject statistics. Group comparisons of FA in a region of interest (ROI) analysis of bilateral uncinate fasciculus, defined using the Johns Hopkins University probabilistic white matter tractography atlas (Mori et al., 2005; Hua et al., 2008) available in FSL, supported our hypothesis. Altruists exhibited several clusters of greater FA in the left uncinate fasciculus ($p < .05$, FWE). At these thresholds, there were no clusters for which controls exhibited greater FA in the left uncinate fasciculus, and no group differences were observed in the right uncinate fasciculus. Further examination of axial ($\lambda 1$) and radial ($[\lambda 2+\lambda 3]/2$) diffusivities in the left uncinate fasciculus revealed a cluster of greater axial diffusivity in altruists ($p < .05$, FWE), in proximity to the orbitofrontal cortex. This pattern of findings in the white matter structure of demonstrated altruists may have important implications for understanding the neural basis of prosocial behavior, and for understanding the nature of extraordinary altruism.

Title: Acute dietary tryptophan manipulation differentially alters social behavior and plasma corticosterone in inbred mice

Authors: W. Q. ZHANG[1,2], P. BARBA-ESCOBEDO[1,3], M. GAMEZ[3], C. M. SMOLIK[1], L. C. DAWS[1], *G. G. GOULD[1]
[1]Physiol., UT Hlth. Sci. Ctr, SA, San Antonio, TX; [2]Biol., Rice Univ., Houston, TX; [3]Biol., Texas A&M San Antonio, San Antonio, TX

Abstract: Metabolism of the neurotransmitter serotonin (5-HT) is abnormal in 20-40% of patients with autism, and in this population elevated levels of whole-blood 5-HT (hyperserotonemia), and higher intestinal 5-HT levels are common. However, there is evidence that brain 5-HT levels and serotonergic neurotransmission may be insufficient for normal brain development and functioning for these autistic individuals. We hypothesize that social behavior impairments may be a product this, and might be ameliorated by increasing brain extracellular 5-HT levels for some patients. Supporting this idea, serum levels of oxytocin, governed by 5-HT transmission, are often reported to be lower in autisitic individuals, selective serotonin reuptake inhibitors improves and tryptophan (TRP; metabolic precursor of 5-HT) depletion worsens all symptoms of autism. However, dietetic studies demonstrate and parents report that unrestricted children with autism consume less TRP than their peers. To examine the impact of varying dietary TRP on social behaviors, we studied the impact of acute (24 h) TRP depletion and supplementation on adult males of three inbred strains of mice. Two of these strains, tufted black

and tan brachyury (BTBRT+/tfJ) and 129S1/SvImJ mice have inherently low levels of social behavior relative to commonly used C57BL/6 mice. We found that TRP depletion significantly worsened the social behaviors of C57BL/6 and 129S mice, while 1% TRP enhancement improved the otherwise impaired social behaviors of BTBR mice ($P<0.05$; N = 8-10) in three-chamber tests. Plasma corticosterone levels following behavior tests were higher in those C57BL/6 and BTBR mice given enhanced TRP diets ($p <0.05$; N=4-10). Marble burying behavior did not differ among strains or treatment groups. Among strains the relative hyperactivity of BTBR and hypoactivity of 129S mice was evident, and these measures were not affected by dietary TRP manipulation. Taken together, our findings support the hypothesis that social behavior is highly sensitive to dietary TRP intake in these mouse strains commonly used in autism research. Based on these findings, studies of conditions under which TRP supplementation may improve sociability deficits, and studies of relevant biomarkers of low central 5-HT stores are warranted.

Title: The role of dopamine in social processing and behavior

Authors: ***M. J. LEVY**[1], A. PETRULIS[2]
[1]Neurosci. Institute, Georgia State Univ., Atlanta, GA; [2]Georgia State Univ., Atlanta, GA

Abstract: Social behavior, including attraction to and evaluation of potential mates, is critical for reproduction. While the brain areas implicated in social behavior have been identified, it is unclear how they communicate with areas involved in reward and reinforcement. The ventral striatum, including the shell of the nucleus accumbens (NAc shell) and the olfactory tubercle (OT), has been implicated in the coding of rewarding stimuli. In addition, these areas can be further sub divided into medial and lateral components, the medial areas implicated in social processing, while the core, or lateral, areas are not. We hypothesize that the interactions of these

two networks to regulate appropriate social processing requires dopamine (DA) in the reward and reinforcement circuit. To test this hypothesis, adult male, sexually naïve Syrian hamsters (Mesocricetus auratus) were given systemic intraperitoneal (i.p) injections of cis-(z)-flupenthixol (CZF), a broad spectrum DA antagonist prior to a non-contact partner preference test. Time spent investigating the male or female live stimuli were then recorded. We found that low doses of CZF did not affect opposite-sex preference, while higher doses caused a non-specific reduction in investigation. Centrally, injections of 6-OHDA were targeted to the NAc shell, OT and the NAc core, as a control. Pilot histological data shows DA depletion with 6-OHDA, as measured by a decrease in tyrosine hydroxylase staining; behavioral data is currently being collected on several tests. These include a non-contact partner preference test as well as a contact preference test, where the subjects can interact directly with tethered male and female stimuli. In addition, subjects are tested for possible alterations in odor discrimination or general changes in motivation.

Title: Glutamate input in the dorsal raphe nucleus as a determinant of escalated aggression in the male mouse

Authors: *A. TAKAHASHI[1], R. X. LEE[3], T. IWASATO[2], S. ITOHARA[4], H. ARIMA[5], B. BETTLER[6], K. A. MICZEK[7], T. KOIDE[1]

Inst., Wako-shi, Saitama, Japan; [5]Nagoya Univ. Grad. Sch. of Med., Nagoya, Japan; [6]Univ. of Basel, Basel, Switzerland; [7]Tufts Univ., Medford, MA

Abstract: The adaptive nature of aggressive behavior in social animals accounts for its prevalence throughout the animal kingdom. However, when aggressive behavior exceeds the species-typical level, called escalated aggression, it is no longer adaptive for animals. The dorsal raphe nucleus (DRN) has been linked to adaptive and maladaptive aggression, and this area contains the largest accumulation of 5-HT neuronal cell bodies in the brain. However, little is known about the modulation of the DRN by other neurotransmitters when an animal is engaging either in species-typical aggression or escalated maladaptive aggression. In this study, we used genetic and pharmacological tools and *in vivo* microdialysis to identify a key neural modulator of the DRN that determines the level of aggression of male mice. Previously, we have shown that local administration of GABAB receptor agonist baclofen into the DRN escalated aggressive behavior of male mice. Here, by using 5-HT neuron specific GABAB receptor knockout mouse, we first demonstrate that the site of action for baclofen to escalate aggression are the GABAB receptors on non-5-HT neurons. Then, we found that intra-DRN baclofen increases glutamate release within the DRN. Microinjection of L-glutamate into the DRN caused dose-dependent escalation of attack bites. *In vivo* microdialysis revealed that there was an increase of glutamate release in the DRN when animals were engaging in aggressive behavior, and the level of glutamate was further increased when the animal engaged in escalated level of aggressive behavior after social instigation. We conclude that our results demonstrated an enhanced glutamatergic input into the DRN which determines the level of aggression in male mice. We will also report our current attempt to measure the change of 5-HT release during species-typical aggressive behavior and during escalated aggression.

Title: Oral intake of monosodium glutamate during the period of development effects on social behavior mediated by gut-brain communication in an ADHD model rat

Authors: *H. HIDA, Y. YOKOYAMA, R. MARUMOTO, Y. SHIMIZU, Y. UEDA, S. MISUMI, A. ISHIDA, C.-G. JUNG

Abstract: Dysfunction of mesocorticolimbic dopaminergic system such in the amygdala (Amy) and prefrontal cortex (PFC) is related to emotional regulation in attention-deficit hyperactivity disorder (ADHD), which is characterized by hyperactivity, impulsivity and inattention. Using an ADHD model rat, spontaneously hypertensive rat (SHR), we previously revealed that administration of a taste substance for umami increased sociality when rats were grown in single isolated condition with monosodium L- glutamate (MSG) for 5 weeks from postnatal day 25 (P25) to P60: parameters for sociality (sniffing time and riding) were significantly reduced in MSG-treated rats in social interaction test. However, the mechanism of the effect on enhanced sociality by MSG administration during the period of development remains unclear. Expression of dopamine receptor expression (D1R, D2R) and oxytocin receptor (OxtR) was first investigated in the Amy and PFC using real-time PCR. Both D1R and D2R were significantly increased in Amy by MSG intake while those was not changed in PFC. On the other hand, OxtR was significantly decreased in Amy while it increased in mPFC. We then investigated the effect of MSG on brain-gut communication via vagus nerve: transection of gastric branch of vagus nerve (vagotomy) was carried out at P25. In social interaction test, increases of sniffing time and riding number to the same level as H2O-treated control were shown by vagotomy. However, no difference was observed in open-field test. Data suggest that MSG intake during the period of development effects on the formation of emotional behavior by the afferent of vagus nerve from the gastrointestinal tract receptor, relating to altered expressions of D1A and D2A and OxtR in Amy and mPFC.

Title: Cocaine- and amphetamine-regulated transcript in the central nucleus of amygdala is enhanced by environmental enrichment in ADHD model rat

Authors: *Y. SHIMIZU, Y. YOKOYAMA, S. MISUMI, A. ISHIDA, C.-G. JUNG, H. HIDA
Neurophysiol. & Brain Sci., Nagoya City Univ. Grad. Sch. of Med. Sci., Nagoya, Japan

Abstract: Spontaneously hypertensive rat (SHR) is an animal model for attention deficit hyperactivity disorder (ADHD). We found that environmental enrichment (EE) for 5 weeks from postnatal day 25 (P25) to P60 decreased hyperactivity and anxiety-like behavior in SHR. We also showed that expression of cocaine and amphetamine regulated transcript (CART) is enhanced by EE in the medial frontal cortex (mPFC) and amygdala (Amy) of SHR. As CART peptide is a factor that effects on locomotion activity, anxiety and stress, we challenged to confirm the localization of CART in mPFC and Amy, trying to answer the question how the increase of CART by EE relates to decreased emotional behaviors in SHR. SHR grown for 5 weeks from P25 was fixed with 4% PFA for CART immunostaining. It revealed that many CART-positive cells was observed in the Amy, especially only in the central nucleus of amygdale (CeA), of SHR that were grown in both EE and standard environment (SE). On the other hand, a few CART positive cells was detected in the mPFC only EE-grown rat. Confirmation of the subtype of CART-positive cells revealed that GABAergic cells in the CeA are not immnoreactive to parvalbumin and calretinin. It also revealed that some of CART-positive cell was colocazied with tyrosine hydroxylase positive fibers in the CeA. Data suggested that EE induced CART expression in the mPFA and CeA and that CART in the CeA localized in GABAergic neurons that is not stained for parvalbumin and calretinin, probably relating to decreased hyperactivity and anxiety-like behavior in SHR.

Title: Berberine blocks 'uptake 2' and enhances mouse sociability

Authors: *A. SANCHEZ[1], C. SMOLIK[1], T. PHAM[2], K. LALANI[2], G. G. GOULD[1]
[1]Physiol., UTHSCSA, San Antonio, TX; [2]Hlth. Careers High Sch., San Antonio, TX

Abstract: Impaired social behavior is a treatment-resistant core symptom of autism. It can manifest in several forms, including indifference to social engagement, social anxiety or empathy deficits. The relative lack of therapeutic efficacy of selective serotonin reuptake inhibitors (SSRIs) to improve social behavior has brought into question their utility as a treatment for autism. Given these limitations associated with treating sociability deficits by targeting the serotonin transporter (SERT), our goal was to characterize the effects of blocking auxiliary 'uptake 2' transporters of serotonin on social and repetitive behaviors in mice. Organic cation (OCT) transporters are among the uptake 2 transporters found in the brain. In three-chamber sociability tests, the uptake 2 transporter blocker decynium-22 (D-22) improves social behavior in otherwise socially-impaired BTBR T+/tf mice. The alkaloid antibiotic berberine has antidepressant-like properties in mice, and also it is both a blocker and substrate of OCTs. Given this, we hypothesized that berberine administration might improve the sociability of BTBR mice, as D-22 does. Indeed, berberine significantly increased BTBR preference for social interactions and social sniffing ($p < 0.05$, N=8-9). Berberine had no impact on the typical sociable behavior of C57BL/6 mice, nor did it alter repetitive marble burying in either strain. We also compared these behaviors in naïve C57BL/6 male mice from different suppliers (Harlan vs. Jackson), and found no significant differences, suggesting that mice from either source can be used interchangeably. Our findings confirm that systemic uptake 2 blockade is a promising strategy for improving social behavior warranting further investigation as a treatment for sociability impairments.

Title: GABAergic and glutamatergic connections in the social neural network

Authors: *A. R. BURNS, A. PETRULIS
Georgia State Univ., Atlanta, GA

Abstract: A conserved network of brain regions is responsible for mediating social behavior in rodents. The bed nucleus of the stria terminalis (BNST), in conjunction with the medial amygdala (MA), is a critical node in this social neural network, integrating hormonal and chemosensory cues. The MA is a heterogeneous structure with the anterior portion (MeA) receiving primarily chemosensory information, whereas the posterior dorsal section (MePD) responds predominately to hormonal cues; this division is preserved in the BNST. The posterointermediate BNST (BNSTpi) receives a large input from the chemosensory MeA whereas the posteromedial BNST (BNSTpm) has numerous steroid-sensitive cells and receives projections from the MePD. However, the chemical nature (GABAergic or glutamatergic) of the connectivity involved in the processing of social information is unknown. To determine if the chemical phenotype of MA projection neurons may encode different social stimuli, we injected the retrograde tracer cholera toxin beta conjugated to Alexa Fluor 594 (CTB) into both the BNSTpm and BNSTpi of male Syrian hamsters. These males were then exposed to one of three conditions, a live male stimulus, a live female stimulus, or no stimulus (a clean cage), in order to induce c-fos expression to identify those neurons responding to a particular stimulus. To our knowledge, there are no available *in situ* hybridization probes for inhibitory or excitatory markers made in hamster. Therefore, we generated Syrian hamster specific mRNA probes for both vGlut2 (a marker of glutamatergic neurons) and GAD65 (a marker of GABAergic neurons). Using these probes, we colocalized labeling for vGlut2 or GAD65 with immunohistochemistry for Fos, and CTB labeled neurons to resolve the chemical nature of neurons involved in processing salient (female) vs. less-salient (male) social cues. Ongoing analyses will determine the percentage of GABAergic and glutamatergic MA neurons that project to the BNST and that are activated by different social cues in male Syrian hamsters.

Title: Adenosine receptor antagonists differentially modulate ethanol-induced impairments on social interaction and recognition in mice

Authors: *M. CORREA[1], L. LÓPEZ-CRUZ[1], N. SAN MIGUEL[1], P. BAYARRI[1], C. CARRATALÁ[1], J. LUCERÓN[1], J. MEDRANO[1], L. DIAZ[1], L. MONFERRER[1], Y. BAQI[2], C. E. MÜELLER[2], J. D. SALAMONE[3]
[1]Psicobiologia. Univ. Jaume I, Castello, Spain; [2]Pharmazeutisches Institut, Pharmazeutische Chemie, Univ. Bonn, Bonn, Germany; [3]Dept. Psychology. Univ. of Connecticut, Storrs, CT

Abstract: Caffeine is a non-selective adenosine A1 and A2A receptor antagonist that increases attention and produces anxiety at high doses, while ethanol, which increases adenosinergic tone, has the opposite effects on these behaviors. Adenosine A1 receptors are broadly expressed in the brain, while A2A receptors are localized in specific brain regions such as striatum and olfactory bulbs, which are involved in behavioral activation, exploration, and social interaction in rodents. Social interaction and recognition measures evaluate the natural preference of an animal for exploring conspecific animals versus objects or familiar animals versus novel animals. In the present work several markers of social interaction were evaluated after administration of caffeine, CPT (A1 antagonist) or MSX-3 (A2A antagonist) alone or in combination with ethanol. Anxiolytic doses of ethanol decreased social interaction and impaired recognition of familiar conspecifics the following day. However, caffeine at anxiogenic doses also reduced social interaction and impaired recognition. The selective receptor antagonists CPT and MSX-3 significantly increased social interaction and did not affect recognition. Surprisingly, a dose of ethanol (1.0 g/kg) that reduced social interaction on its own partially reversed the impairing effects of a high dose of caffeine (30 mg/kg). This reversal was also observed for the memory impairments, although at lower doses. MSX-3 completely reversed social interaction and recognition deficits induced by a high dose of ethanol. Although the A1 receptor antagonist CPT had no effect on ethanol-induced social interaction deficits, it had a positive effect on restoring recognition. Thus, A2A receptors seem to be more important than A1 receptors for mediating caffeine-ethanol interactions in social exploration. However, impairments in memory induced by ethanol could be restored by both A1 and A2A receptor antagonism, indicating a difference between these two processes (exploration and memory) in terms of the involvement of specific adenosine receptors and their interaction with ethanol. It is possible that distinct brain circuits mediate social exploration and recognition, and that these circuits are differentially modulated by drugs acting on A1 and A2A receptors.

Title: Excitation of D2-expressing cells in prefrontal cortex leads to reduced social behavior in mice

Authors: *C. K. HANSEN, I. ELLWOOD, T. PATEL, F. DAVATOLHAGH, V. SOHAL
UCSF, San Francisco, CA

Abstract: Prefrontal cortex plays a key role in many cognitive functions including social behavior. In layer V of prefrontal cortex (PFC), our group has previously characterized two subtypes of pyramidal neurons which project to different areas and either express D1 or the D2 receptors [1]. The D2-expressing subtype exhibits an increase in excitability following D2 receptor (D2R) activation. Since dopamine is involved in prefrontal function and excessive dopamine and/or D2R activation may believed to contribute to symptoms of schizophrenia, the aim of this study was to determine how excitation of these two cell types affects social behavior. Adult C57BL6 male mice were implanted with guide cannulas, and D1R or D2R agonists were infused into right PFC. D1 Cre or D2 Cre animals were injected with either 750 nl of AAV5-DIO-ChR2-YFP or 1500 nl of AAV5-DIO-eNpHR-YFP into right PFC and implanted with either light fibers or guide cannulas. After 4-6 weeks of virus-mediated expression, animals underwent behavioral testing with 473 nm laser, or 532 nm laser stimulation. We tested animals using a social interaction assay in which we introduce a novel juvenile mouse into the home cage of the subject mouse. Following a 5 min break, we introduced a novel object into the home cage for 4 min period. Local infusion of the D2R agonist quinpirole (3 ug) into PFC of adult mice led to reduced social exploration and increased novel object exploration. Optogenetic excitation of prefrontal D2-expressing cells also disrupted social exploration. Conversely, optogenetic inhibition of prefrontal D2-expressing cells could rescue the quinpirole-induced social dysfunction. Infusion of the D1R agonist, SKF-38393, into PFC did not affect social exploration, but increased novel

object exploration. Optical activation of D1-expressing cells caused no change in social behavior, but increased novel object exploration. In conclusion, our results shows that excitation of D2-expressing - but not D1-expressing - cells in PFC leads to a specific reduction in social function, and suggest a mechanism in which D2R activation excites D2R-expressing neurons. These results are consistent with the hypothesis that excessive activation of D2Rs may contribute to prefrontal dysfunction in disorders such as schizophrenia. 1. Gee, S. *et al. J. Neurosci.* **32,** 4959-71 (2012).

Title: Dual, intra-amygdala injection-recording technique to explore oxytocin-mediated changes in social behaviors and neural activity in macaque monkeys

Authors: *P. PUTNAM[1], K. LASZLO[2,3], L. DIECKMAN[3], J.-P. WIEGAND[3], J. ROMAN[3], G. LACY[3], K. GOTHARD[3]
[1]Neurosci., Univ. Of Arizona, Tucson, AZ; [2]Med. Sch., Univ. of Pécs, Pécs, Hungary; [3]Univ. of Arizona, Tucson, AZ

Abstract: The amygdala in primates is critical for normal social behavior, including emotional regulation and evaluation of social stimuli. The amygdala is bidirectionally connected to areas of the primate brain that contain the highest density of oxytocin receptors (nucleus basalis, ventromedial hypothalamus, etc.) Though intranasal administration of oxytocin modulates blood flow in the amygdala of humans performing social tasks, the role of the amygdala in mediating oxytocin-dependent changes in social behavior remains unclear. We have developed a dual recording-microinjection method, allowing delivery of oxytocin into different nuclei of the amygdala while monitoring single neuron activity inside and outside its diffusion radius. This

technique allows us to compare social behaviors and neural activity in the amygdala elicited by intranasal and intra-amygdala administration of oxytocin. We found that intranasal administration of oxytocin enhanced general interest in videos with social content (quantified as total looking time at the monitor) and the frequency of gaze-following saccades in the first monkey tested. Gaze-following saccades were identified based on an ethogram of the viewer's scanpaths, in which we manually identified the region targeted by the saccades of the viewer monkey. Gaze-following saccades met the following criteria: viewers had to first fixate on the eyes of the movie monkey and then saccade within +30 degrees of the movie monkey's line of sight Intra-amygdala administration of oxytocin also increased the frequency of gaze-following saccades and the time spent by the viewer monkeys fixating the eyes of monkeys and humans presented in the videos. The heart rate of the viewer monkey gradually decreased throughout the presentation of videos after receiving intranasal saline but remained elevated after intranasal oxytocin. Ongoing experiments will determine whether intranasal or intra-amygdala administration of oxytocin increases the activity of neurons in the amygdala specialized for processing faces, facial expressions, and eye contact.

Title: Anterior insula mediates social behaviors that are finely regulated by retinoic acid and 5-HT2C receptor in its layer 5 pyramidal neurons

Authors: *S.-H. KIM[1], M. D. RANNALS[2], J. MOORE[1], B. J. MAHER[2], A. SAWA[1]
[1]Psychiatry and Behavioral Sci., Johns Hopkins Univ., BALTIMORE, MD; [2]Lieber Inst., BALTIMORE, MD

Abstract: Our group is interested in how social behavior is mediated by fine regulation of neurochemicals in complex neural networks. Human brain imaging studies have suggested that anterior insula (AI) might be an important hub involved in social and affective behaviors. We hypothesized that molecules that are specifically enriched in this brain region may play a pivotal role in social behavior. From this viewpoint, we underscored Cyp26B1, a retinoic acid (RA)-degrading enzyme. To address our working hypothesis, we locally modulated the expression of Cyp26B1: its knockdown in adult mice resulted in marked increase in RA signaling in the AI and significant behavioral deficits in social recognition/memory paradigms, but not in non-social behaviors. At the electrophysiology level, this genetic manipulation in AI led to a significant reduction of spontaneous excitatory postsynaptic currents (EPSCs) in the layer 5 pyramidal neurons recorded from acute brain slices. To address whether the attenuated neuronal activity of the pyramidal neurons underlies social behavior deficits, we utilized an optogenetic approach and found that deficits in social behaviors elicited by Cyp26B1 knockdown in AI can be normalized by stimulation of layer 5 pyramidal neurons in AI *in vivo*. Furthermore, systemic administration of oxytocin (OT) and an agonist for 5-HT2C receptor could rescue the social behavior deficits, however vasopressin and a 5-HT2C receptor antagonist did not. The 5-HT2C receptor agonist normalized the electrophysiological deficits of the AI pyramidal neurons elicited by knockdown of Cyp26B1, but OT did not. Taken together, we now propose a pivotal role of AI for social behaviors that are finely regulated by RA and 5-HT2C receptor in the layer 5 pyramidal neurons.

Title: Is the speech phenotype of the R553H FoxP2 mutation really due to haploinsufficiency? Insights from the zebra finch (Taeniopygia guttata) FoxP subfamily

Authors: *E. MENDOZA, N. ARPENIK, U. KOBALZ, C. SCHARFF
Verhaltensbiologie, Freie Univ., Berlin, Germany

Abstract: The heterozygous R553H mutation in the DNA binding domain of the Forkhead transcription factor FoxP2 impairs acquisition of speech and language. The cause of this phenotype is thought to be haploinsufficiency of FoxP2. Transcriptional activity of FoxP2 requires dimerization with FoxP2 or with paralogues FoxP1 and FoxP4. It is thus possible that the R553H mutation not only affects FoxP2 quantity, but also interferes with the ability to dimerize. We therefore studied (1) the co-localization of FoxP2 with FoxP1 and FoxP4, (2) dimerization abilities of zebra finch FoxPs, (3) whether the avian version of the FoxP2-R553H mutation can form dimers with wild type FoxP proteins and (4) if dimers including FoxP2-R553H mutation have transcriptional activity. In the zebra finch striatum significantly more neurons expressed all three FoxPs than other combinations, shown via triple immunohistochemistry. Co-immunoprecipitation assays (Co-IP) *in vitro* and *in vivo* revealed that all FoxP subfamily members of the zebra finch can homo- and hetero-dimerize. Co-IPs with zebra finch FoxP2-R553H or with FoxP2- ΔFoxBox (lacking the Forkhead box) showed that they can interact with wild type FoxP1 or FoxP2 or FoxP4 proteins. Co-transfecions of FoxP2-ΔFoxBox with any of the wild type FoxP proteins in HeK cells rescued the abnormal cytoplasmatic localization of singly overexpressed FoxP2-ΔFoxBox and shifted it to the nuclear localization typical for transcription factors. Luciferase assays revealed that zebra finch FoxP1, FoxP2 and FoxP4 regulate the SV40 promoter in a similar manner as reported for the mouse homologues. Overexpression of the R553H-FoxP2 in combination with wild type FoxPs affected the repression of the transcriptional activity. Together these data provide the first evidence that the FoxP2-R553H mutation, and possibly other FoxP mutations, affect all FoxPs co-expressed in the same neurons through dimerization, leading to an additional dominant negative effect.

Title: Changes in FoxP2 expression intensities during functional integration of adult-generated neurons into avian basal ganglia circuits

Authors: *J. F. KOSUBEK, C. SCHARFF
Free Univ. Berlin, Berlin, Germany

Abstract: In zebra finches newly generated neurons are recruited constantly to various brain regions during adulthood. Adult-generated medium spiny neurons (MSNs) in the striatal song nucleus Area X and their progenitors in the ventricular zone express the transcription factor FoxP2. Foxp2 is involved in neural circuit formation in mice by regulating the transition of neural precursors to neurons during embryonic cortical development. Foxp2 also orchestrates maintenance and detachment of neuroepithelial progenitors in the spinal cord, pointing to its potential role adult neurogenesis. In juvenile songbirds FoxP2 is highly expressed in Area X during the phase of song learning and virally mediated knockdown in this sensitive period leads to inaccurate song imitation. FoxP2 knockdown in Area X in adult birds prevents social modulation of song variability, supporting its importance in song production. MSNs in Area X show two FoxP2 expression intensities: the proportion of intense FoxP2 immunoreactive MSNs is higher in juvenile birds and in newly recruited MSNs in adults, whereas low-expressing MSNs become more numerous as the birds age. How FoxP2 expression levels shift in newly recruited MSNs during maturation is still unclear. We hypothesized that FoxP2 levels in new MSNs decrease as they integrate into existing neural circuits and get activated during singing. We analyzed newly generated Area X MSNs in adult male zebra finches for FoxP2 intensities and immediate early gene expression as a marker of activation at several time points after receiving a DNA synthesis marker. Preliminary results indicate that the proportion of activated FoxP2-expressing new MSNs increases during maturation as does the proportion of activated new MSNs expressing low levels of FoxP2. These results suggest that high FoxP2 levels are necessary for recruitment, integration and activation of new MSNs into songbird Area X.

Title: The Reelin receptor VLDLR is a direct target of FoxP2 and regulated developmentally and by singing

Authors: *I. ADAM, E. MENDOZA, U. KOBALZ, S. WOHLGEMUTH, C. SCHARFF
Free Univ. Berlin, Berlin, Germany

Abstract: Mutations of the transcription factor FOXP2 lead to severe speech and language impairments in humans. Structural as well as functional imaging studies indicate that the striatal basal ganglia are especially affected by the mutation. The FOXP2 gene codes for a transcription factor, which is strikingly conserved among vertebrates regarding its sequence as well as its expression pattern. In songbirds it is expressed in a striatal nucleus of the avian basal ganglia, which is necessary for song learning and adult singing. In juvenile zebra finch males FoxP2 is differentially regulated during song learning and in adults by singing. Down-regulation leads to impaired song learning, affects dendritic spine formation and prevents social context induced song plasticity. So far no direct target gene relevant for song learning and song production has been described. We investigated whether the Reelin receptor VLDLR is a direct FoxP2 target gene in zebra finches. VLDLR has been shown to be a direct target of FOXP2 in humans, moreover in songbirds it is regulated by singing. Here we show that FoxP2 can bind to the promoter region of the avian VLDLR gene and activate it *in vitro*. Additionally, VLDLR is co-regulated with FoxP2 during song learning and following adult song performance in zebra finches. Finally we show that experimental down-regulation of FoxP2 in Area X of juvenile males leads to down-regulation of VLDLR. In mice the Reelin pathway is known to be involved in learning and memory e.g. by altering synaptic transmission in the striatum. Vldlr itself is located at the synapse and is able to physically interact with the NMDA receptor-complex. Taken together these results are in line with previous findings suggesting that FoxP2 is involved in synaptic function of striatal spiny neurons. We thus identify a direct target of FoxP2 with putative synaptic function in spiny neurons, which could affect signal propagation through the avian basal ganglia.

Title: FoxP2 expression in the brain after chick calls

Authors: *C. BESSHO[1], T. TSUZUKI[2]
[1]Dept Physics, [2]Kyoto Sangyo Univ., Kyoto, Japan

Abstract: FOXP2 is the first gene linked to human speech and was more expressed in the striatum nucleus Area X of zebra finch than the surrounding tissue at post-hatch days (S. Haesler et al. ,2004). Haesler et al.(2007) showed that zebra finches with reduced FoxP2 expression levels in Area X imitated tutor songs incompletely and inaccurately . Previously, we reported that l-LTP was induced in Area X of brain slice of juvenile male Bengalese finch by five trains of theta stimulus (5Hz, 1S) every three minutes. We showed that Foxp2 was more strongly expressed in the induced brain slices than control slices (C. Bessho et al .2009). Mice pups vocalize in ultrasonic region when they are removed from their mother. Disruption of the Foxp2 gene of mice caused an absence of ultrasonic vocalizations (ult. voc.) (W. Shu et al. 2005). Foxp2 mediates sex differences in ult.voc. by rat pups (J. Bowers et al. 2013). These two studies indicate that FoxP2 expression has an important role in the separated call from their mother. We showed that the Foxp2 in the brain of Degu pups were more strongly expressed in the separated pups from their mother than control (C. Bessho et al .2012). Chick is a non-song-learning bird but it calls after incubation. To understand a relationship between FoxP2 expression and chick call, we did immunohistochemistry of chick brain. and RT-PCR of mRNA. Each baby chick was taken out of the cage and placed for thirty minutes in another litter. A digital voice recorder was placed over the pup. Two minutes of recording commenced after the pup vocalized. Total RNA isolated from the forebrain and hind brain was reverse transcribed to cDNA and FoxP2 gene was amplified by PCR and amplified DNA were separated on agarose gel. Another half brain was fixed in 10 % formalin Neutral Buffer Solution (pH 7.4) over night at 4°C . Slices , 40μm thick, were reacted with Foxp2 antibody, then washed in PBS and were stained with Alex488 second antibody. Green fluorescence of slices in blue light (490 nm) was observed by fluorescence microscope. Preliminary data showed that there was no difference of FoxP2 expression between separated and control pups.

Title: ZEBrA Redux: An improved digital atlas for exploring brain gene expression in the adult male Zebra Finch (www.zebrafinchatlas.org)

Authors: *C. V. MELLO[1], P. V. LOVELL[1], J. B. CARLETON[1], M. WIRTHLIN[1], B. SNIDER[2]
[1]Dept. of Behavioral Neurosci., [2]Ctr. for Spoken Language Understanding, Oregon Hlth. Sci. Univ., Portland, OR

Abstract: The goal of project ZEBrA (Zebra Finch Expression Brain Atlas; www.zebrafinchatlas.org) is to make available to the public an online collection of high-resolution (0.46 μm/pixel) digital images representing the expression patterns for a large set of transcripts in brain of the adult male zebra finches (T. guttata), a representative songbirds species. As a continuously expanding resource, ZEBrA currently houses more than 2,000 images (>100 GB) corresponding to ~500 genes that are expressed in the zebra finch brain, including the major nuclei that comprise the song system. Each gene has been selected based on its relevance for understanding the physiology of the song system (e.g. neurotransmitter receptors, ion channels, signaling systems), or its importance for clarifying issues of vertebrate brain evolution and homology. Following our initial launch in June of 2012, ZEBrA has received thousands of visits from investigators throughout the world. Our on-going mission is to continue to release additional batches of images until we have covered ~1,500-2,000 genes. To facilitate the investigation of brain gene expression, the latest public release of ZEBrA (November 2013) included several major improvements, as well as the addition of new features that have been designed to help users to identify genes of interest, and to explore their expression in the context of songbird neuroanatomy. Major features of ZEBrA include: (1) The *In situ* database - the actual collection of high-resolution *in situ* hybridization images presented along with annotated drawings derived from Karten/Mitra Histological Atlas, (2) A Gene Family Search Page - A feature that facilitates searches for genes based on their membership in specific gene families; (2) A Histological Atlas Browser - A set of 18 annotated drawings prepared in registration with Nissl- and Myelin-stained images of sagittal brain sections derived from the Karten/Mitra atlas, (3) A Neuroanatomical Marker Search Page - A search engine that allows users to retrieve a list of genes that are markers of a given structure, or of multiple structures. ZEBrA represents the

most comprehensive resource available for investigating the brain distribution of genes involved in the physiology, development, and maintenance of functional circuits in the brain of songbirds.

Title: Calcitonin gene related peptide (CGRP) increases neuronal activity in the zebra finch premotor song nucleus RA

Authors: *C. A. WILLIAMS[1], A. F. GARCIA[2], D. J. PERKEL[1,3,2]
[1]Dept. of Biol., [2]Grad. Program in Neurobio. and Behavior, [3]Dept. of Otolaryngology, Univ. of Washington, Seattle, WA

Abstract: An interconnected set of nuclei in the male zebra finch brain underlies the ability to memorize and accurately reproduce vocalizations known as song. These nuclei can be divided into a motor production pathway and a basal ganglia-like loop important for learning, known as the anterior forebrain pathway (AFP). The two pathways split early in the circuit and reconvene at the robust nucleus of the arcopallium (RA), a key candidate site of plasticity for song learning. How the output nucleus of the AFP, the lateral magnocellular nucleus of the anterior nidopallium (LMAN), influences the activity of RA is not well understood. While LMAN releases glutamate onto RA neurons, activating NMDA receptors and affecting song variability, LMAN neurons also express immunoreactivity for calcitonin gene related peptide (CGRP), a neuropeptide that is implicated in pain processing in the spinal cord as well as in migraines. We hypothesized that release of CGRP from LMAN terminals could affect electrical activity in RA. We applied exogenous CGRP to RA neurons in brain slices prepared from adult male zebra finches. Ionotropic glutamate and GABA receptors were blocked with kynurenic acid and picrotoxin, respectively. Extracellular single-unit recordings showed that CGRP (10 – 1000 nM) increased the spontaneous firing rate of RA neurons by 20-150%. The slow time course of the response was consistent with a peptide action. This response was reduced in the presence of either the

peptide CGRP antagonist $CGRP_{8-33}$ or the small molecule antagonist SB268262. In other systems CGRP activates adenylyl cyclase. Application of adenylyl cyclase activator forskolin to RA neurons increased firing rate, mimicking the effect of CGRP. High-frequency (150-400 pulses at 20-100 Hz) stimulation of LMAN afferent fibers resulted in a similar increase in RA neuron firing, rising over approximately 30 seconds and decaying over 10 min. Whole-cell recording showed that activation of LMAN fibers caused a slow inward current. These studies provide evidence that an endogenous neuropeptide in LMAN afferents, putatively CGRP, plays a role in modulating RA activity. It further provides a candidate mechanism to contribute to song plasticity. Finally, and more generally, this connection is a rare example of peptidergic neurotransmission in a cortex-like structure.

Title: Effects of statins on auditory memories, neurogenesis and neuronal morphology in the zebra finch

Authors: *S. C. TSOI[1], A. QURESHI[2], A. BARRIENTOS[2], U. V. AIYA[3], M. L. PIERCE[3], E. SOYMAN[3], D. STALBOW[2], S. RIBEIRO[2], D. S. VICARIO[3], C. L. PYTTE[1,2], M. L. PHAN[3]
[1]The Grad. Center, CUNY, New York, NY; [2]Queens College, CUNY, Flushing, NY; [3]Rutgers Univ., Piscataway, NJ

Abstract: Statins lower serum cholesterol by inhibiting the HMG-CoA reductase in the cholesterol synthesis pathway in the liver. Statins also cross the blood brain barrier and may decrease cholesterol synthesis in the brain. Statins are thought to be neuroprotective in the damaged brain; however, in the healthy brain, statin use has been associated with impaired learning and memory. One mechanism that might explain these findings is altered neurogenesis,

which requires the continual production of new membrane lipids, including cholesterol. Here, we investigated whether statins impact new neuron incorporation and electrophysiological response properties in the caudomedial nidopallium (NCM) of male zebra finches. NCM is a forebrain auditory region that is involved in discrimination and memory for the complex vocalizations of individual conspecifics and also receives new neurons in adulthood. Male birds were given oral doses (40 mg/kg) of either simvastatin, atorvastatin, pravastatin or water vehicle daily for 60 days. Beginning on treatment day 30, birds received injections of bromodeoxyuridine (BrdU, ~0.078 mg/g, IM, 3x/day for 3 days) to label mitotically active cells. After 60 days of statin/vehicle treatment, we recorded simultaneously from multiple electrodes in NCM of awake, restrained birds and compared multi-unit responses to novel conspecific songs and familiar songs that had been presented 20h earlier. Brains were then processed with immunohistochemistry to label BrdU and the neuron-specific protein Neu-N. A second series of sections was processed to label doublecortin (DCX) which is expressed by young neurons. To determine whether new neuron morphology was altered by statin treatment, we traced DCX-expressing cell bodies using NeuroLucida software and compared morphological measurements of soma size and shape between statin-treated and control birds. Counts of BrdU-labeled (30 day old) neurons or DCX-expressing (<30 day old neurons) in NCM showed no significant difference from vehicle controls for any of the 3 statins. However, in the HVC of the song motor pathway we found significant morphological differences in DCX-expressing cells between atorvastatin-treated and control birds. In statin-treated birds, auditory response magnitudes in NCM did not differ between novel and familiar song stimuli, but did differ as expected in vehicle-treated controls, suggesting that 20h neuronal memory may be impaired in statin-treated birds. These results suggest that the impaired ability to form new auditory memories is not associated with altered new neuron survival. Ongoing work is examining neuronal morphology in NCM.

Title: Song-inducible gene expression in the songbird auditory forebrain: evidence for sex differences, regional differences, and a role for estrogen synthesis

Authors: *A. A. KRENTZEL[1], L. REMAGE-HEALEY[2]
[1]Neurosci. and Behavior, [2]Psychological and Brain Sci., Univ. of Massachusetts Amherst, Amherst, MA

Abstract: Estradiol is an important neuromodulator for auditory processing, especially in vocal learning animals such as songbirds. Previous work has shown that when birds are hearing sounds, estradiol synthesis increases rapidly in the auditory forebrain in both males and females. Exogenous estradiol administration has also been shown to enhance auditory representations in the forebrain, and blocking local estradiol synthesis suppresses auditory processing and disrupts auditory-dependent behaviors. Neuroanatomical evidence is consistent with a role for local estradiol synthesis, since aromatase is expressed within neuron terminals in the auditory forebrain. Males have more terminal aromatase activity and expression in the auditory forebrain as compared to females, although it has not been explored whether there is a functional consequence of this sexual dimorphism. Also, the cellular mechanism for these acute actions is unclear, but available evidence is consistent with a non-classical signaling pathway. To explore these questions, we stained for Egr-1, a song-inducible immediate early gene, in brain sections from sixteen male and female zebra finches that received a single oral dose of fadrozole, an aromatase inhibitor, or saline control prior to song presentation. We observed regional dependent decreases in Egr-1 expression in fadrozole-treated males and females in aromatase-positive regions of the auditory lobule, consistent with a role for central estrogen synthesis in modulating audition. In posterior HVC shelf, we also observed a sex difference in which females responded with elevated Egr-1 immunoreactivity as compared to males, regardless of treatment. In alternate sections we also examined the distribution of phosphorylated CREB, a transcription factor that may regulate Egr-1 expression via non-classical estradiol signaling. Preliminary evidence indicates no significant effects of sex or aromatase inhibition on pCREB expression in the auditory forebrain, indicating that this is an unlikely transcriptional candidate for estradiol's influences on Egr-1 expression. These findings are consistent with a role for brain estrogens in modulating auditory representations in the forebrain, although a cell signaling mechanism remains to be elucidated.

Title: Song-mediated activation and habituation of the mTOR cascade in the zebra finch auditory cortex

Authors: *S. AHMADIANTEHRANI[1], S. E. LONDON[2]
[2]Dept. of Psychology, [1]Univ. of Chicago, Chicago, IL

Abstract: Inhibition of the highly conserved mechanistic target of rapamycin (mTOR) cascade attenuates learning and memory formation in multiple training paradigms. For adult zebra finches (Taeniopygia gutatta), learning and recognizing the individual songs of other conspecifics is integral to their social lives. Using this naturally occurring model, we set out to determine if song-mediated mTOR activation habituates to multiple presentations of the same song, an indication that this signaling pathway plays a role in song recognition learning, and, potentially, the formation of untrained, biologically relevant memories. We first confirmed the presence of this signaling cascade in the auditory cortex, the site of song recognition learning, using Western blot analysis for mTOR and its downstream target S6 Kinase (S6K). We next asked whether or not hearing song activates this signaling cascade. We found that a short song stimulus elicited a rapid and long-lasting phosphorylation, and thus activation, of both mTOR and S6K in this brain region. The auditory cortex includes higher order sensory processing areas analogous to the mammalian secondary auditory cortex, the caudomedial nidopallium (NCM) and caudomedial mesopallium (CMM). We used immunohistochemistry to determine the degree and anatomical location of mTOR activation in response to familiar and novel song in a song recognition procedure. On the first day, birds were individually exposed to repeated presentations of the training song for three hours. Twenty-four hours later, birds heard thirty-minute playbacks of the same song or a novel song, or were left in silence. Phosphorylation levels of the ribosomal protein S6, a downstream substrate of S6K, was lower in the NCM and CMM of birds who heard familiar, versus novel, song playbacks. Activation of mTOR following novel but not familiar song playbacks indicates that this cascade habituates in response to recognized song, and suggests that the mTOR cascade is involved in song recognition learning. The mTOR-mediated phosphorylation of S6 facilitates synaptic protein synthesis, a key component of learning and memory. Therefore, these findings lay the groundwork for investigations into the cellular mechanisms that drive mTOR-dependent learning and memorization of song and other socially meaningful behaviors.

Title: Motor and auditory coding of sub-syllabic transitions in zebra finch song

Authors: *Y. LIM[1,4], J. MARKOWITZ[2], T. J. GARDNER[3]
[2]Cognitive and Neural Systems, [3]Biol., [1]Boston Univ., Boston, MA; [4]Ctr. for Bionics, Biomed. Engin. Res. Inst., Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: A recent study has indicated that the representation of time is non-uniform in the pre-motor cortex area HVC of zebra finches (*1*). However, the prior study concluded that inhomogeneities of spike probability are not easily explained in acoustic terms, but rather reflect extrema of air pressure and muscular tension controlling the syrinx. In this study, we defined 4 different automated methods for localizing points of high acoustic contrast in zebra finch syllables. We then examined how well these measures correlate with the firing times of HVC interneurons and HVC_X projection neurons. We found a significant correlation between HVC firing and the acoustic contrast scores. We next examined correlations between these acoustic contrast scores and firing times of neurons in the primary auditory cortex, area L2a. The recordings were performed in un-anesthetized male zebra finches listening to unfamiliar conspecific songs. We found that measures that perform well in explaining firing inhomogeneities in the HVC also perform well in predicting the firing times of primary auditory neurons. These results suggest that the primary auditory cortex may encode syllables in chunks that reflect the timing of motor commands that would be required to produce the same song. This result provides a low-level analog in the zebra finch for the motor theory of speech perception in humans (*2-6*). 1. A. Amador, Y. S. Perl, G. B. Mindlin, D. Title: Recurrent circuitry shapes a sparse premotor neural sequence

Authors: *G. KOSCHE, D. VALLENTIN, M. A. LONG
Neurosci., NYU Sch. of Med., New York, NY

Abstract: In some neural systems, only a small fraction of neurons participate in each percept or movement (Wolfe et al., 2010), and this sparse coding scheme has been proposed to provide important theoretical (Barlow, 2009) and practical (Fiete et al., 2004) advantages for the network. In the song production nucleus HVC (proper name) of the zebra finch (Taeniopygia guttata), premotor (HVC(RA)) cells typically generate only one high-frequency burst at an invariant moment during the song (Long et al., 2010). Different HVC(RA) neurons burst at different moments, and together they form a sparse representation of time (Hahnloser et al., 2002) that ultimately leads to the patterned activation of song-producing muscles. The precise coordination of neural activity is essential to this process, but the circuit mechanisms that underlie the generation of sparse firing and the resulting behavioral sequences remain unclear (Gibb et al., 2009; Li and Greenside, 2006). Here we show that the activity of local circuit interneurons is crucial for establishing precise premotor commands as well as normal singing behavior. In agreement with previous findings (Mooney and Prather, 2005), we find that HVC(RA) neurons and interneurons are densely interconnected. Further, we demonstrate that the high-frequency bursts of HVC(RA) cells during singing strongly engage inhibitory interneurons through highly pervasive and facilitating synaptic connections, leading to a structured pattern of spiking that can dictate principal neuron firing times. These results suggest that inhibitory circuits can play a crucial role in defining the serial order and precise timing of neurons involved in generating skilled action.

Title: Contributions of higher-order auditory cortical areas to adult song maintenance in the zebra finch, Taeniopygia guttata

Authors: *H. SHOENHARD[1,2], N. F. DAY[3], Z. BURKETT[3], M. J. COLEMAN[2]

Abstract: The brain must process raw sensory input until it is fit to inform adaptive behavior. In the case of the male zebra finch, Taeniopygia guttata, auditory input of the song that the bird is producing must feed back into the song motor control area, HVC, such that song can be reliably produced. Large scale changes in the auditory inputs via deafening lead to alterations in song. In addition, perturbations of distinct auditory input lead to changes in HVC activity (Roberts et al., 2012). Higher auditory processing occurs in a network of areas, including nucleus interfacialis (NIf) and the caudomesopallium (CM), which both project directly to, and together provide most of the auditory input to, HVC. In addition, CM contains a subregion, nucleus avalanche (Av), that is reciprocally connected to HVC and NIf (Akutagawa and Konishi, 2010). In an attempt to elucidate how higher-order processing in NIf and non-Av regions of CM could inform motor output, we bilaterally lesioned one or both of these areas and measured the effects upon long-term song production as compared with deafened and sham-deafened birds. As shown previously, long-term loss of NIf showed little effect upon song motor output. However, non-Av CM lesions produced a variety of alterations in song, including merging of adjacent syllables, addition of syllables, and loss of the last syllable of the motif. These effects sometimes took

several months to emerge after lesioning. CM lesions' effects upon syllable characteristics varied between birds. This heterogeneity could be due to differences in lesion location, although this is difficult to determine because CM's borders are not easy to distinguish. Our current analysis focuses on the effects of lesioning Av on song. We hope to discover how each of these areas' higher-order processing of auditory information informs the motor output entrained by HVC. This may ultimately help us discover to how highly specific sensory processing allows animals to accurately produce adaptive motor behaviors.

Title: Hearing the call: HVC lesion disrupts auditory processing of conspecific calls in Bengalese finches

Authors: A. E. ASTON, C. M. URBANO, *B. G. COOPER
Psychology, Texas Christian Univ., FORT WORTH, TX

Abstract: Auditory processing and vocal production in humans and songbirds are inextricably linked. We sought to explore whether frequency selective manipulations of sound production can induce frequency specific changes in auditory perception in adult male Bengalese finches (*Lonchura striata domestica*). Mean peak frequency of Bengalese finch song typically falls between 3-4 kHz. Damage to the left HVC (letters used as proper name) in Bengalese finches lowers the mean peak frequency of their learned song by 40-50% and they produce predominately lower frequency (< 2.2 kHz) syllables; whereas right HVC lesion results in a 20% decrease in peak frequency and a greater retention of syllables above 2.2 kHz compared to left HVC lesion birds. Thus, one can manipulate motor control of song frequency and evaluate whether such changes systematically alter auditory perception. If vocal production modulates auditory perception then lesion to left HVC would bias auditory processing toward lower frequencies. Birds with left or right HVC damage, or sham-treated control birds, were socially isolated for 24 hours. The birds were then exposed to four types of female contact call: a normal

call, a low-pass filtered (<2.2 kHz), a high pass filtered (>2.2kHz), and a synthetic, tonal high frequency (3-5 kHz) contact call. We measured mean number of calls and latency to call within 20s after presentation of each stimulus. We predicted a lesion by call type interaction effect, but this was not observed ($p = .75$). We found the mean number of calls produced by both lesion groups was significantly lower than sham birds ($p<.002$). There were also significant differences in mean number of calls as a function of calltype. Compared to the synthetic call, birds called significantly less to the normal call and the low frequency call ($p<.004$, .003, respectively). Latency to call was not significantly affected by HVC lesion. However, birds responded with the shortest latency to synthetic calls compared to all of the other three calltype categories ($p<.037$, $p<.039$, $p<.004$). Therefore, frequency of the contact call modulates response latency and mean number of calls produced. HVC lesion only reduces the number of calls produced after hearing a conspecific contact call and did not affect latency to call. We suggest that this pattern reflects the importance of HVC in auditory perception, but not sensory processing, of the contact call. These data complement the findings on song discrimination tasks, in which the functional integrity of HVC is required to identify songs, and further illustrate the importance of HVC in auditory processing of conspecific calls.

Title: A novel cell type mediates motor to auditory interactions necessary to feedback-dependent song plasticity

Authors: *E. HISEY, M. TANAKA, R. MOONEY
Neurobio., Duke Univ., Durham, NC

Abstract: The transmission of motor-related signals to sensory regions of the brain is widely speculated to facilitate the learning and maintenance of complex motor skills. For example, in

humans, information flowing from speech motor cortex to the auditory cortex is theorized to facilitate speech learning and maintenance. Songbirds resemble humans in their capacity for vocal learning, but the identity and function of pathways that convey information from motor to auditory regions of the brain remain poorly understood. We recently described a novel cell type in the song premotor nucleus HVC of zebra finches that forms axon terminals in part of the auditory telencephalon (Avalanche, or Av). To begin to better characterize these Av-projecting HVC cells (i.e., HVC_{AV} cells), we made targeted whole cell current clamp recordings from HVC_{Av} cells and other HVC projection neuron (PN) types in brain slices. These recordings revealed that HVC_{AV} cells exhibited intrinsic electrophysiological properties that were distinct from other types of HVC PNs, consistent with their playing a functionally specialized role. Moreover, HVC_{Av} cells receive excitatory input from HVC PNs that project to downstream song motor regions, and thus HVC_{Av} cells could convey motor-related signals to the auditory system. One possibility is that HVC_{Av} cells transmit information to the auditory system that is used for the auditory feedback-dependent modification of song. If this idea is correct, then selectively killing HVC_{Av} cells should not affect previously learned songs, but should prevent song modification in response to changes in auditory feedback. To test this idea, we used an intersectional viral gene targeting method to selectively ablate HVC_{Av} cells in adult zebra finches that had learned to produce highly stable songs. Ablating HVC_{AV} cells had negligible effects on adult song structure, indicating that these cells do not play an essential role in song motor control even though they are embedded in a song premotor structure. However, whereas blocking auditory feedback by deafening triggers rapid degradation in spectral and temporal features of adult song, adult finches in which HVC_{Av} cells were ablated prior to deafening were able to maintain stable syllable sequences and individual syllables also exhibited reduced spectral degradation. These findings are consistent with a forward model in which HVC_{Av} cells transmit motor-related signals to the auditory system to facilitate the feedback-dependent modification of learned vocalizations.

Title: Song-control system or vocal-control system? HVC is active during production of learned aggressive calls

Authors: *S. K. MISCHLER[1,2], E. KARLIN[1], S. A. MACDOUGALL-SHACKLETON[1,2]
[1]Psychology, Univ. of Western Ontario, London, ON, Canada; [2]Advanced Facility for Avian Res., London, ON, Canada

Abstract: Birds' learned vocalizations play an important role in the social interactions that are integral for the viability of flocks, whether it be by communicating movements or producing alarm calls when a predator is near. The neurobiology of such bird calls has been neglected in comparison to the neurobiology of bird songs. Birdsong is used in a reproductive context and tends to be more complex than calls, albeit this distinction is often unclear. Calls are often also assumed to not require imitative vocal learning, but we now know that a variety of calls are plastic. The song-control system in the avian brain is instrumental for the learning, production and maintenance of song is songbirds. This circuit includes the brain regions HVC, the robust nucleus of the arcopallium (RA) and area X. Little work has addressed whether these brain regions are involved in the production of calls. Black-capped chickadees produce a variety of highly complex vocalizations that they use in different contexts. The fee-bee song is the primary long-distance song most often produced by males during the breeding season to defend a breeding territory and attract mates. Production of this song is highly seasonal, but seasonal plasticity of HVC in this species is minimal, which suggests that HVC may be maintained year-round for the production of complex learned non-song vocalizations (e.g. the gargle and the chick-a-dee call). Specifically, the gargle call is an aggressive vocalization used to indicate the propensity of attacking, the chick-a-dee call is used to coordinate group movements within a flock and sometimes as an indicator of mild alarm and the tseet call is understudied and it's function is unclear. In this study, we used motor-driven immediate-early gene expression to assess whether song-control regions were active during the production of a variety of call types by black-capped chickadees. Birds were trapped in London, Ontario and exposed to behavioural manipulations in order to elicit production of the fee-bee song, gargle call, chick-a-dee and tseet calls. Following a session of vocalizing, brains were processed by immunohistochemistry to visualize immediate-early gene (ZENK) expression in the song-control regions of the brain. The birds that produced the gargle call consistently showed significantly more ZENK activation in HVC than birds that produced the fee-bee song, chick-a-dee and tseet calls. This suggests that HVC should be considered a vocal-control brain region rather than strictly a song-control region. Therefore HVC is crucial not only to learning, production and maintenance of song, but other learned vocalizations as well.

Title: Breathing to sing: HVC modulates air pressure during song

Authors: *C. M. URBANO, B. G. COOPER
Dept. of Psychology, Texas Christian Univ., Fort Worth, TX

Abstract: Birdsong is a learned vocal behavior that requires precise coordination between the respiratory and syringeal (vocal organ) motor systems. Subsyringeal air pressure is precisely regulated during phonation to control the acoustic features of song syllables; air pressure amplitude is determined by the combined effects of expiratory muscle activation and syringeal gating of airflow. HVC (used as a proper name) is a premotor nucleus that is important for the control of syllable sequence and song timing. Disruption of HVC neural activity through either ablation or inactivation affects temporal features of song in both juvenile and adult songbirds. Prior research in our lab has shown that unilateral HVC lesion in male Bengalese finches (*Lonchura striata domestica*) reduces air pressure amplitude and increases the duration of intersyllable intervals. These changes in song respiratory features suggest that eliminating HVC activity may influence song tempo by disrupting learned motor coordination of the respiratory and/or syringeal motor systems. Here we explore whether HVC damage transiently or permanently disrupts air pressure patterns and the resultant changes in expiratory muscle activation. Immediately after the lesion, the amplitude of expiratory and inspiratory pulses decreased significantly and there was also a reduction in slope at the onset of the pressure pulse. To investigate how long this reduction in air pressure amplitude persisted, we measured air sac pressure before unilateral HVC lesion and six months postsurgery. Six months after the lesion, we found that air pressure amplitude of expiratory pulses remained attenuated, suggesting that it does not recover. Therefore, without normal bilateral HVC activity, typical subsyringeal air pressure levels cannot be achieved. To determine how expiratory muscle activation changed as a function of HVC damage, we are recording electromyograms of the expiratory muscles (*m. obliquus externus abdominis*) before and after unilateral HVC lesion. These data illustrate the importance of neural control in maintaining temporally precise muscle activity and coordinating independent physiological systems during the production of complex, learned vocalizations.

Title: Aberrant song alters new neuron survival in Area X and NCM in the adult male zebra finch

Authors: ***A. PEREZ**[1], K. WASNER[2], S. RIBEIRO[2], A. LOPEZ[2], E. RODRIGUEZ[3], S. BIENSTOCK[2], C. PYTTE[2]
[1]Grad. Center, City Univ. of New York, New York, NY; [2]Queens Col., Flushing, NY; [3]Duke Univ., Durham, NC

Abstract: Adult neurogenesis provides a continual source of new neurons to a limited number of brain regions. However, the mechanisms regulating new neuron survival are poorly understood. In the adult male zebra finch, the quality of song produced is positively correlated with numbers of new neurons incorporated into the song motor pathway nucleus HVC (proper name), consistent with the idea that appropriate matching between received feedback and expected feedback contributes to new neuron survival. We tested this idea in adult male zebra finch basal ganglia nucleus Area X and in the auditory processing region caudomedial nidopallium (NCM). Both Area X and NCM respond to playback of the bird's own song, demonstrated by electrophysiological responses and fMRI respectively; and both regions receive new neurons throughout adulthood. Area X is required for song learning and is part of the anterior forebrain pathway that generates song variability in adulthood. NCM stores a memory of the tutor's song and also plays a role in conspecific song discrimination. To test whether new neuron survival in these regions is influenced by the quality of the bird's own song, we altered song structure by unilaterally denervating the syrinx and quantified new neurons in Area X and NCM in both hemispheres. Mitotically active cells were labeled with bromodeoxyuridine (BrdU, 3x/day) for four consecutive days. Two weeks after BrdU injections, song was altered by unilaterally sectioning the tracheosyringeal portion of the hypoglossal nerve (NXIIts), which innervates the syrinx. Control birds received sham surgery. Pre and post-treatment songs were compared using Sound Analysis Pro. Two weeks after surgery, birds were perfused and brains were processed

using immunohistochemistry to label BrdU and the neuron-specific protein Hu. We found that left and right NXIIts nerve section decreased the number of new neurons in Area X bilaterally relative to control birds. Interestingly, we found hemispheric asymmetry in effects of treatment on new neurons in NCM. Left NXIIts nerve section decreased the number of new neurons in both left and right NCM. Right NXIIts nerve section decreased the number of new neurons in left NCM and increased new neuron numbers in right NCM, relative to left and right neuron number in NCM of controls. These results suggest that the quality of song production plays an important role in the survival of new neurons and these effects differ by brain region and hemisphere.

Title: A glutamatergic neuron influences pallidal firing patterns in zebra finch Area X

Authors: *A. BUDZILLO[1], D. J. PERKEL[2]
[1]Neurobio. and Behavior, [2]Biol. and Otolaryngology, Univ. of Washington, Seattle, WA

Abstract: Area X is the striato-pallidal component of a basal ganglia loop essential for juvenile song learning and adult song plasticity in the songbird. Area X contains several cell types: three GABAergic interneurons, cholinergic interneurons, novel putative glutamatergic interneurons, and pallidal projection neurons. Pallidal neurons are GABAergic and highly spontaneously active. Subtle disruptions or brief pauses in their firing can increase the probability of firing in the downstream thalamic nucleus DLM. Area X receives excitatory projections from pallial nuclei HVC and LMAN and dense dopaminergic innervation from the midbrain. Dopamine D1 receptors in Area X have been implicated in mediating changes in song variability in an adult social context dependent form of song plasticity. Previously we have described strong, periodic spontaneous excitatory postsynaptic currents (EPSCs) in Area X. These EPSCs arise locally, suggesting the presence of a novel glutamatergic neuron in Area X. Here we explore further the

functional role of these neurons. We made cell-attached recordings from pallidal neurons, which can be easily identified by their high spontaneous firing rates (mean ISI=27.25 ms; n=9) and large cell bodies, in brain slices from adult male zebra finches. Area X was surgically isolated from HVC and LMAN to focus on local glutamatergic signaling. Application of the AMPA receptor antagonist NBQX (10 μM) did not change mean firing rate (mean ISI=26.01; n = 9), but did result in a significant decrease in variability of firing (baseline cv ISI=0.2367; NBQX cv ISI=0.1513; n=9; P=0.039). Thus, local glutamatergic synaptic activity within this microcircuit could alter pallidal cell firing statistics, which in turn could affect downstream signal transmission to DLM. We previously reported that the novel glutamatergic cell in Area X participates in a microcircuit motif that results in tightly coupled EPSC-IPSCs, with an inter-event lag of less than 5 ms. We have recorded spontaneous synaptic activity in whole cell voltage clamp mode in pallidal cells from isolated Area X slices. Further quantification of these coupled events shows that EPSCs are followed within 5 ms by inhibitory postsynaptic currents (IPSCs) 18.1% of the time (n=24 pallidal cells). However, the proportion of events that appear to participate in this motif varied from 0 to 60.4% across cells (n=24). The D1 receptor agonist SKF-38393 (10 μM) increased the overall rate of IPSCs, as well as the relative proportions of coupled EPSCs and IPSCs (n=3 pallidal cells), suggesting the existence of a novel synaptic mechanism for dopaminergic modulation of Area X output in the songbird.

Title: *In vivo* two-photon targeted single-cell labeling in the zebra finch

Authors: *S. BENEZRA[1], R. T. NARAYANAN[2], M. OBERLANDER[2], M. A. LONG[1]
[1]Neurosci., NYU Sch. of Medicine, Dept. of Physiol. and Neurosci., New York, NY; [2]Computat. Neuroanatomy, Max Planck Inst., Tübingen, Germany

Abstract: Humans have the ability to learn and execute a wide range of movement sequences that are integral to everyday life, from playing the piano to speaking, but little is known about how these behaviors are represented within the brain. Songbirds offer an excellent experimental model to study the organization of identified cortical circuits underlying a complex learned motor behavior. Towards that end, we focused on the cortical premotor nucleus HVC (proper name), which contains the neural circuitry enabling song production (Vu et al., 1994; Hahnloser et al., 2002; Long and Fee, 2008). HVC premotor neurons send primary axons to the forebrain motor nucleus RA (robust nucleus of the arcopallium) which ultimately drive song. In addition to these efferent outputs, RA-projecting HVC neurons also send axon collaterals within HVC (Gurney and Katz, 1981; Mooney, 2000), which are thought to form a synaptic chain capable of enabling precise sequences (Long et al, 2010). Despite their implications for a range of HVC circuit models (Fee et al., 2004; Amador et al., 2013), the fine structure of these processes is poorly understood. To address this issue, we examined the morphology of premotor neuron axons by delivering an intracellular tracer (Neurobiotin) *in vivo* using juxtacellular (loose patch) stimulation (Pinault, 1996; Narayanan et al., 2014), coupled with 2-photon imaging (Margrie et al., 2003) in order to specifically target premotor neurons in that nucleus. The axonal arbors were then reconstructed using a semi-automated process (Oberlaender et al., 2007). In addition to a quantification of the arborization patterns and putative target neurons, we are also interested in whether the projection patterns of single premotor neurons can suggest topographic structure, especially in light of recent evidence suggesting that connectivity within HVC may exhibit a directional bias (Stauffer et al., 2012; Poole et al., 2012; Day and Nick, 2013).

Title: Unilateral cooling differentially affects song timing and syntax in Bengalese finch

Authors: *Y. ZHANG, A. A. KOZHEVNIKOV
Pennsylvania State Univ., UNIVERSITY PK, PA

Abstract: Singing in songbirds is a learned complex motor behavior controlled by the nuclei that are symmetrically present in both hemispheres. How the two hemispheres coordinate to produce complex motor sequences that follow certain syntactic rules is unclear. We investigated this question by unilaterally changing temperature in the left or right HVC (proper name, formerly high vocal center) of a Bengalese finch. Song timing is affected primarily by changing temperature in left HVC but not right HVC, suggesting that timing control is lateralized to the left hemisphere. The variable number of syllable repeats is affected by changing temperature unilaterally in HVC, but which hemisphere depends on the syllable. Additionally, some of the syllable branching points change their transition probabilities with temperature change in either hemisphere.

Title: Sensorimotor feedback maintains auditory objects formation

Authors: *S. MA[1,2], M. GAHR[1,2]
[1]Max-planck-Institute For Ornithology, Seewiesen, Germany; [2]Grad. Sch. of Systemic Neurosciences, Ludwig Maximilian Univ. of Munich, Planegg-Martinsried, Germany

Abstract: In an international cocktail party, people are able to identify those who speak the same languages from background noise easier than those who speak other languages. It suggests that there must be neural mechanisms for listener to maintain the language sensitivity of his own languages. Reports in human studies that patients with damage to the Broca's area suffered from aphasia, and also had difficulty in speech comprehension, imply that sensorimotor feedback may influence speech perception. In zebra finch, the sensorimotor nucleus HVC (higher vocal center) corresponds functionally to the Broca's area. Both HVC and Broca's area were mostly studied in motor domain, whereas feedback from motor domain to auditory domain in speech perception is less known. The aim of this study is to investigate the influence of HVC on auditory object formation with regard to the international cocktail party problem. We employed electrophysiological methods to examine responses to auditory objects in both male and female auditory cortices. We found that the habituation rate to auditory objects was higher in male than

in female. Inactivation of HVC in male resulted in decrease of habituation rate. Our results provide direct evidence that sensorimotor integration affects auditory object formation.

Title: Temporal cue cognition of the song auditory information processing in auditory forebrain of zebra finch

Authors: M. ARAKI[1], M. M. BANDI[2], C. P. CONNAUGHTON[3], *Y. YAZAKI-SUGIYAMA[1]
[1]Neuronal Mechanism for Critical Period Unit, [2]Collective Interactions Unit, Okinawa Inst. of Sci. and Technol. (OIST) Grad. Univ., Okinawa, Japan; [3]Mathmatics Inst., Univ. of Warwick, Coventry, United Kingdom

Abstract: As in human speech, avian vocalization is generated and cognized as a sequence of sound patterns. Male zebra finches learn specific songs, from their auditory experience during the juvenile period, and employ it in courtship behavior and individual identification. Songs of zebra finches generally consist of a few acoustical elements, called syllables, which emerge in a stereotyped sequence separated by small silent gaps (~30 ms). In the zebra finch brain, neurons in circuits that are necessary for song learning and production, called the 'song system', show selective auditory responses to conspecific songs, songs they have heard from their own species, or their own songs, depending on the identity of the circuits. In this study we investigated how song auditory information is processed and cognized in the auditory circuit, which projects to the 'song system', especially in the primary auditory area, field L (homologous to the mammalian primary auditory cortex). In subregion L2a (homologous to layer 4 in the mammalian auditory cortex), where neurons receive thalamic inputs, neurons showed auditory responses to continuous white noise (WHN) as well as to conspecific songs (CON), while neurons in the downstream layer, L3, did not respond to WHN. Interestingly, L3 neurons responded to WHN when it was presented with the same durations and intervals as syllable elements of CON. When stimulated with same CON syllables repeatedly, L3 neurons decreased their responses during

repetition with shorter intervals, but not with longer intervals. Moreover, these neurons in the auditory cortex showed the same response magnitudes to CON, even when the frequency phase was scrambled within each syllable. These results suggest that within the auditory information processing for song cognition, temporal cues of syllable onset and offset provide necessary information in the primary auditory cortex.

Title: The role of norepinephrine in acute auditory processing of learned vocalizations

Authors: *M. IKEDA[1], D. JEON[2], L. REMAGE-HEALEY[3]
[1]Mol. and Cell. Biol. Grad. Program, [2]Dept. of Psychological and Brain Sci., [3]Neurosci. and Behavior Grad. Program, Univ. of Massachusetts, Amherst, MA

Abstract: Neuromodulator signaling is important for many cognitive functions, including processing information from the environment. Auditory signal processing is modulated least in part by the actions of catecholamines. From previous studies in rodent and primate auditory cortex, norepinephrine is known to alter neuron firing properties and tone frequency tuning. However, it is not clear how norepinephrine modifies processing of complex vocalizations. Songbirds are one of the few animal taxa in which individuals learn vocalizations and thus provide a good model for studying auditory processing for complex features. In the songbird brain, catecholamine levels and immediate early gene expression in catecholaminergic neurons are elevated in response to songs, suggesting a role for acute norepinephrine modulation of audition. We use zebra finches to investigate the role of norepinephrine in song processing in caudomedial nidopallium (NCM), a region homologous to the secondary auditory cortex in mammals. Previously, in the NCM, we showed that norepinephrine significantly enhances

single-unit auditory-evoked responses relative to baseline firing activity. Here, we test whether the changes in normalized auditory-evoked responses are due to the changes in firing and/or burst frequencies. The results revealed that norepinephrine significantly decreases spontaneous but not stimulus-evoked firing frequency. Moreover, the changes in spontaneous firing frequency during norepinephrine infusion significantly correlated with the average change in stimulus-evoked firing frequency. The spontaneous firing frequency also significantly correlated with the ratios between spontaneous and song-evoked firing, suggesting that norepinephrine acts to change baseline activity to enhance the signal-to-noise ratio for auditory coding. In fact, for all auditory stimuli, ratios between spontaneous and stimulus-evoked firing were increased by norepinephrine treatment. These results together indicate that norepinephrine has an important role in auditory information coding for complex vocalizations. Ongoing analyses are directly testing whether norepinephrine can enhance encoding precision of NCM neurons for time-variant complex vocalizations. Together, this study contributes to the understanding of the role of neuromodulators on complex information processing. Support from NIH R00NS066179 and R01NS182179.

Title: Functional connectivity and nonlinear information propagation in visual cortical circuits revealed by all-optical neurophysiology in the awake mouse

Authors: *J. H. MARSHEL[1], S. YANG[2], W. E. ALLEN[3], R. PRAKASH[3], I. KAUVAR[2], C. RAMAKRISHNAN[1], K. DEISSEROTH[4,1,5]

Abstract: Activity flowing through neural circuits may be refined, amplified, and modulated to more robustly represent new information and more effectively carry this information to downstream circuitry. Understanding how circuits could adapt their activity patterns to transform and transmit information may require the ability to precisely manipulate activity patterns and measure effects with single-cell resolution. Here, we combine two-photon Ca^{2+} imaging using GCaMP6M with single-cell optogenetics using $C1V1_{T/T}$ to manipulate active layer 2/3 visuocortical subnetworks in awake mice viewing defined visual stimuli. Experimental parameters were determined to yield high imaging and stimulation quality while circumventing overlap of $C1V1_{T/T}$ and GCaMP6M excitation spectra and maintaining single-cell resolution for both. We reliably stimulated individual neurons at up to 20 Hz (~2 ms per single-spike stimulus), observing a consistent linear increase in GCaMP6M response with stimulation rate. We employed two methods for multi-neuron stimulation with single cell resolution *in vivo*. One method stimulates neurons in a sequence, rapidly moving among neurons (at most 180 microsecond lag between most distal neurons in the field of view (FOV)). The second method employs two-photon excitation with a phase spatial light modulator (SLM) to stimulate groups of neurons simultaneously. We stimulated groups of orientation-selective neurons (1-9 per group) that preferred the same direction, while the mouse viewed drifting gratings that varied in orientation and direction. When stimulated neurons preferred the orientation presented, their responses were observed to be amplified above the sum of baseline stimulation response (during grey screen) and visual response to the grating without optogenetic stimulation. Stimulating during oblique orientation presentation led to linear summation. Strikingly, when stimulation paired with orthogonal visual stimuli, responses were suppressed below baseline stimulation response. We also found indirectly stimulated neurons (ISNs) that reliably increased responses when other neurons were stimulated in the FOV, revealing excitatory functional connectivity that varied in modulation amplitude with network state. Modulation was strongest when indirect stimulation occurred during presentation of the ISN's preferred direction, and weakest during its oblique and orthogonal orientations. These results reveal nonlinear network mechanisms favoring selective flow of accurate information, compared with mismatched or orthogonal information, through the network, a potentially fundamental property of cortical circuitry.

Title: All-Optical physiology: Combining two-photon calcium imaging with single-cell optogenetic stimulation *in vivo*

Authors: *J. M. DOERING, G. PRAMANIK, E. ROSALES, A. TOSE, Z. BARGER, A. STROH
Focus Program Transl. Neurosci. (FTN) & Inst. for Microsc. Anat. and Neurobiol., Johannes Gutenberg-University, Mainz, Germany

Abstract: Establishing a spatially resolved connectivity map of cortical microcircuitry requires both monitoring and modulation of neuronal activity with single-cell specificity. Here, we combine optogenetic stimulation and calcium imaging with single-cell resolution. Integrating an optogenetic approach with simultaneous *in vivo* two-photon calcium imaging remains challenging, due to the interference of high intensity light pulses used for optogenetic stimulation with the optical readout. To overcome these limitations, we conduct spectrally non-overlapping two-photon calcium imaging with simultaneous two-photon optogenetic stimulation using an Optical Parametric Oscillator (OPO) to test the feasibility of "all-optical physiology". AAVs encoding for the two-photon-excitable opsin C1V1mCherry, under the control of the calcium/calmodulin-dependent protein kinase II (CaMKII) promoter expressed exclusively in excitatory neurons were injected in layer 2/3 of mouse visual cortex. Employing VGLUTII and GAD65/67 immunofluorescence for characterization of the opsin-expressing neurons we observed strong, membrane-bound expression of C1V1mCherry in excitatory neurons. For network analysis, Oregon Green BAPTA-1 (OGB-1) was pressure-injected in the C1V1-expressing region (V1). The calcium indicator (OGB-1) was excited using a Ti:Sa laser at 800 nm while C1V1 was simultaneously excited using the OPO at wavelengths ranging between 1100-1300 nm. *In vivo*, we demonstrate simultaneous two-photon calcium imaging and two-photon optogenetic stimulation without cross-talk. This approach allows for causally investigating the impact of single neuron excitation on microcircuit activity.

Title: A combination study of optogenetics and optical imaging to identify unknown cortico-cortical projection patterns in macaque

Authors: *Y. NAKAMICHI[1], M. HASHIMOTO[2], N. KITAMURA[1], K. HAGIYA[1], T. SATO[1], M. TANIFUJI[1]
[1]Lab. for Integrative Neural Systems, RIKEN/ Brain Sci. Inst., Wako/ Saitama, Japan; [2]Nagoya Univ. Grad. Sch. of Medicine, Dept. of Anat. and Cell Biol., Nagoya, Japan

Abstract: To understand neural circuit mechanisms of signal processing across cortical areas, we have to identify connected pairs of cells (or cortical sites) between cortical areas and then to analyze difference and similarity in response property of the pairs. This strategy, however, is usually not available since it is difficult to find the pairs in large area of cortices *in vivo*. To achieve this goal, here, we establish a technique to identify unknown cortico-cortical projection pattern in macaques by combining optogenetics and optical intrinsic signal imaging (OISI): We used optogenetics to stimulate neurons in one cortical area and OISI to detect the response in the area receiving the projections. We used interhemispheric connections at V1/V2 border region as a model system to test feasibility of our technique. We first crated a vector, AAV9- CaMKIIa-hChR2(ETTC)- EYFP- MBD. MBD, myosin binding domain, was inserted to make channel rhodopsin 2 (ChR2) expression localized mainly in soma and dendrite but not in axon (Lewis TL, 2009). In this way, we can stimulate somas and dendrites with minimum stimulation on passing axonal fibers. In fact, ChR2 expression in axon was decreased by insertion of MBD in mouse cortex. ChR2 expression took about 70 days after the injection to reach plateau and be stable more than 10 months in macaques by monitoring EYFP fluorescence on the cortical surface. Optical stimulation at V1/V2 border of one hemisphere elicited statistically significant intrinsic signals in the other hemisphere reproducibly (Fig. A, arrow). We verified the result by recording multi-unit activities around the activation spot using electrode array (Fig. A, circles) as shown in PSTH and its spectrum (Fig. B and C). To our surprise, we found that optical stimuli in regular spatial intervals along the border elicited activation spots in irregular spacing and number around V1/V2 border in the other hemisphere (Fig. D).

Title: Expanding the dynamic range of genetically-encoded calcium indicators for monitoring high frequency neuronal activity in *Drosophila*

Authors: ***Y. SUN**, J. A. STROTHER, J. P. HASSEMAN, G. TSEGAYE, B. FOSQUE, E. R. SCHREITER, A. NERN, M. B. REISER, K. SVOBODA, L. L. LOOGER, V. JAYARAMAN, D. S. KIM

Abstract: Genetically-encoded calcium indicators (GECIs) have become increasingly popular for monitoring neural activity in genetic model organisms. We recently developed the GCaMP6 family of GECIs that enables single-trial single action potential (AP) detection under favorable conditions. GCaMP6 sensors have relatively high calcium affinities (Kd range: 144-375 nanomolar). They saturate at high firing rates (>50Hz) and have relatively slow off-rates. GCaMP6 variants thus cannot track instantaneous firing rates in neurons with high spike rates. We mutated the calcium-binding domains of GCaMP6 proteins and screened variants in solution and in the *Drosophila* larval neuromuscular junction (NMJ). We identified low affinity (Kd

range: 600 nanomolar to 370 micromolar) variants with high dynamic range. In the NMJ these indicators responded monotonically to spike rates from 1Hz to 160Hz. These GCaMP variants also exhibit improved linearity. Interestingly, some variants have significantly faster on- and off-rates. The off-kinetics of one variant is several-fold faster than those of GCaMP6f, the fastest GCaMP6 variant. We further tested low affinity variants in adult *Drosophila* in visual and olfactory circuit assays and observed improved discriminability in high activity regimes. These next generation, low-affinity GCaMP variants will be useful for monitoring fast-spiking neurons across a wide range of species.

Title: Developing a genetically encoded voltage sensor for visualizing neuronal connectivity *in vivo*

Authors: ***N. FLYTZANIS**[1], C. BEDBROOK[2], H. CHIU[1], S. MCISAAC[3], C. XIAO[1], K. CHAN[1], M. ENGQVIST[3], L. HERWIG[3], P. STERNBERG[1], F. ARNOLD[3], V. GRADINARU[1]

Abstract: The current needs of neuroscience to link the activity of defined brain circuits with behavior are not fully met by currently available tools and techniques, e.g. electrophysiology or functional magnetic resonance imaging. The development of optical methods for the detection of activity within a population of neurons aims to fill the gap in scale between single unit recordings and whole brain scanning. Examples include genetically encoded indicators (GEI) of either cell membrane potential or intracellular calcium. Currently available GEIs suffer from either slow kinetics, low signal-to-noise ratio (SNR), or low baseline fluorescence. Our efforts have focused on the optimization of the microbial rhodopsin voltage sensor, Arch. While Arch exhibits large changes in fluorescence in response to changes in voltage with sub-millisecond kinetics, it suffers from very low baseline fluorescence and light-activated currents that hyperpolarize the cell. Past efforts to abolish these photocurrents have been successful, but have also adversely affected the speed of the sensor. Here, we report two Arch variants, Arch-11 and Arch-22, with larger dynamic range of sensitivity, faster kinetics and higher baseline fluorescence (4-5x and 2-3x respectively) than Arch WT and previously reported mutants. Both variants show greatly reduced photocurrents with 655 nm exposure (the wavelength used for fluorescence excitation) compared to Arch WT (55x and 99x lower respectively). For Arch-11, the combination of these improvements results in a fluorescent voltage sensor that is able to detect action potentials throughout a neuron (cell body and processes) at 40 Hz firing rate. In addition, we used Arch-11 to monitor spontaneous firing and circuit connectivity of multiple mammalian neurons. We show that Arch-11 can be used as an *in vivo* tool by expressing it in worm sensory neurons and tracking fluorescence changes in response to an odorant stimulus. The ability to follow neuronal activity in systems like *C. elegans*, where electrophysiological recordings are inherently difficult, will enable mapping of functional connectivity. With these improvements, Arch-11 provides a basis for further evolution of rhodopsin voltage sensors.

Title: Improved red fluorescent genetically-encoded calcium indicators for *in vivo* imaging

Authors: *H. DANA, Y. SUN, J. P. HASSEMAN, G. TSEGAYE, B. F. FOSQUE, E. R. SCHREITER, B.-J. LIN, S. D. BRENOWITZ, V. JAYARAMAN, L. L. LOOGER, K. SVOBODA, D. S. KIM

Abstract: Genetically-encoded calcium indicators (GECIs) are widely used for *in vivo* imaging of neural activity in specific cell types in various animal models. Currently, the emission spectra of most popular GECIs are in the green range (green GECIs). GECIs with emission in the red wavelength regime (red GECIs) would enable (1) imaging deeper in the brain, (2) combining functional microscopy with optical modulation of neuronal activity using channelrhodopsin-2 or other effectors with blue action spectra, and (3) dual color activity monitoring using both green and red GECIs. Here we report on improved red GECIs and their performance *in vivo*. We made thousands of variants of two red GECIs, RCaMP1h and R-GECO1.0, using structure-guided mutagenesis and tested their responses to action potentials in cultured neurons. *In vivo* performance of selected improved variants were studied in the mouse visual cortex, fly neuromuscular junction, and fly visual system. We discuss the advantages of improved red GECIs and their compatibility with other optical indicators and effectors.

Abstract: Tracking the coordinated activity of individual cellular events across volumes of intact tissue is a major challenge in biology that has inspired considerable technological innovation. However, synchronous measurement of the high-speed activity of individual neurons across three dimensions in brain tissue during behavior has not yet been possible. Here we develop a computational imaging approach (SWIFT3D) that integrates high-dimensional, structured statistics with light field microscopy to allow the synchronous acquisition of single-neuron resolution activity throughout intact tissue volumes at up to 100 Hz during behavior. We first show that this methodology allows fast, simultaneous activity mapping across the entire brain of transparent zebrafish during prey-capture behavior. More surprisingly, we then find that the statistical deconvolution intrinsic to SWIFT3D allows deep high-speed imaging in mammalian brains using conventional wide-field illumination (a modality otherwise unsuitable for light-scattering mammalian tissue). Together with the single-snapshot volume acquisition and large field of view of SWIFT3D, this property enables quantitative characterization of cellular-resolution dynamics simultaneously spanning hippocampal subfields CA1, CA2, and CA3 during contextual learning in awake behaving mice. Finally, we extend SWIFT3D to cellular-resolution high-speed imaging in human brain volumes; we map volumetric dynamical motifs within and across human cortical layers, statistically identifying dependence relationships between individual cells while simultaneously taking into account the dynamics of all other neurons detected in the volume. This ability to record synchronously from volumes of many cells across layers, subfields, and regions opens the door to identifying dynamical motifs and timing dependencies among coordinated cell assemblies during adaptive, modulated, or maladaptive physiological processes. LG, MB, CKK, and CL contributed equally to this work. **Support:** DARPA Neuro-FAST, NIMH, NIDA, NSF, SFARI.

Title: Optogenetic tracing of cell-type specific projections from the pedunculopontine nucleus to midbrain in the rat

Authors: *C. XIAO, J. T. TREWEEK, S. R. KUMAR, K. CHAN, S. L. MCKINNEY, B. YANG, V. GRADINARU
Biol. and Biol. Engin., Caltech, Pasadena, CA

Abstract: The pedunculopontine tegmental nucleus (PPN) provides robust cholinergic (ChAT) and glutamatergic (Glu) excitatory inputs to the midbrain and drives striatal dopamine release, which implicates the PPN in the control of reward processing and voluntary movement. However, validating PPN as a target to treat drug addiction and movement disorders requires better understanding of the precise nature of the PPN to midbrain projections. Herein, cell-type specific optogenetic tools enable reversible and bidirectional activity control in distinct PPN neuron populations with high temporal resolution. Utilizing optogenetics, we selectively tagged 1) PPN ChAT neurons in ChAT-Cre rats with Cre-dependent ChR2-YFP, and 2) PPN Glu

neurons with CaMKIIa-driven ChR2-YFP. By performing acute brain slice patch clamp recordings, we found that in comparison with Glu neurons, ChAT neurons exhibited higher input-resistance, stronger responses to depolarization current injections, and greater maximal firing rates. Blue-light stimulation of ChR2-expressing PPN neurons (10 ms at 10 Hz and 20 Hz) reliably evoked spikes within 5-10 ms after the initiation of light pulse with narrow variations (standard deviation 90% trials in ChAT neurons, but in only <60% trials in Glu neurons. These parameters could inform optogenetic tagging *in vivo* to match waveforms with tagged cell-types. By tracing ChR2-YFP labeled axons, we observed that both ChAT and Glu neurons in PPN project unevenly to midbrain nuclei. The density of ChAT fibers decreased in the following order: the ventral part of the substantia nigra pars compacta (SNc), the ventral tegmental area (VTA), dorsal SNc, and the substantia nigra pars reticulata (SNr). Glu fibers were most abundant in the SNc and VTA, but sparse in the SNr. By delivering light to the midbrain slice, we stimulated axon terminals of opsin-expressing PPN Glu neurons, and recorded time-locked Glu postsynaptic currents in 64% (7/11) of midbrain neurons. In contrast, stimulating ChAT axon terminals in this fashion induced slowly developed nicotinic inward currents (~15 pA) and increased the frequency of spontaneous excitatory postsynaptic currents by ~60% in 30% (6/20) of midbrain neurons. In summary, the projections of PPN ChAT and Glu neurons to midbrain exhibit distinct anatomical and physiological patterns, suggesting a possibility that these neuronal subsets could play distinct roles in reward processing and motor behaviors.

Title: Physical and chemical properties of CLARITY brain-polymer hybrids

Authors: *A. TOM[1], A. MALKOVSKIY[2], Z. BAO[3], K. DEISSEROTH[1,4,5]
[1]Bioengineering, [2]Biomaterials and Advanced Drug Delivery Lab., [3]Chem. Engin., [4]Psychiatry & Behavioral Sci., Stanford Univ., Stanford, CA; [5]Howard Hughes Med. Inst., Chevy Chase, MD

Abstract: CLARITY enables unprecedented resolution of structural and molecular information of intact biological systems via the formation of transparent polymer-tissue hybrids. In order to maximize the utility of CLARITY for application to a variety of tissue sources and types, and to understand the underlying chemistry and physical parameters, a thorough investigation of CLARITY hybrid properties must be conducted. In this study, monomer to cross-linker ratios were varied to determine resulting polymer localization and relative density within mouse cortex, hippocampus, and thalamus using confocal Raman spectroscopy and mechanical compression testing. Furthermore, the influence of polymer crosslinking on tissue morphology was investigated via fluorescence microscopy, scanning electron microscopy, and protein quantification assays. In these investigations, we identify Raman correlates of CLARITY hybrid formation, which may be used to track and quantify tissue clarification. The synthesis of CLARITY hybrids may be tunable for different applications using quantitative descriptors such as these, which may also further enhance our understanding of how polymers form and crosslink within tissue.

Title: Applying CLARITY-based methods for structural interrogation of intact biological systems to diverse peripheral and primate tissues

Authors: *B. HSUEH[1], J. EPP[2], P. PAUERSTEIN[1], L. YE[1], R. TOMER[1], Y. NIIBORI[2], S. KIM[1], D. LYONS[1], A. SCHATZBERG[1], P. FRANKLAND[2], S. JOSSELYN[2], K. DEISSEROTH[1]
[1]Stanford Univ., Palo Alto, CA; [2]The Hosp. for Sick Children, Toronto, ON, Canada

Abstract: A key challenge in biology is obtaining high-resolution structural and molecular information from complex systems while simultaneously preserving global spatial and functional perspective. To address this problem, we developed CLARITY, a technique based on chemical transformation of biological tissue into a hydrogel polymer network, enabling high-resolution light-microscopy imaging and labeling of cleared biological tissues without the need for mechanical deconstruction of samples. Though originally developed with the central nervous system in mind, the advantages of investigating large-scale tissues in the intact, three-dimensional state are not limited to questions of the brain. We developed modified CLARITY methods to biological systems beyond the mouse brain, including spinal, cardiac, musculoskeletal, dermatologic, pulmonary, endocrine and gastrointestinal tissue. CLARITY-based immunostaining was found to enable visualization and tracing of complex, tortuous neurovascular networks in the developing mouse heart, lung, pancreas and hair follicles, and revealed novel pancreatic islet migration defects in Neuropilin-2 knockout mice. CLARITY methods also were found to enable visualization of mitotic markers such as BrdU or Ki67 both in hippocampus and in intestinal crypts, creating new opportunities for studying neurogenesis and stem cell biology in structurally intact niches in health and disease. Finally, the advantages of CLARITY-based methods were extended to non-human primate and human studies, in glucocorticoid-receptor mapping of squirrel monkey cortex, and in islet-mapping and vasculature-tracing in fetal human pancreas. Using this highly diverse set of application domains, we demonstrate that clarified tissue is compatible with an extensive range of immunofluorescence staining techniques, and enables new ways of studying intact system development and function throughout major fields of biomedical science.

Title: CLARITY-based whole brain activity mapping with immediate early gene TRAP

Authors: *L. YE[1,2,3], R. TOMER[1,2,3], B. HSUEH[1,3], C. J. GUENTHNER[2,4], L. LUO[2,4], K. DEISSEROTH[1,2,3]
[1]CNC Program, Stanford Univ., PALO ALTO, CA; [2]Howard Hughes Med. Inst., [3]Departments of Bioengineering and Psychiatry, [4]Dept. of Biol., Stanford Univ., Stanford, CA

Abstract: CLARITY enables transformation of a mammalian brain into a fully assembled hydrogel-hybridized structure that is transparent to both light and macromolecules. This allows visualization of long-range projections, local circuit wiring, and subcellular structures throughout the whole brain without sectioning, providing a platform for detailed intact-circuit analysis and mapping. We now have developed a high-throughput platform to apply CLARITY to brains from mice carrying a signal of past behavior: genetically engineered with an inducible, immediate early gene-based TRAP (Targeted Recombination in Active Populations) system. In a fear conditioning paradigm, we were able to pharmacologically specify 3-hour time windows in which neuronal activity was precisely and permanently labeled with fluorescence signals at the single cell level throughout the whole brain. By combining CLARITY with COLM (CLARITY-optimized light-sheet microscopy), a fully assembled whole brain activity map at subcellular resolution could be rapidly obtained in a truly unbiased manner, registering both well-known and previously uncharacterized anatomical regions of interest to a regions active in an affective state (fear) that was behaviorally verified in the very same animal. CLARITY's unique compatibility with deep molecular phenotyping enabled multiple rounds of molecular characterization of the identified regions, and together, the combination of CLARITY and TRAP illustrates a brain-wide, high-resolution, multimodal activity-mapping methodology.

Title: Single-cell phenotyping within transparent intact tissue through whole-body clearing

Authors: *B. YANG[1], C.-K. CHEN[1], B. E. DEVERMAN[1], R. P. KULKARNI[2], J. B. TREWEEK[1], V. GRADINARU[1]
[1]Div. of Biol. and Biol. Enginerring, Caltech, Pasadena, CA; [2]UCLA, Los Angeles, CA

Abstract: Advances in tissue clearing methods have made molecular phenotyping of brain tissue possible. By matching the refractive index of the brain tissue with its surrounding media, deep brain structures can be imaged and visualized with conventional microscopy. Building on the previously published CLARITY method, we've developed: 1) PACT, for PAssive CLARITY Technique, a practical protocol for passive clearing and staining of up to 3mm thick brain slices; 2) PARS, for Perfusion-assisted Agent Release *in situ*, a whole body clearing method for simultaneous clearing of brain and peripheral organs; and 3) RIMS, for Refractive Index Matching Solution, an affordable FocusClear alternative index matching media for imaging cleared tissue slices or up to 300 μm-thick PFA fixed brain sections. With PARS, all relevant steps including tissue preservation, clearing, labeling and refractive index matching can be performed *in situ* prior to the extraction of the tissue. PARS is scalable both in terms of the number and size of animals that can be processed simultaneously. We can significantly limit the amount of tissue expansion during the clearing procedure, which will facilitate comparing brains across experimental cohorts. Validated for rodent whole-organ and whole-body clearing, PACT, PARS, and RIMS are compatible with endogenous-fluorescence, immunohistochemistry, long-term storage, and microscopy with cellular and subcellular resolution. As a demonstration of the power of this technique, we show PARS-cleared whole brain and peripheral organ images of

mice injected systemically with AAV-eGFP. PARS provides cellular-level reporter expression data from within whole organs, eliminating the need for sectioning and thereby greatly speeding up screening for AAV vectors with desired tropisms. In addition, these methods are relevant to studying central and peripheral nerve anatomy (including connectivity, myelination), tumor margins and heterogeneity, stem cell distribution, all within intact organs or bodies.

Title: Optogenetic investigation of dopamine D2-receptor signaling in risk-preference

Authors: *K. ZALOCUSKY[1,2], C. RAMAKRISHNAN[1], B. KNUTSON[3], K. DEISSEROTH[1,5,4]
[1]Bioengineering, [2]Neurosciences, [3]Psychology, [4]Psychiatry and Behavioral Sci., Stanford Univ., Stanford, CA; [5]HHMI, Chevy Chase, MD

Abstract: The midbrain ascending dopamine system has long been implicated in substance abuse and addiction. More recent work also links dopaminergic signaling to other forms of behavioral addiction, including compulsive over-eating (Johnson et al., 2010) and pathological gambling (Dodd et al., 2005; Grosset et al., 2006; M. Tippmann-Peikert et al., 2007). These studies point to a role of dopamine D2 receptor (D2R) signaling, in particular, in mediating the switch to behavioral addiction. In a novel operant task to examine risk-preference or gambling

behavior, we observed that systemic administration of D2R/D3R agonist pramipexole (PPX) increased risk-seeking choices in a linear, dose-dependent fashion (n = 4-6 per dose, doses range from 0.075 to 0.3mg / kg, r2 = 0.99). To determine which D2R/D3R-expressing brain regions mediate this behavioral change, we infused PPX bilaterally into the nucleus accumbens (NAc) or orbitofrontal cortex (OFC) through permanently-implanted cannulas 30min before the gambling task. We found that D2R/D3R agonism in the NAc, but not the OFC, was sufficient to increase risk-seeking choices (n = 5 in OFC, 6 in NAc; 0.75uL/side of 10µg/µL PPX; p = 0.006). To optogenetically examine (at specific timepoints in the gambling task) the behavioral role of D2R-expressing medium spiny neurons (MSNs), the likely targets of our pharmacological manipulations, we needed to genetically target this cell population in the rat. To this end, we developed a D2R promoter that can be expressed in an adeno-associated viral (AAV) vector and targets opsin expression to D2R-expressing MSNs with 98% specificity (112/114 cells expressing enhanced yellow fluorescent protein (eYFP) were also labeled by anti-D2R antibody). Using this novel construct, we expressed eChR2-eYFP fusion protein specifically in the D2R-expressing cells of the NAc. We found that stimulating these cells with 15mW, 473nm light at 20Hz for 1s during the decision period of the task significantly decreased risky choices in risk-seeking, but not risk-averse, rats as compared to eYFP-expressing controls (n = 17 ChR2, n = 18 eYFP animals; p = 0.008). Finally, to test the duration of the impact of D2R-MSN activity on decision-making, we restricted optical excitation to a pseudo-random subset of trials, with a minimum of 6 trials between light stimulation. Using this protocol, we demonstrated single-trial control of risk-seeking choices with optogenetic stimulation of NAc D2R-expressing MSNs (n = 6, p = 0.046). These findings reveal a highly temporally-specific role for this genetically and topographically-defined population of neurons in risk-seeking behavior.

Title: Top-down bidirectional control of learned fear responses

Authors: *A. ADHIKARI[1], J. FINKELSTEIN[2], T. N. LERNER[2], L. A. GUNAYDIN[2], S. PAK[2], A. LEI[3], K. DEISSEROTH[4,5]
[1]Neurobio., [2]Bioengineering, Stanford Univ., Palo Alto, CA; [3]Bioengineering, Stanford Univ., Stanford, CA; [4]Bioengineering & Psychiatry, Stanford Univ., Palo Alto, CA; [5]Howard Hughes Med. Inst., Palo Alto, CA

Abstract: Previous studies showed electrical stimulation of the ventral medial prefrontal cortex (vmPFC) during cued fear extinction increases extinction retrieval, while stimulation of the dorsal medial prefrontal cortex (dmPFC) has the opposite effect in rats. As fear conditioned responses are dependent on the central amygdala, it has been hypothesized that the opposing effects of these regions on fear is due to their distinct projections to the amygdala. The vmPFC is thought to activate inhibitory intercalated cells in the amygdala, which inhibits the central amygdala, while the dmPFC projects to the basolateral amygdala, which in turns excites the central amygdala, presumably leading to increased fear. These data led to a model in which projections from the vmPFC and the dmPFC to the amygdala decrease and increase, respectively, freezing during extinction retrieval. However, this model has not been directly tested. Here, we tested these ideas directly by optogenetically activating vmPFC and dmPFC cell bodies, as well as their projections to the amygdala during cued and contextual fear extinction. Animals were injected with viral vectors encoding ChR2-YFP or YFP under the CamK2α promoter in the vmPFC or the dmPFC, and fiberoptic cannulae were implanted either in the mPFC or above the amygdala. On day 1 mice were fear conditioned to an auditory tone or to a context by pairing these stimuli with foot shocks. On day 2 mice were exposed to these stimuli without foot shocks to extinguish conditioned freezing fear responses, while receiving optogenetic activation. Lastly, on day 3 mice were tested for retrieval of fear by exposing them again to the conditioned stimuli. We report that optogenetic activation of vmPFC cell bodies ($n=7$ YFP and 7 ChR2, $p<0.05$) during fear extinction decreased freezing specifically during cued, but not contextual, fear extinction retrieval. On the other hand, activation of dmPFC cell bodies during fear extinction did not change freezing in either paradigm ($n=6$ YFP and 6 ChR2). Remarkably, activation of the vmPFC-amygdala projection only during fear extinction decreased freezing both during extinction and retrieval of extinction, for both cued and contextual conditioning ($n=7$ YFP, 10 ChR2, $p<0.05$). Lastly, activation of dmPFC-amygdala projections ($n=12$ YFP and 13 ChR2, $p<0.01$) during extinction selectively increased freezing only during retrieval of cued extinction. These data suggest the vmPFC-amygdala projection robustly inhibits fear elicited by both simple/discrete and complex/contextual fear-conditioned cues, while the dmPFC-amygdala projection selectively increases fear to discrete fearful stimuli.

Title: Decoding zebrafish neural circuits using optogenetics and patterned excitation

Authors: ***A. W. THOMPSON**[1], L. A. HEAP[1], I. A. FAVRE-BULLE[1,2], H. RUBINSZTEIN-DUNLOP[2], E. K. SCOTT[1]

Abstract: Understanding the structure and function of neural circuits remains a fundamental goal of modern neuroscience. We address this problem by observing correlated patterns of activity across broad, defined populations of neurons within a circuit using the zebrafish model organism. Signalling in the optic tectum of 7dpf zebrafish larvae is detected using a genetically-encoded calcium indicator, GCaMP5, in combination with selective-plane illumination microscopy (SPIM). We have paired this imaging technique with a piezo-driven z-stage to capture high-speed, high-resolution scans of the larval zebrafish tectum in 3-dimensions. We have identified stereotypical tectal cells that are active in response to defined, external input including visual and auditory stimuli. In order to determine how tectal circuits encode information from internal sources, we have also imaged tectal GCaMP5 in response to stimulation of upstream brain regions including the cerebellum and thalamus. This is achieved by genetic targeting of the optogenetic protein, channelrhodopsin-2 (ChR2), to these areas. ChR2 stimulation is further restricted using a spatial light modulator (SLM) to induce neural firing in only subsets of cells in these regions, while resulting GCaMP5 activity is imaged in the optic

tectum. These techniques have allowed us to determine a spatio-temporal model of the functional circuits within the larval zebrafish tectum.

Title: Advancements in neuronal silencing using inhibitory chloride-conducting channelrhodopsins

Authors: *A. BERNDT[1], S. LEE[2], C. RAMAKRISHNAN[2], K. DEISSEROTH[2]
[1]CNC Deisseroth Lab., Stanford Univ., Palo Alto, CA; [2]Stanford Univ., Stanford, CA

Abstract: In optogenetics, neuron inhibition is typically achieved by utilizing light activated pumps such as halorhodopsins or archaeorhodopsins. However, the inherent biophysical properties of these tools dictate that only one ion is transported per absorbed photon. Therefore, these pumps are less efficient compared to the excitatory channelrhodopsins, which conduct several hundreds or thousands of ions during each photocycle. For this reason, it has been a major goal of optogenetic engineering to design a channelrhodopsin with altered ion selectivity to inhibit neural activity upon light stimulation. A crucial step towards this objective has been obtaining the x-ray structure of the channelrhodopsin hybrid C1C2, because it allows precise structure-guided engineering of this class of proteins for the first time. Guided by the C1C2 structure, we replaced nine amino acids along the ion-conducting pathway of C1C2 to create an ion-conducting pore more suitable for transporting negatively charged ions. We revealed that this new construct (iC1C2) is not selective for cations, but conducts chloride ions and residual

amounts of protons. Consequently, expression in cultured neurons from rat hippocampus shifted the reversal potential from - 7 mV in C1C2 to -64 mV in iC1C2. This value lies between the average spiking threshold (-55 mV) and the resting potential (-69 mV) of all tested neurons. Unlike other inhibitory tools, iC1C2 transports chloride ions passively over cell membranes utilizing physiological ion gradients. Once activated by light, iC1C2 reduced the input resistance of expressing cells by 50%, which resulted in a spike inhibition probability of 88%. To enable bi-stable inhibition of neuronal activity and greater light-sensitivity of expressing cells, we further engineered iC1C2 by replacing cysteine 167 by alanine. This created a Step-Waveform-Inhibitory-Channelrhodopsin (SwiChRCA) which maintains a negatively shifted reversal potential of -68 mV, and conferred extended lifetime of the conducting state (tau_off = 160 s). As a result, cultured neurons remained inhibited for many seconds after brief blue light stimulation at low intensities. Furthermore, SwiChRCA was immediately deactivated by red light (tauoff = 200 ms) which allowed precisely-timed switching of neurons back into the excitable state. We prepared AAVs coding for CamKII-iC1C2_eYFP and CamKII-SwiChRCA_eYFP, injected mouse pre-frontal cortex, and mapped the ability of these constructs to inhibit generation of action potentials in various intact-tissue settings. Additionally, we present strategies for expanding this next generation of chloride conducting channelrhodopsins.

Title: Achieving dual and separable optogenetic inhibition of different neuronal subtypes within microcircuits

Authors: *S. LEE[1], A. BERNDT[1], C. RAMAKRISHNAN[1], L. FENNO[1], R. PRAKASH[1], F. ZHANG[2], K. DEISSEROTH[1]

Abstract: Optogenetic activation of different neuronal cell types, using multiple excitatory opsins within the same brain region, has revealed new insights into the circuit elements crucial for behavioral and pathological states such as information processing and behavioral dysfunction (Yizhar et al. 2011 Nature). However, this level of circuit dissection has not yet been explored with inhibitory optogenetic tools. Here, we report the development and characterization an inhibitory opsin, eOxy, derived from the proton pump of the marine dinoflagellate Oxyrrhis marina. We first added trafficking sequence motifs necessary to facilitate the expression of eOxy in neurons, allowing for its usage for optogenetic experiments. eOxy showed strong photocurrents (~1 nA) in cultured neurons with a peak activation wavelength at ~510nm, which is further blue-shifted than the currently available inhibitory pumps. Even more interestingly, it showed minimal activity at the red wavelength (633 nm), presenting new opportunities for combining eOxy with other optogenetic tools. To explore the possibility of combinatorial optogenetic inhibition with eOxy, we injected PV-Cre mice with a virus cocktail consisting of a mix of CaMKIIa-eOxy and DIO-NpHR in the CA1 hippocampus or mPFC of PV-Cre mice. In addition, to enable delineation of individual opsin-expressing cells within the densely-packed CA1 pyramidal layer, we added a p2A linker sequence between the opsin and fluorophore, demonstrating that this strategy can work for inhibitory pumps (Prakash et al. 2012 Nature Methods). We performed simultaneous dual whole-cell recordings in acute hippocampal slices with CaMKII-positive excitatory pyramidal neurons (expressing eOxy) and PV (parvalbumin)-positive fast-spiking interneurons (expressing NpHR) using different wavelengths (510 nm and 633 nm). Our experiments showed that we could inhibit electrically-evoked spiking in both cell populations, or specifically in just the PV+ interneuron population. We also performed *in vivo* optrode recordings in the mPFC of injected animals, where eOxy showed robust ability to inhibit spontaneous multi-unit activity while the inhibition of PV cells with NpHR demonstrated a small increase in spontaneous activity. In conclusion, we present here the first demonstration of combinatorial optogenetic inhibition with a new inhibitory optogenetic tool, eOxy. The dual or selective silencing of distinct neuronal populations will allow for a refined study and dissection of neuronal microcircuits.

Title: Subsecond cholinergic dynamics underlying hippocampal network state in freely-behaving rats

Authors: *T. J. DAVIDSON[1], E. B. ANDERSON[3], T. N. LERNER[1], C. RAMAKRISHNAN[1], J. MATTIS[1], L. M. GROSENICK[1], I. V. KAUVAR[1], L. M. FRANK[3], K. DEISSEROTH[2]

Abstract: The role of the neuromodulator acetylcholine (ACh) in hippocampus (HPC)-dependent memory is of long-standing research and clinical interest. *In vitro* and behavioral data suggest that varying ACh levels may dynamically tune HPC circuits for encoding (higher [ACh]) or retrieval (lower [ACh]) (ref. 1). ACh has also been hypothesized to regulate subsecond, behavior-linked changes in HPC network connectivity (ref. 2). However, the activity of identified HPC-targeting ACh neurons in freely-behaving animals has never been reported, and no causal link between rapid ACh dynamics and HPC function has been established. We have used optical methods in freely-moving rats to both record from and stimulate a genetically-defined population of ACh neurons in the medial septum/diagonal band (MSDB) that provides the major ACh projection to HPC. We had previously developed a transgenic Cre driver rat line to target ACh neurons, and here we have used a viral strategy to express the excitatory opsin ChR2 or the genetically-encoded calcium indicator GCaMP6F in these cells. In slice physiology recordings, ChR2-expressing neurons displayed characteristic features of ACh neurons (broad spike and slow after-hyperpolarization potential) and were reliably driven by blue light pulses (473nm) at firing rates of at least 20Hz. To record the activity of this population, we used fiber photometry (ref. 3) to monitor population fluorescence in GCaMP6F-expressing cells during open field exploration. We recorded transients of up to 30% $\Delta F/F$, and signal-to-noise ratios >10 under minimally-bleaching illumination (~100μW). Consistent with predictions of graded ACh modulation of HPC network state, we observed a strong correlation between fluorescence and log(running speed), ($R^2 = 0.22$-0.50, $p \ll 0.001$). Finally, to test the effects of these dynamics on HPC, we optogenetically stimulated ACh cells in MSDB while recording local field potentials in dorsal HPC. 8Hz stimulation markedly reduced the rate of sharp-wave ripple complexes

(SWR) in HPC (0.8 to 0.1 Hz, p<10^-4). This decrease was complete ~250 ms after light onset, and recovered ~1 s after light offset. Our results therefore are consistent with a role for septohippocampal ACh in rapidly modulating HPC network activity. 1. Hasselmo et al. Prog. Brain Res. 145, 207-231 (2004). 2. Title: Brain-wide imaging of an anhedonic state using awake optogenetic functional MRI (ofMRI)

Authors: ***E. FERENCZI**[1], C. LISTON[2], K. ZALOCUSKY[1], K. KATOVICH[3], M. R. WARDEN[2], D. AMATYA[2], B. PATENAUDE[4], L. GROSENICK[1], C. RAMAKRISHNAN[2], P. KALANITHI[5], A. ETKIN[4], B. KNUTSON[3], G. H. GLOVER[6], K. DEISSEROTH[7]
[1]Neurosciences & Bioengineering, [2]Bioengineering, [3]Psychology, [4]Psychiatry, [5]Neurosurg., [6]Radiology, [7]Howard Hughes Med. Institute, Bioengineering and Psychiatry, Stanford Univ., Stanford, CA

Abstract: We combined optogenetics and functional magnetic resonance imaging (ofMRI) to examine whole-brain spatiotemporal patterns of Blood Oxygen Level Dependent (BOLD)

activity during stimulation of medial prefrontal cortex (mPFC) pyramidal neurons in awake rodents. Human neuroimaging studies have demonstrated that mPFC activity (subcallosal cingulate gyrus, also known as area 25) is elevated in patients with depression (Mayberg et al, 2005) and rodent investigations have shown that increased excitability of mPFC excitatory neurons reduces social interaction in mice (Yizhar et al, 2011). Here, we assessed the causal role of mPFC in regulating the hedonic response to sucrose in rats. We expressed a stable step function opsin (SSFO) driven by the calmodulin kinase IIα promoter to target pyramidal neurons in the mPFC of wild type Sprague Dawley rats. We found that stimulation of mPFC pyramidal neurons by SSFO caused anhedonic behavior, manifested by a small (8-9%) but significant decrease in sucrose preference ($n = 8$ for SSFO, $n = 10$ for YFP controls, $p < 0.01$ for interaction in 2-way ANOVA). We performed awake functional MRI scans (7T magnet) to assess brain-wide patterns of BOLD activity arising from this stimulation. Awake scanning was enabled by a 5-10 day habituation protocol in a MRI simulation environment. Scans were performed using a single shot (0.5 s TR) variable density spiral in-out pulse sequence to obtain functional images with 470 μm in-plane spatial resolution. As a positive control, the BOLD response to a natural sensory (visual) stimulus was monitored through unilateral retinal illumination with green light. Activation of mPFC (2 s continuous 470 nm light) yielded a robust BOLD response at the fiber site ($n = 6$, $p < 0.01$ corrected), which was absent in YFP controls ($n = 5$). We then performed resting state scans to assess changes in whole-brain functional connectivity following mPFC activation by SSFO (5 s continuous 470 nm light at the start of a 5 min resting state scan). We observed significant increases in positive BOLD signal correlation between mPFC and a number of brain regions including ventral striatum and medial orbital cortex ($p < 0.01$ corrected, $n = 4$ for SSFO and $n = 4$ for YFP). *In vivo* multi-site electrophysiological recordings suggest that mPFC activation by SSFO modulates the spectral profile of the local field potential by increasing the ratio of high to low gamma power in functionally connected targets of mPFC. We discuss the potential role of these changes in whole brain network dynamics in contributing to psychiatric symptoms related to the altered experience of reward, as seen in depression, schizophrenia and addiction.

Title: Thalamic driving of cortical spindles and seizures with on demand loss of consciousness

Authors: *J. PAZ[1], J. SOROKIN[2], T. J. DAVIDSON[3], K. DEISSEROTH[3], J. R. HUGUENARD[2]
[1]Neurol., Gladstone Inst. / UCSF, San Francisco, CA; [2]Neurol., [3]Bioengineering, Stanford, Stanford, CA

Abstract: Neural interactions between cerebral cortex and thalamus mediate sensation, perception, and consciousness and generate rhythms associated with sleep and epilepsies. The causal roles of thalamus in the control of cortical rhythms has been controversial. To probe the role of thalamocortical neurons in cortical rhythmogenesis, we combined *in vitro* and *in vivo* electrophysiology and closed-loop optogenetic control of neural circuits in freely behaving rats and mice. Driving synchronized burst firing mode at 8-12 Hz of thalamic relay neurons was sufficient to drive cortical sleep-spindles, absence type seizures and loss of consciousness. Destabilizing thalamocortical output by reduction in firing with halorhodospin was sufficient to desynchronize cortical rhythms and abruptly terminate seizures in real time. These approaches provide a toolbox for reliable real-time control of thalamocortical rhythms of therapeutic interest for psychiatric and neurological disorders.

Title: Mechanisms of neuromodulatory control of the zebrafish acoustic startle response: Optogenetic control with the light-controlled metabotropic glutamate receptor 2 (limglur2)

Authors: *C. J. PANTOJA, A. HOAGLAND, E. CARROLL, E. ISACOFF
Dept. of Mol. & Cell Biol., Univ. of California, Berkeley, Berkeley, CA

Abstract: Great inter-individual variation is present in the acoustic startle behavior (ASR) in wild-type populations of zebrafish. In invertebrates, neuromodulators play a role in behavioral diversity by diversifying the output of fixed neuronal networks. Neuromodulators act through G protein-coupled receptors (GPCR) and affect intracellular signaling pathways in neurons. To connect GPCR activity in specific circuits to behavioral control we re-engineered the mammalian Gi/o-coupled receptor mGluR2 to make it light-sensitive with a photoswitchable tethered ligand (PTL). The light-controlled metabotropic glutamate receptor 2 (LimGluR2) is turned ON/OFF when exposed to light of different wavelengths (380nm vs. 490nM) (Levitz et al., 2013). We showed that optical control of the Gi signaling pathway in distinct Gal4-expressing neuronal populations differentially modulates the ASR behavior. Specifically, LimGluR2 activation in a Gal4 pattern that includes the Mauthner cell induced a decrease in ASR probability that was not reversible within minutes. In contrast, activation of LimGluR2 in a pan-neuronal pattern reversibly increased the ASR probability. Animals expressing LimGluR2 did not behave significantly different from siblings not expressing the receptor. We speculate that behavioral control by the Gi pathway might be part of the native control of the ASR during ethologically-relevant situations and may contribute to behavioral diversity.
