Title: Differential conservation of transcription factor codes specifying mouse and human olfactory bulb interneuron phenotypes

Authors: *N. FUJIWARA[1], J. W. CAVE[1,2];
[1]BURKE MEDICAL RESEARCH INSTITUTE, WHITE PLAINS, NY; [2]WEILL CORNELL MEDICAL COLLEGE, BRAIN AND MIND RESEARCH INSTITUTE, New York, NY

Abstracts: The mechanisms that generate neuronal phenotypic diversity in the mammalian brain are not fully established. To better understand these mechanisms, this study examined transcription factor specification of olfactory bulb interneuron phenotypes. Most studies examining phenotypic diversity in olfactory bulb interneurons have been conducted with rodents and have indicated that individual phenotypes are specified by combinatorial co-expression of different transcription factors. To establish whether the transcription factor codes established in the mouse are conserved in the human olfactory bulb, we examined adult human and mouse olfactory bulb tissue by immunofluorescence. These studies compared the co-expression of MEIS2, SP8, FOXP2 and PAX6 transcription factors in interneurons specified by the expression of either Calretinin, Calbindin or Tyrosine Hydroxylase. In both species, FOXP2 and PAX6 were co-expressed with Calbindin and Tyrosine Hydroxylase, respectively. MEIS2 was co-expressed with both Calretinin and Tyrosine Hydroxylase in both species, but co-expression with Calbindin was only observed in mice. SP8 was co-expressed with Calretinin in both species, but in humans, it was also observed in cells containing either Calbindin or Tyrosine Hydroxylase. The co-expression of SP8 with Calbindin in humans coincided with a co-expression of Calbindin and Calretinin that was not observed in mice. The human-specific co-expression of Calbindin and Calretinin revealed a novel olfactory bulb interneuron phenotype not observed in mice. Together, the findings in this study show some significant differences in transcription factor co-expression patterns in mouse and human olfactory bulb interneurons, which may underlie differential phenotype specification between these species.

Title: Mechanisms of neuronal maturation are impaired in the developing neocortex of Mecp2 null embryos

Authors: ***F. BEDOGNI**[1], C. COBOLLI GIGLI[1], D. POZZI[2], R. ROSSI[3], L. SCARAMUZZA[1], C. ZELI[1], C. KILSTRUP-NIELSEN[4], M. MATTEOLI[2], N. LANDSBERGER[1];

Abstracts: Rett syndrome (RTT) is a neurological disorder that affects mainly girls (1/10.000 live born female) and is characterized by autistic features, seizures, ataxia and stereotypical hand movements. Due to the timing of the onset of RTT symptoms (6-18 months of life), researchers so far mainly studied the postnatal period. However, evidences of subtle defects at birth (both in humans and RTT animal models) are now increasing, while the investigation of any possible prenatal neurodevelopment impairments has been largely neglected. We thus hypothesized that MeCP2 (the cause of roughly 90% of RTT cases worldwide) could play a role during embryonic and early postnatal development, as we detected Mecp2 expression in both progenitors and post-mitotic neurons of the cerebral cortex as early as E10. Searching for possible transcriptional impairments, possibly leading to subtle alterations during early stages of development, we performed a microarray analysis on wt and Mecp2 null embryonic cortical tissues (E15). Overall, our transcriptional screening highlighted the deregulation of a large plethora of genes typically expressed by maturing or matured neurons. This is suggestive of a delay (or possibly a stall) in the acquisition of the full mature neuronal identity, as many of these genes were accordingly deregulated at later time points (E18 and P8). Of particular interest for their involvement in activity dependent maturation, we detected defects in the transcription of several receptors and ionic channels that likely produced perturbation in down stream signalling pathways, as verified with functional experiments. Our data suggest the intriguing hypothesis that impairments during early embryonic maturation of the Mecp2 null cortex can lead to subtle pre-symptomatic features

and concur to the typical neuronal impairments in adulthood, thus opening up new perspectives on the aetiology of RTT neurological features.

Abstracts: What pathways specify retinal ganglion cell (RGC) fate in the developing retina? Here we report on mechanisms by which a new molecular pathway involving Sox4/Sox11 required for RGC differentiation from retinal progenitor cells (RPCs) and for optic nerve formation in mice *in vivo*, and sufficient to differentiate human induced pluripotent stem cells into electrophysiologically active RGC-like cells. We show a regulatory network where by the previously described inhibitor of RGC differentiation, REST, depends on suppression of Sox4 expression, and provide evidence for a novel soluble regulator for RGC differentiation, TGFβ superfamily member GDF-15, which also acts through Sox4 to induce RGC differentiation from

progenitor cells. Although our data suggests that Sox4 and Sox11 are independently required for RGC development, the two family members interact such that the normal SUMOylation of Sox11, which decreases its nuclear localization and suppresses its pro-RGC activity, is decreased in the absence of Sox4, allowing Sox11 to compensate for Sox4 absence. These data define novel regulatory mechanisms for this SoxC molecular network, and suggest pro-RGC molecular manipulations with potential promise for cell replacement-based therapies for glaucoma and other optic neuropathies.

Title: Genetic control of dopaminergic neuron subtype differentiation in zebrafish

Authors: ***W. DRIEVER**, M. MANOLI, M. RATH, E. CARL, T. MUELLER, A. FILIPPI; Univ. Freiburg, Freiburg, BW 79104, Germany

Abstracts: Distinct groups of dopaminergic neurons develop at defined anatomical sites in the brain to modulate function of a large diversity of local and far-ranging circuits involved in motor control, perception, sleep and the regulation of emotion-related behavior. We use zebrafish embryos as genetic models to understand how transcriptional regulatory networks control dopaminergic subtype identity, co-transmitter phenotypes and projection behavior. Zebrafish

embryos develop dopaminergic neurons at anatomical sites similar to mammals, except for the lack of a mesencephalic dopaminergic group. We have mapped the complete projectome of all dopaminergic groups in zebrafish, and have also characterized gabaergic and glutamatergic co-transmitter phenotypes for each dopaminergic subtype. The only dopaminergic neurons in zebrafish to provide ascending projections into the subpallium/striatum are A11-type posterior tubercular dopaminergic neurons which depend on the Orthopedia transcription factor for their development. these neurons share glutamatergic co-transmission with the mammalian ascending systems. Zebrafish develop an endostriatal dopaminergic system, which provided most of the dopaminergic arborization within the striatum. this striatal system is characterized by gabaergic cotransmission, providing dopaminergic activity with two distinct co-transmitter phenotypes to the striatum. We have systematically mapped transcription factor expression to each of the anatomical dopaminergic groups in zebrafish to define their transcriptional codes, and use genetic loss- and gain-of-function approaches to functionally dissect the transcriptional networks controlling dopaminergic subtype specificity. Our data suggest specific combinations of patterning, neurogenesis and differentiation transcription factors to drive dopamine subtype specification, co-transmitter phenotypes and projection behavior.

Title: The significance of NeuroD1 for external germinal layer formation

Authors: M. HANZEL[1], T. BUTTS[1], *R. J. WINGATE[2];
[1]MRC Ctr. for Developmental Neurobio., [2]MRC Ctr. Dev Neurobiol, King's Col. London, London, United Kingdom

Abstracts: The cerebellum has evolved elaborate foliation in the amniote lineage as a consequence of extensive transit amplification in a transient external germinal layer (EGL) mediated by the bHLH transcription factor, Atonal 1 (Atoh1). At the end of transit amplification,

granule cell precursors (GCPs) transition into mature neurons having undergone a massive expansion in number. Differentiation is associated with the down regulation of Atoh1 and upregulation of NeuroD1. To explore the characteristics of transit amplifying cells, we have examined cerebellar development in the embryonic chicken, mouse and Xenopus. Electroporation of conditional reporters *in vivo* in chick at E6-E8 and in cerebellar slice of both chick and mouse cultured at E10-14 and P1-5, respectively, has allowed us to directly observe individual granule cells from their origins at the rhombic lip to their descent into the internal granular layer (IGL) and explore the relationship between NeuroD1 and Atoh1. Our assay employs two bHLH transcription factor enhancer constructs: NeuroD1::GFP and Atoh1::Cre-recombinase. By titrating the concentration of this cre-recombinase with co-electroporated "lox-stop-lox" plasmids encoding either GFP or mCherry, we label progressively sparser cells. Using this strategy, we show that Atoh1 is expressed in granule cell precursors displaying a variety of different morphological characteristics. By contrast, the NeuroD1 enhancer construct labels GCPs as they leave the cell cycle and initiate an inward radial migration suggesting a key role for NeuroD1 in differentiation. To investigate this, we overexpressed full-length NeuroD1 within the chick GCP population and assessed the consequences for granule cell development. When expressed in early rhombic lip migrants (E5), NeuroD1 upregulation cell autonomously inhibits the formation of EGL cells. When expressed in GCPs of the EGL, NeuroD1 cell autonomously terminates proliferation, triggers radial migration and down regulates Atoh1. NeuroD1 is thus sufficient to trigger exit from the EGL. Intriguingly this regulatory relationship appears to be a relatively recent amniote innovation. In the frog (an anamniote), which has a simple unfoliated cerebellum, NeuroD1 and Atoh1 are co-expressed in a transient granule cell layer that forms on the surface of the cerebellum at metamorphosis. This external layer is nevertheless non-proliferative and thus does not comprise an external germinal layer. The evolution of transit amplification in the EGL thus required adaptation of NeuroD1, both in the timing of its expression and regulatory function, with respect to Atoh1 in amniotes.

Title: Analyzing the role of FoxD4 in neuronal differentiation using a mouse embryonic stem cell model

Authors: *J. H. SHERMAN[1], B. KARPINSKI-OAKLEY[2], M. FRALISH[1], S. MOODY[1], A. LAMANTIA[1], T. MAYNARD[1];
[1]The George Washington Univ., Washington, DC; [2]The, Washington, DC

Abstracts: *Foxd4* is a forkhead box family transcription factor. In Xenopus embryos, *foxD4/5* serves as a master regulator of numerous neural transcription factors and plays a key role in directing embryonic stem cells towards a neural stem cell (NSC) lineage. The homologous gene in mice, *FoxD4*, is expressed in the embryonic central nervous system in a pattern similar to Xenopus. Our data indicates that this transcription factor may play similar role in promoting the development of mammalian NSCs. We used mouse embryonic stem cells (mESCs) to assess the NSC-promoting activity of Foxd4. A stable mESC line expressin a *Foxd4* targeted siRNA was used to reduce *Foxd4* expression in mESCs in a LIF/RA dependent NSC differentiation assay. Our results show clearly that this loss of *Foxd4* function diminishes the capacity of mESCs to respond to the NSC-promoting environment in the LIF/RA NSC differentiation assay. We also found that *Foxd4* knockdown does not affect mESCs pluripotency. Furthermore, FoxD4 knockdown results in decreased levels of neural differentiation markers, high levels of undifferentiated cell markers and lack of expression of mature neuronal markers. In addition, a mESC line was generated that over-expresses FoxD4 to assess the consequences of gain of function. We found that FoxD4 upregulation results in low levels of undifferentiated neuronal markers with increased expression of markers for neuronal maturation and differentiation. We also confirmed that Foxd4 (the murine gene) has similar functions to its Xenopus counterpart by injecting full length *Foxd4* into frog oocytes and assessing its effects on neural induction. As is the case for *foxD4/5*, murine Foxd4 accelerates and enhances expression of neuronal precursor and differentiation marker. Finally, localization analysis indicates that Foxd4 is expressed in the neural tube and olfactory placode epithelium at midgestation. We are currently using siRNA electroporation in an olfactory placode explant assay to assess the function of Foxd4 in developing embryonic neurogenic ectoderm. Together, our results show that Foxd4, like its Xenopus orthologue, is a key regulator of the transition from embryonic stem cell to committed neurogenic neural stem cell.

Title: Stat3 promotes motor neuron differentiation by collaborating with motor neuron-specific LIM complex

Authors: S. SEO[1], *J. C. RHEE[2], S. LEE[1], R. SHEN[3], H. CHO[3], J. LEE[3], S. LEE[3]; [1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Dept. of Pharmacol., SNU Pharm., Seoul, Korea, Republic of; [3]OHSU, Portland, OR

Abstracts: The motor neuron (MN)-hexamer complex consisting of LIM homeobox 3, Islet-1, and nuclear LIM interactor is a key determinant of motor neuron specification and differentiation. To gain insights into the transcriptional network in motor neuron development, we performed a genome-wide ChIP-sequencing analysis and found that the MN-hexamer directly regulates a wide array of motor neuron genes by binding to the HxRE (hexamer response element) shared among the target genes. Interestingly, STAT3-binding motif is highly enriched in the MN-hexamer-bound peaks in addition to the HxRE. We also found that a transcriptionally active form of STAT3 is expressed in embryonic motor neurons and that STAT3 associates with the MN-hexamer, enhancing the transcriptional activity of the MN-hexamer in an upstream signal-dependent manner. Correspondingly, STAT3 was needed for motor neuron differentiation in the developing spinal cord. Together, our studies uncover crucial gene regulatory mechanisms that couple MN-hexamer and STAT-activating extracellular signals to promote motor neuron differentiation in vertebrate spinal cord.

Title: Postmitotic dorsal spinal cord neurons are transfated into commissural neurons by induced misexpression of *Barh1*

Authors: *T. SATO[1,2], Y. MUROYAMA[3], T. SAITO[3];
[1]Dev. Neurosci. Grad. Sch. of Med. Tohoku Univ., Sendai, Japan; [2]Current Address: Dev. Neurosci., Grad. Sch. of Med., Tohoku Univ., Sendai, Japan; [3]Dept. of Dev. Biol., Grad. Sch. of Med., Chiba Univ., Chiba, Japan

Abstracts: Mammalian *Barh1* (*Mbh1*), which is a Bar-class homeobox gene, has been shown to confer commissural neuron identity on dorsal cells in the mouse embryonic spinal cord. In our previous experiments, *Mbh1* was transfected into neural stem/progenitor cells and misexpressed in both neural stem/progenitor cells and postmitotic neurons using *in vivo* electroporation and a ubiquitous CAG promoter vector. It has not been clear whether *Mbh1* functions in neural stem/progenitor cells or postmitotic neurons during the fate change into commissural neurons. We have recently established a gene induction method by combining *in vivo* electroporation with the newest version of the Tet-On system. This method enables efficient and strict induction of gene expression in targeted postmitotic neurons in the presence of doxycycline (Dox). In the absence of Dox, leaky expression occurrs only at extremely low levels. We have applied the method to the developing mouse spinal cord to determine whether postmitotic cells would be transfated into commissural neurons by *Mbh1*. After *in vivo* electroporation, postmitotic cells that were highly labeled with BrdU, six hours before the induction of *Mbh1*, became neurons positive for Dcc, which is a netrin receptor and a marker of commissural neurons in the developing spinal cord, mimicking the phenotype of *Mbh1* misexpression under the control of the CAG promoter. This finding suggests that even postmitotic neurons are transfated into commissural neurons by *Mbh1*. Title: Molecular interactions between Gsx2 and Ascl1 in lateral ganglionic eminence (LGE) progenitors of the mouse

Authors: *K. ROYCHOUDHURY, M. NAKAFUKU, B. GEBELEIN, K. CAMPBELL; Developmental Biol., Cincinnati Children's Hosp., Cincinnati, OH

Abstracts: Homeobox and basic helix loop helix (bHLH) transcription factors play critical roles in progenitor maintenance vs. differentiation in the ventricular and subventricular zones of the embryonic telencephalon. Within progenitors of the lateral ganglionic eminence (LGE), Gsx2 helps maintain progenitors in the undifferentiated state while Ascl1 plays an important role in progenitor maturation. The molecular mechanisms underlying the maturation of LGE progenitors are unknown. In this study, we report a direct protein-protein interaction between Gsx2 and Ascl1 in the embryonic mouse telencephalon. We mapped the Gsx2 binding site on Ascl1 to amino acid residues in the bHLH domain of Ascl1. This interaction appears to inhibit Ascl1's ability to bind the E-box sequence. Moreover, this interaction inhibits heterodimerization of Ascl1 with E-proteins that are critical for its transcriptional activity. We are currently, establishing an E-box-driven luciferase assay to test, *in vitro*, whether the Gsx2-Ascl1 interaction inhibits transcription of Ascl1 targets. Furthermore, we will attempt to generate a Ascl1 mutant, which is incapable of interaction with Gsx2 but can still bind the E-box to examine its impact on neurogenesis, *in vivo*. Based on our data, we propose a model whereby Gsx2-Ascl1 double expressing LGE cells are primed for neurogenesis, but do not differentiate until Gsx2 is down-regulated.

Title: Identification and characterization of the genes that play important roles for the development of motor neurons

Authors: *K. SUZUKI[1], S. LEE[2], R. SHEN[1], J. W. LEE[1], S.-K. LEE[1];
[1]Papé Family Pediatric Res. Inst, Dept of Pediatrics, Vollum Inst., Oregon Health& Sci. Univ., Portland, OR; [2]Col. of Pharm. and Res. Inst. of Pharmaceut. Sci., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstracts: Motor neurons (MNs) and V2a interneurons in the vertebrate spinal cord are critical constituents of the motor circuit that coordinates locomotion. MNs project axons to muscles and control their contraction, while V2a interneurons make connections with other neurons. The transcription factors that control generation of MNs and V2a interneurons have been relatively well studied. We have previously shown that the Isl1-Lhx3 hexamer complex consisting of Islet-1 (Isl1), LIM homeobox 3 (Lhx3), and nuclear LIM interactor directs the specification of MN cell fate in the developing spinal cord. We also found that Chx10, a V2a interneuron-specific transcription factor, suppresses expression of motor neuron genes. These findings led us to hypothesize that the key genes for establishment of MN identity are induced by the Isl1-Lhx3 hexamer complex in MNs while being repressed by Chx10 in V2a interneurons. To identify the key genes for MN development, we established two embryonic stem cell (ESC) models; Isl1-Lhx3-ESCs and Chx10-ESCs, in which the expression of Is1l-Lhx3 and Chx10 are induced by doxycycline, respectively. We then identified the genes that are induced by Isl1-Lhx3 and suppressed by Chx10 using RNA-seq in the ESC models. Combined these RNA-seq datasets with ChIP-seq datasets that define the genomic binding sites for Isl1-Lhx3, we selected 17 genes for the further analysis of their possible functions in MN development. First, we investigated expression pattern of these genes in mouse developing spinal cord using *in situ* hybridization. 7 out of 17 genes are predominantly expressed in developing spinal MNs. Second, we checked whether those genes can be induced by Isl1-Lhx3 hexamer using in ovo electroporation. The expression of 4 out of 7 genes was ectopically induced by Isl1-Lhx3 in the dorsal spinal cord. Together, our study identified downstream target genes of the Isl1-Lhx3 complex, which may play important roles in the development of MNs.

Abstracts: Healthy cognitive function relies on the balanced interaction of tens to hundreds of excitatory and inhibitory neuronal cell types as well as glial cells. The distinct physiology of each cortical cell type emerges during pre- and post-natal brain development through epigenetic, transcriptional and morphological processes that define cells' mature state. Brain cells make use of unique mechanisms of epigenetic regulation, including abundant non-CG methylation, yet the distribution of these marks across cell types is unknown. Existing methods for isolating cell populations from mammalian tissues are difficult to use for analyses of DNA and RNA in brain tissue. We therefore developed a strategy to purify fluorescently labeled nuclei of specific cell types from fresh mouse tissue by using the cre-lox system to induce expression of an epitope-tagged nuclear membrane protein in defined cell types. Our purification procedure isolates both rare and abundant target cells with high yield and purity. We used this system to purify neocortical pyramidal neurons, parvalbumin (PV)-expressing fast-spiking interneurons, and vasoactive intestinal peptide (VIP)-expressing interneurons, followed by transcriptome and whole-genome methylome profiling (RNA-Seq and MethylC-seq). Genome-wide, base-resolution DNA methylation profiles reveal global and local cell specific patterns of methylation in both the CG and non-CG contexts. We identify thousands of differentially methylated regions (DMRs) across the three cell types, and integrate these data with published methylomes from fetal and developing brain as well as astrocytes. Regions that lose CG methylation during development of a specific neuron type (CG-DMRs) are enriched in active histone marks and cell type-specific transcription factor motifs. We also identify cell type-specific patterns of non-CG methylation that co-vary with gene transcription across cortical neuron types. Overall, our analysis of cell type-specific gene expression and DNA methylation gives insight into the genes and regulatory elements that may play a role in the maturation and maintenance of distinct neuronal identities.

Title: Hedgehog and Wnt Signaling determinants of the outcome of demyelination revealed by Sox17 transgenesis

Authors: X. MING[1], *L.-J. CHEW[1], J. DUPREE[2], V. GALLO[1];
[1]Ctr. Neurosci Res., Children's Res. Inst., WASHINGTON, DC; [2]Virginia Commonwealth Univ., Richmond, VA

Abstracts: Our previous studies showed that Sox17 inhibits Wnt/beta-catenin (b-cat) signaling *in vitro* and its overexpression in CNP-Sox17 transgenic mice regulates postnatal oligodendrocyte (OL) development, ultimately preventing OL loss after focal lysolecithin (Lyso) demyelination. Our present studies investigate the effects of Sox17 on signaling pathways which attenuate myelin damage in subcortical white matter (WM) of P60 mice. Immunohistochemical analysis revealed increased bcl-2+, Gli2+, and Sonic Hedgehog+ cells, decreased FAS, and enhanced generation of new Gli2+ and Olig2+ cells in the intact CNP-Sox17 WM. These suggest that Sox17 promotes OL lineage cell survival and regeneration by inducing Hedgehog signaling. However, increased b-cat+ cells and total b-cat protein levels were also found in the adult CNPSox17 WM. The increased Gli2+ and b-cat+ cells in the CNP-Sox17 WM were both sensitive to reduction by cyclopamine-KAAD, implicating Smoothened activation by Sox17. Further focal injections of cyclopamine-KAAD in WM of BATGAL mice revealed a hierarchy which places Smoothened upstream of b-cat. Despite elevated b-cat, the levels of activated b-cat (ABC) were surprisingly not proportionately higher in the CNPSox17 WM, suggesting that Sox17 prevents changes in ABC, resulting in smaller changes in OPC maturation. This may be achieved through Axin2, which is increased in CNPSox17 WM. Focal injections of the b-cat antagonist CCT036477 (CCT) into the corpus callosum of P60 WT and CNPSox17 mice

showed, in the absence of cell death, clear reduction of ABC+ cells in both strains, but decreased total b-cat+ cells only in CNPSox17, suggesting enhanced turnover. Importantly, CCT produced significantly greater enhancement of the NG2+O4+, total O4+ cells, and reduction of NG2+O4- OPCs in WT. This also suggests that pharmacological ABC control in WT may improve OPC maturation and remyelination. Focal co-injections of CCT with Lyso in WT indeed prevented the loss of CC1+ cells, without affecting the OPC response. Interestingly, as previously observed with Lyso lesions in CNP-Sox17, CCT prevented the Lyso-induced decline in Gli2+ cells in WT. Given the role of Hedgehog in immune quiescence, it is possible that ABC control and Hedgehog signaling both regulate OL damage in CNP-Sox17. The induction by Lyso of ABC+Iba1+ microglia and ABC+Caspase3+ apoptotic cells was found to be significantly lower in CNPSox17 mice, and Gli inhibition with GANT61 in these mice abolished protection against Lyso damage. Our findings indicate that Sox17 regulates both b-cat and Hedgehog signaling in the adult WM, and the outcome of WM injury is modulated by crosstalk between these pathways.

Title: Interactions of sox10 with tgf-b signaling in schwann cells

Authors: *J. RODRIGUEZ-MOLINA[1], J. MORAN[2], J. SVAREN[3];
[1]Cell. and Mol. Pathology, [2]Waisman center, [3]Comparative Biosci., Univ. of Wisconsin, Madison, WI

Abstracts: Schwann cell development is regulated by integration of intrinsic gene expression programs and external cues that affect Schwann cell proliferation and differentiation. One regulator of Schwann cell development is TGF beta signaling, which controls proliferation and apoptosis of embryonic Schwann cells, and Schwann cells themselves can also synthesize TGFbeta molecules. However, as Schwann cells mature, they become less responsive to TGF beta signaling. Sox10, an SRY-related HMG-box transcription factor, is crucial for embryonic

development and ultimate differentiation of Schwann cells. While Sox10 has been shown to activate a number of molecules in Schwann cell development, we explored the possibility that Sox10 may also directly repress certain genes. Microarray analysis of Schwann Cells treated with an siRNA targeting Sox10 identified several genes that become induced. The induced genes were analyzed and found that several of the Sox10-repressed genes are involved in the TGF-B pathway. Reduction of Sox10 also lead to induction of a Smad 2/3-responsive (SBE) reporter plasmid, and activation of the reporter plasmid by TGFb1 is amplified when Sox10 is ablated. Furthermore qRT-PCR studies showed TGF-B target genes induced by Sox10 downregulation and this induction was further augmented under TGF-B ligand treatment. Together, these data suggest that Sox10 represses the TGF-B pathway in SCs. However, Sox10 ChIP-Seq data did not show any binding sites for Sox10 around TGFbeta target genes, suggesting that Sox10 do not repress TGFbeta components directly. Overall, these results suggest that Sox10 inhibits TGFbeta pathway activation in Schwann cells, although the mechanism by which Sox10 represses the pathway is not yet known.

Abstracts: Previous and ongoing studies demonstrate that a majority of preterm birth patients display significant neurological deficits. A primary etiology of these deficits involves desaturated or reduced cerebral blood flow, resulting in restricted oxygen supply. Since glial cells are sensitive to hypoxic environments, white matter injury represents a major cause underlying

neurological deficits in preterm patients. The subventricular zone (SVZ) generates neural stem/progenitor cells (NSPCs) that replenish damaged glia in the brain via endogenous gliogenesis throughout the human lifespan. Because the SVZ is highly vascularized, and a majority of SVZ NSPCs are in direct contact with blood vessels, hypoxia-induced, pathological alterations in gliogenesis from subventricular zone (SVZ)-derived NPSCs represent crucial cellular/molecular mechanisms underlying neurological impairments in preterm births. The porcine brain, including the SVZ, shares significant anatomical/structural similarities to its human counterpart. Here, our preliminary data show that chronic hypoxia induces a significant boost in proliferating Olig2+ cells in the SVZ of perinatal piglets. Additionally, we see an increase in gliogenesis in the periventricular white matter underlying the frontal cortex. Taken together, these findings suggest that hypoxia induces gliogenesis in order to repopulate damaged white matter.

Title: Alpha-synuclein expression in rodent and human pluripotent stem cell-derived oligodendrocytes: Implications for Multiple system atrophy

Authors: *M. DJELLOUL[1], C. VIGNON[1], K. FOG[2], L. ROYBON[1];
[1]EMV, Lund Univ., Lund, Sweden; [2]H. Lundbeck A/S, Neurodegeneration-1, Copenhagen,, Denmark

Abstracts: Multiple system atrophy (MSA) is an adult-onset, rapidly progressing, fatal neurodegenerative disease of unknown etiology. The disease involves a combination of atypical Parkinsonism, cerebellar ataxia, and pyramidal dysfunction, and at later stage autonomic failure. MSA is classified as a synucleinopathy. The hallmark of the disease is the presence of alpha-synuclein (α-syn)-rich glial cytoplasmic inclusions (GCIs) in the oligodendrocytes. α-syn is an intracellular protein predominantly synthesized in neurons of the central nervous system. Adult mature oligodendrocytes do not express α-syn and studies performed using postmortem tissue from MSA patient failed to significantly show increased abundance of α-syn mRNA in GCIs-containing oligodendrocytes. Thus, the source of α-syn present in the GCIs is still of debate. One possibility that could explain the presence of α-syn in the GCIs relies on transfer of α-syn from the extracellular environment into the oligodendrocytes. Another relies on a maintained or de novo expression of the SNCA gene encoding for α-syn in oligodendrocytes. Whether oligodendrocytes express SNCA remained to be determined. Here, we generated rodent and human pluripotent stem cells, which we differentiate into oligodendrocytes and assessed SNCA expression in these cells. We first defined the temporal expression of oligodendrocytes markers NKX2.2, OLIG2, SOX10, PDGFR-α, CNPase and O4; we could then determine that a significant proportion of oligodendrocyte progenitors defined by the expression of O4 and SOX10 stained positively for α-syn. This novel finding will be of high interest to those studying the origin of α-syn in GCIs, and open new research avenues using patient-derived pluripotent stem cells for assessing the consequences and functional role of α-syn in oligodendrocytes under physiological and pathological conditions.

Title: Non-synaptic junctions on myelinating glia promote preferential myelination of electrically-active axons

Authors: *R. D. FIELDS[1], H. WAKE[2], F. C. ORTIZ[3], P. R. LEE[4], M. C. ANGULO[3]; [1]NICHD, NIH, BETHESDA, MD; [2]National. Inst. Basic Biol., NINS, Japan, Japan; [3]INSERM, Paris, France; [4]NICHD, Bethesda, MD

Abstracts: The myelin sheath on vertebrate axons is critical for neural impulse transmission, but whether electrically active axons are preferentially myelinated by glial cells, and if so, how, are long-standing questions of significance to nervous system development, plasticity, and disease. The surprising discovery of synapses formed on glial progenitors, oligodendrocyte progenitor cells (OPCs, also called NG2 cells) has remained enigmatic for over a decade, but it has been hypothesized that these synapses could promote myelination of electrically active. We find that oligodendrocytes do preferentially myelinate electrically active axons, but synapses from axons onto myelin-forming oligodendroglial cells are not required. Instead, vesicular release at non-synaptic axo-glial junctions induces myelination. These non-synaptic functional junctions induce a local rise in cytoplasmic calcium in glial cell processes in contact with active axons and this signaling stimulates local translation of myelin basic protein to initiate myelination of axons releasing neurotransmitter from vesicles. Preferential myelin induction on electrically active axons would have profound effects on circuit function by the resulting increased conduction velocity, and thus provide another mechanism of plasticity complementing synaptic plasticity.

Title: Function of CD44 in NG2 progenitor cell differentiation and the potential of CD44 as the therapeutic target for multiple sclerosis

Authors: *T. UEKI[1], S. IDE[1], M. MURANO[1], K. SHIBASAKI[1], S. MORIKAWA[1], Y. OUCHI[2];
[1]Dept. of Anat. and Neurosci., [2]Photon Med. Res. Ctr., Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan

Abstracts: Recent investigation has revealed that glial cell lineage is not simply classified into three types of cells, astrocyte, oligodendrocyte and microglia, as classically described, but another new population, NG2 cell, should be taken into consideration as a member of glial family. Among functions of NG2 cells shown by previous physiological studies, modification of synaptic transmission, generation of new neuron and oligodendrocyte to repair the injured CNS, and regulation neural functions via neuron-NG2 cell synapse are included, but molecular machinery underlying various functions of NG2 cell is still to be solved. Interestingly, prominent evidence demonstrated the high expression level of CD44 in NG2 cell. CD44 is a membrane protein, which is cleaved by γ-secretase related to the etiology of Alzheimer's disease. Because the involvement of CD44 in NG2 cell's function has not been appreciated well yet, the present study investigated how CD44 works to accomplish multiple roles of NG2 cell in the CNS by newly developing molecular imaging system on the basis of FRET technology, where functional fluorescent probe switches on and emits fluorescence upon the shedding of membranous CD44 by activated γ-secretase. Utilizing the newly developed imaging method, the generation of intracellular fragment of CD44 could be visualized under fluorescent microscope, and the present results demonstrated that the activation of γ-seceretase induced astrocytic differentiation of NG2 cell, whereas the inhibition of γ-secretase arrested NG2 cells in immature status. These data propose the possibility that membranous CD44 of NG2 cell should be therapeutic target to treat demyelinated disorders such as multiple sclerosis, in which immature NG2 cells are accumulated in the affected brain. Further investigations are required to identify the transcriptional target of the intracellular domain of CD44 in NG2 cell, and also to appreciate the precise implication of γ-secretase in glial development and interaction with neuron.

Title: Identification and characterization of novel intronic enhancer elements of the mouse Cspg4 gene in oligodendrocyte lineage cells

Authors: *H. GOTOH[1,2], T. NOMURA[1], K. ONO[1], A. NISHIYAMA[2];
[1]Dept. of Biol., Kyoto Prefectural Univ. of Med., Kyoto, Japan; [2]Dept. of Physiol. and Neurobio., Univ. of Connecticut, Storrs, CT

Abstracts: NG2 cells are proliferating oligodendrocyte precursor cells and are characterized by the expression of NG2 encoded by the Cspg4 gene. NG2 is an integral membrane protein that regulates proliferation and differentiation of NG2 cells and is downregulated as they undergo terminal differentiation. However, the cis-regulating elements and trans-activating factors that are critical for the regulation of Cspg4 transcription in NG2 cells have remained unknown. In order to identify the regulatory sequences of Cspg4, we screened the promoter and enhancer sequences of the C57BL/6 mouse Cspg4 contained in the bacterial artificial chromosome plasmid that had been reported to recapitulate endogenous NG2 expression. When we tested a 1.5-kb promoter sequence, it directed transcription in neurons and astrocytes but not in NG2 cells when tested on primary cultures from neonatal mouse brains. Additional screening identified a novel 1.4-kb enhancer region in the first intron of the Cspg4 gene. We next established a transgenic mouse line that expressed enhanced green fluorescent protein (GFP) under the regulation of the intronic enhancer. Interestingly, GFP signals were observed in oligodendrocyte lineage cells, with strong expression in NG2 cells and weaker expression in oligodendrocytes but not in astrocytes or neurons. Interestingly, GFP was not detected in vascular pericytes that also express NG2 protein in the CNS. This observation suggests that Cspg4 transcription in NG2 cells is differentially regulated from that in pericytes. Furthermore, luciferase assays were used to test the effects of key oligodendrocyte transcription factors on the activity of the Cspg4 enhancer. We found that Sox9, Sox10, Olig2, and Mash1 positively regulated the activity of the Cspg4 enhancer. In addition, we found that Sox family transcription factors and bHLH transcription factors cooperated on the intronic enhancer to upregulate the activity. These findings provide novel insight into glial cell-specific transcription of Cspg4 as well as provide a useful tool for targeting genes specifically to oligodendrocyte lineage cells.

Title: Role of myosin light-chain kinase in schwann cell cytoskeletal organization, differentiation, and myelination

Authors: *T. TOSEEF, C. V. MELENDEZ-VASQUEZ;
Hunter College, CUNY, New York, NY

Abstracts: Myelination in the peripheral nervous system is carried out by Schwann cells (SC), which surround all axons. Non-muscle myosin II (NMII), an actin-binding motor protein, is a key regulator of cytoskeleton dynamics necessary for interactions between SC and axons that lead to normal myelination. NMII activity is regulated by the phosphorylation of its regulatory light chain (MLC). Previous data suggests that one of the kinases that phosphorylates MLC, myosin light chain kinase (MLCK) may be involved in pathways that are activated by axonal signals at the onset of myelination. The purpose of this work is to identify proteins that may regulate the activity of MLCK in SC during myelin formation and repair. Firstly, using co-immunoprecipitation of MLCK from primary SC line, we will identify other proteins that are regulating the activity of MLCK. Secondly, we will characterize changes in MLCK expression after a peripheral nerve injury and evaluate the role of MLCK and its binding partners in promoting myelin repair and remyelination. The results from this work will provide insight into mechanisms that SC use to differentiate during development and dedifferentiation after injury, which is a prerequisite for successful nerve repair.

Title: A critical role of tuberous sclerosis complex-1 (tsc1) for myelination in the cns

Authors: *M. JIANG[1], L. LIU[2], X. HE[1], Q. R. LU[1];
[1]Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [2]West China Med. Univ. of Sichuan Univ., Chengdu, China

Abstracts: Oligodendrocyte development and myelination is a highly regulated process controlled by intrinsic and extrinsic signaling. Tuberous Sclerosis Complex-1 (TSC1) is an upstream negative regulator of mTOR, the mammalian target of rapamycin complex (mTOR) that is a master regulator of cell growth and proliferation. Tsc1 deficiency can lead to mTOR hyperactivation. Previous studies have shown that mTOR deficiency causes a defect in myelination. In this study we assessed the function of activated mTOR in myelination by deleting Tsc1 in oligodendrocyte lineage. We hypothesize that the increase of mTOR signaling would promote oligodendrocyte precursor differentiation. To our surprise, ablation of TSC1 in oligodendrocyte progenitors causes a severe defect in oligodendrocyte differentiation and myelination. Intriguingly, the number of oligodendrocyte precursor cells (OPC) is reduced in the TSC1 mutant brain. Our data suggest that TSC1 deficiency causes an increase of oligodendrocyte cell death *in vivo* and *in vitro*. Gene expression profiling analysis of the control and TSC mutants reveals a decrease of myelination-related genes and a concomitant increase of death-inducing signaling complex. Moreover, deletion of TSC1 in post-mitotic oligodendrocyte lineage cells impairs oligodendrocyte myelination but not OPC expansion. Our results demonstrate a stage specific function of TSC1 in regulation of oligodendrocyte lineage progression and myelination, and indicate that balancing of mTOR activity is critical for proper development of oligodendrocyte and myelination.

Title: Juxtacrine signalling via Notch and ErbB receptors in the switch to fate commitment of bone marrow-derived Schwann cells

Authors: *D. K.-Y. SHUM[1], E. W. Y. TAI[2], G. K. H. SHEA[1], A. Y. P. TSUI[1], K. H. Y. LEUNG[1], Y. S. CHAN[2];
[1]Dept. of Biochem., [2]Dept. of Physiol., Fac Med, The Univ. of Hong Kong, Hong Kong, China

Abstracts: Our strategy of deriving Schwann cells from bone marrow stromal cells exploits purified dorsal root ganglia (DRG) neurons to provide Schwann cell-like cells (SCLCs) with juxtacrine signals that mediate commitment to the Schwann cell fate. In search for the signals, we found both Notch ligands and neuregulin-1 type III localized on the surface of DRG neurons. Immunopositivity for cell surface Notch-1 receptor was detectable on bone marrow-derived SCLCs but the ErbB2/3 heterodimeric receptors of neuregulin-1 were barely detectable. In co-cultures, the Notch ligands on DRG neurons triggered nuclear translocation of Notch intracellular domain (NICD), corresponding increase in ErbB2/3 expression in the SCLCs and attainment of the Schwann cell fate. Treatment of co-cltures with DAPT or a DLL-1 blocking peptide to perturb Notch signaling deterred not only the increase in ErbB2/B3 expression in SCLCs but also the progress of SCLCs to the Schwann cell fate. We conclude that juxtacrine signalling via Notch plays a key role in the upregulation of ErbB receptors for neuregulin-driven commitment of SCLCs to the Schwann cell fate.

Title: Optogenetic modulation of endogenous adenylate cyclase level in cultured schwann cells

Authors: *X. FENG, W. XIE, Z. WANG, Z. ZHOU, Y. ZHOU, Y. QIU, L. WANG;
Shenzhen Inst. of Advanced Technol., Guang Dong, China

Abstracts: Recently, optogenetics has brought innovative insight into neuroscience. A photoactivated adenylyl cyclase (bPAC) was combined as a kind of light driven enzyme with high cyclic adenosine monophosphate (cAMP) synthesis ability. In Schwann cells (SCs), cAMP

plays an essential role to initiate myelination and deeply involves both in proliferation and differentiation. Forskolin administration into cultured SCs can increase the cAMP level and induce myelination in SC/neuron co-culture system. In order to avoid nonselective effect of this traditional method, we delivered photoactivated bPAC gene by lentiviral vector with MBP promoter into SCs and 455nm blue light was used to trigger the transfected cells. It was proposed the transfected SCs would started the myelination procedure after light stimuli. As expected, 2-min light pulse light stimuli indeed induced a giant 500-fold increase of intracellular cAMP level; and the extent of cAMP rise had significant time-dependent trend. However surprisingly, single 2-min light pulse stimuli failed to upregulate the expression of mRNA or proteins associated with myelination such as P0, Krox-20, MBP, MAG, or downregulate of non-myelinating SC phenotype. We also tried to extend light stimuli to once a day for 5 days. Our results showed long time light stimuli couldn't induce myelination-like morphological change similar to previous single stimuli. Moreover, we found after single 30-min light flash, SCs gradually presented a form similar to apoptosis. Our studies indicated that light stimuli triggered time-dependent cAMP remarkable elevation in SCs resulted in apoptosis tendency rather than inducing proliferation or differentiation. It is suggested that a steady and appropriate cAMP level is essential for cellular functional modulation in SCs.

Title: Nanofiber-mediated microRNA delivery for enhanced oligodendrocyte differentiation

Authors: *S. CHEW[1], H. DIAO[1], W. LOW[2], U. MILBRETA[3], R. Q. LU[4];
[2]Ch, [3]Chem. & Biomed. Engin., [1]Nanyang Technological Univ., Singapore, Singapore; [4]Dept. of Pediatri, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstracts: MicroRNAs, miR-219 and miR-338, regulate oligodendrocyte differentiation and myelination. Independently, recent studies have also demonstrated the ability of fiber constructs to modulate oligodendocyte myelination. Therefore, nanofiber-mediated delivery of miR-219 and/or miR-338 may have promising applications in treating traumatic central nervous system injuries by controlling oligodendrocyte behavior. In this study, electrospun, aligned poly-ε-caprolactone (PCL) nanofibers of three different average fiber diameters (300nm, 700nm & 2.0 um) were modified with DOPA-melanin coating and adsorbed with miRNAs/ TransIT-TKO® (miRNA/TKO) complexes to evaluate the synergistic effects of fiber diameter, miR-219, and miR-338 on the differentiation and maturation of seeded oligodendrocyte progenitor cells (OPCs). Randomly-oriented 2.0 um fibers were also included to study the fiber orientation effect on OPCs behavior. The loading efficiency of miRNA/TKO complexes was more than 86% for all scaffolds. Four days post-transfection, miR-219 treatment alone or in combination with miR-338 (denoted as 'miR-219+338') successfully silenced the negative regulators of oligodendrocyte differentiation (Sox6, FOXJ3, ZFP238 and PDGFR-alpha) on 300 nm aligned fibers. A higher proportion of MBP^+ (mature marker) and RIP^+ (intermediate marker) oligodendrocytes were observed with miR-219 and miR-338 treatment. Enhanced OPC maturation was also observed with larger fiber diameter (2 um >700 nm>300 nm). On 300 nm and 700 nm fibers, the effects of miR-219 and miR-219+338 treatment were more prominent, inducing significant OPCs differentiation to MBP^+ oligodendrocytes as compared to negative microRNA controls (miR-NEG) ($p=0.037$, ANOVA). Altogether, nanofiber-mediated microRNAs delivery enhanced OPCs differentiation to oligodendrocytes. Such constructs may serve as potential platforms for controlling OPC differentiation through synergistic topographical and biochemical signaling.

Title: Sox17 affects oligodendroglial cell lineage progression

Authors: M. FAUVEAU, B. WILMET, C. KERNINON, C. DEBOUX, *B. NAIT-OUMESMAR;
ICM, Inserm-Upmc UMRS-1127, CNRS UMR 7225, Paris, France

Abstracts: In the central nervous system (CNS), myelination is a crucial process, timely regulated by oligodendroglial cell lineage progression. During development, the transition from proliferative/migrating oligodendrocyte precursor cells (OPCs) stage towards myelinating oligodendrocytes occurs through OPC cell cycle exit and differentiation. SOX transcription factors are key regulators of oligodendroglial cell proliferation and differentiation. Among them, SOX17 (subgroup F) was recently identified as a new regulator of oligodendrocyte development. In the developing CNS, SOX17 expression is detected in oligodendroglial cells and is highest in differentiating oligodendrocytes. Furthermore, in primary OPC cultures, SOX17 expression peaks at the pre-myelinating stage, correlating with the transition between OPC proliferation and differentiation. These findings suggest that SOX17 may play critical functions in OPC cycle exit and differentiation. To investigate the functional role of SOX17 *in vivo*, we generated a transgenic mouse model overexpressing SOX17 and the EGFP reporter in SOX10+ oligodendroglial cells, in a doxycycline (DOX) inducible manner (Tet-ON system). To trigger SOX17 overexpression in all oligodendroglial subpopulations, DOX treatment was initiated from embryonic day 12.5 (E12.5) to post-natal day 15 (P15). In DOX-treated transgenic mice, SOX17 gain-of-function was specifically detected in OLIG2+ cells, PDGFRα+ OPCs and CC1+ oligodendrocytes. Interestingly, we found that SOX17 overexpression enhanced OPC proliferation and decreased the proportion of CC1+ differentiated oligodendrocytes. Nevertheless, the pool of OLIG2+ and TUNEL+ apoptotic cells were not significantly modified in SOX17 transgenic mice compared to controls. MBP immunohistochemistry and electron microscopy analysis revealed a severe defect of myelination in SOX17 transgenic mouse spinal cord. At later developmental stages, the differentiation impairment was compensated. However, according to g-ratio analysis, myelin sheaths remained thinner in SOX17-overexpressing mice. Altogether, our data reveal critical functions of SOX17 in OPC maintenance and lineage progression.

Abstracts: The role of Wnt effector TCF7l2 in controlling postnatal oligodendrocyte (OL) development is unknown, though prior important studies suggest that TCF7l2 negatively regulates OL differentiation through TCF7l2-mediated Wnt activity in oligodendroglial progenitor cells (OPCs). However, no genetic data have been reported thus far to support this hypothesis. Our prior study reports that APC ablation leads to fewer differentiated oligodendrocytes (OLs), aberrant activation of Wnt signaling and down-regulation of TCF7l2, the two latter of which are seemingly conflict each other. Here we found that APC disruption stalled OPCs in a population of NG2-/PDGFRa+/Ki67- status where another member of Wnt effectors LEF1 was significantly induced to subsequently mediate the aberrant activation of Wnt signaling we have observed. These data have three novel implications of TCF7l2 biology we proposed here: (1) TCF7l2 is upregulated normally in differentiated OLs but not OPCs - thus its' reduction reflecting fewer differentiated OLs in APC-KO; (2) TCF7l2 promotes rather than inhibits postnatal OL differentiation - its' conditional ablation leading to significant fewer OLs; (3) TCF7l2's role of OL differentiation is independent of Wnt activation - disruption of TCF7l2 not altering Wnt signaling activity. Using immunohistochemistry and mRNA *in situ* hybridization, we demonstrated that TCF7l2 was exclusively expressed in post-mitotic Mbp and Cnp-mRNA and protein-expressing, newly differentiated OLs in the central nervous system except for neurons in forebrain thalamus. Using Wnt reporter mice BAT-lacZ, we showed that the expression and upregulation of TCF7l2 in OLs were not correlated with the activation of Wnt/b-catenin signaling. Using an inducible Cre-loxP system, we found that TCF7l2 ablation in oligodendroglial lineage cells inhibited OL differentiation, without affecting the OPC proliferation and apoptosis. We also found that TCF7l2 was induced in post-mitotic newly differentiated OLs after myelin damage in the cuprizone-elicited demyelinative/remyelinative

model and in the autoimmune-induced myelin oligodendrocyte glycoprotein (MOG35-55)-peptide EAE model. Genetic ablation of TCF7l2 in oligodendroglial lineage cells inhibited OL differentiation and timing remyelination in cuprizone model. Furthermore, the induction of TCF7l2 in oligodendroglial lineage cells was not associated with the activation of Wnt/b-catenin signaling after myelin damage. Collectively, our study suggests that TCF7l2 is a positive regulator for OL differentiation, promoting OL differentiation independent of Wnt/b-catenin signaling.

Title: Oligodendrocyte dynamics in the adult brain

Authors: *E. G. HUGHES, D. E. BERGLES;
Dept. of Neurosci., Johns Hopkins Sch. of Med., Baltimore, MD

Abstracts: Oligodendrocytes facilitate rapid communication between neurons by accelerating the propagation of action potentials, reducing the energetic cost of information transfer, and providing metabolic support to axons. Although the majority of myelination occurs during young adulthood, oligodendrocyte precursor cells (OPCs) continue to generate oligodendrocytes in the adult brain, raising the possibility that myelination is a dynamic process that can be modified by experience. However, it is not known whether oligodendrogenesis in the adult brain represents *de novo* production of new oligodendrocytes or oligodendrocyte replacement due to natural turnover. It is also unclear whether these new cells fill gaps along myelinated axons (e.g. internode replacement or addition) or myelinate previously unmyelinated axons. To study oligodendrogenesis and myelination in the adult CNS, we performed *in vivo* two-photon time-lapse imaging in the somatosensory cortex of transgenic mice in which EGFP is expressed

specifically in mature oligodendrocytes (*MOBP-EGFP* mice). Histological analysis revealed that EGFP is expressed by nearly all myelinating oligodendrocytes in the CNS of *MOBP-EGFP* mice, allowing visualization of cell somata and internode processes *in vivo*. To determine the extent of oligodendrocyte generation and the stability of internode segments, we repeatedly imaged oligodendrocytes through a cranial window for up to two months in mice > 5 months-old. Our studies indicate that the majority of oligodendrocytes are stable, with the small number of oligodendrocytes formed in cortical gray matter adding to the total population. Although most oligodendrocyte internode segments were also stable, some increased in length while others retracted, indicating that myelin segments along some axons are remodeled. These results suggest that adult oligodendrogenesis represents *de novo* myelination rather than a response to oligodendrocyte turnover and that the myelination state of axons is not fixed. To monitor differentiation of OPCs *in vivo*, we generated triple transgenic mice (*Olig2-CreER*; *R26-lsl-tdTomato*; *NG2-mEGFP*) in which membrane-anchored EGFP is expressed by OPCs, and all stages of the oligodendrocyte lineage express tdTomato. Fate tracing studies in these mice revealed that the majority of OPCs that differentiated died in the premyelinating stage, with only a small proportion maturing into myelinating oligodendrocytes. This ongoing cycle of OPC differentiation, death and replacement in the adult CNS, may facilitate rapid regeneration of oligodendrocytes following demyelination and help alter the pattern of myelination with life experience.

Title: Terminal Schwann cells sense the spillover of ACh at the neuromuscular junction by muscarinic and α7 nicotinic receptors

Authors: *E. KREJCI[1], E. GIRARD[2], C. COLASANTE[3], V. BERNARD[4], N. LENIZ[5], D. SAMIGULLIN[5], J. LEROY[1], B. PLAUD[1], E. NIKOLSKY[6], K. PETROV[6];
[1]COGNAC G, UMR 8257 CNRS, Paris, France; [2]CNRS UMR 5239/ENS, Lyon, France; [3]Fac. of Medicine, Univ. of "Los Andes", Merida, Venezuela, Bolivarian Republic of; [4]Neurosci. Paris Seine, Univ. Pierre et Marie Curie, Paris, France; [5]Kazan Inst. of Biochem. and Biophysics, Kazan, Russian Federation; [6]Arbuzov Inst. of Organic and Physical Chem., Kazan, Russian Federation

Abstracts: The terminal Schwann cells (TSC) sense the synaptic activity but it remains unclear how. Acetylcholine (ACh) is one of the signal at the mammalian neuromuscular junction (NMJ). The action of ACh is well controlled by acetylcholinesterase (AChE) that is clustered by ColQ in the basal lamina that runs between the nerve terminal and the muscle fiber. AChE prevents the repetitive binding of ACh on the muscle nicotinic receptors (nAChR). In addition to AChE, butyrylcholinesterase (BChE) is also abundant at the NMJ. In contrast to AChE, BChE is specifically anchored at the surface of the TSC by the small protein PRiMA, the transmembrane protein anchor of brain AChE. We indeed found by using a specific monoclonal antibody against mouse BChE that BChE is localized at the surface of the TSC in wild type NMJ but retained inside the TSC in PRiMA KO mice. Inhibition of BChE did not change directly the activation of the muscle nAChR but depressed significantly the release of ACh. This depression was unchanged after treatment with 1μM atropine to block the all muscarinic ACh receptors (mAChR) or in β2 or β4nAChR KO mice but was prevented in α7 nAChR KO mice or after treatment with MLA (a specific blocker of α7 nAChR). We have then used antibodies against α7 nAChR to localize the receptor and we observed a weak labelling at the TSC in WT but not in α7 nAChR KO mice. Moreover, we found pattern of nerve stimulations that triggered calcium waves in the TSC that were abolished after MLA treatment. On the other hand, different experiments have shown that the activation of mAChR may also trigger calcium waves in the TSC, supporting the presence of mAChR at the surface of the TSCs. The presence of α7 nAChR on the surface of TSC together with mAChR challenges the unifying hypothesis that slowly desensitizing high-affinity receptors determines both the selectivity and the sensitivity of glial activation. We also established that BChE controls the spillover of ACh even when AChE is active supporting a specific role of BChE.

Title: Differential regulation of non-myelinating & immature gene expression profiles in schwann cells from Cx32-null mice

Authors: *M. M. FREIDIN[1], C. K. ABRAMS[2];
[1]Dept Neurosci., Albert Einstein Col. of Med., Bronx, NY; [2]Neurol., SUNY Downstate, Brooklyn, NY

Abstracts: Connexin32 (Cx32) is found in the non-compact myelin of the paranodes and Schmidt-Lanterman incisures in myelinated peripheral nerve. Myelinating Schwann cells (SCs) express Cx32 in coordination with other myelin genes in mature and developing peripheral nerves. Recent studies have demonstrated that Cx32 is also regulated in non-myelinating SCs during development and in regenerating peripheral nerve following injury. Myelinating and non-myelinating SCs represent the terminal step of SC differentiation *in vivo*. The present studies use real time PCR expression profiling to determine whether disruption of Cx32 influences SC expression of genes identified with non-myelinating and de-differentiating phenotypes in proliferating and regenerating SCs from Wild Type (WT) and Cx32-null (32KO) mice. Based on analysis of a large microarray data set comparing uninjured and injured sciatic nerves from WT and 32KO mice at 5, 7, and 14 days post crush, a panel of genes associated with mature myelinating and de-differentiated immature SCs were used to screen cultured SCs and samples from uninjured and axotomized sciatic nerves from WT and 32KO mice. Levels of p75NGFR, a marker for non-myelinating and immature SCs, were increased in uninjured nerves and cultured SCs from 32KO mice. Other key regulators of myelin gene expression were significantly altered in 32KO SCs; suggesting that loss of functional Cx32 leads to expression of genes associated with immature and injured SCs and dysregulation of pathways required for the maintenance of normal peripheral nerves and re-differentiation to mature myelinating phenotypes in regenerating nerves following injury.

Title: Unravelling the PLPnull phenotype: Identification of SIRT2 targets in oligodendrocytes

Authors: K. KUSCH, O. JAHN, I. TZVETANOVA, H. B. WERNER, J. M. EDGAR, B. KASAPOGLU, *K. .-A. NAVE;
Neurogenetics, Max-Planck-Institute of Exptl. Med., Goettingen, Germany

Abstracts: Absence of the NAD+ dependent protein deacetylase, sirtuin 2 (SIRT2), in the myelin fraction was the most prominent finding in analysis of the proteolipid protein (Plp1) knock out mouse, a model for spastic paraplegia type 2 (Werner et al. 2007). In order to investigate the pathology in this model, we focus on functions of SIRT2. While deletion of Sirt2 leads to no pathological phenotype, SIRT2 deficiency in the context of a Cnp knockout results in axonal swellings, neuroinflammation and premature death. The role of SIRT2 as an oligodendroglial disease modifier is supported by an oligodendrocyte specific conditional Sirt2xCnp double knockout, mimicking the phenotype of the full double knockout. For SIRT2 target protein identification, we performed a proteomic screen comparing cytosolic CNS protein fractions derived from SIRT2null or WT mice, with respect to alteration in protein net charge. A verification by IEF-immunoblot proved SIRT2 dependent PTM changes in carbonic anhydrase 2 (CA2) and glucose-6-phosphate-isomerase (G6PI). Acetylation sites of CA2 were identified using Ion Mobility-Enhanced Mass spectrometry. Acetylated lysine residues might interfere with protein interaction of CA2 and monocarboxylate transporter 1 (MCT1) (Klier et al. 2014) in oligodendrocytes and thereby efficient axonal metabolic support with lactate.

Title: Tubulin post-translational modifications in Schwann cells

Authors: *S. D. GADAU[1,2], S. SECHI[2], R. COCCO[2], A. MURA[2];
[2]Dept. of Vet. Med., [1]Univ. of Sassari, Sassari, Italy

Abstracts: Microtubules (MTs), are heterodimers of α- and β-tubulin, generally involved in different cellular processes including mitosis, cell motility, intracellular transport, cell shape and polarization. In most eukaryotes tubulins, especially the α, are subjected to several post-translational modifications (PTMs) which include acetylation, tyrosination, detyrosination, Δ2 modification, polyglutamylation, that characterize different type of MTs and regulate the interactions between MTs and certain MAPs or motor proteins. Unlike neurons, in which presence and distributions of tubulin PTMs are most studied, in other neural cells little is known about the different tubulin PTMs amount, distribution and their functional role. So that, the purpose of the present work was to deepen the knowledge about the diverse tubulin PTMs in a commonly used immortalized Schwann cell line. Undifferentiated RT4-D6P2T rat schwannoma cells were cultured in standard conditions for 48 hours. Prior to reach complete confluence, cells were or fixed or collected and homogenized for underwent to immunofluorescence staining and Western blot procedures respectively. Our results, displayed some original data. Both Western blot analysis and immunofluorescence staining revealed significant levels of polyglutamylated and Δ2-modification α-tubulins, usually considered mainly expressed in neurons. In addition we found differences in amount and distribution of tubulin PTMs in Schwann cells. In details, Western blot analysis showed a higher amount of polyglutamylated and tyrosinated α-tubulin, whereas acetylated, Δ2 and detyrosinated α-tubulin were less expressed, in comparison with total α-tubulin. Immunofluorescence staining, highlighted the distribution of acetylated and detyrosinated α-tubulin along the Schwann cells prolongations, showing a pattern similar with neurons, were the detyrosinated and acetylated isoforms are usually most detectable in axons and dendrites. In contrast, polyglutamylated α-tubulin was more detectable close to the cell body of Schwann cells, whereas the Δ2-modification was mainly distributed round the nuclear profile, forming a characteristic and complete ring. The tyrosinated α-tubulin isoform, appeared uniformly distributed both in the cytoplasmic processes and to the cell body. Summing up, our investigation offers insight on several tubulin PTMs amount and distribution in Schwann cells. This could be a further contribution to better understand both the role played by different MTs in myelination processes and the possible microtubular involvment in the pathogenesis of certain Schwann cells disorders.

Title: Loss of Pals1 in Schwann cells leads to radial sorting defects

Authors: *D. R. ZOLLINGER[1], K.-J. CHANG[2], T. BAUER[1], K. BAALMAN[1], S. KIM[3], M. N. RASBAND[1];
[1]Neurosci., [2]Program in Developmental Biol., Baylor Col. of Med., Houston, TX; [3]Dept. of Anat. and Cell Biol., Temple Univ. Sch. of Med., Philadelphia, PA

Abstracts: Schwann cells in the peripheral nervous system (PNS) and oligodendrocytes in the central nervous system (CNS) surround axons with myelin to enable rapid and reliable action potential propagation by sequestering sodium channels at nodes of Ranvier. The developmental mechanisms regulating myelin formation and the radial sorting of axons in the PNS are only partially understood. Recently, highly conserved polarity proteins have been implicated in myelination and radial sorting. One polarity protein, Protein Associated with Lin7 (Pals1), which localizes to paranodes, Schmidt-Lanterman incisures, and the adaxonal domain in Schwann cells, has been proposed to regulate myelin thickness, length, and ultrastructure. To determine whether Pals1 is important in myelination, we generated conditional knockout (cKO) mice lacking Pals1 in Schwann cells and oligodendrocytes using the Cre-lox recombinase system under the control of the 2′,3′-cyclic nucleotide phosphodiesterase (CNP) promoter. As adults, CNP-Cre;Pals1 cKO mice demonstrate hind limb clasping and impaired motor coordination. Axons in the CNS and PNS of adult cKO mice are myelinated. Mature Schwann cells exhibit normal length and thickness and subcellular domains are present. However, some axon bundles in the sciatic nerve are aberrantly myelinated. Developmental analysis reveals a significant delay in PNS myelin formation up to postnatal day 21. Furthermore, transmission electron microscopy reveals that radial sorting of axons by non-myelinating Schwann cells is perturbed up to postnatal day 21. In contrast, CNS myelination is normal throughout development, suggesting divergent polarity mechanisms between Schwann cells and oligodendrocytes.

Title: Ablation of NG2 glial cells induced neuronal cell death in the hippocampus through apoptotic pathway

Authors: *M. NAKANO[1,2], Y. TAMURA[1], A. EGUCHI[1], M. YAMATO[1], S. KUME[1], Y. MIYASHIGE[1], Y. KATAOKA[1,2];
[1]RIKEN Ctr. for Life Sci. Technologies, Kobe / Hyogo, Japan; [2]Osaka City Univ. Grad. Sch. of Med., Osaka, Japan

Abstracts: Glial progenitor cells expressing chondroitin sulfate proteoglycan 4 (NG2), are termed as NG2 glial cells (or oligodendrocyte precursor cells), and comprise the majority of proliferative cells in the adult central nervous system (CNS). Recently, it was reported that NG2 glial cells rapidly migrate and proliferate to restore their density in response to focal loss of the cells, such as acute CNS injury, ischemia, and demyelination. Moreover, NG2 glial cells are known to receive direct synaptic inputs from neurons, and are often located adjacent to neuronal somata, suggesting any interactions between NG2 glial cells and neurons, although substantive roles of the NG2 glial cells without cell reproduction have not been elucidated. Cell-specific ablation using transgenic animals is a powerful method to reveal cellular function. Thus, we produced transgenic rats expressing herpes simplex virus thymidine kinase (HSV-TK), known as a suicide gene, under control of the promoter for NG2 to explore the roles of NG2 glial cells. In the brain of transgenic rats, almost all NG2 glial cells expressed HSV-TK. We tried to selectively ablate proliferating NG2 glial cells by continuous administration of the anti-viral agent into the lateral ventricle, and succeeded in rapid ablation of NG2 glial cells in the tissue around the lateral ventricle including the hippocampus. In almost all of regions in the hippocampus, surprisingly, the number of hippocampal neurons was dramatically decreased depending on the reduction of NG2 glial cells. To investigate the mechanism of neuronal cell death, we applied microarray analysis to the hippocampal tissue following ablation of NG2 glial cells. The expression profile revealed that ablation of NG2 glial cells increased the expression of pro-apoptotic genes related to extrinsic pathway for apoptosis. Immunohistochemical staining demonstrated that the hippocampal neurons contained death receptors involved in the signaling pathway for apoptosis. Furthermore, TUNEL staining actually revealed that hippocampal neurons underwent apoptosis following the NG2 glial cell ablation. These results suggested that NG2 glial cells maintain neuronal survival by regulating anti-apoptotic pathways under the physiological condition.

Title: Development of interneuron progenitors from human Down syndrome (Trisomy 21) induced pluripotent stem cells (iPSCs)

Authors: *A. BHATTACHARYYA, Y. LIU, M. MUSSER, A. PRASAD, R. REESE, S.-C. ZHANG;
Waisman Ctr., Univ. Wisconsin, MADISON, WI

Abstracts: Down syndrome (DS, trisomy 21, Ts21) is the most common genetic neurodevelopmental disorder and is characterized by mild to moderate intellectual disability and high risk for Alzheimer's disease. Abnormalities in DS brain suggest that developmental differences underlie neuroanatomic abnormalities and contribute to the specific cognitive deficits in individuals with DS. Reductions in both excitatory and inhibitory neurons appear to be present in many cortical regions in DS. Yet, our understanding of the subtype and cause of these deficits is largely unknown. Excitatory and inhibitory neurons that populate the cortex have different developmental origins. Excitatory projection neurons are derived from dorsal forebrain while inhibitory interneurons originate from ventral forebrain. Interneuron progenitors arise from the three neurogenic areas of the ventral telencephalon, with most developing from the medial ganglionic eminence (MGE). Analysis of the Ts65Dn DS mouse model shows an increased number of interneurons in the cortex. Although this data conflicts with the reductions in neuron number in human DS brain, the data highlight the fact that interneuron development is faulty in DS and warrant more studies in human. It is likely that mechanisms at play in mouse and human interneuron development differ. For example, the superficial cortical layers are considerably larger in human thus requiring generation of more interneurons and more complex developmental mechanisms. To investigate human interneuron development in DS, we differentiated human Ts21 induced pluripotent stem cells (iPSCs; Weick et al., PNAS, 2013) into NKX2.1-positive MGE-like progenitors (Liu et al., Nature Protocols, 2013) and compared them to isogenic euploid controls. Gene expression differences were observed in the Ts21 MGE

progenitors including misexpression of LHX6 and DLX genes that are known to be critical in interneuron migration. These results suggest that Ts21 may affect the migration of interneuron progenitors during cortical development. Further experiments will test whether Ts21 MGE progenitors have deficits in other steps of interneuron generation.

Title: Modeling the neuromuscular junction in C9ORF72-associated motor neuron disease using iPSCs

Authors: *E. SWARTZ[1], M. PRIBADI[2], J. BAEK[2], G. COPPOLA[2];
[1]Neurosci., UCLA, Los Angeles, CA; [2]Departments of Psychiatry & Neurol., Semel Inst. for Neurosci. and Human Behavior, Los Angeles, CA

Abstracts: A hexanucleotide expansion in the gene C9ORF72 is the most common cause of familial frontotemporal dementia (FTD), motor neuron disease (MND), and FTD/MND. Induced pluripotent stem cells (iPSCs) offer a way to explore the pathogenic mechanisms caused by specific genetic mutations in the tissues of interest. Because motor neuron dysfunction causes functional and structural abnormalities of the neuromuscular junction, we sought to model *in vitro* the neuromuscular junction by co-culturing motor neurons and muscle cells. We reprogrammed into iPSCs fibroblasts from (1) carriers of a C9ORF72 repeat expansion, (2) individuals diagnosed with sporadic FTD, and (3) healthy controls. iPSCs were differentiated into both motor neurons and skeletal muscle cells and seeded onto opposing sides of a microfluidic plate with two chambers connected by microgrooves. The microfluidic plate allows for the extension of motor neuron axons into the adjacent chamber which harbors skeletal muscle cells, and the establishment of neuromuscular junctions that can be monitored *in vitro* over many weeks. We use this platform to analyze the interactions between patient and control-derived cell types and explore hypothesized pathogenic mechanisms, such as the accumulation of RNA foci or dipeptide aggregates. Additionally, this system will allow for testing candidate compounds interfering with the hexanucleotide expansion.

Title: Single transfection of a synthetic polycistronic self-replicative RNA yields human iPSCs that can be efficiently expanded & directed to neural progenitor cells

Authors: ***V. T. CHU**[1], M. LU[2], N. YOSHIOKA[3], S. DOWDY[4];
[1]EMD Millipore, TEMECULA, CA; [2]EMD Millipore, Temecula, CA; [3]Dept. of Cell. & Mol. Med., [4]UCSD Sch. of Med., La Jolla, CA

Abstracts: Various methods utilizing DNA, RNA, miRNA and protein have been described to generate integration-free induced pluripotent stem cells (iPSCs). Some disadvantages to these methods include low reprogramming efficiency (i.e. DNA and protein), a requirement for negative selection and subsequent recloning steps to remove persistent traces of the virus (i.e. Sendai virus) or for daily transfections of four individual *in vitro* generated mRNAs over a 14 day period (i.e. mRNA based). Recently, an RNA species from non-infectious (non-packaging), self-replicating Venezuelan equine encephalitis (VEE) virus was engineered to encode all four reprogramming factors (RF; OCT4, KLF4, SOX2 and GLIS1) in a polycistronic RNA transcript that mimic cellular mRNA. Advantages to the RNA replicon system are that (1) the RNA can self-replicate for a limited number of cell division hence obviating the requirement for multiple transfections, and (2) the RNA only persists under positive selection and can be quickly cleared when the positive selective pressure (i.e. puromyocin) is released. A single transfection of the RNA replicon used in combination with a small molecule boost supplement efficiently reprogrammed two lines of human foreskin fibroblasts (HFFs). Reprogramming efficiencies using the RNA replicon ranged from 0.3% in the slower proliferating BJ fibroblasts to 1.1% in the faster proliferating HFF. The resulting human iPSCs displayed all the hallmarks of pluripotent cells and could be rapidly expanded in serum-free, feeder-free expansion systems and could also be readily directed to multipotent neural progenitor cells that retained capacity to differentiate into neurons and oligoglial cells.

Title: Characterization of iPSC-derived neuronal preparations and bioassays for use in transplantation in Parkinson's disease

Authors: *T. M. OSBORN, J. L. JANSSON, G. A. SMITH, J. A. BEAGAN, Z. E. SCHNEIDER-LYNCH, D. A. AHMADI, J. A. KORECKA, P. J. HALLETT, O. ISACSON; Neuroregeneration Res. Inst., McLean Hospital/Harvard Med. Sch., Belmont, MA

Abstracts: Patients with Parkinson's disease can gain improved motor function upon fetal ventral midbrain cell transplantations (Mendez et al. Nat Med. 2008 May;14(5):507-9). Fetal cell sources are however limited and patients receiving transplantations require immunosuppression. Induced pluripotent stem cells (iPSCs) present opportunities for autologous transplantations, provided that the cells are safely and effectively differentiated to midbrain dopaminergic neurons. We have derived iPSCs from cynomolgus monkeys for future and ongoing autologous transplantations. 6-OHDA lesioned hemi-parkinsonian rats have been transplanted with these iPSCs differentiated using previously published floor-plate-based protocols for midbrain dopaminergic fate (Cooper et al., 2010, Mol Cell Neurosci;45(3):258-66, Sundberg et al., 2013 Stem Cells;31(8):1548-62) in order to determine long-term (6 months) graft characteristics. Midbrain dopaminergic survival, presence or absence of proliferating cells and neural precursors, blood vessel growth in grafts, graft morphology and behavioral recovery have been documented in preparation for clinical IND applications. Furthermore, we have optimized our midbrain dopaminergic differentiation protocol to be feeder-free and xeno-free and to generate TH/FoxA2 expressing neurons at a similar level as previously described (Cooper et al., 2010, Mol Cell Neurosci;45(3):258-66, Sundberg et al., 2013 Stem Cells;31(8):1548-62). Cells generated using these protocols are being characterized using qPCR and ICC at the end of the protocol and after

long-term culturing *in vitro*. Together with the ongoing autologous transplantations into non-human primates, the long-term xenogeneic transplantations and *in vitro* characterizations evaluate the safety and efficacy of iPSC therapy for Parkinson's disease at a pre-clinical level. The collected data will be used when establishing GMP-grade midbrain dopaminergic neurons from patient-derived iPSCs for future clinical applications.

Title: Expression of oxidative stress genes in human stem cells in physiological versus atmospheric oxygen levels

Authors: *K. M. KLEMAN[1], R. REESE[2], S. HANSON[1], A. BHATTACHARYYA[2]; [1]Gilson, Middleton, WI; [2]Waisman Ctr., Univ. of Wisconsin-Madison, Madison, WI

Abstracts: Oxidative stress plays a role in the development as well as the degeneration of the brain. Oxygen levels in the developing embryo are low and proper regulation of oxygen levels is crucial for stem cells, neural progenitor cells and neurons. *In vitro* models enable examination of the mechanisms involved in neural development,neuronal function and neuronal responses to injury. However, most neuronal culture methods employ non-physiological oxygen conditions. Standard cell culture is performed at atmospheric (20%) oxygen levels. The ability to study oxidative stress in neurons in hyperoxic (atmospheric) conditions is particularly problematic when studying disorders that are characterized by oxidative stress. Therefore, it is crucial to investigate oxidative stress features of cells in a context that enables elucidation of the intrinsic features of the cells. Recently, it has become clear that culturing cells, particularly stem and neural progenitor cells, in low (physiological) oxygen makes the cells grow faster, healthier, less stressed, and with less DNA damage). We therefore investigated the role of oxidative stress in human induced pluripotent stem cells (iPS cells) by testing expression of several genes involved

in the cellular oxidative stress response when cells were maintained in different oxygen concentrations. iPS cells were cultured in 5% oxygen (physiological) or 20% oxygen (atmospheric) and analyzed for expression of specific chromosome 21 genes known to be involved in oxidative stress (SOD, APP, ETS2) and genes known to be upregulated in response to oxidative stress (CAT, CRYZ). Quantitative PCR (384-well) was performed using the PIPETMAX pipeting station with associated qPCR Assistant software and compared to manual pipetting. Automated plate setup enabled easy file export to ABI ViiA thermocycler. The results show that the expression of all of these genes is reduced when iPS cells are cultured in low oxygen. These results have implications for culturing and analyzing disease specific iPSC to model diseases that have an oxidative stress component.

Title: The role of Olig2 gene function in the production of interneurons in Down syndrome

Authors: *C. CHEN[1], P. JIANG[2], Y. LIU[3], W. DENG[2];
[1]Dept. of Biochem. and Mol. Med., [2]Univ. of California, Davis, Sacramento, CA; [3]Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX

Abstracts: Down syndrome (DS), caused by triplication of human chromosome 21 (HSA21), is the most frequent genetic cause of intellectual disability. Previous studies have reported a

widespread over-abundance of interneurons (INs) throughout the forebrain of Ts65Dn mice, the most widely used model of DS. The over-inhibition is one of the underlying causes of the cognitive deficits in Ts65Dn mice. However, it is largely unknown whether overproduction of INs and over-inhibition occur in human patients. Olig genes, including Olig1 and Olig2 are mapped to HSA21. Olig genes are highly involved in the production of INs during development. The early neural progenitor cells (NPCs) that express Olig2 give rise to GABAergic INs in the forebrain. In Ts65Dn mice, normalizing the over-dosage of Olig1 and Olig2 genes rescues the phenotype of over-abundance of GABAergic INs. Contradictorily, a recent study shows that Olig1 represses production of GABAergic neurons throughout the brain. To reconcile these contradictory observations, it is important to study the role of Olig2 in interneuron production during brain development, particularly by using human neural cells. In this study, we differentiated human Olig2-GFP human embryonic stem cell (hESC) reporter line to Olig2+/GFP+ NPCs with ventral forebrain identity and further purified them by FACS based on the expression of GFP fluorescence. Under neuronal differentiation condition, we found that these Olig2+/GFP+ NPCs gave rise only to GABAergic INs and astrocytes. Furthermore, human induced pluripotent stem cells (hiPSCs) reprogrammed from fibroblasts of DS patients (DS hiPSCs) generated significantly higher number of Olig2+ NPCs, compared to their isogenic control hiPSCs with identical genetic background and disomy 21 (Di-DS hiPSCs). Subsequently, the NPCs derived from DS iPSCs (DS NPCs) gave rise to more GABAergic INs under neuronal differentiation condition, compared to the NPCs derived from Di-DS hiPSCs (Di-DS NPCs). We then engrafted the DS NPCs and Di-DS NPCs into the brains of neonatal immune-deficient mice. Three months after cell transplantation, we found that both NPCs could largely repopulate the forebrain of the animals. Most interestingly, the DS NPCs generated more GABAergic neurons *in vivo* than Di-DS NPCs. Thus, the *in vitro* and *in vivo* hiPSC differentiation models provide us with a powerful tool to the study the role of Olig2 in the production of INs during human brain development in normal and diseased conditions. Findings from this study will also provide new insights into developing potential therapeutic applications for DS by regulating the expression of Olig genes to manipulate interneuron production.

Title: The role of SHANK3 in ASD

Authors: *A. KATHURIA, G. COCKS, P. NOWOSIAD, V. WOOD, R. DIXON, W. LUCCHESI, D. SRIVASTAVA, J. PRICE;
King's Col. London, London, United Kingdom

Abstracts: Autism spectrum disorder (ASD) is a group of neurodevelopmental disorders characterized by persistent deficits in social interaction, restricted repetitive behavior and decreased cognitive abilities (Burbach et al. 2014). Recent genetic and genomic data have identified over 180 genes associated with ASD (Gauthier et al. 2009, 2010; Hamdan et al. 2011; Denayer et al. 2012; Boccuto et al. 2012). One of the most promising candidates is the SHANK3 gene, which encodes for a postsynaptic scaffolding protein PROSAP2. SHANK3 deletions have been identified in more than 600 patients affected with Phelan McDermid syndrome (22q13 deletion syndrome) in which SHANK3 is strongly implicated in autistic like behavior (Burbach et.al 2014). The various mouse models with mutant forms of SHANK3 exhibit abnormal behavior, synaptic dysfunction and deficits in learning. (Bozdagi et al. 2010, Wang et.al 2011, Peca.et al 2012). Pervious studies have also linked Shank3's role in spine morphology, striatal dendritic morphology and synapse formation (Peca.et al 2012,Durand et.al 2012).To study the role of Shank3 in ASD we have generated 4 iPS cell lines from two patients with ASD that have a terminal deletion of chromosome 22 including the genes SHANK3, ACR and RABL2. As controls, we used iPSCs from healthy individuals, as described previously (Cocks et al., 2013). In this study, we investigate the morphological properties of the control and Shank3 neurons. We use to two assays to assess the morphological features- the transient transfection via GFP and the ThermoScientific Cellinsight Personal Cell Imager. Morphological differences were found in the Shank3 neurons at day 30 (immature neurons) and day 45 (young neurons) of neuronal development. The cell soma diameter was lower in the patient neurons while the neurite length and the mean number of neurites per neuron was higher at both the stages. Thus, our data indicates that the SHANK3 gene has a role in the development of the neuronal structure.

Title: Disease-relevant genomic DISC1 disruption has selective effects on DISC1 expression and Wnt signaling

Authors: *P. SRIKANTH[1,2], C. R. MURATORE[1,2], D. J. SELKOE[1,2], T. L. YOUNG-PEARSE[1,2];
[1]HMS, Boston, MA; [2]Neurol., Brigham and Women's Hosp., Boston, MA

Abstracts: Schizophrenia is a debilitating psychiatric disorder that affects approximately 1% of the world's population. Genetic and clinical association studies have identified disrupted-in-schizophrenia 1 (DISC1) as a strong candidate risk gene for schizophrenia and other major mental illnesses. DISC1 was initially associated with mental illness upon the discovery that its coding sequence is interrupted by a balanced chr(1;11) translocation in a Scottish family, in which the translocation cosegregates with schizophrenia, bipolar disorder and major depression. DISC1 modulates many neuronal processes, including proliferation, Wnt signaling, synaptic maturation, neurite outgrowth, and neuronal migration. The relevance of a DISC1 loss-of-function versus gain-of-function model to the human disease state remains unclear. We are currently exploring the consequences of DISC1 interruption on human neurodevelopment using TALE nucleases (TALENs) and clustered regularly interspaced short palindromic repeat (CRISPR)-Cas to disrupt the genome of human induced pluripotent stem cells (iPSCs) at the DISC1 locus. We have targeted DISC1 to disrupt all known transcripts or near the site of the Scottish translocation, resulting in isogenic wild-type, total-, and disease-relevant-DISC1 disrupted iPSCs. Genome-edited cells have been differentiated to neural progenitor cells (NPCs) and cortical neuronal fates and examined for altered gene expression, Wnt signaling, proliferation, and migration. We find that total DISC1 disruption dramatically reduces all DISC1 transcript levels, whereas disease-relevant DISC1-decreases expression of only longer DISC1

splice variants. In addition, we show diminished Wnt responsiveness in disease-relevant DISC1-targeted NPCs but not in iPSCs, implicating Wnt signaling in the pathophysiology of this disease-associated mutation. These data and future studies will help identify those functions of DISC1 which are likely to be perturbed in patients with the chr(1;11) translocation and which, when disrupted, contribute to the development of major mental illness.

Title: Modeling enteric nervous system function in children with Autism Spectrum Disorder

Authors: *A. L. WAGONER[1,2], D. L. MACK[3], E. E. MCKEE[2], S. J. WALKER[2];
[1]Wake Forest Univ. Hlth. Sci., Winston-Salem, NC; [2]Wake Forest Inst. for Regenerative Med., Winston-Salem, NC; [3]Inst. for Stem Cell and Regenerative Medicine, Univ. of Washington, Seattle, WA

Abstracts: Children with Autism Spectrum Disorders (ASDs) often have co-morbid medical conditions. One of the most debilitating of these is chronic gastrointestinal (GI) symptoms, which occur in as much as 70% of this population. The successful treatment of GI symptoms in ASD is often accompanied by improvements in behavior and cognition, suggesting that the gut and brain are interconnected. Numerous genes have been shown to harbor mutations or deletions that result in functional consequences in central nervous system (CNS) neurons of ASD individuals. Many of these genes, for example Shank3 and Neuroligin3, are also expressed in the enteric nervous system (ENS), making it likely that mutations causing CNS dysfunction are also operating at the level of the ENS. To explore this relationship we are developing an *in vitro* induced pluripotent stem cell (iPSC) model system for the characterization of ENS function in ASD children with GI symptoms. We have identified cell lines from two male siblings with ASD from the Autism Genetic Resource Exchange (AGRE) for our preliminary studies. These patients have chronic GI symptoms and mutations in Shank3, a mutation known to negatively impact

synaptic development and function. IPSCs, generated from Epstein-Barr virus (EBV) immortalized lymphoblastoid cell lines (LCLs), appeared Day16 post-transfection with Epi5 Episomal iPSC reprogramming plasmids. Four clonal iPSC lines (two from each parent LCL) were propagated out to passage 23. We have confirmed iPSC clones to be plasmid- and EBV-free. Three of four clones had expected expression of cell-autonomous pluripotency genes and normal karyotype. All clonal lines were allowed to spontaneously differentiate into embryoid bodies and were assayed for pluripotency markers and germline-specific transcripts using the Taqman® human pluripotent stem cell Scorecard™ Panel. Results indicated that all four iPSC lines are suitable for neuronal differentiation protocols. In parallel experiments, neural crest cells, differentiated from human embryonic stem cells, showed proper gene expression and cell morphology. Optimized protocols are currently being applied to ASD-iPSCs to generate enteric neurons. Function of these neurons, compared to neurons derived from individuals with unaffected synaptic proteins, will be fully characterized in a smooth muscle/enteric neuron co-culture system. ENS function in ASD children has not been studied nor have mature enteric neurons from ASD patient-derived cells been generated and functionally tested. This model will provide a useful tool to better understand neuropathogenesis of ASD in the gut and a screening mechanism for drug therapies.

Title: Tissue responses and repair in cortical stroke after transplant of distinct iPS progenitor populations

Authors: *A. CRUZ[1], I. L. LLORENTE[3], J. CINKORNPUMIN[4], C. MALONE[2], W. E. LOWRY[4], S. T. CARMICHAEL[5];

[2]Biol., [1]California State University, Northridge, Northridge, CA; [4]Molecular, Cell and Developmental Biol., [5]Neurol., [3]UCLA, Los Angeles, CA

Abstracts: Stroke is the leading cause of disability in Americans. There is limited endogenous tissue repair in the brain after stroke. Stem/progenitor transplantation has emerged as a mechanism to enhance this endogenous repair. Induced pluripotent (iPS)-derived precursor cells provide a way to deliver a progenitor cell to areas of damage that may stimulate repair. With the wide range in differentiation potential of iPS cells, it is not clear what type of cell might be the most potent in this process. To study iPS precursor types in ischemic stroke, a photothrombotic cortical stroke was induced in NSG mice, causing cortical and a small amount of subcortical white matter damage. Two different types of induced pluripotent stem progenitor cells were utilized, IPS-Neural progenitor cells (iPS-NPCs) and iPS-Glial restricted progenitor cells (iPS-GRPCs). These iPS-NPCs or iPS-GRPCs were injected adjacent to the infarct area (100,000 cells/microL) 7 days after induced stroke to observe potential migration, differentiation of the transplanted cells and the effect of these cells on local tissue responses. Control stroke mice received no cell transplantation. Immunostains were used to identify microglia (IBA-1), astrocytes (GFAP), immature neurons (DCX), oligodendrocytes (Oligo2), myelin (MBP), and a transfected marker of the iPS cells (GFP). Endogenous neurogenesis defined by DCX migration to the stroke lesion, is observed 15 days after iPS-NPCs are transplanted. iPS-GRPC transplants have been completed and are under analysis. These experiments will provide further insight to the possibility of induced pluripotent stem cell treatment for ischemic stroke.

Title: Modeling of major mental disorders using GABAergic interneurons derived from patient iPSCs with a defined DISC1 mutation

Authors: *X. WANG[1,2], Z. WEN[2,3], H. NGUYEN[2,4], C. ZHANG[2], H. SONG[2,3,4], G.-L. MING[2,3];
[1]Dept. of Anatomy, Histology & Embryology, Fudan Univ., Shanghai, China; [2]Inst. for Cell Engin., [3]Dept. of Neurol., [4]Grad. Program in Cell. and Mol. Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstracts: Schizophrenia is one of the most common mental disorders that affect about 1% of the population world-wide. Increasing clinical, pharmacological and genetic data suggest that the pathogenesis of schizophrenia is neurodevelopmental in nature with a prominent genetic basis. Disrupted-in-schizophrenia 1 (DISC1), has been suggested as one of the best supported susceptibility genes for major mental illness. For example, in an American family, many members carry a four-nucleotide deletion in the DISC1 gene and the majority of whom have been diagnosed with schizophrenia, schizoaffective disorders and major depression. How DISC1 dysfunction results in the clinical manifestation of a large set of severe psychological symptoms is largely unknown. Patient-derived induced pluripotent stem cells (iPSCs) provide a unique platform to study the contribution of the DISC1 locus to the etiology of schizophrenia and other major mental disorders. We have generated iPSCs from the American family with the DISC1 4-nucleotide deletion, as well as healthy family members without the mutation as controls. GABAergic interneurons are known to play a key role in psychiatric disease. By manipulating the Sonic Hedgehog pathway, we are able to generate a high-purity population of ventral forebrain NPCs which are NKX2.1+ and Lhx6+ from both patient and control iPSCs. These ventral forebrain NPCs can be further differentiated to cortical GABAergic interneurons including PV+, SST+, calretinin+, and calbindin+ interneurons. This system allows for the investigation of the molecular and cellular role of DISC1 in the development of interneurons and their potential contribution to the manifestation of major mental illness.

Autism Speaks

Angelman Syndrome Foundation

Title: Synaptic pathophysiology in stem cell-derived neurons from dup15q autism and Angelman syndrome patients

Authors: *J. J. FINK[1], T. M. ROBINSON[2], K. A. BOLDUC[2], E. S. LEVINE[2];
[1]Neurosci., [2]Univ. of Connecticut Hlth. Ctr., Farmington, CT

Abstracts: Individuals with a maternal deletion of chromosome 15q11-q13 suffer from Angelman syndrome (AS). Interestingly, individuals with a duplication of the same region suffer from a form of autism known as 15q duplication syndrome (dup15q), which is one of the most frequent chromosomal abnormalities associated with autism. Both of these syndromes are neurodevelopmental disorders that often present with common features, including intellectual disability, impairments in language, and seizures. The gene believed to be responsible for these phenotypes encodes the ubiquitin ligase UBE3A, although other genes may also contribute. In both syndromes, alterations in synaptic signaling and plasticity appear to play a critical role in the disease phenotype, but the relevant downstream targets of UBE3A and their functional consequences are unknown. The discovery of genomic reprogramming of human somatic cells into induced pluripotent stem cell (iPSC) lines provides a novel way to generate patient-specific neurons for *in vitro* studies. In this study, we are using electrophysiological approaches and calcium imaging to examine synaptic activity and plasticity of iPSC-derived neurons from AS, dup15q, and control subjects. Low levels of spontaneous excitatory synaptic activity were seen after six weeks *in vitro* in both patient-derived and control neurons. After twelve weeks, control neurons displayed a dramatic increase in the frequency of synaptic events, which was significantly greater than the frequency in both AS-derived neurons and dup15q-drived neurons, suggesting a genotypic difference in synapse number and/or release probability. There was no significant difference in mean amplitude across genotype. These iPSC-derived neurons also

show spontaneous action potential firing and synchronous activity, which can be enhanced by NMDA receptor activation and increased intracellular cAMP levels. We are currently exploring potential differences in these processes in AS and dup15q-derived neurons using single cell recordings and multi-cell calcium imaging. Overall, these approaches may prove useful for identifying novel targets for drug discovery and for screening potential therapeutics aimed at reversing the seizures, movement disorders, and language and cognitive impairments in Angelman syndrome and autism.

Therapeut., [7]Univ. de Barcelona (UB)-Campus Bellvitge, Barcelona, Barcelona, Spain; [8]Inst. of Biochemistry, Emil-Fischer Zentrum, Friedrich-Alexander-Universitaet Erlangen-Nuernberg, Erlangen, Germany

Abstracts: Hereditary spastic paraplegias (HSPs) are a heterogeneous group of inherited motor neuron diseases characterized by progressive spasticity and weakness of the lower limbs. They are classified genetically as autosomal dominant, autosomal recessive and X-linked HSP.

Mutations in the Spastic Paraplegia Gene11 (SPG11), encoding spatacsin, cause the most frequent form of autosomal recessive HSP. Partly due to lack of a relevant disease model, the underlying molecular mechanisms have not been studied in detail. To overcome this limitation we, for the first time, generated induced pluripotent stem cells (iPSCs) from two SPG11 patients, having heterozygous nonsense and/or splice site mutations, and two age matched controls. We differentiated these iPSCs into forebrain neurons and investigated the neuronal pathology associated with the disease. SPG11 patients' derived neurons exhibited severely impaired outgrowth and branching of axonal processes, implicating a compromised neuritic complexity compared to controls. Gene expression analysis further revealed down regulation of specific motor, synaptic and microtubule associated genes. A reduced expression of acetylated tubulin in the neuronal cells was indicative of the axonal instability, which was further corroborated by ultra structural analysis of these cells showing pathological accumulation of membranous bodies within axonal processes. Finally, time lapse assays performed in SPG11 patients' derived neurons highlighted a reduction in the anterograde vesicle trafficking indicative of impaired axonal transport. Altogether, our SPG11-iPSC model provides the first evidence that mutations in SPG11 have a detrimental effect on the homeostasis of neuronal cells and more importantly disturb the critical balance of transport activity in SPG11 patients' neurons. Furthermore, our human model offers an ideal platform to define new targets to intervene the course of this progressing motor neuron disease.

Title: The role of SLC25A12 on interneuron development

Authors: *J. CHEN[1,2], X. ORTIZ-GONZALEZ[2], A. RAVINDRAN[2], D. C. WALLACE[2], S. A. ANDERSON[2];

[1]Mahoney Inst. of Neurolog. Sci., Philadelphia, PA; [2]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstracts: SLC25A12 is a nuclear-encoded mitochondrial glutamate-aspartate carrier highly expressed in the brain. Genetic studies suggest that alterations of SLC25A12 may be associated with autism, and researchers have identified patients carrying homozygous loss of function SLC25A12 mutations. These patients suffer from developmental delay, autism-related symptoms, and intractable seizures, possibly resulting from an imbalance of excitation and inhibition (E/I) in the brain. To understand whether SLC25A12 loss of function results in altered E/I balance, we focused on interneuron development using homozygous SLC25A12 null mice (KO) and human induced pluripotent stem cells (hIPSCs) generated from an SLC25A12 patient. Similar to the human patients, and as previously reported, the KO mice are developmentally delayed and have abnormal brain electrical activity. Current studies are examining cortical histology and electrophysiology in the mouse model, in parallel with differentiations of the patient-derived hIPSCs. The goal is to identify the seizure-causing pathology in these samples, and use this knowledge to design and test novel treatments.

Title: Dissecting the role of FOXG1 in patients with autism using induced pluripotent stem cells

Authors: *J. MARIANI[1], G. COPPOLA[1], P. ZHANG[1], J. R. HOWE[2], F. M. VACCARINO[1,3]; [1]Child Study Ctr., [2]Dept. of Pharmacol., [3]Dept. of Neurobio., Yale Univ., New Haven, CT

Abstracts: We generated induced pluripotent stem cells (iPSCs) from individuals of 5 families each comprising a child with idiopathic ASD and macrocephaly. Large head circumference (HC) and brain volume (macrocephaly) in patients with ASD is associated with poorer outcome,

suggesting that it represents a core feature of the disorder. IPSCs from patients and unaffected family members were differentiated into cortical organoids containing pyramidal neurons as well as telencephalic GABAergic interneurons. RNA sequencing of 45 telencephalic organoids from patients and controls at three different stages of differentiation revealed alterations in cell signaling, Extracellular matrix organization, neural development and synaptic transmission, suggesting a significantly different developmental trajectory between patients and controls. Gene co-expression network analysis revealed various modules of genes differentially expressed between probands and controls. The top upregulated module was characterized by genes involved in neuronal development, particularly synaptic transmission and cell projection morphogenesis. At the immunocytochemical level we detected increased cell proliferation, enhanced GABAergic neuron fate and simplified neuronal architecture. Consistently, neuronal cells from patients showed increased expression of sodium channels with phenotypic properties similar to Nav1.1, an isoform preferentially expressed in inhibitory neurons. Transcription factor analysis on the up-regulated neuronal module showed enrichment for the Forkhead transcription factor family. FOXG1 was among the top upregulated genes in ASD-derived neurons. Using lentiviruses carrying short hairpin RNAs (shRNAs) targeting FOXG1, we then tested whether an attenuation of FOXG1 expression level in patients' neural cells was able to revert some of the neurobiological alterations, including cell proliferation, GABA/glutamate neuron fate, and architecture of neuronal connections. Patients' neuronal cells where FOXG1 was attenuated to a more physiological level showed restored balance between GABA/glutamate neuronal differentiation. Our results suggest a causal role for FOXG1 and its interacting genes in producing some of the neurobiological alterations found in cells of individuals with ASD. Establishing a direct relationship between the biological alterations found in patients' cells on the one hand, and FOXG1 and connected genes on the other, has concrete implications for finding target genes underlying the pathogenesis of idiopathic ADS with macrocephaly and new targets for therapeutic strategies.

Abstracts: Interneuron Alterations in iPSC Models of Bipolar Disorder Melvin G McInnis, Monica Bame, Cynthia J. DeLong, Aislinn Williams, Yao-chang Tsan, Omar Mabrouk, Robert Kennedy, K. Sue O'Shea Interneuron dysfunction has been suggested to underlie a number of neuropsychiatric conditions including bipolar disorder (BP), schizophrenia, and autism spectrum disorders. Alterations in the specification, tangential migration or function of cortical interneurons would be expected to disrupt the excitatory-inhibitory balance in the cortex, which may contribute to BP. We have derived iPSC from three individuals with BP and three healthy controls and differentiated them into telencephalic neurons. Microarray analysis of RNAs from undifferentiated and neuronally differentiated iPSC identified significantly increased transcripts that confer dorsal telencephalic fate in the control group, including: EMX2, GLI1,2,3, PAX6, SOX6, TBR2, TCF3,4, VGLUT, ZNF536. Neurons derived from BP iPSC expressed transcripts involved in the differentiation of ventral (MGE) brain regions, including: FOXP2, NKX2-1, and LHX8, which controls neuronal expression of SHH. Consistent with the expression of transcripts involved in interneuron cell fate, mass-spec analysis of the culture supernates indicated that GABA expression by BP neurons was elevated throughout the 7-week culture period and was significantly increased compared with controls following stimulation of an action potential ($p \leq 0.018$, Anova). To determine if the dorsaala/ventral phenotype could be altered, iPSC were exposed to ventralizing agents (purmorphamine) or dorsalizing agents (lithium). iPSC from both BP and controls were responsive to patterning factors; both groups increased expression of the dorsal marker EMX2 following lithium exposure, but only C iPSC respond to additional ventral cues by down-regulating EMX2. Although only 20% of the total number of cortical neurons, interneurons play a critical role in maintaining the normal balance in cortical activity by making local synapses on long-projecting excitatory pyramidal neurons. Alterations in neuronal fate allocation during early CNS differentiation, in their subsequent tangential cell migration or in the function of cortical interneurons could alter cortical lamination and cortical circuitry in BP.

[4]NIH/NINDS, Rockville, MD

Abstracts: Induced pluripotent stem cells (iPSCs) reprogrammed from patient-derived primary fibroblasts have become an increasingly utilized and needed resource for the study of human disease and have proven especially valuable in studying neurodegenerative disorders for which disease models are difficult to establish. The National Institute of Neurological Disorders and Stroke (NINDS) Repository is a public resource established in 2002 aiming to provide a centralized and open collection of biological samples (DNA, lymphoblastoid cell lines, fibroblasts, iPSCs, biofluids such as plasma, serum, cerebrospinal fluids, and urine) and associated de-identified clinical data from a diverse population of patients and normal controls. Since 2011, the NINDS Repository has added to its web-based catalog (http://ccr.coriell.org/NINDS) close to 50 iPSC and 165 fibroblast lines. Most iPSC lines are contributed by Parkinson's disease (PD), amyotrophic lateral sclerosis (ALS) or Huntington's disease (HD) investigators from NINDS-sponsored Stem Cell Consortia. By making available to the research community neurodegenerative disease iPSCs and fibroblasts, the NINDS Repository continues to fulfill the NINDS mission of reducing the burden of neurological disease - a burden borne by every age group, by every segment of society, by people all over the world. To ensure the quality of these valuable resources, all iPSCs and fibroblasts submitted to the NINDS Repository by iPSC Consortia and other investigators undergo rigorous quality assessments (viability, pluripotency, karyotyping, differentiation status, gene expression analysis, sterility) prior to distribution by the NINDS repository. The results are summarized in a Certificate of Analysis and/or displayed on the web-based catalog along with the recommended culturing protocol. The NINDS Repository fibroblast and iPSC collections include mostly cell lines bearing specific genetic mutations associated with PD, ALS, HD, frontotemporal degeneration, or Alzheimer's disease, as well as samples derived from neurologically normal controls. For

certain affected individuals, the parental fibroblast, corresponding iPSC line, and whole blood DNA are available. The NINDS Repository serves as a unique and effective centralized resource where these iPSCs, fibroblasts and their de-identified phenotypic data, are available to basic and applied research investigators worldwide.

Title: Extracellular vesicle-mediated spread of α-synuclein in the pathogenesis of multiple system atrophy

Authors: *J. FISCHER[1], R. GORRIS[1], A. LEINHAAS[1], K. DE MIROSCHEDJI[2], B. GIEBEL[2], M. KARUS[1], O. BRUESTLE[1];
[1]Inst. of Reconstructive Neurobio. Life & Brain Ctr., Bonn, Germany; [2]Univ. Duisburg-Essen, Inst. for Transfusion Med., Essen, Germany

Abstracts: Intercellular communication and cargo delivery (e.g. proteins and nucleic acids) via small extracellular vesicles (EVs) under physiological and pathophysiological conditions has gained much attention throughout recent years. For the central nervous system it has been proposed that EV-mediated trafficking might contribute to the cellular spread of pathological agents, eventually culminating in severe neurodegeneration. Here, we address the question whether EV-mediated spread of α-synuclein (SNCA) might contribute to the pathogenesis of Multiple System Atrophy (MSA), a spontaneous neurodegenerative disorder characterized by neuronal and oligodendroglial cytoplasmic SNCA inclusions. To this end, we initially generated hiPSCs from MSA patients and further differentiated these cells into a radial glia-like neural stem cell population (RGL-NSCs). RGL-NSCs readily give rise to neurons, astrocytes, and, most importantly, oligodendrocytes. RT-PCR and immunocytochemical analyses revealed that SNCA is strongly expressed by neurons in our culture system. In contrast, oligodendrocytes (OLs) do not express the SNCA gene. However, they exhibit strong SNCA immunoreactivity in mixed neural cultures differentiated from RGL-NSCs, suggesting a yet unknown uptake-mechanism of SNCA by oligodendrocytes. Upon employing Western-blot analyses of neuronal cell culture

supernatants we detected SNCA and CD63, a tetraspanin typically used as EV marker protein. We next harvested EVs from neuronal cell culture supernatants. Biochemical and biophysical characterization demonstrated that SNCA was present in vesicles with diameters of 120-170 nm. These data imply that SNCA being expressed in neurons is secreted as an EV cargo protein and taken up by oligodendrocytes via EV trafficking. Interestingly, pathological aggregation of SNCA can be induced in both neurons and oligodendroytes via inhibition of mitochondrial or proteasomal function. We expect this iPSC-based culture model to provide novel insights into the pathomechanisms underlying MSA-associated SNCA spread and aggregation.

Title: Glucocerebrosidase deficiency results in lysosomal depletion and autophagy block in neuropathic Gaucher disease ipsc-neurons

Authors: *O. AWAD[1], C. SARKAR[2], M. LIPINSKI[2], D. MILLER[1], X. ZENG[3], L. M. PANICKER[1], J. A. SGAMBATO[1], R. A. FELDMAN[1];
[1]Dept. of Microbiology and Immunol., [2]Departments of Anesthesiology, Anat. and Neurobio., Univ. of Maryland, Baltimore, MD; [3]Buck Inst. for Age Res., Novato, CA

Abstracts: Gaucher's disease (GD) is the most common lysosomal storage disease (LSD). GD is caused by mutations in the GBA1 gene, which encodes the lysosomal enzyme glucocerebrosidase (GCase). Neuropathic form of GD is associated with neurodegeneration of the central nervous system with either rapid (type 2), or slow progression (type 3). To investigate the mechanisms by which GCase deficiency leads to neurodegeneration, we used iPSC-derived neurons from patients with types 1, 2 and 3 GD as a model system. We found that types 2 and 3 but not non- neuropathic type 1 GD neurons exhibited widespread depletion and defective clustering of LAMP1-labeled lysosomes. Neuropathic GD neurons also showed increase in the basal levels of both the autophagosome-associated protein, LC3 and the ubiquitin-binding

protein, p62/SQSTM1. Autophagy induction by treatment with the mTOR inhibitor, Rapamycin resulted in accumulation of GFP-LC3-labeled autophagosomes and p62/SQSTM1 protein in GD-neurons, indicative of an autophagy block. Prolonged Rapamycin treatment resulted in decreased survival of neuropathic but not non-neuropathic GD neurons, suggesting that the defective autophagic clearance can lead to neuronal death. To determine whether the reduction in lysosomal number in GD neurons is caused by decreased lysosomal biogenesis, we examined the expression of transcription factor EB (TFEB), the master regulator of autophagy and lysosomal genes. TFEB levels were significantly decreased in types 2 and 3 GD neurons suggesting altered lysosomal biogenesis. Treatment of neuropathic GD-neurons with recombinant GCase enzyme reverted lysosomal depletion and the autophagy block. These results suggest for the first time, that normal GCase activity is required for maintaining a functioning pool of intraneuronal lysosomes, and that this action is likely mediated through TFEB. Our results provide new insights into the mechanisms of GD- associated neurodegeneration and illustrate the value of GD-iPSC to study disease mechanisms and as a platform for drug discovery.

Abstracts: Neurons derived from human pluripotent stem cells represent new cellular tools for investigation of human cortical physiology and psychiatric disorders. In cortical circuits, dendritic spines play a major role in the establishment of excitatory synapses. However, their quantitative analysis in reprogrammed neurons remains poorly documented. For this study,

fibroblasts from two control individuals were reprogrammed to iPSCs. These pluripotent cells were then derived in pyramidal glutamatergic neurons of superficial cortical layers (II-IV), according to published protocol (Boissart C et al, Transl. Psychiatry, 2013, 3, e294). Spinogenesis was analyzed in pyramidal glutamatergic cortical neurons by using a three-dimensional quantitative approach. We labelled neurons using a GFP lentiviral vector coupled to double immunofluorescence. Fluorescent signals were detected by confocal microscopy, and spine quantification was performed on deconvolved images after three dimensional reconstructions, using Huygens Pro and Imaris software. Under our experimental conditions, pyramidal glutamatergic cells accounted for 80 % of total cells. The remaining cells were mostly GABAergic and sparse astrocytes. Nestin and beta III tubulin labelling were used to follow neuronal differentiation. Spinogenesis was followed on glutamatergic neurons over a period of 70 days post differentiation. Our preliminary results show the presence of detectable spines with variable morphologies. Only filopodia and thin spines could be detected at early stages of differentiation of neural stem cells (< 20 days). At 40 days post differentiation, spine shapes were diverse with a high proportion of cup-shaped / branched spines. Stubby spines were predominantly represented at later stages (60-70 days post differentiation). Our ongoing studies include the analysis of pre- and postsynaptic compartments, with a specific focus on Shank proteins. Indeed, Shank proteins are known to promote spinogenesis. In addition, morphological spine defects have been observed in neurons transfected with SHANK mutations identified in patients with autism spectrum disorders (ASD). Synaptic and spine morphologies will be analyzed in reprogrammed cortical neurons from patients with ASD carrying SHANK3 mutations.

Abstracts: The lack of effective treatments for Alzheimer's disease (AD) underscores the importance of developing better human-specific models of AD to further understand disease mechanism and provide better platforms for therapeutic screening. Human induced pluripotent stem cells (iPSCs) and their differentiated progeny provide a powerful new approach to study the relationship of genotype to molecular function for disease-related mutations, where affected genes are expressed under endogenous transcriptional and posttranslational control in non-transformed human cell types affected by the disease in question. We recently published a study in which we created a familial Alzheimer's disease (FAD) iPSC model analyzing neural progenitors from *presenilin*-1 (PSEN1) mutant carriers and their unaffected relatives. PSEN1 is the most common gene mutated in FAD, and forms the catalytic core of the gamma-secretase complex that cleaves amyloid precursor protein among other targets. In order to reduce inherent variability between iPSCs derived from different subjects, we are developing an allelic series, in which PSEN1 mutations can be introduced into an unaffected control line via TALEN-mediated gene editing. We have successfully knocked in heterozygous and homozygous PSEN1 M146L mutations, as well as generated cell lines with homozygous PSEN1 knockout. We are now studying FAD phenotypes in the context of a more specific disease-relevant cell type, namely basal forebrain cholinergic neurons (BFCNs). BFCNs are vulnerable in AD, and are the target of cholinesterase inhibitors such as Donepezil (Aricept), which are one of the few classes of drugs that can ameliorate AD symptoms in some patients. We have developed a method of isolating an iPSC-derived BFCN neural progenitor by FACS, which can then be propagated as a neuronal embryoid body (NEB). NEBs can be subsequently dissociated into a monolayer for terminal differentiation and phenotypic analysis. We are currently optimizing our differentiation protocol and translating it to an automated platform. Automated BFCN differentiation will allow investigation of a large cohort of late-onset AD iPSCs, which is critical for understanding and further dissecting the far more common sporadic forms of the disease. Recent phenotypic analysis of FAD BFCNs will be presented at the meeting.

Title: Targeting aspartoacylase-deficiency in a mouse model of canavan's disease using human induced pluripotent stem cell-derived neural cells

Authors: ***V. C. KAPS**[1], M. MIZHOROVA[1], J. FISCHER[1], M. REISENHOFER[2], M. BLOSCHIES[1], J. SASS[3], T. QUANDEL[1], M. KARUS[1], O. BRUESTLE[1];
[1]Reconstructive Neurobio., Bonn, Germany; [2]Paul-Flechsig-Institute, Leipzig, Germany; [3]Clin. Chem. & Biochemistry, Univ. Children's Hosp. Zuerich, Zuerich, Switzerland

Abstracts: Canavan's Disease (CD) is an early onset, autosomal-recessive neurodegenerative disorder characterized by massive demyelination and spongiform appearance of the brain parenchyma. Such severe histopathological alterations are accompanied by elevated systemic levels of the neural metabolite N-acetylaspartate (NAA), which is usually hydrolysed by the oligododendroglial enzyme aspartoacylase (ASPA) to aspartate and acetate. Mutations in the ASPA gene have been identified as the main genetic course of CD. We reasoned that stem cell-mediated administration of functional ASPA might represent a beneficial strategy to tackle CD-associated alterations in a mouse model of CD. For that purpose, we initially reprogrammed fibroblasts from 3 CD patients with mutations in the ASPA gene into human induced pluripotent stem cells (hiPSCs) using Sendai viral vectors. The resulting CD-hiPSCs were fully validated for virus inactivation, pluripotency marker expression (Tra1-60, Tra1-81, and SSEA4) and their ability to differentiate into all three germ layers *in vitro* and *in vivo*. CD-hiPSCs were then differentiated into proliferative radial glia-like neural stem cells (RGL-NSCs) according to a recently established protocol. CD-RGL-NSCs expressed typical radial glia markers including BLBP, CD133, Nestin, SOX2, SOX9 and PAX6. Moreover, under defined conditions CD-RGL-NSCs could be successfully differentiated into βIII-tubulin-/MAP2-positive neurons, GFAP-/NFIA-positive astrocytes and OLIG2-/O4-/MBP-positive oligodendrocytes. Based on the initial

differentiation capacity two lead CD-RGL-NSC lines were next chosen for lentiviral overexpression of the wild-type human ASPA gene. The successful overexpression in the resulting ASPA-RGL-NSCs could be verified both on transcript and protein level. Overexpression did neither affect marker expression nor genomic integrity of the cells. A potential therapeutic value of the ASPA-RGL-NSCs in comparison to CD-RGL-NSCs will be assessed using transplantation into an immundeficient ASPA-mutant mouse strain. We expect these studies to provide important information about the applicability of stem cell-based enzyme replacement as a potential therapeutic strategy to treat CD.

Title: Aβ promotes astrocyte activation in iPSC-derived neural cultures from familial Alzheimer's disease lines

Authors: *C. R. MURATORE[1,2], T. SHIN[1,2], D. G. CALLAHAN[1,2], C. ZHOU[1,2], T. L. YOUNG-PEARSE[1,2];
[1]Neurosci., Harvard Med. Sch., Boston, MA; [2]Neurol., Brigham and Women's Hosp., Boston, MA

Abstracts: Alzheimer's disease (AD) is a complex neurodegenerative disorder, characterized by extracellular plaques consisting primarily of amyloid beta (Aβ), and intracellular tangles consisting primarily of tau. Additionally, inflammation appears to be a strong component in the pathophysiology of AD. Many studies have revealed evidence of inflammation in the AD brain, including 1) an increase in cytokines and chemokines and 2) an increase in activated astrocytes and microglia. Activated astrocytes and microglia have been shown to surround Aβ plaques, and

clear and degrade Aβ, and it is likely that astrocytes and microglia play a central role in the disease process. While these glial cells aid in clearance of Aβ, gliosis may also stimulate and accelerate the progression of AD through the induction of neuronal damage following the release of cytokines, chemokines and ROS by activated astrocytes and microglia. Here, we aim to interrogate whether altered Aβ levels secreted from familial AD (fAD) neurons are sufficient to induce activation of astrocytes. We have previously shown that fAD iPSC-derived neuronal cells secrete an elevated Aβ42/40 ratio, as well as express increased levels of total and phosphorylated tau, compared to control iPSC-derived neurons. Here we show that astrocytes generated in fAD neural cultures express increased levels of GFAP by immunostaining, Western blot and NanoString technologies, without an increase in overall astrocyte numbers. Additionally, fAD neural cultures show significantly higher levels of secreted IL-6, indicating an activated immune response. Co-culture of fAD neurons, but not control neurons, with WT astrocytes induced astrocyte activation. Likewise, treatment of WT astrocytes with fAD neuronal conditioned media (CM), but not control CM, induced astrocyte activation. Astrocyte activation induced by fAD CM is attenuated through the inhibition of Aβ secretion from fAD neurons. Immunodepletion of fAD Aβ also prevented the increase in astrocyte activation, when compared to mock-immunodepleted media. These results indicate that the elevated Aβ42/40 ratio observed in the fAD lines may largely contribute to the gliosis phenotype observed *in vitro*. Interestingly, the gliosis phenotype is present in our neural cultures prior to any Aβ plaque or tangle formation (60-120 days of differentiation). Taken together, these results suggest that human iPSC-derived neural cultures provide a well-controlled and biochemically amenable system to model the role of gliosis in AD pathophysiology, and suggest that astrocyte activation and altered cytokine secretion may emerge early on in the disease process.

Title: Motor neurons from spinal muscular atrophy patients exhibit hyperexcitability

Authors: *H. LIU, J. LU, H. CHEN, Z. DU, S.-C. ZHANG;
Physiol., Waisman Ctr., MADISON, WI

Abstracts: Motor Neurons from Spinal Muscular Atrophy Patients Exhibit Hyperexcitability Huisheng Liu[1], Jianfeng Lu[1], Hong Chen[1], Zhongwei Du[1], and Su-Chun Zhang[1, 2] [1]Waisman center, University of Wisconsin, Madison, WI, 53705, USA [2]Department of Neuroscience and Department of Neurology, School of Medicine and Public Health, University of Wisconsin, Madison, WI 53705, USA Spinal Muscular Atrophy (SMA) is caused by mutations in the survival motor neuron (*SMN)* gene, resulting in diminished production of the full length (FL) SMN protein. It is characterized by selective spinal motor neuron (MN) impairment, muscle weakness/atrophy, and eventual MN degeneration. However, animal models of SMA show severe muscle weakness, but with limited MN loss, at an early stage, suggesting potential functional alteration in MNs that contributes to SMA symptom presentation. Induced pluripotent stem cells (iPSCs) derived from SMA patients offer an alternative model to dissect the relationship between SMN and MN function. By comparing MNs that are derived from SMA and non-SMA iPSCs, we observed that SMA MNs were efficiently generated and survived for several weeks in a similar manner as non-SMA MNs. However, by electrophysiological recording, we found that SMA MNs exhibited increased membrane input resistance and action potential size, and hyperpolarized threshold, thus displaying hyperexcitability. Furthermore, we discovered that enhanced sodium channel activity (increased current size and faster recovery) in SMA MNs is associated with the hyperexcitability. Interestingly, non-MNs differentiated from SMA iPSCs did not exhibit hyperexicitability. We propose MN hyperexcitability as a compensatory mechanism for reduced neurotransmission, which exacerbates neuromuscular transmission via a negative feedback loop, thus contributing to severe symptoms in early stage SMA.

Abstracts: The method of differentiating human iPS cells toward different kinds of tissue is an attractive model to use in the study of pathological processes and pharmacological substances on human tissue. In the present study we have differentiated human iPS cells of chondrocytic origin towards cortical neurons and characterized them using electrophysiology, immunocytochemistry and biochemistry. We used patch-clamp recordings to investigate action potential firing and spontaneous synaptic activity at different holding potentials. Culture media was collected during neuronal development, up until 90 days of differentiation. Secreted levels of sAPPα, sAPPβ and Aβ 38, 40 and 42 within the media were measured using Mesoscale. The levels of total tau and P-tau were measured using ELISA. The maximum rate of rise of the action potentials more than doubles between day 60 and 90, indicating clear maturation of the neurons. AMPA and NMDA synaptic activity was detected by application of specific antagonists. At 0 mV we also detected spontaneous synaptic activity that was blocked by picrotoxin, indicating the presence of GABA synaptic activity. Immunocytochemical staining indicated the presence of astrocytes, as well as excitatory cortical neurons. Secreted Aβ 40 and 42, sAPPα and both total tau and P-tau in the media increased markedly at day 60 of differentiation, while the secretion of Aβ 38 started later, at day 70. Between days 75 to 85 we observed an increase in sAPPβ. These results show that human iPS cells of chondrocytic origin differentiated toward cortical neurons as demonstrated by the presence of action potentials, excitatory and inhibitory synaptic inputs. The maturation of electrophysiological properties was paralleled by a distinct pattern of secreted Aβ-species, sAPPα/β, total tau and P-tau.

Title: Lineage priming in pluripotent human stem cells

Authors: S.-K. KIM, A. JAISHANKAR, Y. WANG, G. STEIN O'BRIEN, S. SEO, C. COLANTUONI, J. SHIN, J. G. CHENOWETH, *D. HOEPPNER, R. D. MCKAY;
Lieber Inst. For Brain Develop., Baltimore, MD

Abstracts: Significant investments are being made worldwide in basic and translational research on stem cell biology in an effort to reveal the next generation of molecular targets for neurologic and psychiatric disorders. These *in vitro* models have yielded novel insight into signaling pathways that restore CNS function *in vivo* and are strongly informing novel regenerative therapeutic strategies. The powerful new idea revealed by these studies is that the molecular pathways that regulate stem cell function in development also play key roles throughout life in both homeostasis and disease. Factors associated with risk for neurodevelopmental disorders such as AKT1, ERBB family members, and NRG1 are critical regulators of stem cell survival, growth, and proliferation. Here we show lineage bias and reversible differences in susceptibility to differentiation exist in distinct spatial regions of human pluripotent stem cell colonies. The expression of core pluripotency regulators OCT4, NANOG and SOX2 are regulated in a spatially constrained way. OTX2 and SOX21, transcription factors essential for brain development, are dynamically regulated in pluripotent cells playing a crucial role in the early specification of neurectoderm. Neuregulin 1 -ERBB2/3 signaling suppresses neurectoderm specification through AKT activation. This work shows that NRG1-AKT signaling regulates the balance between spatial domains biased towards mesendodermal or neurectodermal fates under self-renewing conditions. Genome specific regulation of these early mechanisms opens the way to a systematic definition of the developmental landscape of genetic risk for brain disorders.

Title: The *in vitro* development of oligodendrocytes from oligodendrocyte precursor cells derived from human pluripotent stem cells

Authors: *M. R. LIVESEY[1], D. MAGNANI[2], B. T. SELVARAJ[2], K. BURR[2], N. A. VASISTHA[2], D. STORY[2], G. E. HARDINGHAM[1], S. CHANDRAN[2], D. J. A. WYLLIE[1]; [1]Ctr. for Integrative Physiol., [2]Ctr. for Clin. Brain Sci., Univ. of Edinburgh, Edinburgh, United Kingdom

Abstracts: Generation of regionally defined cellular populations from human pluripotent stem cells (hPSCs) provides an important experimental resource for the study (and potentially treatment) of neurodevelopmental and neurodegenerative disorders. We developed a protocol that generates highly enriched PDGFRα-positive oligodendrocyte (OL) precursor cells (OPCs), derived from multiple hPSC lines, that differentiate into O4, GalC and myelin basic protein expressing OLs. Co-expression of PDGFRα and O4 was evident in <10 % of OPCs whilst the majority of O4-positive OLs also expressed the mature OL-marker myelin basic protein (>85%). We observed that OL differentiation coincided with an increase in cell size (OPCs: 8.4 ± 0.1 pF, n = 22; OLs: 25.8 ± 0.3 pF, n = 36) and OL development was associated with an increase in the number and length of OL processes, as quantified by Sholl analysis. Using pharmacological and biophysical approaches we have examined the profile of passive membrane properties of hPSC-derived OPCs through to their maturation into OLs. Depolarization of OPCs induced large, sustained outwardly rectifying currents. Tetrodotoxin-sensitive spiking activity was also observed in OPCs. OL differentiation was associated with a loss of spiking activity and a reduced rectification of outward currents that indicated a change in the ion channel expression profile of OLs compared to those expressed in OPCs. Specifically, the decreases in ion channel current densities as cells differentiated from OPCs to OLs were: tetrodotoxin-senstive voltage-gated Na^+-channels (OPCs: 29.1 ± 1.1 pA/pF, n = 18; OLs: 0 pA/pF, n = 5), TEA-sensitive delayed-outwardly rectifying K^+-channels (OPCs: 26.4 ± 0.4 pA/pF, n = 15; OLs: 0.5 ± 0.1 pA/pF, n = 9) and transient A-type K^+-channels (OPCs: 105.6 ± 4.5 pA/pF, n = 12; OLs: 8.1 ± 0.8 pA/pF, n = 6). Conversely, immunohistochemistry revealed prominent expression of inwardly-rectifying K^+-channel 4.1 subunits in OLs, whereas expression of this channel subunit was only negligibly detected in OPCs. Our data are in good agreement with ion channel

expression profiles exhibited by native (rodent) OL-lineage cells and indicate many aspects of rodent OL-lineage cell development are recapitulated in OPCs and OLs derived *in vitro* from hPSCs. This data provides a platform for the assessment of whether the maturation profile of channel expression and density are similar in OLs and OPCs derived from hPSC lines obtained from patients suffering from neurological diseases.

Title: Efficient generation of NKX2.2 and OLIG2 positive progenitor cells from human pluripotent stem cells in defined serum free culture

Authors: ***Y. CHEN**, N. ASBROCK, V. CHU;
EMD Millipore, Temecula, CA

Abstracts: During embryonic development, NKX2.2 and OLIG2 positive progenitors reside in the ventral neural tube and later give rise to oligodendrocyte in the spinal cord. To identify conditions that would override intrinsic cell line lineage propensities and specify cells toward an oligodendrocyte lineage, extrinsic factors such as sonic hedgehog, retinoic acid, PDGF and thyroid hormone were tested using a modified neural induction platform called NIM. At day 4, when the neuroectodermal lineage would be specified, a potent sonic hedgehog agonist was introduced to initiate ventral patterning. A pulse treatment of retinoic acid was added at a specified timepoint and found to upregulate NKX2.2 and OLIG2 expression. Highly pure populations of NKX2.2 and OLIG2 positive progenitors were efficiently generated in as little as 8 days from 3 separate lines of human pluripotent stem cells, two of which possessed known lineage propensity. H9 and H7 human ES cell lines are widely known to have neuroectodermal and mesodermal potential, respectively. A third human iPS cell line was also evaluated. Expandable NKX2.2 and OLIG2 positive progenitors are useful tools to screen for small molecules that can overcome intrinsic cell line differences and to specify a majority of the cells towards a mature oligodendrocyte lineage.

Abstracts: Recent advances in stem cell technology have enabled generation of neuronal cell lines from induced pluripotent stem cells (iPSCs) derived from human peripheral tissues. This opens unprecedented opportunities for investigation of human brain disease linked to known genetic variations. However, the lack of the natural brain microenvironment in a dish can influence the phenotype and maturation. One potential strategy to overcome these limitations is transplantation of iPSC-derived neuronal precursor cells (NPCs) into the mouse brain. Previous studies have proved the feasibility of this “chimeric” approach and demonstrated that the transplanted neurons form synaptic connections using electrophysiological recordings in brain slices (1, 2). Ideally, however, activity of human neurons should be measured in the intact mouse

brain. In the present study, we addressed this challenge by using *in vivo* 2-photon calcium imaging. Human iPSC-derived NPCs were injected into the brains of newborn mice. In adult mice, the cell bodies of human neurons were typically found in clusters along the injection track. Calcium indicator OGB1 was loaded using the standard procedures at the location of a cluster and was uptaken by both mouse and human neurons. Human dendrites, however, extended outside the volume of loaded mouse tissue allowing selective measurements of their activity. Stimulation was delivered using a puff of glutamate through a glass micropipette inserted into the tissue within ~100 microns from the imaging field of view (FOV). Glutamate produced clear increases in OGB1 fluorescence in the human dendrites. Figure 1 illustrates the response to 9 consecutive stimulus trials; the regions of interest are color-coded on the FOV image. Thus, human iPSC-derived neurons *in vivo* have functional glutamate receptors and calcium channels. The chimeric approach may become a translational tool for studying disease mechanisms and evaluating candidate drugs on adult human neurons. 1.Muotri AR, et al. Abstracts: Mutations in the gene encoding presenilin 2 (PSEN2), expressed by neurons and microglia and involved in the cleavage of amyloid precursor protein, cause familial Alzheimer's disease (fAD). The clinical and pathological parallels between fAD and sporadic AD suggest that identification of pathogenic mechanisms in PSEN2 fAD may provide mechanistic clues relevant to the development of effective therapeutics in AD. *In vivo* experiments using transgenic animals are limited with respect to imaging live interactions between microglia and neurons, and cells isolated from transgenic animals retain caveats with regard to species-specific genetic regulation. Therefore, the aim of this work was to establish an *in vitro* model of neuron-microglia interaction using cells derived from human induced pluripotent stem cells (iPSCs) for the purpose of evaluating neuron function and survival in the context of two AD associated PSEN2 mutations. iPSCs harboring either a single N141I mutation or a recently reported 2 base pair deletion in the PSEN2 gene were differentiated toward neurons via embryoid body formation followed by dual smad inhibition and treatment with brain-derived neurotrophic factor and neurotrophin-3. The iPSCs were also differentiated toward microglia via embryoid body formation, dual smad inhibition, and treatment with growth factors. Cell phenotypes were validated by immunocytochemistry, flow cytometry, and FM4-64 synaptic vesicle dye incorporation, and mutant PSEN2 genes were confirmed with PCR and sequencing. In addition, mutant iPSC lines were “reverted” to wild type genotypes using clustered regularly interspaced short palindromic repeat/Cas9 nuclease genome editing (CRISPR/Cas9) and were differentiated toward microglial and neuronal phenotypes. Mutant and “reverted” iPSC-microglia and -neurons were co-cultured with one another or with microglia and neurons derived from wild type human iPSCs, and neurons were assessed for viability and function via caspase 3 staining, gamma-secretase activity, and FM4-64 dye incorporation. Assessment of spontaneous miniature excitatory postsynaptic currents was performed over 10 second intervals through whole-cell voltage clamping of neurons at a constant voltage of -70mV. This model offers a useful platform for future investigations into the mechanisms of PS2-mediated neurodegeneration and for pharmaceutical investigations into the amelioration of dysfunctional PS2 production by microglia.

Abstracts: Axonal regeneration in the CNS remains an intractable problem. One way to augment regeneration could be through reorganization of the cytoskeleton to rejuvenate damaged axons and promote growth cone formation. Microtubule dynamics are regulated by posttranslational modifications and play a key role in maintaining axonal integrity and growth. Microtubule acetylation, which is found at higher levels on stable microtubules along the axon shaft is a reversible process controlled by two enzyme families, the Histone Deacetylases (HDACs) and the Histone Acetyl Transferases (HATs). Recent studies show that HDAC5 and HDAC6, upregulated in response to injury, may play a role in axonal regeneration. Studies also show that overexpression of alpha tubulin acetyl transferase (aTAT1), which also regulates microtubule dynamics independently of catalytic activity, can increase stability. We hypothesize that modulating HDAC5, and aTAT1 expression can alter microtubule stability, increasing the rate of axonal growth. In this study, a lentivirus was generated to express GFP-HDAC5 (Lenti-

HDAC5) and a novel lentivirus construct containing GFP-aTAT1 (Lenti-aTAT1) was cloned. Microfluidic chambers have also been fabricated to investigate the effects of overexpressing HDAC5 and aTAT1 on axon growth *in vitro*. Adult rat DRG neurons are plated onto laminin and into the cell body compartments of microfluidic chambers where they can extend axons uniformly along parallel microchannels towards distal compartments. To investigate both axonal outgrowth and behavior of regenerating axons encountering an inhibitory border, chondroitin sulfate proteoglycans (CSPG) stripes are placed perpendicular to the microgrooves in between the cell body and distal compartments. Using this model, we are testing the effects of Lenti-HDAC5 and Lenti-aTAT1 expression on axonal outgrowth and on the CSPG crossing assay. Furthermore, we plan to injected Lenti-HDAC5 and Lenti-aTAT1 into adult rat lumbar (L4/L5) dorsal root ganglia after dorsal root rhizotomy and we will assess the ability of axons to re-grow beyond the DREZ. By using lentiviruses to deliver both HDAC5 and aTAT1 to damaged neurons, we will better understand the effects of microtubule acetylation and microtubule stability on axonal regeneration in adult neurons after injury.

Title: Cytoskeleton remodeling as a target for TTR-induced neurodegeneration

Authors: J. EIRA[1], M. SOUSA[2], *M. LIZ[1];
[1]Neurodegeneration Group, [2]Nerve Regeneration Group, IBMC, Porto, Portugal

Abstracts: Mutations in transthyretin (TTR) are associated with familial amyloid polyneuropathy (FAP), a neurodegenerative disorder characterized by the deposition of insoluble TTR aggregates, particularly in the peripheral nervous system. However the molecular mechanism that underlies TTR toxicity in peripheral nerves is unclear. Abnormalities in

cytoskeletal organization are a common feature of many neurodegenerative disorders. Amyloidogenic proteins such as beta-amyloid peptide (Aβ) have been shown to mediate neurotoxicity by inducing major alterations in both microtubules and actin filaments. In this work we aimed to examine the effect of TTR on the cytoskeleton organization of dorsal root ganglion neurons (DRG). We observed that TTR oligomers promoted a complete reorganization of both actin and microtubules in the growth cones of DRG neurons, whereas soluble TTR has no significant effect. TTR oligomers led to a marked reduction in the growth cone area with the phalloidin staining showing a complete depletion of the typical filopodial and lamelipodial actin structures of neuronal growth cones. Regarding microtubule organization, in control neurons we observed the usual organization of neurons growing in permissive substrates with tightly bundled axonal microtubules entering the growth cone in half of the growth cones, whereas in the other half, microtubules splayed out as they entered the growth cone. In contrast, in neurons treated with TTR oligomers while growth cones with splayed microtubules were still observed, the remaining half of the growth cones were dystrophic with microtubules confined to the central zone with little extension into the periphery. Based on these observations, our study proposes growth cone cytoskeletal components as a target for TTR-induced neurodegeneration in FAP.

Title: Live STED nanoscopy of the actin organization in the axon initial segment

Authors: E. D'ESTE, *D. KAMIN, A. EL HADY, S. W. HELL;
NanoBiophotonics, Max Planck Inst. for Biophysical Chem., Göttingen, Germany

Abstracts: The axon initial segment (AIS) is thought to be the site of action potential initiation and the border between the somatodendritic compartment and the axon. Recent studies performed mainly with electron microscopy reveal a peculiar organization of the cytoskeleton in the AIS but led to results that are discordant from the ones obtained with optical imaging techniques. The main reason is the technical difficulty in preparing samples in which the actin structures are preserved. Here we use SiR-Actin, a new actin labelling probe, in combination with two-color Stimulated Emission Depletion (STED) optical nanoscopy. SiR-Actin is

membrane permeable and fluorogenic, meaning that it fluoresces only when it is bound to its target, providing an excellent signal-to-noise ratio. These features make it highly suitable for live-cell fluorescence nanoscopy. Thus, possible artifacts due to sample preparation or transfection become of lesser concern. Our study of the AIS in living cultured hippocampal neurons using SiR-Actin reveals the presence of an actin lattice with ~180 nm of spacing in both the AIS and the distal axon, in agreement with a previous study using STORM on fixed samples. We demonstrate that this peculiar structure arranges already after two days *in vitro* (DIV), before the AIS is formed. After five DIV, virtually all axons exhibit actin rings but lack any indication for the presence of an actin filter barrier. These results have been confirmed by conventional phalloidin staining, indicating that no significant alteration of the actin structure is caused by SiR-Actin. In agreement with what has been reported by electron microscopy studies, live STED imaging shows the presence of some actin patches along the axon. Immunolabelling with the synaptic markers Bassoon and Synaptotagmin-1 reveals that these actin patches represent synaptic sites in mature cultures. In conclusion, STED nanoscopy reveals the presence of an actin lattice in the axons of living hippocampal neurons, which spans all over the length of the axons. We were not able to prove the existence of an actin barrier in the AIS. Furthermore, we speculate that there may be interplays between actin patches that can be observed along the axon and synaptic sites.

Title: APC and alpha-catenin binding regions for beta-catenin differentially and cooperatively modulate growth cones, arborization and targeting of optic axons *in vivo*

Authors: *T. M. ELUL[1], E. WU[2], G. PENG[2];
[1]Touro Univ., Vallejo, CA; [2]Touro Univ. California, Vallejo, CA

Abstracts: Formation of neuronal circuits involves axons navigating specific paths to their targets in the brain, where they then elaborate terminal arbors that form synaptic connections. β-catenin is a target of Wnt and Cadherin ligands that regulates axon pathfinding and branching, but the mechanisms of its' associated factors are not well studied. Here, we examined how

domains in APC and α-catenin that bind β-catenin differentially sculpt optic axons, their growth cones and their arbors in tectal midbrains of intact, living Xenopus tadpoles. Overexpression of the APCβ-cat binding domain both dispersed and disorganized optic axons in the optic tract, whereas the α-catNTER domain that binds β-catenin dispersed optic axons in the optic tract but did not perturb their organization. Optic axons expressing APCβ-cat also formed narrow growth cones with no or a single long filopodia while many α-catNTER expressing growth cones were wider with no filopodia. At a later stage, APCβ-cat axons developed arbors with very short branches that targeted to the appropriate region in optic tecta of intact tadpoles. In contrast, axons that expressed α-catNTER developed arbors that had fewer branches and were frequently mistargeted within the tectum. These data suggest that the APC and α-catenin binding domains for β-catenin differentially and cooperatively regulate growth cones, arbors and target locations of optic axons *in vivo*.

Title: Actin and myosin-dependent localization of mrna to dendrites

Authors: ***V. BALASANYAN**, D. ARNOLD;
USC, Los Angeles, CA

Abstracts: The localization of mRNAs within axons and dendrites allows neurons to manipulate protein levels in a time and location dependent manner and is essential for processes such as synaptic plasticity and axon guidance. However, an essential step in the process of mRNA localization, the decision to traffic to dendrites and/or axons, remains poorly understood. Here we show that Myosin Va and actin filaments are necessary for the dendritic localization of the mRNA binding protein Staufen 1 and of mRNA encoding the microtubule binding protein Map2. Blocking the function or expression of Myosin Va or depolymerizing actin filaments leads to localization of Staufen 1 and of Map2 mRNA in both axons and dendrites. Furthermore,

interaction with Myosin Va plays an instructive role in the dendritic localization of Hermes 1, an RNA binding protein. Wild-type Hermes 1 localizes to both axons and dendrites, whereas Hermes 1 fused with a Myosin Va binding peptide, localizes specifically to dendrites. Thus, our results suggest that targeting of mRNAs to the dendrites is mediated by a mechanism that is dependent on actin and Myosin Va.

Title: MEC-17 regulates α-tubulin acetylation and modulates axon growth in hippocampal neurons

Authors: *L. BAO, D. WEI, N. GAO;
Inst. of Biochem. and Cell Biology, Chinese Acad. of Sci., Shanghai, China

Abstracts: Objective Neuronal morphogenesis is a fundamental process during the brain development. This process is regulated by cytoskeleton components. Microtubule dynamics can be modulated by posttranslational modifications to tubulin subunits. Acetylation of α-tubulin at lysine 40 is important in regulating microtubule properties, and it is controlled by acetyltransferase and deacetylase. MEC-17 is an α-tubulin acetyltransferase that has been found to play major roles in the acetylation of α-tubulin in different species *in vivo*. However, the physiological function and mechanism of MEC-17 during neuronal morphogenesis are largely unknown. The present study is to explore the roles of MEC-17 in neuronal morphogenesis. **Methods** The MEC-17 truncation and mutation plasmids were constructed. The level and distribution patterns of α-tubulin acetylation were detected by immunoblotting and immunohisto/cytochemistry. The MEC-17 expression was regulated by knockdown using shRNA electroporation and knockout. The culture of hippocampal neurons from rats and mice has been used for studying the effect of MEC-17 on neuronal morphogenesis. **Results** (1) MEC-17 acetylated α-tubulin via its N-terminus sequence and displayed strong interaction with α-tubulin through its C-terminus sequence. (2) MEC-17 knockdown promoted axon elongation and

axonal branching of cultured rat hippocampal neurons. Hippocampal neurons cultured from MEC-17 knockout mice displayed longer axons and more axonal branches compared with those from wildtype mice. (3) Both α-tubulin acetylation and strong tubulin interaction of MEC-17 is necessary for regulation of neuronal morphogenesis. (4) *In situ* upregulation of α-tubulin acetylation reduced axon elongation and axonal branching of cultured rat hippocampal neurons. **Conclusion** MEC-17 and α-tubulin acetylation are important for neuronal morphogenesis.

Title: Pftaire kinase (eip63e/cdk14) regulates axogenesis via rhoa activation in *Drosophila* melanogaster and mice during embryonic cns development

Authors: *Y. RODRIGUEZ GONZALEZ, F. KAMKAR, P. JAFARNEJAD, S. WANG, L. SANCHEZ ALVAREZ, P. ALBERT, R. S. SLACK, M. SONNENFELD, D. S. PARK; Neurosci., Univ. of Ottawa, Ottawa, ON, Canada

Abstracts: Characterizing the processes that mediate the development of the Central Nervous System (CNS) is fundamental to our ability to develop successful therapies that modifies them. PFTAIRE kinase 1 and 2 (Pftk1/ Pftk2) are members of the family of Cyclin Dependent Kinases (Cdks), a group of kinases with diverse functions important to the CNS beyond cell cycle regulation. We hypothesized that, analogous to Cdk5 - the best characterized of neuronal Cdks - Pftks play a role CNS development. Importantly, Pftk1 is highly expressed in neurons in Cdk5-like patterns; Pftk1 and Cdk5 share the highest amino acid sequence similarity within the cdk family (~50-52%) and the *Drosophila* melanogaster Pftk (Eip63E) is required for development, since Eip63E deficient flies die at early larval stages. Our unpublished data shows that Eip63E is required in neurons to regulate axogenesis, since Eip63E deficiency or neuronal downregulation (using RNAi) leads to premature axon outgrowth, axon misguidance and defasciculation *in vivo*. We also show that Eip63E and Rho1 functionally interact in fly-embryos, since neuronal co-expression of Eip63E-RNAi and dominant-negative (DN) or constitutively active (CA) Rho1 leads to modification of the axon defects. Equally, using primary murine cortical neurons, we found that overexpression of DN-Pftk1 leads to faster-growing processes when compared to controls. This was recapitulated by the discovery that cultured E13 Pftk1-deficient cortical neurons elongate their axons significantly more rapidly than their wildtype littermates. We have also determined that this correlates with a lack of detectable RhoA activity in Pftk1-deficient neurons, in spite of an upregulation of RhoA protein levels when compared to wildtype neurons. Additionally, we show that Pftk1 directly phosphorylates RhoA *in vitro*. Our work represents the first steps in the characterization of Pftks neuronal functions and points to a novel mechanism of RhoA activation to regulate axogenesis.

Title: Formins in neuronal cells

Authors: *A. HLEIHEL, D. HYNDS;
TWU, Denton, TX

Abstracts: Formins are actin-nucleating proteins that assist in the formation of unbranched actin structures like those seen in filopodia. Filopodia are the finger-like shaped structures observed in several neuronal areas including the growth cones that are formed at the tips of the neurites during neuronal development and regeneration. Dynamic rearrangement of the actin cytoskeleton through polymerization and depolymerization enables filopodia to explore their environment, leading to extending, retracting, and steering behaviors. Formins, including isoforms of the diaphanous subfamily (Dia1, Dia2, and Dia3), are major actin nucleators in filopodia. However, their distribution and interplay is not completely defined in several neuronal models, including B35 rat neuroblastoma cells. . Using Immunocytochemistry (ICC) and Co-Immunoprecipitation (C0-IP), we found that the diaphanous proteins are expressed in B35 neuroblastoma cells and they co-localize in growth cone filopodia. Their expression and co-localization suggest potential interaction between formin isotypes. Therefore, we are currently assessing their physical interactions and identifying their specific roles through gain-of-function and loss-of-function approaches. Collecting these data will improve our understanding the process of neuronal development and regeneration.

Title: Analysis of correlation between second messenger dynamics and structural changes of the growth cone

Authors: *F. NAGASE, T. KOBAYASHI, K. HOTTA, K. OKA;
Dept. of Biosci. & Informatics, Keio Univ., 3-14-1 Hiyoshi, Kohoku-Ku, Yokohama, Japan

Abstracts: Axon growth directed by the growth cone plays an important role during neural circuit formation. The growth cone is a sensory and motile part at the tip of the axon, and its main function is path finding. It receives chemical guidance cues from circumstance via specific receptors. A variety of attractive and repulsive guidance cues and following cascades inside the

growth cone have been revealed by previous reports (Tojima et al. 2011). Moreover, spatiotemporal crosstalk between second messengers such as cAMP, cGMP, and Ca2+ had been revealed (Kobayashi et al. 2013). These whole cascades, finally, triggers the structural changes of actin filaments and microtubules. However, the spatiotemporal relationship between the second messenger dynamics and following cell structure change has been poorly understood. Previous our study (Kobayashi et al. 2013) was mainly focused on the movement of the growth cone but not detailed structural change of actin and tubulin. Here, we show the correlation in these second messenger cascades in dorsal root ganglia neurons from rats. To reveal these mechanisms, we used FRET sensors to monitor concentration of second messengers and fluorescent-labeled actin and tubulin, simultaneously. We visualized second messenger dynamics without stimulation in specific sub-domains in the growth cone: peripheral and central domain. We found that cAMP is dominant at the peripheral domain of the growth cone during the axon outgrowth. Ca2+ concentration at the peripheral domain also increases with fluctuation during the outgrowth. To reveal the growth cone structure reconstruction, we visualized actin at the peripheral domain and checked the relationship to the outgrowth. We found that actin concentration increases gradually during the outgrowth. These results, demonstrate that the dominant increase of cAMP and Ca2+ at the peripheral domain of the growth cone causes the actin concentration increase and the following outgrowth of the axon.

Title: Activation of Sonic Hedgehog signaling in dendrites accelerates axon outgrowth in hippocampal neurons

Authors: P. J. YAO, F[1], *R. S. PETRALIA[2], M. P. MATTSON[1,3];
[1]Lab. of Neurosciences, NIA/NIH, Baltimore, MD; [2]Advanced Imaging Core, NIDCD/NIH, BETHESDA, MD; [3]Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstracts: The Sonic hedgehog (Shh) signaling pathway is known to play important roles in development of the nervous system where it functions as a morphogen that controls progenitor cell proliferation and induction of the floor plate, and regulation of cell fate. In addition, recent

findings suggest that Shh signaling can enhance axon growth, although the underlying mechanisms are unknown. We previously showed that the cell surface Shh receptor Patched, and the Shh signal transducer Smoothened, are preferentially localized to the dendrites of hippocampal neurons. Here we provide evidence that activation of Shh receptors in dendrites enhances axon outgrowth in embryonic hippocampal neurons. Using microfluidic chambers in which neurons are plated in one chamber, and their axons grow through microgrooves into another chamber, we show that application of Shh to the dendritic compartment accelerates axon outgrowth, whereas application of Shh directly to the axons does not affect their outgrowth. Shh has no observable direct or indirect effect on dendrite outgrowth. The axon outgrowth induced by dendritic Shh signaling requires a Gli transcription factor. Shh-treated neurons expressed elevated levels of the actin modifier protein profilin, while the level of activated cofilin, another actin modifier was reduced. Our findings suggest a scenario in which Shh released by one neural cell (presumably a neuron or glial cell) onto the dendrites of a neuron can stimulate the growth of the axon of the same neuron. We are currently working to better understand the molecular sequence of events underlying this intriguing polarized subcellular signaling pathway, and its physiological roles in developmental and adult neuroplasticity.

Title: Ezrin regulates neuritogenesis through down-regulation of RhoA signaling pathway

Authors: Y. MATSUMOTO[1], *M. INDEN[2], A. TAMURA[3], R. HATANO[1], S. TSUKITA[3], S. ASANO[1];

Abstracts: Establishment of neural circuits in the central nerve system requires generation and development of multiple dendrites and single axon. Cultured neurons that showed sequence of morphological changes are well studied for neuronal development. Ezrin/Radixin/Moesin (ERM) proteins link between membrane proteins and actin cytoskeleton, contribute to maintenance of cellular function and morphology. In cultured hippocampal neurons, suppression of both radixin and moesin showed deficits in growth cone morphology and neurite extensions. On the other hand, down-regulation of ezrin using siRNA caused impairment of netrin-1-induced axon outgrowth in cultured cortical neurons. However, roles of ezrin in the neuronal morphogenesis of the cultured neurons have been poorly understood. In this report, we performed detailed studies on the roles of ezrin in the cultured cortical neurons prepared from the ezrin knockdown (Ezrin KD) mice embryo that showed a very small amount of ezrin expression compared with the wild-type neurons. First, we confirmed that ezrin was mainly expressed in cell body in the cultured cortical neurons as repoted in other types of cultured neurons. We demonstrated that the cultured cortical neurons prepared from the Ezrin KD mice embryo exhibited impairment of neuritogenesis, not neurite and axon outgrowth. We next examined whether ezrin knockdown affects RhoA activity in the cultured cortical neurons using Rho GTPase pull-down assay. GTP-bound RhoA in the Ezrin KD neurons was increased more than three-folds compared with the wild-type neurons. In contrast to RhoA, other Rho family members, Rac1 and Cdc42 were not affected by ezrin knockdown. Moreover, we observed increased phosphorylation of myosin light chain 2 (MLC2), as a downstream effector of RhoA in the Ezrin KD neurons. In addition, treatment of Y-27632, an inhibitor specific for Rho kinase, rescued the abnormalities in neuritogenesis in the Ezrin KD neurons. These data altogether suggest a novel role of ezrin in the neuritogenesis of the cultured cortical neurons via down-regulation of RhoA/Rho kinase/MLC2 pathway.

Title: Mical is required for retinal ganglion cell axon repulsion

Authors: *K. P. ATKINSON-LEADBEATER[1], C. L. HEHR[2], J. JOHNSTON[2], G. BERTOLESI[2], S. MCFARLANE[2];
[1]Psychology, Mount Royal Univ., Calgary, AB, Canada; [2]Cell Biol. and Anat., Univ. of Calgary, Calgary, AB, Canada

Abstracts: Axons are guided in their development through the actions of extracellular cues on the growth cone, a sensory-motile structure found at the tip of the growing axon. In order to guide developing axons, these cues must have the ability to effect changes in the intracellular structure of the growth cone. Sema3a, a secreted Semaphorin, is a guidance molecule known to repel developing axons in many systems. In *Drosophila* the binding of Sema3a to a Plexin/Neuropilin holoreceptor is thought to recruit a Molecule Interacting with CasL (Mical). Once recruited, Mical triggers F-actin disassembly and actin reorganization, thereby linking Sema3a signaling with cytoskeletal rearrangement. It is currently unknown whether Mical is important in the guidance of vertebrate axons. Xenopus laevis retinal ganglion cell (RGC) axons rely on repulsive signals from Sema3a and Slit1 to repel them through a caudal turn in the mid-diencephalon, which directs these axons to their midbrain target. We used RGC axon navigation of this caudal turn to ask whether Mical also mediates the repulsive actions of Sema3a in vertebrate axon development. Importantly, mical3a mRNA is expressed in Xenopus RGCs during the period of axon outgrowth. We exposed developing RGC axons *in vivo* to the inhibitor of Mical epigallocatechin gallate (EGCG). In the presence of EGCG the majority of axons failed to make the mid-diencephalic turn and stalled in the dorsal diencephalon (control 3% stalls, n=33; 25 uM EGCG 81% stalls, n=27). A similar phenotype was observed as we showed previously, when the expression of both Sema3a and Slit1 was inhibited. Furthermore, in the presence of jasplakinolide, a compound that promotes actin polymerization, RGC axons also fail to navigate the mid-diencephalic turn (control 3% stalls n=36; 75 uM Jas 56% n=17). These data are consistent with a model proposing that RGC axon repulsion requires actin depolymerization, and that Mical function is critical for repulsive cues to exert their effects on developing axons.
We would like to thank the Canadian Institutes of Health Research for their support.

Title: Neurotropin suppresses lidocaine-induced inhibition of neurite growth in cultured rat spinal neurons

Authors: *R. ISONAKA[1], T. TAKENAMI[2], T. KATAKURA[1], T. KAWAKAMI[1];
[1]Physiol., [2]Anesthesiol., Kitasato Univ. Sch. of Med., Sagamihara, Japan

Abstracts: Neurotropin is an analgesic agent, and commonly used for the treatment of chronic pains in the fields of orthopedics, neurology and anesthesia. It is a non-protein extract from inflamed skin of rabbits inoculated with vaccinia virus. Lidocaine is one of the typical local anesthetics and it relieves a variety of neuropathic pain, while sometimes it has neurotoxicity. In clinical practice, neurotropin is used for the treatment in addition to lidocaine to prevent neurotoxicity. However, the mechanism of these reactions remains unclear. In this study, we investigated that the effects of lidocaine and neurotropin on neurite growth in cultured rat spinal neurons. Spinal neurons are stained with mouse anti-phosphorylated neurofilaments (SMI-31) antibody. The length of the individual neurites of SMI-31-immunoreactive neurons was measured using NIH Image software on the captured images. Neurotropin alone had no effect on neurite growth, whereas it protected against the growth inhibitory effects of lidocaine in spinal neurons. These results suggested that neurotropin may lead to rescue lidocaine-induced neurotoxicity.

Abstracts: Endocannabinoids are recently recognized regulators of brain development, but molecular effectors downstream of neuronal type-1 cannabinoid receptor (CB1R) activation remain incompletely understood. We report atypical coupling of neuronal CB1Rs, after activation by endo- or exocannabinoids such as the marijuana component Δ9-tetrahydrocannabinol, to heterotrimeric G12/G13 proteins that triggers rapid and reversible non-muscle myosin II (NM II) dependent contraction of the actomyosin cytoskeleton, through Rho-associated kinase (ROCK). This induces dramatic rapid neuronal remodeling, such as neurite retraction, elevated neuronal rigidity, reshaping of somatodendritic morphology and retraction of axonal growth cones. Chronic pharmacological inhibition of NM II prevents cannabinoid-induced reduction of dendritic development *in vitro* and leads, similarly to blockade of endocannabinoid action, to excessive growth of CB1R-expressing corticofugal axons into the subventricular zone *in vivo*. Our results suggest that CB1R can rapidly transform the neuronal cytoskeleton through actomyosin contractility, resulting in cellular remodeling events ultimately able to affect neuronal architecture and brain wiring.

Title: TACC3 is a microtubule plus-end tracking protein that promotes axon elongation and microtubule polymerization in growth cones

Authors: *L. A. LOWERY, B. NWAGBARA, A. FARIS, B. ERDOGAN, E. BEARCE, P. EBBERT, M. EVANS, C. BAKER, T. ENZENBACHER;
Boston Col., Chestnut Hill, MA

Abstracts: Proper neural connections, essential to nervous system function, depend upon precise navigation by the growth cone during development. A fundamental problem in growth cone biology is how guidance pathways are integrated to coordinate cytoskeletal dynamics and drive accurate axonal navigation. To address this question, we focus on the plus-ends of microtubules (MTs), which explore the growth cone and play a key role in growth cone steering. MT plus-end dynamics are regulated by a conserved family of proteins called 'plus-end-tracking proteins' (+TIPs). Yet, it is unclear how +TIPs interact with each other and with plus-ends to control MT behavior, and how signaling mechanisms downstream of extracellular cues coordinate +TIPs to guide the growth cone in the right direction. We previously determined that the microtubule minus-end regulator, TACC3, interacts with the +TIPs, CLASP and XMAP215, in multiple developmental contexts, including during eye development. However, TACC3 has not yet been defined as a +TIP, its possible function during neurite outgrowth has not been explored, and the detailed mechanism by which it interacts with other +TIPs has not been elucidated. Here, by using automated analysis of live-imaging data of cultured Xenopus laevis growth cones, we show that TACC3 promotes axon outgrowth and regulates microtubule dynamics by increasing microtubule polymerization rates *in vivo*. We also demonstrate that TACC3 performs this function by acting as a +TIP in vertebrate growth cones. Using high-resolution live-imaging data of tagged +TIPs, we reveal that TACC3 localizes to the distal-most tip of MTs in growth cones, where it is directly in front of the microtubule polymerization marker, EB1, and specifically co-localizes with the microtubule polymerase XMAP215. As we previously highlighted that XMAP215 displays multiple functions within growth cones, including both a plus-end-dependent polymerization function as well as a microtubule-lattice binding-dependent microtubule translocation function, we hypothesize that TACC3 specifically enhances the ability of XMAP215 to drive microtubule polymerization downstream of axon guidance cue signaling. We are currently testing this model, to further decipher the regulatory mechanisms that control the growth cone cytoskeletal machine.

Title: The role of tau phosphorylation in regulating cytoskeletal dynamics in cortical growth cones during axon outgrowth

Authors: *S. BISWAS, Q. GAN, K. KALIL;
Dept. of Neurosci., Univ. of Wisconsin, Madison, WI

Abstracts: Tau is a highly phosphorylated microtubule associated protein (MAP) that binds directly to microtubules (MTs) and regulates their dynamics, which is essential for growth cone function during axon growth and guidance. Tau has also been implicated in association with actin filaments, suggesting that tau might modulate actin/microtubule interactions. The state of tau phosphorylation is known to be important in regulating MT dynamics by changing the ability of tau to bind to MTs. Previously we found that inhibiting phosphorylation at a single site on tau, Serine 262, prevented the dynamic reorganization of MTs in cortical growth cones required for axon outgrowth and guidance in response to the morphogen Wnt5a. Phosphorylation at different sites on tau has been shown to regulate MT dynamics in cell free systems. However, the influence of tau phosphorylation on cytoskeletal dynamics has been little studied in living neurons. To address this question we transfected cultured hamster cortical neurons with various forms of tau mutated at different residues to increase or reduce tau phosphorylation. We then applied Wnt5a to increase axon outgrowth. Using immunocytochemistry and biochemical analysis, we found that Wnt5a increases phosphorylation at tau S262 at the leading edge of cortical growth cones, suggesting that tau phosphorylation at S262 increases its association with actin filaments prevalent at the leading edge. We are currently performing live cell imaging with TIRF microscopy on axonal growth cones of neurons transfected with various phospho mimetic and phospho deficient mutations in tau. We are labeling actin filaments with tdTomato tractin and the dynamic plus ends of MTs with EB3-EGFP in neurons transfected with tau constructs with mutations on different phosphorylation sites. We are imaging cytoskeletal dynamics in the growth cones of these neurons during axon outgrowth stimulated by Wnt5a. We are particularly interested in whether changes occur in the association of tau with actin filaments versus MTs as a consequence of phospho mutations in tau. Further, we are investigating whether such changes in tau associations with the cytoskeleton regulate the ability of actin/MT interactions to promote growth cone extension during axon outgrowth.

Title: The WAVE regulatory complex links diverse neuronal receptors to the actin cytoskeleton

Authors: *B. CHEN[1], P. CHIA[2], K. BRINKMANN[3], Z. CHEN[1,4], C. W. PAK[1], Y. LIAO[1], P. LI[2], S. SHI[1], L. HENRY[1], N. V. GRISHIN[1], S. BOGDAN[3], K. SHEN[2], M. K. ROSEN[1]; [1]Dept. of Biophysics, UT Southwestern Med. Center, HHMI, Dallas, TX; [2]Dept. of Biol., Stanford University, HHMI, Stanford, CA; [3]Inst. für Neurobiologie, Univ. Münster, Münster, Germany; [4]Tsinghua Univ. - Current Address, Beijing, China

Abstracts: WAVE proteins play an essential role in actin cytoskeletal dynamics throughout the development of the nervous system. In cells, WAVE exists in a heteropentameric protein assembly, named the WAVE Regulatory Complex (WRC), which stimulates the actin-nucleating activity of the Arp2/3 complex at distinct membrane sites. However, the factors that recruit the WRC to specific locations remain poorly understood. Here, we have identified a large family of potential WRC ligands, consisting of ~120 diverse membrane proteins, mainly enriched in the nervous system, including protocadherins, ROBOs, netrin receptors, neuroligins, GPCRs, and ion channels. Structural, biochemical, and cellular studies reveal that a consensus sequence motif (WRC interacting receptor sequence, or WIRS) that defines these ligands binds to a highly conserved interaction surface of the WRC formed by the Sra and Abi subunits. In *Drosophila*, mutating this binding surface disrupted oogenesis and retinal neuron targeting. In *C. elegans*, mutating the WIRS motif in the synaptic cell adhesion protein SYG-1 leads to loss of local F-actin, synaptic vesicles and active zone proteins, and axonal branches. Our findings directly link diverse neuronal membrane proteins to the WRC and actin cytoskeleton and have broad

physiological and pathological ramifications in metazoans.

Title: Protein arginine methylation of CRMP and tubulin in neurons - a role in axonal development?

Authors: ***N. K. JWAD**[1], L. HEJAZI[2], R. GAMSJAEGER[1], N. J. SUCHER[4], S. C. PILLER[3]; [2]Sch. of Med., [3]Sch. of Sci. and Hlth., [1]Univ. of Western Sydney, Campbelltown, Australia; [4]Roxbury Community Col., Boston, MA

Abstracts: Collapsin response mediator proteins (CRMPs) are a family of five cytosolic phosphoproteins that are expressed during different stages of the development of the nervous system. Originally, CRMPs were identified to play a role in the growth cone collapse pathway. Later studies showed that CRMPs have multiple functions in the developing brain, mainly in axonnal formation, extension, elongation and branching. CRMPs are homologous proteins, sharing 50-75% of their sequence and exist as homo- and heterotetramers. In the process of

axonal growth, CRMP-2 acts as an escort protein for tubulin heterodimers along the growing axon. The binding of CRMP-2 to tubulin heterodimers is regulated by CRMP-2 phosphorylation. Tubulin itself is highly modified by multiple post-translational modifications such as acetylation and glutamylation. Post-translational modifications of tubulin also seem to regulate its binding affinity to motor neurons and microtubule-associated proteins. In this study, arginine methylation of α-tubulin, β-tubulin and CRMP-2 was investigated. Asymmetrical di-methylation of CRMP-2, α-tubulin and β-tubulin was detected using immunoprecipitation and Western blotting. The site of methylation was confirmed with mass spectrometry, revealing two methylated arginine residues on α-tubulin (R79 and R390), two arginines on the β-subunit (R62 and R282, and various arginine residues on of members of the CRMP family proteins (R226 in CRMP-1 and R173 in CRMP-2, and R238 and R270 in CRMP-3). We also found, using Cco-immunoprecipitation experiments indicated, that the inhibition of methylation in mouse primary cortical neurons seems appeared to results in a change in the binding pattern of CRMP-2 and tubulin. The location of methylated arginine on α-tubulin and β-tubulin suggests a potential role in microtubule stability as well as protein-protein interactions with microtubule-associated proteins such as CRMP-2. The location of methylated residues in CRMPs suggests points to a possible association with the regulation of tetramer formation. In summary, our results indicate that protein arginine methylation plays an important role in the regulation of CRMP-tubulin interaction and in axonal development in primary cortical mouse neurons.

Title: Identification of a novel developmental mechanism that promotes sensory axon collateral formation via the regulation of microtubule bundling

Authors: S. TYMANSKYJ, *L. MA;
Zilkha Neurogenetic Inst., USC, LOS ANGELES, CA

Abstracts: In complex neural circuits, neurons often make contacts with multiple targets by sprouting collateral branches from single axonal shafts. Development of these collaterals is highly regulated by intrinsic genetic programs and extracellular environments. Using sensory neurons in the dorsal root ganglia (DRG) as a model, we have identified a novel intrinsic branching mechansim mediated by a microtubule associated protein, MAP7 (also known as ensconsin or E-MAP-115). First, MAP7 expression in the DRG is developmentally regulated, appearing in neurons only at the onset of collateral initiation and reaching to all neurons at the peak of collateral formation. Second, perturbation of MAP7 expression in isolated DRG neurons demonstrates its branch promoting function: MAP7 over-expression stimulated precocious branch formation in young DRG neurons that have no collaterals formed yet and normally do not branch in culture, whereas shRNA knockdown in old neurons with collaterals already formed *in vivo* reduced their ability of promoting branch formation in culture. Further molecular characterization of MAP7 reveals that this branching function requires both the amino-terminal microtubule binding (N) domain and the central phosphorylation (P) domain. In addition, the two domains (NP) together can reorganize microtubules into long and curly bundles when overexpressed in COS cells. Such functional correlation suggests a critical role of microtubule bundles in branch formation. This conclusion is further supported by the study of a spontaneous mouse mutant, as it expresses a truncated NP-equivalent protein and exhibits excessive entries of DRG axons in the spinal cord, a phenotype that is consistent with an increase in collateral branches. Finally, both microtubule bundling and axon branching depend on a specific phosphorylation site in the P domain, suggesting that these activities can be regulated by extracellular cues. Thus, our study uncovers a novel intrinsic program for collateral branch development and demonstrates an importance role of microtubule bundles in branching regulation.

Title: Fully automated quantification of growth cone dynamics at high resolution reveals differential regimes in RhoGTPase function

Authors: *M. M. BAGONIS[1,2], L. FUSCO[2], G. AZARIAS[2], O. PERTZ[2], G. DANUSER[1]; [1]Cell Biol., Harvard Univ., Brookline, MA; [2]Univ. of Basel, Basel, Switzerland

Abstracts: Elucidating the signaling mechanisms of neurite outgrowth is essential for understanding, and eventually manipulating, larger-scale biological processes associated with neuronal development and the re-establishment of functional neuronal connections after injury. How the geometrically distinct actin sub-networks of the growth cone integrate to elicit larger-scale growth cone functional behavior, such as growth cone advance and turning, is still not completely clear. This is due to the complexity of the growth cone cytoskeletal architecture making it difficult to quickly and robustly quantify the totality of growth cone morphological changes during a specific larger-scale functional event. Here, using a combination of live-cell fluorescent imaging and computer vision, we have developed a method for the automated quantification of growth cone structural and dynamic parameters. Using this assay we methodically compared the growth cone dynamic profiles corresponding to several RhoGTPase activity perturbation conditions leading to different neurite outgrowth phenotypes. We found that very diverse growth cone structural/dynamic profiles can lead to enhanced neurite outgrowth. Furthermore, we quantitatively compared the effects of direct, global perturbation of RhoGTPase activity to indirect, potentially spatially/temporally localized, perturbation of RhoGTPase activity via the knockdown of several putative upstream RhoGTPase activity regulators of Rac1 activity. We found that while knockdown of the presumed RhoGTPase activators mimicked some aspects of the corresponding RhoGTPase knockdown, consistent with a role for these proteins in RhoGTPase regulation, knockdown of these proteins likewise elicited distinct growth cone architectures and dynamics. Therefore, we show that this technique is capable of deciphering highly nuanced growth cone phenotypes and therefore is ideal for studying how regulation of smaller scale local dynamic changes in growth cone cytoskeletal architecture elicit different types of global functional neurite behavior. While here we focus on the outgrowth responses elicited in N1E-115 neuroblastoma cells in the presence of the extracellular matrix protein laminin, our method for measurement of growth cone structure and dynamics is generic and provides a means to quickly and unbiasedly quantify functionally relevant growth cone signaling outputs in response to an extracellular cue - a vital first step in future studies aiming at the reconstruction of signaling pathways regulating neurite outgrowth

Title: Regulation of mouse cochlear spiral ganglion neuron innervation by EphA7

Authors: *Y. KIM[1], L. A. IBRAHIM[1], S.-Z. WANG[2], H. W. TAO[1], L. I. ZHANG[1];
[1]USC, Los Angeles, CA; [2]Neurol., Univ. of California, San Francisco, San Franscisco, CA

Abstracts: During the cochlear development, different types of spiral ganglion neuron (SGN) fibers are precisely wired to hair cells (HCs) in the organ of Corti, giving rise to a fine tonotopic organization of SGN-HC connectivity. This requires carefully orchestrated series of events including axon outgrowth and guidance. In the current project, we sought to determine signaling pathways influencing SGN development by generating gene expression profiles in mouse cochlea with RNA-sequencing. We found significant EphA7 expression in the cochlea, which was restricted to SGNs and the greater epithelial ridge (GER). In EphA7-/- mutant mice, we found a significant reduction in SGN fibers innervating hair cells. This reduction was caused by diminished outgrowth of type I afferent fibers, which resulted in reduced number of ribbon synapses on inner hair cells. *In vitro* analysis indicated that both forward and reverse signaling of EphA7 could have the same effect of promoting SGN neurite outgrowth. Furthermore, we identified extracellular signal-regulated kinase 1&2 as possible downstream targets of EphA7 signaling pathway. Our results suggest that EphA7 regulates the outgrowth of type I SGN fibers to ensure optimal connectivity between SGNs and inner hair cells.

Title: CLAC-P/collagen type XXV in muscle, but not in motor neurons, is required for intramuscular development of motor axons

Authors: *H. OIZUMI[1], T. TANAKA[1], S. NISHIO[1], H. MUNEZANE[2], T. HASHIMOTO[2], A. HARADA[3], T. WAKABAYASHI[2], T. IWATSUBO[2];

Abstracts: CLAC-P/collagen type XXV was identified as a component of amyloid plaques in Alzheimer's disease brains. To reveal the *in vivo* function of CLAC-P, we previously generated Col25a1 knock-out (KO) mice, of which the motor axons failed to arborize within the target muscles during embryonic development, followed by massive cell death of motor neurons. Because Col25a1 mRNA was expressed both in motor neurons and in myotubes during neuromuscular development, we examined whether CLAC-P expressed in motor neurons or that in myotubes is required for the intramuscular development of motor axons. To address this question, we generated Col25a1 conditional KO mice by crossing Col25a1flox mice with Cre-expressing mice. In this study, we used two Cre-expressing mouse lines, i.e., Hb9-Cre mice and HSA-Cre mice to abolish Col25a1 gene specifically in motor neurons and myotubes, respectively. When we disrupted the Col25a1 gene in motor neurons just after their differentiation using Hb9-Cre mice, the motor axons arborized normally within the target muscle and formed neuromuscular junctions by E16.5. In contrast, the motor axons of muscle-specific Col25a1 KO embryos lacked intramuscular arborization at E12.5, which completely disappeared from the diaphragm muscles by E15.5. Consistently, the number of motor neurons of muscle-specific Col25a1 KO fetuses was dramatically decreased to an extent similar to that of conventional Col25a1 KO fetuses. These results clearly demonstrate that CLAC-P expressed in skeletal muscles, but not in motor neurons, is essential for the axonal development and survival of the cell bodies of motor neurons. Currently, investigations into the molecular mechanism of CLAC-P function in neuromuscular development are underway by searching for its receptor that may presumably be expressed on the motor axon side.

Title: The role of α6β4 integrin receptor in laminin-mediated axon outgrowth

Authors: J. WETHERELL, A. BUONACCORSI, N. DOPPLER, *M. I. JAREB;
Sacred Heart Univ., FAIRFIELD, CT

Abstracts: Previous data suggest that a laminin receptor is localized in the axons of chick forebrain neurons mediating the axon-growth promoting properties of laminin. Many heterodimers from the integrin family of proteins have previously been identified as laminin receptors, including the α6β4 heterodimer. We tested the role of β4, β1, and α6 integrins in laminin-induced increases in axonal growth using function blocking antibodies. Axons of neurons grown on laminin treated with β4 integrin function blocking antibodies or α6 integrin function blocking antibodies were significantly shorter compared to untreated cultures or cultures treated with a β1 integrin function-blocking antibody. These data are consistent with the hypothesis that the α6β4 heterodimer acts as the axonal laminin receptor in embryonic chick forebrain neurons and is important in axonal development and growth. To directly test whether α6 or β4 integrin was localized specifically to axons, we transfected cultured forebrain neurons from embryonic chick with DNA constructs encoding both α6 and β4 integrin genes. Preliminary results show α6 and β4 integrin expression in axons.

Title: Investigating the role of integrins in Caenorhabditis elegans axon patterning

Authors: D. OLIVER[1], M. M. FRANCIS[2], *M. L. LEMONS[1];
[1]Dept. of Natural Sci., Assumption Col., WORCESTER, MA; [2]Neurobio., Univ. of Massachusetts Med. Sch., Worcester, MA

Abstracts: During development, billions of neurons extend axons to their appropriate targets. Growth cones at the tips of extending axons integrate extracellular cues and guide axons to their correct destinations. Although this navigational ability is essential for proper wiring of the nervous system, the molecular mechanisms of neurons' GPS systems are not yet well understood. Here we show that members of the integrin family of transmembrane receptors regulate axon patterning in a cell type-specific manner in *Caenorhabditis elegans*. This genetically powerful model organism provides a well-defined landscape to examine integrin function *in vivo* due to: 1) the transparency of the animal, 2) the abundance of axon markers, 3) the known spatial and temporal aspects of axonal projections and 4) the limited number of integrin subunits (three compared to ~twenty four vertebrate subunits). In addition, viable integrin hypomorphic worm strains are readily available. We initially focused our studies on INA-1, a laminin-binding integrin subunit that shares sequence homology with vertebrate alpha subunits 3, 6 and 7. We evaluated a strain carrying a missense mutation in a region of *ina-1* that is thought to be critical for integrin activation (*i.e.* a conformational change to a high ligand-affinity state). We found that decreased *ina-1* function produced: 1) striking defects in the patterning of commissural axons from GABA neurons, 2) strong, but less robust effects on commissural axons from ACh neurons, and 3) no obvious effects on longitudinal axons projecting from the tail to the head *(e.g* from the interneuron DVA). Using a transgenic strain expressing GFP-tagged INA-1, we found that INA-1 was expressed in both GABA and ACh motor neurons, suggesting that *ina-1* may act cell autonomously in these neurons. Interestingly, errors in GABA and ACh axon patterning were most pronounced at distinct times during development. For example, axon patterning defects in GABA neurons were most pronounced at the third larval stage (L3), whereas defects in ACh neurons were most pronounced at L4. This evidence suggests that the role of integrins is not equal in all neurons, nor is the functional contribution of integrins equal over time. Future studies will elucidate mechanisms by which integrin signaling achieves cell-type specific effects on axon guidance as well as synapse development.

Title: Proteolytic cleavage of IgLON adhesion proteins by MMPs promotes neurite outgrowth

Authors: *R. L. SANZ, A. FOURNIER;
Neurol. and neurosurgery, McGill Univ., Montreal, QC, Canada

Abstracts: Matrix metalloproteinases (MMPs) are a family of zinc endopeptidases capable of cleaving extracellular matrix and cell surface proteins resulting in degradation or release of biologically active fragments. Processing of surface proteins through MMPs affects developmental processes including axon guidance, survival and synaptogenesis. Moreover, MMPs process ligands and receptors that regulate neuronal plasticity and neurite growth following injury in the Central Nervous System. In the present study, we evaluated the role of MMPs in regulating neurite growth. We find that pan-MMP inhibitors inhibit outgrowth of cortical neurons and dorsal root ganglion neurons (DRGs) and that this effect is dependent on the stage of neuronal maturity. Outgrowth assays with the endogenous MMP inhibitors (TIMPs) confirmed our previous result with the pan-MMP inhibitors. Moreover, through the TIMP inhibitory profile we find that a member of the ADAM family of MMPs is likely responsible for promoting neurite growth. Through tandem mass spectrometry we identified the IgLON family of glycosyl-phosphatidyl inositol (GPI)-anchored neural cell adhesion molecules as proteins that are shed in an MMP-dependent manner. IgLONs are the earliest and most abundant GPI-anchored proteins expressed in the nervous system and are implicated in the process of neuronal outgrowth and cell adhesion. Using reverse-transcription PCR and cell surface biotinylations, we observed a correlation between the expression of IgLON family members *in vitro* and our outgrowth phenotype with MMP inhibitors. Our findings suggest that a near full length fragment of the IgLON ectodomain is cleaved from the surface of cortical neurons in an MMP-dependent manner. Outgrowth experiments on immobilized full-length IgLON proteins identified Neurotrimin and LSAMP as IgLON family members that promote neurite extension in cortical neurons. Together our findings support a role for MMP-dependent shedding of IgLON family members in regulating neurite extension.

Title: Vstm5, a putative cell adhesion membrane protein, regulates dendritic protrusion and synapse formation in hippocampal neurons

Authors: A.-R. LEE[1,2], H. LEE[1,2], M.-R. SONG[1,2], *C.-S. PARK[1,2,3];
[1]Sch. of Life Sci., GIST, Gwangju, Korea, Republic of; [2]Cell Dynamics Res. Ctr., Gwangju, Korea, Republic of; [3]Natl. Leading Res. Lab., Gwangju, Korea, Republic of

Abstracts: Dendritic protrusions are highly dynamic structures in neurons, and morphological change from dendritic filopodia to spines is closely related with the stabilization and strengthening of synapse during neuronal development. Here, we report that Vstm5 (V-set and transmembrane domain containing protein 5), a cell adhesion molecule belonging to the Ig superfamily, is found in various regions of mouse brain. Using cultured hippocampal neurons, we examined the functions of Vstm5 in neuronal development and synaptogenesis. To elucidate the function of Vstm5 in neuronal morphology, we analyzed the dendrites and dendritic protrusions in Vstm5-overexpressing and Vstm5-deficient neurons. Overexpression of Vstm5 caused a dramatic increase in both dendrite complexity and the density of dendritic filopodia. Conversely, Vstm5-deficient neurons showed a decreased density of dendrites and filopodia. At late stage, Vstm5 expressing neurons showed increased in total spine density especially thin-type spine and the number of clusters of the presynaptic vesicle-associated protein synaptophysin. In Vstm5-knockdown neurons, the density of spines and synapses are significantly decreased. These results demonstrate that Vstm5 regulates neuronal morphology by promoting the dendritic protrusion and dendrite formation and it caused synapse formation. In addition, we found that Vstm5 regulate neuronal morphology changes *in vivo*, it caused delayed neuronal migration. Taken together, these results indicate that Vstm5 may be a new member of cell adhesion protein critically involved in dendrite morphology and synapse formation through promotion of neuronal membrane dynamics.

Title: Calcium/Calpain dependent cleavage of Talin and FAK regulates axon pathfinding

Authors: *P. C. KERSTEIN, K. PATEL, T. M. GOMEZ;
Dept. of Neurosci., Univ. of Wisconsin-Madison, Madison, WI

Abstracts: Intracellular calcium (Ca^{2+}) is an essential second messenger of many signaling events within neuronal growth cones. Remarkably, Ca^{2+} can mediate opposing affects on growth cone motility downstream of axon guidance cues. The diversity of Ca^{2+} signaling arises from precise localization of Ca^{2+} influx into microdomains containing specific Ca^{2+} effectors. Previously, we showed that changes in mechanical and chemical composition of the underlying substrata elicit local Ca^{2+} signals within growth cone filopodia that regulate axon outgrowth through activation of the protease calpain. We hypothesize that calpain influences axon guidance through local modulation of adhesion dynamics. Here, we investigated the role calpain mediated proteolysis of specific adhesion proteins in *Xenopus* neuronal growth cones. Our results suggest that Talin and Focal Adhesion Kinase (FAK) are cleaved by calpain in spinal neurons *in vitro* and *in vivo*. Inhibition of calpain increases the localization of endogenous adhesion signaling to growth cone filopodia. Further, pharmacological and molecular inhibition of calpain increased adhesion turnover through increased formation and decreased duration of paxillin-mediated adhesions. Using specific calpain-resistant point-mutants of talin and FAK (Talin L432G, FAK V744G), we demonstrate that calpain specific cleavage events are necessary for proper adhesion formation and turnover *in vitro*. Finally, inhibition of calpain proteolysis *in vivo* leads to increased Rohan-Beard peripheral axon outgrowth into the skin. These data suggest that calpain serves an important role in regulating adhesion dynamics and growth cone motility in axon pathfinding.

Title: The role of focal adhesion kinase in axonal remodeling

Authors: A. I. NAVARRO, *B. RICO;
Inst. de Neurociencias,UMH-CSIC, Sant Joan Alacant, Spain

Abstracts: During the last phases of brain development, once neurons reach their final destination, they extend axons that arborize through the extension of collaterals that bifurcate again to form terminal fields. Neurons typically produce more collaterals and axon terminals that will eventually endure in the adult brain, since many of them are pruned. It has been described two different types of pruning: large-scale pruning with an elimination of long collaterals, and small-scale pruning with a local refinement of axons within the termination zone. This remodeling of the axonal arbor allows the refinement of the network and generates a precise adult connectivity. Over the past few years our group has explored the function of Focal Adhesion Kinase (FAK) in neural circuits development. We have described that FAK controls axonal arborization of hippocampal neurons *in vitro*. Mutant neurons form bigger axonal arbors due to both: increase in branch formation and reduction in branch retraction. Here we have combined mouse genetics with a set of different experimental approaches to show that FAK is required for the proper remodeling of axonal arbors *in vivo*. The absence of FAK causes specifically an impaired small-scale remodeling but does not affect the long-scale pruning. In particular, FAK-deletion in pyramidal cells leads to an abnormal refinement of the axons in the terminal field. Remodeling of the axons could be mediated by local and transcriptional changes. To understand the molecular mechanisms by which the kinase commands this process *in vivo*, we focused in a possible implication in pathways that promote transcriptional changes. FAK has been shown to be upstream of ERK-signaling cascades. Also, FAK can physically associate to regulatory regions of the targeting genes, regulating gene expression. Therefore, to test its role in transcription we have carried out a high throughput screening of genes that are transcriptionally regulated by FAK, using microarray analysis.

Title: Loss of neural recognition molecule NB-3 delays the normal projection and terminal branching of developing corticospinal tract axons

Authors: *Y. LIU;
Inst. of Neuroscience, Soochow Univ., Jiang Su, China

Abstracts: Neural recognition molecule NB-3 is involved in neural development and synapse formation. However, its role in axon tract formation is unclear. In this study, we found that the temporal expression of NB-3 in the deep layers of the motor cortex in mice was coincident with the development of the corticospinal tract (CST). Clear NB-3 immunoreactivity in the CST trajectory strongly suggested that NB-3 was expressed specifically in projecting CST axons. By tracing CST axons in NB-$3^{-/-}$ mice at different developmental stages, we found that these axons were capable of projecting and forming a normal trajectory. However, the projection was greatly delayed in NB-$3^{-/-}$ mice compared to wild-type (WT) mice from the embryonic to postnatal stages, a period that is coincident with the completion of the CST projection in mice. Subsequently, although their projection was delayed, CST axons in NB-$3^{-/-}$ mice gradually completed a normal projection. By stage P21, the characteristics of CST projections in NB-$3^{-/-}$ mice were not statistically different from those in WT mice. In addition, we found that the branching of CST axons into spinal gray matter also was delayed in NB-$3^{-/-}$ mice. The CST innervation area in the spinal gray matter of NB-$3^{-/-}$ mice was greatly reduced in comparison to WT mice until P30 and gradually became normal by P45. These data suggest that NB-3 is involved in the normal projection and terminal branching of developing CST axons.

Title: Spatiotemporally coordinated Tetraspanin-3 proteins provide a functional microdomain for Nogo-A-D20-induced spreading and neurite outgrowth inhibition

Authors: *N. K. THIEDE-STAN[1], D. ALBRECHT[2], B. TEWS[3], Z. RISTIC[1], H. EWERS[2], M. SCHWAB[1];
[1]Brain Res. Inst. UZH and Dept. of Hlth. & Technol. ETH, Zuerich, Switzerland; [2]Randall Div. of Cell and Mol. Biophysics, King's Col. London, London, United Kingdom; [3]Div. of Mol. Mechanisms of Tumor Invasion, German Cancer Res. Ctr., Univ. of Heidelberg and DKFZ, Heidelberg, Germany

Abstracts: Neurite outgrowth and axonal regeneration are restricted by myelin-associated inhibitors, in particular Nogo-A. Nogo-A-D20 (rat aa544-725) is besides Nogo-66 the most potent neurite growth inhibitory fragment of the membrane-spanning protein Nogo-A, which additionally restricts adhesion and spreading of non-neuronal cells. Recently, the G-protein-coupled receptor Sphingosine-1-phosphate receptor 2 (S1PR2) has been identified in a yeast two-hybrid system as specific Nogo-A-D20 signal-transducing receptor. The same screen revealed the 4-transmembrane-spanning protein Tetraspanin-3 (Tspan-3) as an additional high-affinity binding partner for Nogo-A-D20. Based on the described minor relevance of Tetraspanin proteins in direct signal transduction, but their pronounced feature as microdomain organizers, we hypothesized a coordinative co-receptor function for Tspan-3 in a potential multi-subunit Nogo-A-D20 receptor complex. Direct binding assays showed Tspan-3 as high-affinity binding partner for Nogo-A-D20. siRNA or lentiviral shRNA-mediated knock-down of Tspan-3 leads to a significant counteraction of Nogo-A-D20-mediated cell spreading inhibition, revealing a functional relevance of Tspan-3 in Nogo-A-D20 signaling. Tspan-3 accompanies Nogo-A-D20 along its multi-step route from cell surface binding to early endocytosis and noticeably affects Nogo-A-D20 cell surface binding at a very early stage of initial contact with the cell surface. Live-imaging single-molecule-localization microscopy revealed that Nogo-A-D20 induces a spatiotemporally coordinated Tspan-3 re-organization. Tspan-3 co-localizes minimally with S1PR2 in absence of Nogo-D20; addition of Nogo-D20 induces an increased dynamically regulated complex formation of Tspan-3 and S1PR2. Palmitoylations (post-translational S-acylation with palmitate of juxtamembrane protein cysteine residues) are known to stabilize assemblies of Tetraspanins and Tetraspanin-associated proteins in Tetraspanin-enriched microdomains. Interference with palmitoylations with 2-Bromopalmitate (2-Bp) counteracts Nogo-A-D20-induced spreading inhibition. Furthermore, 2-Bp treatment or Tspan-3 knock-down decrease Nogo-A-D20-induced RhoA activation. These results point to a relevant modulatory role of a Tetraspanin-3 microdomain in the Nogo-A-D20-induced G protein 13 - LARG - RhoA

signaling axis. Our findings provide new insights into the succession and coordination of major cell biological mechanisms in Nogo-A-D20-mediated growth inhibition.

Title: Determining the influence of confinement on growth cone response to inhibitory biochemical borders

Authors: ***M. S. SMIRNOV**[1], H. M. GELLER[3], J. S. URBACH[2];
[1]IPN, [2]Physics, Georgetown Univ., Washington, DC; [3]Natl. Heart, Lung, and Blood Inst., NIH, Bethesda, MD

Abstracts: Developing and regenerating axons *in vivo* encounter many chemical and topographic guidance cues. The response to these cues is mediated by the growth cone, a structure at the axonal tip. The morphology of the growth cone is often correlated with growth rate, e.g., growth cones increase in complexity and size and also slow down at decision regions. The details of this mechanism are not well-understood. We hypothesize that confinement of growth cones increases axonal extension and makes them less sensitive to guidance cues. To approach this problem, we have created a model system for evaluating growth cone behavior at the interface between molecular and structural cues under direct microscopic observation. In this system, we use two-photon laser ablation of polyvinyl alcohol to create laminin-coated, micron-scale adhesive channels (Smirnov, et al., Biomaterials, 2014). We then create local depositions of inhibitory chondroitin sulfate proteoglycans on the pattern, forming a distinct permissive/inhibitory boundary within each channel. Mouse postnatal cerebellar granule neurons are plated onto the substrate and the behavior of growth cones is observed with time-lapse microscopy. This system permits the study of growth cone sensitivity to guidance cues, as well as their cytoskeletal mechanisms, based on changes in channel width.

Authors: *V. L. SAVCHENKO[1,2];
[1]Geriatrics, Univ. of Arkansas, Little Rock, AR; [2]Anesthesiol., Univ. of Florida, Gainesville, FL

Abstracts: The maintenance of excitatory and inhibitory neurons and their axonal projection are determined by different factors during development. An imbalance of glutamatergic and GABAergic neurons leads to abnormal brain development. The aim of this study was to assess the regulation of excitatory and inhibitory synapses in developing cortical neurons during the modulation of synaptic activity. Vesicular glutamate transporter 1 (vGlut1) and vesicular GABA transporter (vGAT) were used as markers for glutamatergic and GABAergic synapses, respectively, and their expression was established on MAP-2-labeled soma and dendrites of cortical neurons using immunofluorescent methods and quantitative analysis. The concentration of neurotransmitter in synaptic vesicles depends on the density and activity of vesicle transporters. The expression of vesicle transporters was evaluated as an average intensity of fluorescent signals during the modulation of neuronal activity. APV, an antagonist of NMDA receptors, inhibited spontaneous activity. APV regulated the distribution of vGlut1- and vGAT-labeled synapses. On the other hand, NMDA increased vGlut1 expression and decreased the number of vGlut1 labeled synapses. APV given prior to NMDA treatment prevented the reduction of glutamatergic synapses. The activation of NMDA receptors induced c-Fos expression in cortical neurons, and APV attenuated this effect. APV also enhanced the adhesive properties of cortical neurons and their synapses. This suggests that the inhibition of NMDA receptor activity induces Neuroligin and Neurexin adhesive trans-synaptic interaction in cortical neurons. An alteration of synaptic activity is significant for the regulation of vGlut1 and vGAT expression during axonal growth and synaptogenesis.

Title: Electrically driven axonal outgrowth on multi-electrode arrays

Authors: *S. A. WEYDERT, C. FORRO, J. CHAABAN, H. DERMUTZ, L. DEMKO, J. VOROS;
Lab. of Biosensors and Bioelectronics, ETH Zurich, Zurich, Switzerland

Abstracts: One of the grand challenges of this century is to learn how our brain functions. Despite of the vast amount of technical possibilities we still have very little insight (and especially consensus) into e.g. how memory is stored. One reason for this might be that our current knowledge in neurosciences mostly derives from single cell technologies such as patch clamping, or system level studies (e.g. MRI). Multi-electrode arrays (MEA) try to fill in this gap by providing information about neural slices and cultures, however, even though several attempts have been made to build more controlled neuron networks (microcontact printing, microfluidics, etc.) there is still no reliable technology that could provide well-defined *in vitro* networks with oriented connections on MEA chips. Due to the lack of such "study networks", the field is forced to perform experiments on highly complex systems which makes a complete understanding of the fundamental aspects very difficult. In this work we describe a comprehensive method to realize small neuronal networks on MEA chips in a controlled and reproducible manner. The type, number, position of the neurons, as well as the connections and their directionalities can be defined and kept under control by combining PDMS sheets and electrically driven axonal outgrowth. The role of the PDMS sheets are multifold: first they provide control over the seeding concentration and cell positions, then they confine neurite outgrowth into the predefined directions and make closed compartments for improved electrical recordings. We demonstrate the applicability of the method with a self-designed MEA chip as a proof of concept, by realizing directed small neuronal loops of rat hippocampal neurons and measuring their activity. Here the specially arranged electrodes also have multiple roles: they can induce electrochemically controlled surface chemistry changes, can be used as "electric fences" to control neurite outgrowth, and of course can also fulfill their primary duty of recording extracellular activities and applying electrical stimuli.

Title: The proinflammatory cytokine, interleukin-17A, augments axonal plasticity and mitochondrial function of cultured adult sensory neurons

Authors: ***T. HABASH**[1,2], A. SALEH[1], S. ROY CHOWDHURY[1], P. FERNYHOUGH[1,2]; [1]St-Boniface Hosp. Res. Ctr., Winnipge, MB, Canada; [2]Pharmacol. and therapeutics, Univ. of Manitoba, Winnipeg, MB, Canada

Abstracts: Rationale and hypothesis: Diabetic neuropathy involves dying back of nerve endings that reflects impairment in axonal plasticity and regenerative nerve growth. Metabolic changes in diabetes can lead to a dysregulation of hormonal mediators, such as cytokines. Thus we studied the effect of interleukin-17A (IL-17A), a proinflammatory cytokine produced by T-cells, on the phenotype of sensory neurons derived from control or diabetic rats. We hypothesized that diabetes induces suboptimal cytokine levels in neurons that reduces axonal growth and this may underlie impaired axon regeneration and plasticity within the skin leading to sensory loss. Objectives: Determine the ability of IL-17A to enhance neurite outgrowth in cultured sensory neurons. Investigate the signalling pathways activated by IL-17A and mechanistically link to neurite outgrowth. Study the ability of IL-17A to improve mitochondrial function of sensory neurons (since axon outgrowth consumes high levels of ATP). Methodology: Cultured adult dorsal root ganglia (DRG) sensory neurons derived from age matched control or streptozotocin (STZ)-induced type 1 diabetic rats were fixed and stained for fluorescent imaging to determine total neurite outgrowth. Western blotting determined the levels of MAPK and PI-3K activation by IL-17A and for measuring levels of proteins of mitochondrial oxidative phosphorylation pathway. Mitochondrial bioenergetics function was tested in cultured DRG neurons using the Seahorse XF Analyzer. Results: We found that IL-17A (10 ng/ml; $P<0.05$) significantly increased total neurite outgrowth in cultures derived from both control and STZ-diabetic rat models. This enhancement was mediated by IL-17A-dependent activation of MAPK and PI-3K

pathways with maximal effect at 15 minutes ($P<0.05$). Pharmacological blockade of one of these activated pathways led to total inhibition of neurite outgrowth. IL-17A improved mitochondrial bioenergetics function of sensory neurons. Bioenergetics function was associated with augmented expression of proteins of mitochondrial oxidative phosphorylation. Conclusion: IL-17A enhanced axonal plasticity through activation of MAPK and PI-3K pathways and was associated with augmented mitochondrial bioenergetics function in sensory neurons.

Abstracts: Axons of developing neurons are known to contain packets of vesicles and other membranous structures required for synaptogenesis. Here, we used cryo-electron tomography to image developing hippocampal neurons grown in culture. As a result, we obtained three-dimensional images of fully hydrated, vitrified neuronal processes. Our analysis focused on axonal varicosities, in particular on those that contained synaptic vesicle packets or other membranous structures. In addition to describing morphology of vesiclular and tubulovesicular structures, we analyzed the vesicle organization and their inter-connectivity in a quantitative manner. Our results indicate that synaptic vesicles are interconnected by filamental structures, as is the case in presynaptic terminals of mature synapses that we analyzed in the past, but are significantly less tethered to the plasma membrane then the vesicles of mature synapses. In addition, we used automated segmentation methods to detect and visualize actin in axonal varicosities and filopodia.

Title: Sirtuin 2 is a sensor of energy status and inducer of neurite outgrowth in adult sensory neurons

Authors: ***E. D. SCHARTNER**[1,2], A. SALEH[1], R. VIEIRA DA SILVA[1], S. CHOWDHURY[1], D. SMITH[1], P. FERNYHOUGH[1,2];
[1]St. Boniface Hosptial Res., Winnipeg, MB, Canada; [2]Pharmacol. and Therapeut., Univ. of Manitoba, Winnipeg, MB, Canada

Abstracts: Introduction: Diabetic sensory neuropathy is a nerve disorder that results in distal dying back of nerve fibers. Neuronal mitochondrial function is impaired in diabetes and Sirtuin 2 (SIRT2) is a key sensor of redox state that regulates cellular bioenergetics. We hypothesized that defective SIRT2 signaling contributed to deficiencies in energy supply and nerve regeneration in diabetic neuropathy. Objectives: We studied the different mechanisms of SIRT2 signaling within adult sensory neurons that drive axon regeneration and how these pathways were impaired under diabetic conditions. Methods: Type 1 diabetes was induced in rodents by intraperitoneal injection of streptozotocin (STZ). Dorsal root ganglia (DRG) were isolated from age matched and 5 month STZ-diabetic mice and SIRT2 protein levels analyzed. DRG sensory neurons derived from control and STZ-diabetic rats were cultured in defined media with varying concentrations of neurotrophic factors and D-glucose. Quantitative Western blotting was performed to determine protein levels and immunocytochemistry utilized to quantify neurite outgrowth. Lentiviral transduction and plasmid transfection were instigated for shRNA knockdown of SIRT2 and overexpression of SIRT2 constructs. Results: SIRT2 isoforms 2.1 and 2.2 were reduced by 20-30% in DRG of diabetic mice ($P<0.05$). In cultured adult sensory neurons derived from age matched control or STZ-diabetic rats over-expression of wild-type SIRT2 significantly enhanced total neurite outgrowth. Overexpression of the dominant negative mutant (SIRT2-H150) or shRNA to SIRT2 blocked neurite outgrowth. Application of varying doses of AGK2, a selective inhibitor of SIRT2, significantly reduced total neurite outgrowth ($P<0.05$). Treatment with

increasing doses of NAD+, an endogenous activator of SIRT2, significantly enhanced neurite outgrowth. After 72hrs in media with high D-glucose (25mM), cultured sensory neurons showed a significant 2-fold ($P<0.05$) decrease in the protein levels of SIRT2 isoforms. Conclusions: SIRT2 is a key component driving axon regeneration and this pathway was impaired in diabetic sensory neuropathy.

Title: Process retraction requires the calcium-activated protease calpain in homolog avoidance leading to tiling by motor neurons

Authors: L. SOLANO[1], E. R. MACAGNO[1], *M. W. BAKER[2];
[1]Div. of Biol. Sci., UCSD, La Jolla, CA; [2]Div. of Biol. Sci., Unive California, San Diego, La Jolla, CA

Abstracts: Oppositely directed projections of some homologous neurons in the developing CNS of the medicinal leech, such as the AP cells, undergo a form of contact-dependent homolog avoidance, a form of cellular tiling behavior. Embryonic APs extend axons within the connective nerve toward adjacent ganglia, in which they (1) meet and form gap junctions (GJs) with the oppositely directed axons of their segmental homologs, (2) stop growing, and are (3) later permanently retracted (Wolszon et al., 1994, J. Neurosci. 14). However, early deletion of an AP neuron (Gao and Macagno, 1987, J. Neurobiol. 18) or selective knockdown of the gap junction gene Inx1 (Baker at al., 2013, J. Neurosci. 33), leads to resumed growth and permanent maintenance of the projections of neighboring APs. Continued growth was also observed when a closed-channel mutant of Inx1 was expressed by the AP neuron indicating the likely exchange of a soluble signal between the cells. Here we explore the nature of the signal that causes the AP's

connective processes to retract. Following the formation of the transient GJ, the distal processes of the AP neuron were observed to undergo Wallerian fragmentation, suggesting the possible activation of an intracellular protease. Calcium imaging has also revealed that these distal GJs permit calcium exchange between the contacting processes suggesting that one potential candidate for mediation may be the calcium-activated protease calpain which has been shown to function downstream of calcium transients. Accordingly, we employed RNAi to knockdown a neuronal leech calpain (CalI) in individual AP neurons in the developing embryo and found that homolog avoidance was significantly impaired. AP neurons were observed to extend processes into and beyond their adjacent ganglia, mimicking the effects of cellular ablation or Inx1 knockdown. Ongoing studies will explore the possible link between GJ signaling and CalI activation by targeting the source of compartmental calcium transients by examining the role-played by voltage-gated calcium channels and mechanisms for the release of calcium from internal stores.

Title: The quantitative proteomes and transcriptomes of projection-specific growth cones from mouse brain

Authors: *A. POULOPOULOS, A. J. MURPHY, P. F. DAVIS, J. D. MACKLIS;
Stem Cell and Regenerative Biol., Harvard Univ., Cambridge, MA

Abstracts: The development of wiring diagrams in the nervous system is driven by the cellular machineries of growth cones, the leading edges of extending axons. These specialized cellular compartments contain select sets of macromolecules that enable growth cones to determine the paths, and ultimate target fields of their dedicated axon projections. Though we lack an understanding of the integrated molecular mechanisms, and layers of complex orchestration, neuronal circuit development may be viewed as an emergent property of the coordinated interactions between the molecular machinery of individual growth cones, and the sequence of molecular surroundings they encounter. This hierarchical organization from growth cone to brain circuits is made possible by the high degree of molecular specialization, compartment autonomy,

and acute responsiveness to stimuli that growth cones display. Functioning at great distances from the cell soma, growth cones contain specific and functionally integrated sets of proteins, RNA, and lipids, endowing each class of growth cones with a distinct molecular complement so as to contribute its part to the wiring diagram. This makes growth cones highly heterogeneous, likely mirroring the heterogeneity of neurons and axon projections themselves. As such, growth cone heterogeneity is an important feature of nervous system development, but also a major experimental obstacle to the comprehensive, analytical study of the physiological molecular machineries that drive circuit development. In order to have direct experimental access to the molecular compositions of individual classes of growth cones in their native context, we have developed a new approach, combining *in vivo* hodological and genetic labeling techniques, biochemical fractionation, and FACS to obtain the endogenous growth cone proteomes and transcriptomes of individual projection classes in the mouse brain. Applying this approach to projections that cross the corpus callosum, we have acquired quantitative datasets that provide a comprehensive view of the growth cone molecular machinery, its compartmentalization, and heterogeneity.

Title: Functions of Cdk12 in axonal elongation and neural development

Authors: ***M.-J. FANN**, H.-R. CHEN, C.-K. HUANG;
Dept of Life Sci., Natl. Yang-Ming Univ., Taipei, Taiwan

Abstracts: Cdk12 is a Cdc2-related protein and expresses at high levels in the developing nervous system. We explored the roles of Cdk12 in neuronal differentiation in the P19 neuronal differentiation model. Upon knockdown of Cdk12, there is no effect on numbers of differentiated cells, but it generates a substantial decrease of numbers of neurons with long neurites. Similarly, knockdown of Cdk12 in cultured cortical neurons shortens the averaged axonal length. A

microarray analysis was used to examine changes in gene expression after knockdown or overexpression of Cdk12 and we identified Cdk5 as a molecule potentially involved in mediating the effect of Cdk12. Depletion of Cdk12 in P19 cells significantly reduces Cdk5 expression at both the mRNA and protein levels. Furthermore, overexpression of Cdk5 protein in P19 cells partially rescues the neurite outgrowth defect observed when Cdk12 is depleted. To define the role of Cdk12 during neural development *in vivo*, we conditionally targeted Cdk12, using a mouse line expressing Cre recombinase driven by a nestin promoter. Cdk12 cKO mice die around P1 and exhibit a significant size reduction of the brain, especially in the cortex, but are indistinguishable in body sizes. Cdk12 ablation results in reduced thickness of the neuronal layers and delayed migration of late-born neurons in the Cdk12-ablated E14.5 dorsal telencephalon. In addition, expression of Cdk5 protein in developing mouse brain is reduced in Cdk12 cKO mice proportionally to the amounts of residual Cdk12 protein. Deficiency of Cdk12 also markedly attenuates phosphorylation of Erk in neural tissues. Taken together, function of Cdk12 is crucial for several aspects of neuronal development, including axonal growth and cell migration, by modulating Cdk5 expression.

Abstracts: The mammalian olfactory sensory neurons are regenerated through the life of an animal. Each sensory neuron specifically expresses only one type of olfactory receptor out of a ~1000 repertoire. The axons of the neurons expressing the same receptor converge into the same stereotypic position in the brain, thus forming a topographic map, critical for odorant perception.

This precise connection between olfactory sensory neuron and the brain is maintained through life. Regenerated sensory neurons must project properly to the target glomeruli. We have identified a critical period during the postnatal development of the olfactory sensory neuron. After the critical period, the olfactory sensory neuron adopts a different axon guidance mechanism and follows existing axons of the same receptor type. This observation suggests a mechanism for the maintenance of the odor map. Furthermore, we have taken a RNA-seq approach to study the genetic program and to identify a group of potential genes that may be involved in the control of the critical period.

Title: Understanding the roles of intrinsic and extrinsic influences on fetal arcuate nucleus neuron development in gestational obesity

Authors: T. R. SANDERS, *C. JASONI;
Ctr. for Neuroendocrinology and Dept. of Anat., Univ. of Otago, Dunedin, New Zealand

Abstracts: An association has been clearly shown in humans and rodent models between maternal obesity during pregnancy, and subsequent risk for later life disease, including obesity and the metabolic syndrome, in the offspring. Furthermore, we and others have shown that the ability of body weight regulating neurons in the arcuate nucleus of the hypothalamus (ARC) to innervate their targets is disrupted in the prenatal and postnatal offspring of obese mothers. However, the mechanism behind this is unknown. It has recently emerged that maternal obesity is associated with increases in certain inflammatory cytokines, including interleukin-6 (IL-6), in both the maternal and fetal circulation. Further to this, we have used *in vitro* cultured explants from gestational day 17.5 (GD17.5) mouse ARC, to show that IL-6 dose dependently retards

neurite outgrowth and is able to significantly alter the expression of DCC and Unc5d, receptors for the axon growth regulator Netrin-1. These developmental gene expression changes as well as retarded growth of ARC NPY neurites to one of their target structures, the paraventricular nucleus of the hypothalamus, were also observed *in vivo* in the fetuses of pregnancies complicated by maternal obesity. Although it appears that IL6 causes NPY neurons to alter their responsiveness to Netrin-1, whether this effect is direct or indirect, and/or whether an environment of maternal obesity alters the intrinsic ability of NPY neurons to develop normally is unknown. To address this further, we have established a novel *in vitro* culture system in which ARC neurons, in particular the weight regulating NPY (Neuropeptide Y) and POMC (Pro-opiomelanocortin) neurons, from fetuses developing in either obese or normal weight mothers are assessed for their intrinsic neurite growth properties. In these cultures, the relative proportions of surviving NPY and POMC neurons mirror the normal proportions observed *in vivo* across ARC development, indicating that this novel system adequately represents normal ARC development. In summary, the cytokine IL-6 has the ability to perturb the normal growth of developing ARC neurites, a mechanism which could explain maternal obesity-induced decreases in the ability of offspring ARC neurons to innervate their targets. Establishment of a novel cell culture system, which mirrors normal development, gives us the ability to identify both intrinsic differences in ARC neuronal growth characteristics, and extrinsic modulators of normal development. Data from these experiments is critical to understanding the underlying brain-level changes that elevate offspring health risk in pregnancies complicated by maternal obesity.

Title: Presynaptic mitochondrial capture is required for proper axon branching *in vitro* and *in vivo*

Authors: *T. LEWIS, JR, J. COURCHET, F. POLLEUX;
Dept. of Neurosci., Columbia Univ. Med. Ctr., New York, NY

Abstracts: The mechanisms underlying axonal development are inadequately understood but are critical for the proper formation of neural circuits. We have uncovered a new role for LKB1 and its downstream kinase NUAK1 in regulating axon branching both *in vitro* and *in vivo* by controlling mitochondria immobilization along axons (Courchet, Lewis et al., Cell 2013). Using manipulation of Syntaphilin, a protein necessary and sufficient to arrest mitochondrial transport specifically in the axon, we demonstrate that the LKB1-NUAK1 kinase pathway regulates axon branching by promoting mitochondria immobilization. Finally, we show in dissociated neuronal cultures that LKB1 and NUAK1 are necessary and sufficient to immobilize mitochondria specifically at nascent presynaptic sites. To determine if mitochondrial dynamics and capture are similar *in vivo*, we are using sparse labeling of layer 2/3 pyramidal neurons followed by live time-lapse microscopy in brain slices and head-fixed mice. Our results reveal a link between presynaptic mitochondrial capture and axon branching.

Title: Hyperactivating mutations in alpha2-chimaerin alter motor neuron development to cause Duane Retraction Syndrome

Authors: *A. A. NUGENT, Y. WEI, J. G. PARK, M. M. DELISLE, E. C. ENGLE;
Boston Children's Hosp., Boston, MA

Abstracts: In Duane Retraction Syndrome (DRS), the abducens cranial nerve does not appropriately innervate the lateral rectus (LR) eye muscle and the oculomotor nerve may aberrantly innervate the LR, resulting in limited outward gaze and globe retraction upon inward gaze. People with DRS can carry heterozygous, gain-of-function missense mutations in *CHN1*, which hyperactivate the encoded protein α2-chimaerin. We have introduced one of the human

DRS mutations into mouse, creating a *Chn1* L20F mutant knock-in (*Chn1*^{KI}). *Chn1*$^{WT/KI}$ and *Chn1*$^{KI/KI}$ mice are viable and fertile, but have an external eye retraction phenotype, with varying penetrance. In developing *Chn1*$^{WT/KI}$ and *Chn1*$^{KI/KI}$ mice, mutant α2-chimaerin causes aberrant axon growth and guidance of VI and subsequent elimination of Hb9-positive abducens motor neurons in the hindbrain nucleus. Inhibiting apoptosis does not prevent abducens nerve growth and guidance defects, suggesting DRS is primarily an axon growth or guidance disorder. The oculomotor nerve aberrantly branches toward the LR, suggesting *Chn1*^{KI} mice recapitulate human DRS. Additional motor neuron populations appear abnormal in *Chn1*$^{KI/KI}$ mice, as the trochlear nerve, facial nerve, and first cervical segment of the spinal cord also have developmental defects. While patients can exhibit oculomotor and trochlear nerve dysinnervation and/or misinnervation, it remains to be determined whether human DRS patients have facial or spinal nerve abnormalities. This work establishes and characterizes a mouse model for DRS, and provides the basis for further studies to investigate the etiology of DRS.

Title: Competing aPKC isoforms regulate neuronal polarity

Authors: S. S. PARKER[1], S. M. HAPAK[2], E. K. MANDELL[3], *S. GHOSH[3];
[1]Univ. of Arizona, Tucson, AZ; [2]Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA; [3]Yale Univ. Sch. of Med., New Haven, CT

Abstracts: Atypical Protein Kinase C (aPKC) isoforms zeta and iota interact with polarity complex protein Par3 and are evolutionarily conserved regulators of cell polarity. The Prkcz gene encodes the proteins aPKCzeta and PKMzeta, a truncated, neuron-specific alternative product, while Prkci gene encodes aPKCiota protein. Here we show that, in embryonic hippocampal neurons, two aPKC isoforms - aPKCiota and PKMzeta are expressed. The localization of these isoforms is spatially distinct in a polarized neuron. aPKCiota, as well as

Par3, localizes at the presumptive axon, while PKMzeta and Par3 are distributed at non-axon forming neurites. PKMzeta competes with aPKCiota for binding to Par3 and disrupts the aPKCiota-Par3 complex. Silencing of PKMzeta, genetic ablation of Prkcz locus or overexpression of aPKCiota in hippocampal neurons alters neuronal polarity, resulting in neurons with supernumerary axons. In contrast, the overexpression of PKMzeta prevents axon specification. Our studies suggest a molecular model wherein mutually antagonistic intermolecular competition between aPKC isoforms directs symmetry breaking and allows for the establishment of neuronal polarity.

Title: Sildenafil promotes axonal growth of dorsal root ganglia neurons under high glucose conditions

Authors: *L. JIA;
Neurol. Res., Henry Ford Hosp., Detroit, MI

Abstracts: Objective: Diabetic peripheral neuropathy impairs the sciatic nerve. Sildenafil, a phosphodiesterase type 5 inhibitor, ameliorates neurological function in diabetic peripheral neuropathy. However, the direct effect of sildenafil on axonal growth has not been investigated. Using rat primary dorsal root ganglia (DRG) neurons cultured in a microfluidic chamber, we investigated the effect of sildenafil on axonal growth under a high glucose conditions. **Methods and Results:** DRG neurons were harvested from embryonic day 18 Wistar rats and cultured in a microfluidic chamber that separates axons from neuronal cell bodies. The neurons were cultured under regular glucose (25mmol/L, RG), high glucose (45mmol/L, HG), or high glucose with sildenafil (300ng/ml). Axonal length was measured on day 3 *in vitro*. The HG condition significantly reduced the axonal growth **(**838±189mm) compared to the RG condition **(**1073±203mm, n=45/group, $P<0.01$**).** However, sildenafil suppressed HG-reduced axonal growth **(**1096±198mm, n=45, $P<0.01$). Real-time RT-PCR and immunocytochemistry analysis of DRG neurons revealed that HG downregulated miR-146a levels (0.54 ± 0.12 vs. 1±0.02 in RG, n=6, $P<0.01$) and substantially ($p<0.01$) increased miR-146a target gene, IRAK1 (32±6% vs.18.9% in RG, n=6/group) and TRAF6 (34±6% vs.17.5% in RG, n=6/group) positive neurons. In contrast, sildenafil significantly ($p<0.01$) reversed HG-reduced miR-146a levels (0.93 ± 0.18, n=6) and HG-increased IRAK1 (16±3.1%) and TRAF6 (17±2.3%) positive cells. Elevation of miR-146a in DRG neurons by transfection of miR-146a mimics significantly increased axonal growth (362±68mm vs.313±56mm, n=6) under HG condition, while decrease of miR-146a by miR-146a inhibitor reduced axonal growth (196±23mm vs.305±43mm, n=6). **Conclusion:** Our data suggest that sildenafil suppresses the inhibitory effect of high glucose on axonal growth of DRG neurons and miR-146a and its target genes, IRAK1 and TRAF6 may mediate this process.

Title: Post-transcriptional control of axonal growth by binding of HuD and KSRP to common neuronal targets

Authors: A. S. GARDINER[1], C. GOMES[2], J. SAAVEDRA[1], J. L. TWISS[2], *N. PERRONE-BIZZOZERO[1];
[1]Neurosciences, Univ. of New Mexico HSC, ALBUQUERQUE, NM; [2]Biol. Sci., Univ. of South Carolina, Columbia, SC

Abstracts: Post-transcriptional mechanisms are known to play important roles in neuronal development as they allow for faster responses to environmental cues and provide spatially restricted compartments for local control of protein expression in both axons and dendrites. Among these mechanisms, the control of mRNA stability by the interaction of RNA-binding proteins (RBPs) with AU-rich instability elements (ARE) in the 3' UTR is one of the least understood. We have recently shown that two ARE-BPs, HuD and KSRP, compete for binding to the ARE in GAP-43 mRNA (Bird et al, PLoS One 2013). HuD binding stabilizes and localizes GAP-43 mRNA, promoting axonal outgrowth, while KSRP binding destabilizes GAP-43 mRNA and stunts outgrowth. These results suggest that these proteins compete for the control of target expression and process outgrowth during neuronal development. Supporting this idea, we recently found that KSRP and HuD show a different temporal pattern of expression both in culture and *in vivo*, with HuD preceding KSRP expression. Moreover, HuD and KSRP localize

to different RNA granules both in the cell body and processes. To initially identify the repertoire of neuronal transcripts regulated by these ARE-BPs, we used UV-crosslinking and RNA immunoprecipitation followed by microarray assays (CLIP-chip). Briefly, E18 C57BL/6 mouse neocortical tissue was processed for CLIP using antibodies to HuD, KSRP or control IgG and RNAs from the IPs analyzed on Affymetrix GeneChip 430 2.0 arrays. Results from these assays were validated using qRT-PCR and KSRP KO mice. We found that KSRP and HuD bound both distinct and shared sets of target mRNAs. Besides GAP-43, other common targets included β-actin *(Actb),* catenin β1 *(Cttnb1),* eukaryotic initiation factor 4G2 *(Eif4g2),* fasciculin 1 *(Fscn1),* heat shock cognate protein 70kDa *(Hspa8),* myristoylated alanine-rich protein kinase C substrate *(Marcks*), Stathmin 1 *(Stmn1),* transthyretin *(Ttr)*, and Tubulin β2b *(Tubb2b).* Interestingly, many of these targets are localized to axons and upregulated in KSRP KO mice, which express normal levels of HuD protein. Localized mRNAs binding selectively to either HuD or KSRP were also identified, including *Atxn10*, *Eif5, Pebp1* and *Tuba1b* (KSRP) and *Calr, Tpm3, Tubb5*, and *Vim* (HuD). These results suggest that the opposing roles of HuD and KSRP in axonal outgrowth are due in part to the differential regulation of common and unique targets, with HuD stabilizing and KSRP destabilizing localized transcripts.

Title: Extracellular vimentin promotes axonal growth via IGF1R

Authors: *M. SHIGYO, T. KUBOYAMA, C. TOHDA;
Div. of Neuromedical Sci., Inst. of Natural Medicine, Univ. of Toyama, Toyama, Japan

Abstracts: Vimentin, an intermediate filament protein, is generally known as an intracellular protein related to cell adhesion and cell migration. Recently, we reported that vimentin secreted from astrocytes promoted axonal growth in cultured mouse cortical neurons. The effect of extracellular vimentin in neurons was a new finding, but its signal pathway was unrevealed. In this study, we aimed to clarify the signaling mechanism of extracellular vimentin that facilitates axonal growth. Primary cultured rat cortical neurons (SD, E17) were treated with human recombinant vimentin (1.75 μM) for 10 min, and then cell lysates from vehicle treated or vimentin-treated neurons were analysed with phosphoprotein arrays. As a result, IGF1R was identified as a highly phosphorylated molecule by vimentin stimulation. In primary cultured mouse cortical neurons (ddY, E14), vimentin (1.75 μM) as well as IGF1 (1.3 μM) facilitated axonal growth at 6 days after the treatment. Vimentin-elicited axonal growth was completely inhibited by pretreatment with an IGF1R inhibitor (IGF1-analog) and with a neutralizing antibody of IGF1R. Phosphorylation level of IGF1R by vimentin was peaked at 30 min after the stimulation. The level was higher than that by IGF1 treatment at a similar dose. ELISA experiment confirmed that IGF1 was not released from neurons into culture medium within 30 min after the vimentin stimulation. These results suggest that vimentin stimulates IGF1R, leading to axonal growth. Our results show the new signaling of axonal growth via IGF1R by extracellular vimentin. The finding may provide a novel strategy to induce axonal growth in neurodegenerative diseases.

Title: Goα protein modulates the neuritogenesis in primary neurons

Authors: *H.-H. OH[1,2], J.-M. CHOI[1], S.-P. YOON[1], Y.-D. LEE[1,2], S.-S. KIM[1], H. SUH-KIM*[1,2];
[1]Dept, of Anat., [2]Neurosci. Grad. Program, Ajou University, Sch. of Med., Suwon, Korea, Republic of

Abstracts: Heterotrimeric G-proteins mediate signal transduction generated by numerous neurotransmitters and hormones. Among all G-proteins, Goα, a member of the Go/i family, is the

most abundant G protein in brain. Although Goα has been implicated in neuronal differentiation, the mechanism of how Go modulates neuronal differentiation has not been defined. We previously showed that Goα may modulates neurite outgrowth in F11 cells. Expression of Goα decreased the average length of neurites but increased the number of neurites per cell by interfering cAMP-PKA-CREB signaling (Ghil et al., 2000 and 2006). In this study, we investigated the roles of Goα during the neuritogenesis in primary cultured neurons through the aspects of cytoskeletal filament such as microtubule and F-actin. Short protrusions or neurites were found to be less extended in Goα knock-out neurons. Our data showed that the formation of protrusions/neurites is delayed in the absence of Goα. The data also suggest that Goα may induce the formation of protrusions/neuritis at earlier time. Further, we will discuss the mechanisms by which Goα regulate the neuritogenesis during differentiation and maturation of neuronal cells.

Title: Dual roles of Unc-51-like kinase 1/2 in embryonic and postnatal mouse brain development

Authors: *B. WANG[1,2], M. KUNDU[2];
[1]Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN; [2]Dept. of Pathology, St Jude Children's Res. Hosp., Memphis, TN

Abstracts: Unc-51-like kinases 1 and 2 (ULK1/2), the mammalian homologues of *C. elegans* unc-51, are highly conserved serine/threonine kinases. Previous *in vitro* studies revealed important function of ULK1/2 and their homologues in regulating both invertebrate and mammalian neurodevelopment and in regulating autophagy, a bulk lysosome-mediated degradation pathway. ULK1 or ULK2 single-knockout (KO) mice show no overt phenotype, and ULK1/2 double-KO (DKO) mice die perinatally; therefore, the physiological role of ULK1/2 *in vivo* remains largely unknown. To evaluate embryonic neurodevelopmental defects and the contribution of ULK1/2-mediated autophagy to the maintenance of homeostasis in mature neurons, we generated central nervous system specific ULK1/2 conditional DKO (cDKO) mice. Approximately half of the ULK1/2 cDKO mice survived to adult age but showed severe growth

retardation and compromised motor performance. Distinct from Atg7 cKO mice, in which axonal guidance is normal, the ULK1/2 cDKO mice consistently show general defects in the axonal guidance in the forebrain, causing dysgenesis of corpus callosum and anterior commissure. However, no overt defects in neurogenesis and migration were observed. Adult cDKO mice also developed degenerative axonal swelling in the deep cerebellum nuclei, hippocampal pyramidal neuron loss in the CA1 region, and subsequently degeneration in the CA3 region. The phenotypic difference between ULK1/2 KO mice and the previously characterized Atg7 KO mice highlights essential dissimilarities between the function of ULK1/2 and canonical autophagy. Understanding the autophagy-related and -unrelated roles of ULK1/2 in physiologic and pathologic conditions is important since drugs targeting these kinases are being developed to inhibit autophagy for therapeutic purposes.

Title: Characterization and differential expression analysis of polyadenylated and non-polyadenylated riboRNA-depleted transcripts during maturation of defined population of CNS neurons

Authors: *E. F. TRAKHTENBERG[1], D. W. PITA-THOMAS[2], D. VELMESHEV[3], S. M. DOMBROWSKI[4], J. L. GOLDBERG[5];

[1]Neurosurg., Boston Children's Hospital, Harvard Med. Sch., Boston, MA; [2]Anat. and Neurobio., Washington Univ., St. Louis, MO; [3]Mol. and Cell. Pharmacol., Univ. of Miami Sch. of Med., Miami, FL; [4]Genomatix Software; and Wayne State Univ. Sch. of Med., Ann Arbor; and Detroit, MI; [5]Shiley Eye Ctr., Univ. of California San Diego, La Jolla, CA

Abstracts: Molecular changes during maturation of the central nervous system (CNS) neurons are associated with multiple developmentally regulated biological processes, such as decline in intrinsic axon growth capacity, regulation of axon pathfinding, maturation of dendritic arborization, and establishment of neural circuits. Thus, understanding the intrinsic molecular changes involved in maturation of CNS neurons is important for studying their development and function. Retinal ganglion cell (RGC) is a prototypical CNS projection neuron, previously used for studying transcriptional changes associated with neuronal maturation. However, the developmental changes in RGCs were studied using older version of microarray chips, which were limited by gene probes' availability and reliability, by most could not discern between alternatively spliced transcripts from the same locus, and the probes for tens of thousands of small and long-non coding RNAs were not available. Next Generation Sequencing (NGS) using RNA sequencing (RNA-seq) overcame these limitations by affording the ability to analyze expression of coding and non-coding RNAs, discern between alternatively spliced transcripts, and identify novel transcripts. Here, we purified by immunopanning embryonic and postnatal mouse RGCs, and used the NGS analysis to evaluate the prevalence of non-coding transcripts in the RGC transcriptome, and to investigate the developmental changes in coding and non-coding transcripts expression during RGC maturation. For identification of developmentally regulated mRNA transcripts we used a polyA-specific RNA isolation kit, for non-coding RNAs (ncRNA) we used total RNA after ribosomal RNA depletion. We found 19872 differentially expressed transcripts (2-fold or greater) across 5332 loci in the polyA-selected RNA samples, and 29391 differentially expressed transcripts (2-fold or greater) across 14347 loci in the ribosomal RNAs depleted samples. We also provided evidence supporting the hypothesis that polyA-selected- and ribosomal RNA-depleted transcriptomes are more dissimilar than similar, and that the difference is accounted for primarily by non-coding RNAs. These NGS analyses characterize the transcriptome diversity and developmental changes in a population of CNS primary neurons, as well as point to novel potential regulators of neuronal maturation and axon growth.

Title: Involvement of thyroid hormone receptor alpha in GnRH neuronal migration

Authors: *A. LAMARCA, E. FLANNERY, S. WRAY;
Celular& Developmental Neurobio. Section, Natl. Inst. of Hlth., Bethesda, MD

Abstracts: Migration of gonadotropin-releasing hormone-1 (GnRH) neurons from the nasal placode to their correct location within the brain during mammalian development is a critical step for sexual maturation and reproductive function. It is well documented that these neurons migrate from the nasal placode to the hypothalamus where GnRH is released during puberty. It is also known that a failure of this processes leads to hypogonadotropic hypogonadism (HH), resulting in delayed puberty and infertility. However, our understanding of the mechanisms controlling GnRH migration is still limited. Microarray analysis revealed novel molecules that were highly expressed in prenatal migrating GnRH neurons, including thyroid hormone receptor alpha (THRα). Co-expression of THRα has been reported in a subset of GnRH neurons in adult hamster and sheep (Heiko et al, 1997), but the physiological role of signaling via this receptor in GnRH cells remains unclear. Notably, thyroid hormone influences neuronal migration and differentiation, such as migration of postmitotic granule cells and terminal differentiation of purkinje cells (Morte et al., 2002). The aim of this work is to determine whether signaling via THRα plays a role in the migration of GnRH neurons. Double label immunofluorescence confirmed expression of THRα in mouse primary prenatal GnRH neurons maintained in explant tissue. Using this model system and *in situ* migration assays, functional analysis with pharmacological and genetic approaches is being performed to determine the action of thyroid hormone via THRα in the neuronal migration of GnRH cells. The importance of thyroid hormones during brain development has been appreciated for many decades. Yet, a limited number of genes activated by thyroid hormone in developing neurons have been identified as compared to genes activated in glial cells. As such, examining the role of thyroid hormone in GnRH neuronal migration may reveal novel molecules modulated by thyroid hormone during development. Title: Mild and persistent axon stretch upregulates developmental and regenerative associated genes

Authors: *J. R. LOVERDE[1], P. SOTEROPOULOS[2], B. J. PFISTER[1];
[1]Dept. of Biomed. Engin., New Jersey Inst. of Technol., Newark, NJ; [2]Ctr. for Applied Genomics, Rutgers Univ. - New Jersey Med. Sch., Newark, NJ

Abstracts: The integration of long nerve fibers throughout the body is distinctive among somatic tissues. Single, individual motor neurons grow to a meter in length or more as they maintain connectivity with sacral areas of the spinal cord from the brain during development. Similarly, homologous growth also occurs within the peripheral nervous system. The most widely studied aspect of axon development has been the extension and migration of growth cones. However, following growth cone extension, axonal fibers continue to grow in synchrony with the expansion of somatic tissues. A known regulatory mechanism which accommodates for such symbiotic interaction is the biomechanical stretching of axons, a formidable stimulus of neuronal growth. Here, utilizing custom designed bioreactors, unidirectional axon stretch growth of embryonic rat dorsal root ganglia (DRG) neurons was optimized for gene expression profiling *in vitro*. A daily strain of 25% was applied until a maximum stretch of 3mm/d was reached and sustained. Genome-wide microarray analysis was performed following 8d of persistent stretch growth. Bioinformatics analysis using Ingenuity® pathway analysis software revealed the most significant molecular changes in lipid metabolism, molecular transport, and small molecule biochemistry. Further, stress response and regenerative associated genes including SPRR1a and ATF3 were upregulated 5 and 3-fold, respectively, implicating a novel role in developmental growth in addition to their transient expression following injury. These results suggest that axon stretch growth is a process whereby neuronal expansion is regulated by developmental stress, which leads to a unique transcriptional profile that accommodates for axonal growth.

Title: LKB1 and NUAK1 kinases regulate terminal axon branching in cortical neurons through control of presynaptic mitochondria capture and function

Authors: ***J. COURCHET**, T. L. LEWIS, F. POLLEUX;
Neurosciences, Columbia Univ., New York, NY

Abstracts: The molecular mechanisms underlying axon branching and circuit formation in the developing brain are still poorly understood. Impairment of these processes can lead to socially-devastating neurodevelopmental defects such as autism spectrum disorders or mental retardation. The polarity kinase LKB1/STK11 is required for the polarization of cortical neurons and in particular axon formation, both *in vitro* and *in vivo* (Barnes et al., Cell 2007). Using a CRE-based inactivation of the Lkb1 gene after axon specification, we uncovered a previously unknown function for LKB1 in controlling the outgrowth and terminal branching of the axon of cortical neurons (Courchet, Lewis et al., Cell 2013). We also identified that this novel function of LKB1 involves the phosphorylation and activation of NUAK1/ARK5, a poorly characterized downstream target of the AMPK-related kinase family. In parallel, we discovered that the LKB1-NUAK1 kinases promote the capture of mitochondria specifically at nascent presynaptic sites and demonstrated through a series of rescue experiments that direct control of mitochondrial immobilization in axons mediates the function of the LKB1-NUAK1 kinase pathway during axon branching. To determine what function of presynaptic mitochondria underlie their function during axon branching, we have developed novel approaches to probe dynamics of ATP homeostasis in cortical neurons and their axons. Our results suggest that LKB1 or NUAK1 deficiency impairs the production of ATP by axonal mitochondria, which play a critical role during axon morphogenesis.

Title: HDAC6 inhibition promotes axon growth by selectively modifying the acetylome in the distal axon

Authors: *A. L. KALINSKI[1,2], P. BRITO-VARGAS[1], M. RIVECCIO[3], B. LANGLEY[3], J. L. TWISS[1];
[1]Univ. of South Carolina, Columbia, SC; [2]Drexel Univ., Philadelphia, PA; [3]Burke Med. Res. Inst., White Plains, NY

Abstracts: Histone deacetylase 6 (HDAC6) is a class IIb deacetylase that has preference for non-histone proteins. Known substrates in other cellular systems include α-tubulin, HSP90 and cortactin. Cytoplasmic functions for HDACs have been implicated in many biological processes including cell migration, degradation of misfolded proteins, cell spreading and stress granule formation. Both HDAC6 and HDAC5 have been implicated in axon regeneration. We previously showed that chemical inhibition of HDAC6 allows axons to grow on non-permissive substrates, and this occurred independent of ongoing transcription (Riveccio et al., 2009). This implicates an axon-intrinsic mechanism for growth inhibiting affects of HDAC6. However, the intra-axonal targets for HDAC6 have not been determined. Cultured DRG neurons treated with tubastatin A, a specific HDAC6 inhibitor, show a rapid redistribution of post-translationally modified α-tubulin. In contrast to control cultures, the tubastatin A-treated neurons show growth cones filled with acetylated and tyrosinated α-tubulin by quantitative immunofluorescence. The overall levels of these modified α-tubulins does not appear to change with HDAC6 inhibition. Acetylated HSP90 and cortactin show similar changes suggesting that HDAC6 activity selectively deacetylates distal axon and growth cone substrates. Interestingly, mitochondrial mobility is decreased with even short term HDAC6 inhibition, with organelles accumulating in the distal axon and growth cone where the acetylated α-tubulin, HSP90 and cortactin proteins accumulate. Our data suggests that the post-translational modifications associated with HDAC6 inhibition

alter transport and structure of the distal axon, which may help to explain how this manipulation supports axonal growth on non-permissive substrates.

Title: Local translation of Down syndrome cell adhesion molecule in axon growth and guidance

Authors: *S. JAIN, K. WELSHHANS;
Dept. of Biol. Sci., Kent State Univ., Kent, OH

Abstracts: Down syndrome cell adhesion molecule (*Dscam*) is known to play an important role in many neurodevelopmental processes such as axon guidance, dendrite arborization and synapse formation. *DSCAM* is located in the Down syndrome trisomic region of human chromosome 21 and implicated as one of the genes directly contributing to the Down syndrome brain phenotype, which includes a reduction in the formation of long-distance connectivity. Here, we find that overexpression of DSCAM in mouse cortical pyramidal neurons results in a decrease in axon outgrowth and branching. This finding directly implicates DSCAM as a contributor to the formation of improper neuronal connectivity in Down syndrome. Thus, it is of significant interest to understand the underlying molecular mechanisms by which *Dscam* regulates axon pathfinding. The local translation of a select group of mRNA transcripts within growth cones is necessary for the formation of appropriate neuronal connectivity. Interestingly, we have found that *Dscam* mRNA is localized to growth cones of C57BL/6J mouse hippocampal pyramidal neurons. Localization of *Dscam* mRNA to growth cones decreases in response to the axon guidance molecule, netrin-1. However, netrin-1 stimulation results in an increase in locally translated DSCAM protein in growth cones. Locally translated mRNAs are transported in a translationally dormant state as a part of a ribonucleoprotein complex. We find that two RNA

binding proteins, fragile X mental retardation protein (FMRP) and cytoplasmic polyadenylation element binding protein (CPEB), colocalize with *Dscam* mRNA in growth cones, suggesting their regulation of *Dscam* mRNA localization and translation. We are currently examining the specific connectivity defects that occur during neural development in Down syndrome model mice, and how dysregulated local translation of *Dscam* mRNA contributes to this process. Taken together, these results have implications for Down syndrome, because dysregulated local translation of *Dscam* during embryonic development may contribute to inappropriate neural connectivity and the etiology of this neurodevelopmental disorder.

Title: Exploring the role of the mitochondria/endoplasmic reticulum (ER) interface in axonal development

Authors: *Y. HIRABAYASHI, F. POLLEUX;
Neurosci., Columbia Univ., New York, NY

Abstracts: Axon arborization and assembly of presynaptic terminals are critical for the formation of functional neural circuits. Our group studies the role of the serine/threonine kinase LKB1 (also called STK11 or Par4) in axon morphogenesis (Barnes et al. Cell 2007) and we recently discovered that LKB1 and one of its 14 downstream kinase, NUAK1, controls axon branching by promoting mitochondria immobilization at nascent presynaptic sites (Courchet, Lewis et al. Cell 2013). Importantly, the LKB1-NUAK1 pathway immobilized mitochondria specifically at nascent presynaptic sites. These results suggest that presynaptic mitochondria capture plays an important role in axonal/presynaptic development. However, what anchors mitochondria at specific presynaptic sites is currently unknown. The physical coupling of mitochondria with ER represents one of the best characterized organelle interface at least in

simple eukaryotic cells such as yeast. We are currently testing the potential role of mitochondria/ER coupling in the control of axon and presynaptic development. In the current study, we developed novel ways to visualize this organelle interface in developing neurons and we examined the dynamics of ER/mitochondria interaction in developing axons. Our results suggest that the mitochondria-ER interface might play a role in mitochondria localization presynaptically and thereby might play a role during axon morphogenesis.

Title: The scaffold protein mAKAPα regulates retinal ganglion cell survival and axon growth

Authors: *J. L. GOLDBERG[1], Y. WANG[1], J. LI[2], T. L. STILES[1], J. HERTZ[3], M. D. KRITZER[2], T. NGUYEN[1], M. S. KAPILOFF[2];
[1]Shiley Eye Ctr., UC San Diego, La Jolla, CA; [2]Departments of Pediatrics and Medicine, Univ. of Miami, Miami, FL; [3]Bascom Palmer Eye Inst., Miami, FL

Abstracts: Retinal ganglion cells (RGCs) and other central nervous system neurons die after axon injury. Many molecular signaling pathways, including cAMP, Ca2+, and neurotrophin-dependent pathways, have been implicated in the regulation of neuronal survival and apoptosis. Muscle A-kinase anchoring protein (mAKAP) is the scaffold for a large 'signalosome' located at the nuclear envelope in neurons and striated myocytes that in myocytes orchestrates localized cAMP, Ca2+, hypoxia, phospholipid and MAPK-regulated stress signaling. We now show that the neuronal α form of mAKAP is expressed in the retina in RGCs. By conditional ablation of a mouse floxed allele, mAKAPα deletion early in prenatal RGC development did not affect RGC density in the adult retina, indicating that mAKAPα was not necessary for RGC differentiation or survival through development. In contrast, when RGCs were stressed by optic nerve axon injury,

loss of mAKAPα exacerbated RGC death, revealing a new neuroprotective function for this scaffold. Furthermore, intravitreal injection of BDNF and/or cAMP, which promote RGC survival after axotomy, had no such effect in the absence of mAKAPα. These results show that the mAKAPα scaffold is required in RGCs after optic nerve injury for the transduction of pro-survival signaling, including that induced by BDNF and cAMP, and suggest a broader role for mAKAPα signalosomes in neuroprotection after nerve trauma and stroke.

Title: Plexin-a4 mediates the maintenance of postnatal callosal axons

Authors: *A. I. SON[1], F. SUTO[2], Y. MOROZOV[3], S. ISHII[1], P. RAKIC[4], P. LEVITT[5], K. HASHIMOTO-TORII[1], M. TORII[1];

Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [3]Dept. of Neurobio., [4]Yale Kavli Inst. for Neurosci., Yale Univ. Sch. of Med., New Haven, CT; [5]Keck Sch. of Med., USC, Los Angeles, CA

Abstracts: The corpus callosum is the largest axonal tract within the mammalian brain and plays a pivotal role in interhemispheric communication, with deficits being associated with an assortment of cognitive disabilities. Development of this structure is a sophisticated multistage process, first involving the genesis and migration of cells with distinct upper layer neuronal phenotypes and the initial elaboration of their axons during prenatal stages, followed by the overproduction and subsequent pruning of axons and their synapses. However, the molecular mechanisms underlying the refinement of this tract during the postnatal pruning period remain largely unknown and grossly understudied. We have recently found that a member of the plexin-A subfamily of signaling molecules, plexin-A4, plays an integral role in the maintenance of the corpus callosum at early postnatal stages. Plexin-A4-/- mice develop normal callosal projections, but is followed by hypoplasia during the second week. Plexin-A4 expression is prominent within both the neocortex and corpus callosum during early postnatal stages. Silencing of plexin-A4 in cortical neurons by *in utero* electroporation causes the pruning of crossed callosal axons, whereas overexpression of plexin-A4 appears to suppress pruning. Together, these data indicate that plexin-A4 plays an important role in the selective stabilization of callosal axons postnatally during the period when fine-tuning of cortical projections occurs.

Title: Developmental connectomics of axonal reorganization in avian ciliary ganglion

Authors: *R. EGAWA, S. HOSOSHIMA, T. ISHIZUKA, H. YAWO;
Tohoku Univ. Grad Sch. Life Sci., Sendai, Japan

Abstracts: During the later developmental stages of both central and peripheral nervous systems, axonal branches and synapses are massively reorganized to form mature connections. Although it is a classically-known process, the morphology at single axon level and the molecular mechanisms are not fully understood due to technical difficulties which come from the

complexity of neural circuitry. Here, with a combination of sparse expression system and tissue clearing method, we revealed the morphological characteristics of axonal reorganization in developing chick ciliary ganglion (CG), a conventional model system of synaptic development. Plasmid vectors, which express tdTomato under the modulation of sparse expression promoter Thy1s (Ako et al, 2011), were introduced into the midbrain presynaptic neuron using in ovo electroporation method (Odani et al, 2008). The CG was isolated at E8-14, cleared with ScaleA2 protocol (Hama et al, 2011) and imaged as a whole under two-photon microscopy. Each intertangled axon was three-dimensionally traced and quantitatively analyzed. We found that the total length and branching number of the axons are gradually decreased with development and that many axons lose their branches before E14. Our results were complementary to the previous electromicroscopic/electrophysiological studies carried out by Landmesser and Pilar in 1970s which showed the decrease in presynaptic inputs from multiple to single during E8-14. It is suggested that the excess presynaptic branches are pruned to form one-to-one connections without any "winners" of the synaptic competition which form oligopoly connections over postsynaptic targets. With the combination of genetic manipulations, our system of developmental connectomics would facilitate further understanding of the fundamental principles and molecular mechanisms underlying developmental axonal reorganization.

Title: Regulation of axonal trafficking of nuclear-encoded mitochondrial COXIV mRNA

Authors: *A. KAR[1], N. KHOSHAB[2], N. M. GERVASI[2], S. S. SCOTT[2], C. Y. CHEN[2], J. KOWALAK[3], A. E. GIOIO[2], B. B. KAPLAN[2];
[1]SNB, LMB, Natl. Inst. of Mental Hlth., [2]SNB, LMB, NIMH, [3]NINDS-NIMH Proteomics Core, NIMH, NIH, Bethesda, MD

Abstracts: It is now well-established that a distinct subset of nuclear-encoded mitochondrial mRNAs such as Cytochrome C oxidase IV (COXIV), are selectively transported and translated in the distal structural/functional domains of neurons (i.e. axons and presynaptic terminals). Local translation of the COXIV mRNA, which encodes a key subunit of oxidative phosphorylation complex IV, plays an important role in axonal energy metabolism, function and growth. Disruption of local COXIV expression leads to compromised mitochondrial membrane potential, decreased ATP levels and generation of reactive oxygen species (ROS) in the axon. However, relatively little is known about the mechanisms involved in regulating the axonal trafficking of these nuclear-encoded mitochondrial transcripts. In previous studies, we identified a putative 38-nucleotide stem-loop structure (zipcode) in the 3'-untranslated region of the COXIV transcript that was necessary and sufficient for the axonal localization of COXIV mRNA in superior cervical ganglion (SCG) neurons. To identify proteins involved in the axonal transport of the COXIV transcript, we used this 38-nucleotide COXIV RNA zip-code as bait for RNA-protein binding studies. Gel-shift assays of the biotinylated COXIV-zipcode incubated with retinoic-acid differentiated SHSY5Y cell lysates showed that the zipcode binds endogenous proteins and forms nucleoprotein complexes. Mass spectrometric analysis of proteins isolated by affinity purification using biotinlylated COXIV-zipcode oligomer incubated with SHSY5Y cell-lysates lead to the identification of a number of RNA-binding and mitochondria-associated proteins such as fused in sarcoma/translated in liposarcoma (FUS/TLS) and Parkinson disease protein 7 (PARK7/DJ-1) respectively. Validation using western blotting analyses confirmed the presence of the candidate proteins in the COXIV-zipcode affinity purified complexes from SHSY5Y lysates. In addition, using immunohistochemical and western blotting analyses, we also established the presence of these candidate COXIV-zipcode binding proteins in SCG neurons. Future experiments are aimed at confirming the interaction of these candidate binding proteins with the endogenous COXIV mRNA in SCG neurons and assessing the *in vivo* significance of the candidate proteins in axonal transport of COXIV mRNA.

Title: RACK1 regulates local translation at point contacts in growth cones

Authors: *L. J. KERSHNER, J. SERRE, K. WELSHHANS;
Dept. of Biol. Sci., Kent State Univ., Kent, OH

Abstracts: The formation of appropriate connectivity in the developing nervous system is dependent on the process of local translation. In developing neurons, a population of mRNAs is transported to and locally translated within growth cones, which are the pathfinding structures located at the tip of extending axons. However, the specific regions in which local translation takes place and the molecular mechanisms underlying this process are not well understood. Growth cone adhesion to the extracellular matrix occurs at point contacts, which play a critical role in regulating axon growth and guidance. Here, we investigate whether local translation occurs at point contacts, and examine the role of receptor for activated C kinase (RACK1), a member of the point contact complex, in axon growth and guidance. We have previously demonstrated that the local translation of β-actin mRNA is dependent on the phosphorylation of RACK1, a ribosome scaffolding protein, and zipcode binding protein 1 (ZBP1), an mRNA binding protein. ZBP1 binds to the 3'UTR of β-actin mRNA, represses its translation, and localizes it to growth cones. In response to stimulation with brain-derived neurotrophic factor (BDNF), RACK1 binding of the ZBP1/β-actin mRNA complex on ribosomes is increased. Phosphorylation of RACK1 then facilitates the release of β-actin mRNA from ZBP1 and its subsequent translation. Interestingly, we have now found that RACK1 is localized to point contacts, which led us to hypothesize that point contacts might be a site of β-actin mRNA local translation in growth cones. Thus, we examined the location of the ZBP1/β-actin mRNA complex relative to point contacts under both basal and growth factor stimulated conditions in cortical neurons of embryonic day 17 C57BL/6J mice. β-actin mRNA, RACK1 and ribosomes colocalize with paxillin, a marker of point contacts in growth cones. BDNF stimulation increases the colocalization of β-actin mRNA and RACK1 with paxillin. Additionally, BDNF stimulation increases the number of point contacts within growth cones, and this increase is dependent on RACK1 phosphorylation. RACK1 also plays a critical role in the regulation of axon growth and growth cone area. Taken together, these data suggest that point contacts are a site of local translation within the growth cone, and that RACK1 is critical to the formation of point contacts,

the local translation process, and appropriate neuronal development. These data provide further insight into how and where local translation is regulated within growth cones, and thereby leads to appropriate connectivity formation in the developing nervous system.

Title: The UNC-23-HSP-1 chaperone system determines localization of Parkinson disease-related kinase LRK-1 in *C. elegans*

Authors: *T. ALAM, T. FUKUZONO, S. PASTUHOV, O. FUKUSHIMA, C. LI, A. HATTORI, H. HANAFUSA, K. MATSUMOTO, N. HISAMOTO;
Div. of Biol. Sci., Grad. Sch. of Sci., Nagoya Univ., Nagoya, Japan

Abstracts: Neuron is a polarized cell that contains distinct sets of proteins in its axon and dendrite. Synaptic vesicles (SV) proteins are exclusively localized in the presynaptic regions but not in dendrites. Previously, we have shown that LRK-1, a *Caenorhabditis elegans* homolog of the familial Parkinsonism gene *PARK8/LRRK2*, determines the polarized sorting of SV proteins to axons at Golgi apparatus. However, the molecular mechanism that regulates localization of LRK-1 at the Golgi remained unclear. Here, we identified two human proteins, BAG2 and HSC70, as LRRK1/2-binding proteins. LRRK1/2 associate directly with HSC70, and indirectly with BAG2 via HSC70. BAG2 induces the release of LRRK1/2 from HSC70. We further characterized the role of their *C. elegans* homologs, UNC-23 and HSP-1, in the regulation of LRK-1. We found that in *unc-23* mutants , SV proteins are mislocalized, a phenotype also observed in *lrk-1* mutants. In addition, we identified mutations in the *hsp-1* gene as suppressors for the SV mislocalization phenotype of *unc-23* mutants. In *C. elegans* sensory neurons, LRK-1 exclusively localizes at Golgi apparatus, which acts as a platform that controls the proper delivery of SV proteins to axons. In *unc-23* mutants, however, the LRK-1 localization at Golgi was significantly reduced. This reduction was suppressed by the *hsp-1* mutations. Thus, the UNC-23–HSP-1 chaperone system has an important role for intracellular localization of LRK-1 in the control of polarized sorting of SV proteins.

Title: Investigating the role of mechanical cues in axon guidance

Authors: ***G. SHERIDAN**[1], H. SVOBODA[2], D. E. KOSER[2], A. DWIVEDY[2], A. J. THOMPSON[2], M. P. VIANA[4], L. F. COSTA[4], J. GUCK[3], C. E. HOLT[2], K. FRANZE[2]; [1]PDN, [2]Physiol. Develop. & Neurosci., [3]Dept. of Physics, Univ. of Cambridge, Cambridge, United Kingdom; [4]Inst. of Physics at Sao Carlos, Univ. of Sao Paulo, Sao Paulo, Brazil

Abstracts: During Xenopus laevis embryogenesis, development of the visual system involves the projection of retinal ganglion cell (RGC) axons from eye primordia to correct synaptic contacts in the optic tectum of the brain. There are well-characterised chemical attractant and repellent cues that guide axons to their target locations. During chemotactic migration, however, growing axons also physically interact with their surrounding environment. Therefore, it is possible that mechanical interactions could also impact their guidance to the tectum. To probe RGC mechanosensitivity, we cultured stage 35/36 Xenopus eye primordia *ex vivo* on compliant polyacrylamide hydrogels with increasing rigidities. We found clear morphological differences in axons grown on soft and rigid substrates. RGC axons on stiff hydrogels grow relatively straight and appear longer. RGC axons cultured on softer gels, however, grow faster and display a more contoured trajectory as they emanate from the eyeball. Moreover, axons cultured on softer hydrogels fasciculate to a greater extent and display thicker axon bundles than on rigid substrates. Finally, RGC axons grown on stiffness gradients turn away from the hard surface and grow toward the softer side. This suggests that RGC axons are mechanosensitive and can sense the mechanical properties of the extracellular environment during axon path-finding. Using *in vivo* atomic force microscopy-based stiffness mapping of Xenopus exposed brains, we found stiffness gradients along the path RGC axons grow. We reveal, for the first time, how RGC axons migrate through relatively soft brain structures until they reach the more rigid optic tectum, where they terminate. Presently, we are investigating if the tectum acts as a durotactic

landmark for RGC axon termination in addition to chemotactic cues present. Moreover, Xenopus brains exposed to chondroitin sulphate undergo softening and experience changes in the observed stiffness gradients, leading to axon guidance defects. Furthermore, exposing developing Xenopus embryos (stages 32-40) to inhibitors of mechanosensitive ion channels causes RGC miswiring. Treated RGC axons de-fasciculate before reaching the optic tectum; strongly suggesting that the mechanical properties of the extracellular environment may significantly contribute to axon guidance in the developing brain.

Title: α2-chimaerin function in spinal motor axon guidance

Authors: *T.-J. KAO[1,2], G. C. B. NICHOLL[3,4], J. A. JOHANSEN[5], A. KANIA[2,6,7], A. BEG[3,4]; [1]Taipei Med. Univ., Taipei, Taiwan; [2]Inst. de Recherches Cliniques de Montréal, Montréal, QC, Canada; [3]Univ. of Michigan Med. Sch., Ann Arbor, MI; [4]Univ. of Michigan, Ann Arbor, MI; [5]Central Michigan Univ., Mt. Pleasant, MI; [6]McGill Univ., Montréal, QC, Canada; [7]Univ. de Montréal, Montréal, QC, Canada

Abstracts: The relay of axon guidance signals to the actin cytoskeleton at the growth cone remains poorly understood. We are studying this question in the context of spinal lateral motor column (LMC) motor axons innervating ventral and dorsal limb muscles. This trajectory choice by LMC axons is, in part, controlled by a repulsive ephrin:Eph signaling: EphA4-expressing lateral LMC axons are repulsed into the dorsal limb from ephrin-As expressed in the ventral limb, whereas EphB1-expressing medial LMC axons are repulsed into the ventral limb from ephrin-Bs in the dorsal limb. The Rac-GAP protein, α2-chimaerin, has been implicated to participate in Eph signal relay; however, its function in the context of motor axon pathfinding has not been established prompting us to examine the role of α2-chimaerin in LMC axon guidance. Using *in situ* hybridization technique, we determined that α2-chimaerin mRNA is expressed in LMC motor neurons of chick and mouse embryos at the time of limb trajectory selection. The loss of α2-chimaerin function leads to the selection of inappropriate lateral LMC axon trajectories in both chick and mouse embryos. In addition, α2-chimaerin knockdown attenuated the retargeting of LMC axons caused by EphA, but not EphB over-expression, suggesting that α2-chimaerin participates in EphA-mediated lateral LMC motor axon guidance. To determine the extent to which α2-chimaerin participates in other axon guidance events, such as those mediated by c-Ret-GDNF, which also contribute to LMC axon guidance, we will examine the effect of α2-chimaerin knockdown in c-Ret-overexpressing LMC motor neurons.

Title: A simple technique for directed axonal guidance on multi-electrode arrays with arbitrary topology

Authors: *C. FORRO, L. DEMKO, H. DERMUTZ, J. VOROS;
Lab. of Biosensors and Bioelectronics, ETH Zurich, Zurich, Switzerland

Abstracts: The use of cultured neuronal networks as a model for their *in vivo* counterparts allows researchers to study the central nervous system, especially the brain, in a controlled environment. Specific neuronal connectivity patterns in the brain are implicated to play a role in the perception, processing and storage of information, so the building of small neuronal networks with controlled topology is a promising approach to investigate the basic circuits of the nervous system. Realizing such bottom-up systems on multi-electrode arrays (MEA) makes a way to study the dynamics of functional neural networks systematically as a function of the network structure. The present work focuses on a simple and robust technique developed in our group to realize small neuronal networks with well-defined topology, directly on MEA chips with arbitrary electrode arrangements. The technique utilizes special PDMS sheets which provide control over the type, number, position of the neurons, as well as the connections between them, and the main emphasis is on the pre-defined directions of these connections achieved by simple geometric constraints. We demonstrate the applicability of the developed method on MEA chips with different electrode patterns. The results show the proof of concept by realizing directed connections between rat hippocampal neurons sitting on neighboring electrodes, and analyzing the resulted neuronal activity from the measured extracellular signals. By creating reproducible neuronal networks with the well-defined topology, our vision is to bridge the gap between micro and macro, the molecular or few cell level and whole brain experiments. With the results, we aim to provide insights into the role of neuronal and synaptic properties such as synapse development, plasticity and connectivity, and extract the algorithms that support information processing and neurocomputation in brain tissue.

Title: Activity-dependent structural maturation of the cisternal organelle in the axon initial segment of visual system neurons *in vivo*

Authors: ***M. ENGELHARDT**[1], A. SCHLÜTER[1], S. ROSSBERGER[2], S. VORWALD[1], C. SCHULTZ[1];

[1]Dept Neuroanatomy, Univ. Heidelberg, Med. Fac. Mannheim, Mannheim, Germany; [2]Kirchhoff Inst. for Physics, Heidelberg Univ., Heidelberg, Germany

Abstracts: Normal CNS maturation fundamentally depends on correct network formation during postnatal 'critical periods', which shape and manifest the mature wiring of neurons by permitting certain levels of neuronal plasticity in dependence of experienced sensory activity. The structural components that allow a neuron to function properly within such dynamic networks are organized in electrogenic microdomains such as the axon initial segment (AIS), which is required for action potential generation, and has been shown to be dynamically regulated during development and maturation. In fact, we recently demonstrated that maturation of visual system AIS is subject to a complex tri-phasic development regulated by visual experience. It remains unclear, which axonal features drive this dynamic remodeling of the AIS. A possible candidate is the cisternal organelle (CO), a Ca2+-storage/release compartment specifically localized in the AIS. The CO is composed of stacks of smooth endoplasmic reticulum. An involvement of the CO in neuronal AIS plasticity is conceivable since it has a structural and functional homologue in the highly dynamic dendritic spine apparatus (SA), which is involved in remodeling mechanisms aimed at adjusting the strength of excitatory synapses to persisting changes in network activity. Whether synpo and the CO in AIS undergo similar remodeling events during development and neuronal plasticity is unknown. Furthermore, the precise subcellular localization of the CO, especially in relation to AIS-specific protein complexes, is currently unidentified. Therefore we investigated the developmental maturation of the CO by comprehensive immunofluorescence and biochemical analysis of the expression of synaptopodin (synpo), an actin-associated protein specifically localized in the SA and CO, respectively. Utilizing murine visual cortical and retinal neurons, we present data indicating (1) a dynamic regulation of the CO during visual system development, and (2) an activity-dependent structural remodeling of the CO. Finally, to further elucidate the subcellular localization and potential interaction of synpo with other essential AIS molecules, we employed high resolution microscopy (structured illumination in combination with single molecule localization microscopy) of CO clusters in the AIS of retinal neurons. Taken together, our findings indicate that CO maturation in the visual system is subject to activity-dependent structural remodeling. Future studies aim at providing more conclusive information on the potential interaction of synpo with other structurally essential AIS protein clusters.

Title: RNA-binding protein SFPQ regulates axonal bclw mRNA to promote axon viability

Authors: *S. J. FENSTERMACHER[1,2], K. E. COSKER[1,2], M. F. PAZYRA-MURPHY[1,2], R. A. SEGAL[1,2];
[1]Dana Farber Cancer Inst., Boston, MA; [2]Neurobio., Harvard Med. Sch., Boston, MA

Abstracts: Localized translation of axonal mRNAs has important roles in axonal growth and long term viability. While numerous cis-acting elements and trans-acting factors have been identified that regulate axonal localization of mRNAs, little is known about the RNA-binding proteins that coordinate transcription, transport, and translation of axonal mRNAs to promote axonal viability. We now demonstrate that the RNA-binding protein, splicing factor proline/glutamine rich (SFPQ), is present in nuclei and axons of sensory neurons and is necessary for neurotrophin-mediated axonal survival. Neurotrophin stimulation increases phosphorylation of SFPQ and regulates binding of SFPQ to select mRNAs, including c-fos and bclw mRNA. While SFPQ functions in neurotrophin-dependent transcription of cfos, interestingly SFPQ instead functions in the intracellular trafficking of bclw mRNA. We find that SFPQ binds to multiple regions of the long 2.7kb bclw 3'UTR, and this region is critical for neurotrophin-dependent axonal localization. Previous studies have demonstrated that bclw is a major anti-apoptotic regulator of axonal viability, suggesting that the effects of SFPQ on axonal maintenance may reflect changes in Bclw synthesis. Together these studies suggest a model whereby SFPQ bound bclw mRNA exits the nucleus and is assembled into an RNA transport granule to localize bclw into axons for localized translation to promote the health and viability of long sensory axons.

Title: Netrin 5 expressed by boundary cap cells prevents motor neuron migration out of the ventral horn of the spinal cord

Authors: *A. M. GARRETT, T. J. JUCIUS, S. L. ACKERMAN, R. W. BURGESS;
The Jackson Lab., Bar Harbor, ME

Abstracts: The Netrins are a family of evolutionarily conserved secreted proteins that act as guidance cues for migrating cells and axons during development. Netrins are bidirectional cues; they can be both chemoattractant and chemorepellant depending on the receptors present on the responding cells. Three classical Netrins have been described in mice - Netrin 1, 3, and 4 - as well as two GPI-linked G-Netrins. Here we describe Netrin 5, a previously unstudied classical Netrin. The mouse *Ntn5* gene is on chromosome 7 where its exons interdigitate with *Sec1,* a gene encoding a fucosyl transferase, on the opposite strand. We examined the pattern of *Ntn5* expression by *in situ* hybridization during development and found restricted labeling at the motor exit point (MEP) and dorsal root entry zone (DREZ) of the developing spinal cord. These cells co-expressed *Krox20*, a marker for boundary cap cells. Boundary cap cells are a transient neural-crest-derived population that forms a functional boundary between the central and peripheral nervous system during development. To investigate the function of *Ntn5,* we generated knockout mice through standard homologous recombination targeting exons 2-6 without disrupting *Sec1*. Whole embryo staining for neurofilament at E11.5 demonstrated normal gross dorsal root organization and cranial nerve guidance. Boundary cap cells have been previously studied by ablation, and we reasoned that *Ntn5* knockouts would have a subset of the phenotypes reported in the ablation studies. Dorsal boundary cap cells differentiate into a subset of sensory neurons in the DRG, but we did not find any reduction in sensory neurons *Ntn5* mutants. We also have not observed invasion of oligodendrocytes into spinal roots. We did, however, find ectopic motor neuron cell bodies migrating out of the ventral horn into the ventral roots, consistent with ablation studies. In addition, these ectopias have also been observed in chicks and mice mutant for members of the semaphorin family of guidance molecules and their plexin/neuropilin receptors. In those mutants, more ectopic motor neurons were observed caudally, whereas we found more ectopic motor neurons rostrally in *Ntn5* knockouts. Furthermore, the motor neurons found in the ventral roots in *Ntn5* mutants are not strongly positive for neuropilin 2, suggesting that separate populations of motor neurons depend on Netrin 5 signaling and semaphorin signaling to maintain cell body position. Currently, we are analyzing mutants for known Netrin receptors to find which transduces the Netrin5 signal to maintain motor neuron position in the ventral horn.

Title: Identification and genetic characterization of new ligands for receptor tyrosine phosphatases

Authors: ***N. BALI**, H.-K. LEE, K. G. ZINN;
Div. of Biol., Caltech, Pasadena, CA

Abstracts: Axon guidance during *Drosophila* development is controlled by attractive and repulsive signals, some of which are transduced through receptor tyrosine kinases and receptor tyrosine phosphatases (RPTPs). *Drosophila* RPTPs are expressed in CNS axons and are required for normal motor and CNS axon guidance. To understand the regulation of axon guidance, it is necessary to determine how RPTP activity is controlled by interactions with extracellular ligands. Only a few RPTP ligands have been identified thus far, making this an important subject for research. Our group showed that Syndecan is a ligand for the Lar RPTP in 2005. More recently, we found that a transmembrane receptor called Stranded at second (Sas) is a ligand for Ptp10D (Lee et al., Neuron 78, 813-826 (2013)). In the same screen that identified Sas, we also found ~25 candidate ligands for four different RPTPs (Ptp10D, Lar, Ptp69D, and Ptp99A). To identify the ligands, lines bearing insertions of 'UAS'- element-containing transposable elements upstream of 311 genes coding for cell surface and secreted (CSS) proteins were crossed with GAL4 'driver' lines expressed in a variety of tissues, including embryonic muscle. The resulting embryos with ectopic expression of individual CSS proteins were incubated with dimeric RPTP-placental alkaline phosphatase (AP) fusion proteins, followed by antibody staining to detect AP. Candidate ligands were those which conferred RPTP-AP fusion protein staining of muscles and other tissues. In wild-type embryos, each RPTP-AP fusion binds only to CNS axons. We further characterized these candidate RPTP-ligand interactions by 'reverse-binding' experiments, in which the RPTPs were ectopically expressed using tubulin-GAL4 or engrailed-GAL4 driver lines. We then analyzed whether ligand-AP fusion proteins were able to bind to the ectopically

expressed RPTPs. In the published paper, we performed these tests for Sas. Since then, we have further confirmed 9 novel RPTP-ligand interactions by reverse-binding. We are now examining whether these ligands bind to the RPTPs *in vitro* using a modified ELISA assay. We have been able to detect binding for a number of ligands in this manner. Many of the candidate ligands, like the RPTPs themselves, are highly conserved between flies and mammals, indicating that insights derived from this work should be applicable to human systems. We are employing similar approaches to find novel ligands for extracellular leucine-rich repeat proteins (LRRs) which play important roles in axon guidance and synaptogenesis.

Abstracts: Local environmental cues are indispensable for axonal growth and guidance during brain circuit formation. Here, we show that excess 2-arachidonoylglycerol, an endocannabinoid affecting directional axonal growth, triggers corpus callosum enlargement due to errant CB1 cannabinoid receptor (CB1R)-containing corticofugal axon spreading. This phenotype mechanistically relies on the premature differentiation and end-feet proliferation of CB2R-

expressing oligodendrocytes. The binding of secreted Slit ligands to Roundabout (Robo)1/2 receptors evokes repulsive axon guidance decisions. We combine genetic and pharmacological tools, as well as systems neuroanatomy in human fetuses and mouse models to hierarchically link endocannabinoid and Slit/Robo signaling systems to show the dependence of both axonal Robo1 positioning and oligodendroglial Slit2 production on cell-type specific cannabinoid receptor activation. Accordingly, Robo1 and/or Slit2 manipulation limits endocannabinoid modulation of axon guidance. We conclude that endocannabinoids can configure focal Slit2/Robo1 signaling to modulate directional axonal growth, which provides a novel basis for brain wiring deficits associated with prenatal illicit drug abuse and metabolic deficits.

Title: Targeting of cochlear inner hair cells by type I spiral ganglion neurons is controlled by Sema3f/Nrp2 signaling

Authors: *T. M. COATE[1,3], K. T. ISGRIG[2], M. W. KELLEY[2];
[1]NIH/NIDCD, Rockville, MD; [2]NIH/NIDCD, Bethesda, MD; [3]Biol., Georgetown Univ., Washington, DC

Abstracts: The mouse cochlea provides an excellent model for investigating molecular mechanisms associated with sensory organ innervation. To establish appropriate hearing function in the cochlea, type I spiral ganglion neurons (SGNs) must synapse with the mechanosensory inner hair cells (IHCs), whereas type II SGNs must synapse with outer hair cells (OHCs). In addition, low-spontaneous rate (low-SR) SGNs target the medial side of IHCs, whereas high-SR SGNs target the lateral side of IHCs. To better understand cochlear innervation, we developed a live imaging model in which sparse numbers of SGNs express tdTomato, while all hair cells

express GFP. Using this we have determined that supernumerary type I SGNs project to the OHCs around E15, but then retract to the IHCs through P0. These data support the hypothesis that cues within the hair cell environment direct different SGN subtypes to different hair cell regions. Cells within the OHC region express the axon guidance factor Semaphorin-3F (Sema3F) while the SGNs express its receptor, Neuropilin-2 (Nrp2). To characterize the role of these factors with high optical resolution, we combined Nrp2 mutants with our imaging model and documented the projection of each labeled SGN. Nrp2 deletion leads to the ectopic projection of type I SGNs into the OHC region, but does not alter the arrangement of low- and high-SR type I SGNs. The loss of Nrp2 also leads to increased numbers of OHC ribbon synapses and changes in auditory brainstem response thresholds, suggesting this receptor is necessary for the establishment of normal hearing function. In addition, treating cultured cochleae with Sema3F causes SGN branches to collapse, suggesting Sema3F normally acts as a chemorepellant. These data support a model whereby Sema3F within the cochlear epithelium activates Nrp2 on type I SGNs to sequester them at the IHC. We are currently examining how processing of the co-receptor Plexin-A3 dictates differential targeting by SGNs. Funding by NIDCD.

Title: The pattern of activity in injured and non-injured axons after selected axonal microdissection in microchannels

Authors: *R. HABIBEY, A. GOLABCHI, M. NANNI, F. DIFATO, A. BLAU;
Neurosci. and Brain Technologies (NBT), Italian Inst. of Technol. (IIT), Genova, Italy

Abstracts: An *in vitro* method for monitoring axonal and network activity after controlled axonal injury would help in investigating network response to injury as well as understanding axonal function during repair (1). Laser microdissection is used for highly controlled ablation of microchannel-confined axons while other parts of the network remain intact (2). In addition, axonal activity and propagation of action potentials could be recorded by custom-made or commercial electrode arrays (3). In the present study, we combined these techniques. We cultured cortical neurons on top of commercial microelectrode arrays (MEAs) and forced axons

to grow into polydimethylsiloxane (PDMS) microchannels. Axons were accessible for laser microdissection while recording from both the whole network and axons inside the microtunnels. The PDMS devices included two 100 µm-high rectangular-shaped reservoirs (400 µm X 1600 µm). Reservoirs were connected by eight rows of 30 µm wide and < 5 µm high microtunnels. Neurons were seeded from above into one of the freely accessible reservoirs. A PDMS device was aligned with the MEA electrodes recording electrophysiological activity from neurons inside the reservoir and from growing axons inside the microtunnels. Electrical activity was recorded before and for 12 DIVs after axonal dissection. The activity pattern and morphology of injured and non-injured axons and within the network was evaluated at different time points. Figure 1 Spike frequency before and until 12 DIVs after laser microdissection of some axons in microchannels. Data are represented as mean frequency. References: 1.Difato F et al. Title: Mathematical model of the epidermal axon growth

Authors: ***Y. KOBAYASHI**[1], M. TSUTSUMI[2], J. KUMAMOTO[2], M. DENDA[2], M. NAGAYAMA[1];
[1]Hokkaido Univ., Sapporo, Japan; [2]Shiseido Co., Ltd., Yokohama, Japan

Abstracts: Itchiness is one of our fundamental sensations caused by various internal and/or external stimuli. While histamine-caused itch that can be suppressed by dosing the histamine antagonist is well understood, little is known about the itchiness accompanied by atopic dermatitis (AD), where the histamine antagonist has little effect. Recent experiments have indicated that scratching behavior in mice is associated with the increase in the density of axons penetrating into the epidermis. It has also been reported that axons tend to intrude into the epidermis in the case of AD. These findings might indicate the possibility that abnormal growth of the nerve axons in AD skins alters the spatio-temporal propagation pattern of the nerve pulses, leading to sustained itchiness. Developing a mathematical model of the axons in the epidermis and simulating propagation patterns of the nerve pulses for various nerve growth patterns would therefore be a great help to understand the mechanism of the generation of itchiness. For this purpose, it is necessary to have an appropriate mathematical model of growing axons inside the epidermis. In this study, we construct such a model where the axon is approximated by a bead-spring system, which consists of particles connected by springs with the bending rigidity. The tip of the axon is guided by the chemical attractant, the gradient of which induces the torque on the tip so that it tends to direct to the high concentration of the attractant. The growth of the axon is represented by the continuous addition of new particles at the tip. We check the validity of our model by simulating an AXIS experiment, in which dorsal root ganglions are cultivated in one chamber and various chemicals are put in the other chamber separated by the slit to see how the growth pattern changes depending on the added chemicals. Performing simulations with various conditions, we also present a quantitative measure for the degree of the axon guidance that can be applicable in the AXIS experiment.

Title: Serotonin regulates midline axon crossing via ephrinb2 and is involved in remodeling after hypoxia

Authors: *J. BONKOWSKY[1], L. XING[1], J.-H. SON[2], T. STEVENSON[2];
[1]Dept. of Pediatrics, Univ. of Utah Sch. of Med., SALT LAKE CITY, UT; [2]Univ. of Utah, Salt Lake City, UT

Abstracts: Serotonin neurons and their axon projections are widespread in the CNS in early development. Disruption of serotonergic signaling leads to diffuse CNS abnormalities with a wide range of behavioral phenotypes. This suggests a non-classical role for serotonin in development. In mice, serotonin can modulate axon responsiveness to netrin-1, causing thalamocortical axons to adopt a more ventral pathway and altered fasciculation of medial pre-frontal cortex neurites. While serotonin appears necessary for axon guidance, no one has explored its role in commissure formation. Moreover, the mechanism of serotonin action in pathfinding is poorly understood. To determine the role of serotonin in commissure formation and characterize the molecular mechanism, we used embryonic zebrafish to visualize axon guidance decisions, in transgenic lines with precise expression in subsets of well-defined axon pathways. Using pharmacological blockade of serotonin signaling, genetic ablation of the serotonergic neurons, or knock-down of serotonin receptors, we found that axons of telencephalic neurons fail to cross the midline, indicating a role for serotonin in commissural axon guidance. We further demonstrate that serotonin acts through its main excitatory G protein-coupled receptor htr2a. Blockade of htr2a elevates receptor-tyrosine kinase ephrinB2 levels, causing failure of commissural axon midline crossing. Blockade of serotonin signaling rescues commissural axon errors induced by hypoxia. Thus, our study demonstrates an unexpected instructive role for serotonin in axon pathfinding choice, and identifies ephrinB2 as a key mediator in serotonin-regulated pathfinding.

Title: Coronin-1 mediates hierarchal neurotrophin signaling required for sympathetic neuron target innervation

Authors: *D. SUO, J. PARK, C. DEPPMANN;
Dept. of Biol., Univ. of Virginia, Charlottesville, VA

Abstracts: Developing axons traverse multiple growth niches; first moving in fascicles along blood vessels then ramifying in the final target. In postganglionic sympathetic neurons this transition is driven by two neurotrophins acting through the same receptor tyrosine kinase, TrkA: vascular derived neurotrophic factor 3 (NT3) and final target derived nerve growth factor (NGF). We find that the NGF-induced gene, Coronin-1, represents a molecular switch critical for axon transition from intermediate to final targets. Both neurotrophins are capable of inducing MAPK and PI3K through TrkA, however; only NGF induces coronin-1 dependent calcium signaling. Prior to final target innervation NT3-TrkA promotes axon growth and inhibits branching through MAPK, whereas upon coronin-1 upregulation, Coronin-1 dependent calcium signaling decreases axon growth rate and branching in the final target. Neither intermediate nor final destination niche displays branching commensurate with patterning of a final target, suggesting the existence of an additional niche. We provide evidence for a “transition window” where axons are exposed to NGF but coronin-1 expression has not yet been induced. In this niche NGF-TrkA-PI3K induces a remarkable increase in PI3K-dependent growth rate and branching, which we suggest is a key determinant for axon patterning in target organs.

Title: Elimination of cortico-motoneuronal connections during development by Sema6D-PlexA1-mediated axon pruning in mice

Authors: *J. KALAMBOGIAS[1], Z. GU[2], M. UENO[2], A. KUMANOGOH[3], J. MARTIN[4], Y. YOSHIDA[2];
[1]The City Col. of New York, New York, NY; [2]Div. of Developmental Biology, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [3]Osaka Univ., Osaka, Japan; [4]Dept. of Physiology, Pharmacol. & Neuroscience, The City Col. of the City Univ. of New York, New York, NY

Abstracts: The corticospinal tract (CST), originating primarily in motor cortex (M1), is a key spinal pathway for voluntary movements. In many monkey species and humans, the CST makes mostly contralateral and some ipsilateral monosynaptic connections directly with motoneurons (MN) as well as indirectly via interneurons. In mice and most other species CST connections are made primarily with contralateral interneurons. Establishment of these circuits is preceded by transient projections that are subsequently eliminated, leading to the mature pattern. Whereas the role of activity- and use-dependent processes in refining CST connections and motor development is well-studied, the molecular mechanisms are poorly understood. By labeling the CST with GFP using mouse genetics, we find that CST projections in wild-type mice descend in the dorsal, ventral and lateral columns at cervical levels at P2 and terminate throughout much of the gray matter, including the motor pools. By P14 most of the ipsilateral descending and motor pools projections are eliminated, leading to a predominantly contralateral projection to spinal interneurons. By contrast, PlexA1, as well as Sema6D (a PlexinA1 receptor), mutant mice fail to eliminate transient ipsilateral descending and motor pool projections. CST contacts remain on motoneurons, producing a bilateral projection to interneurons and MNs. To assess CST physiological actions in mature mice, we used M1 microstimulation (14 stim; 333 Hz) to evoke limb movements and facilitation of sustained forelimb EMG activity (single stim; post-stimulus facilitation, PStF). In the PlexA1 mice, threshold stimulation at most M1 sites evoked bilateral forelimb movements, consistent with bilateral CST projections, while threshold stimulation in controls evoked contralateral responses. Remarkably, PlexA1 mice displayed shorter PStF latencies compared with controls, consistent with maintenance of direct MN connections into maturity. PlexA1 mice reached with both forelimbs, instead of one or the other, and displayed a grasping impairment, suggesting disrupted left-right and inter-joint coordination. Our results show the importance of PlexA1-Sema6D in refinement of exuberant CST projections in the white matter and ventral horn, as well as development of voluntary motor skills. These findings complement the role of motor experience and activity in CST axon refinement. Importantly, the anatomical and physiological data suggest cortico-motoneuronal connections in the PlexA1

mice. This finding provides new insights into why the mouse CST does not have monosynaptic cortico-motoneuronal connections, whereas the human CST does.

Abstracts: Axons in the injured adult CNS do not regenerate, in part due to the inflammatory response. Outside the nervous system, released histones are detected in response to inflammation. In the CNS, up-regulation of a cytoplasmic isoform of histone H1 was reported in neurons and astrocytes in a mouse model of prion disease and in humans with Alzheimer's disease. Adult mouse ischaemic brain slices released histones H1 and H2B into the media. Examination of conditioned media from naïve astrocytic cultures revealed secretion of Histones H2A and H4. This suggests that histones are released extracellularly in the CNS under pathological conditions. Here, we show that primary rat cortical and hippocampal neurons extended long neurites when grown on permissive monolayers of CHO cells; however, when we

simultaneously added exogenous histones (a mix of all isoforms) to the co-cultures, we observe significantly shorter neurites (up to 70% shorter). Using microfluidic chambers, a technique which isolates the cell bodies from the neurites, we plated cortical neurons on PLL and after one week we observed long neurites growing across the micro-grooves of the chamber. In contrast, when histones were applied to either the cell body- or neurite-containing parts of the chambers, we observed that neurites were unable to grow a significant distance past the micro-grooves. Furthermore, exogenous application of histones to primary cortical neurons activates Rho GTPase. Using western blot analysis, we determined that levels of extracellular histones are increased *in vivo* after dorsal column lesion and are released into the CSF within 24hrs. Together with our *in vitro* data, these findings suggest that extracellular histones may inhibit axonal regeneration in spinal cord injury as well. Extracellular histones can be cleaved by APC, an enzyme that is part of coagulation system. In microfluidic chambers with cortical neurons, the inhibitory effect of histones on neurite outgrowth can be blocked with the addition of APC. In addition, delivery of APC after dorsal column injury or optic nerve crush promotes axonal regeneration *in vivo*. Our data suggests that extracellular histones released after injury to the CNS are inhibitory to axonal regeneration and administration of APC can block this inhibitory effect and promote regeneration.

Title: Systems therapeutic approach for axonal regeneration in the injured CNS

Authors: ***M. M. SIDDIQ**[1], Y. ZORINA[3], V. RABINOVICH[1], E. KAPLAN[2], M. T. FILBIN[4], R. IYENGAR[1];
[1]Pharmacol. and Systems Therapeut., [2]Ophthalmology, Mount Sinai Sch. of Med., NEW YORK, NY; [3]Acorda Therapeutics, Inc, Ardsley, NY; [4]Biol., Hunter Col., New York, NY

Abstracts: Axons in the injured CNS do not regenerate, in part due to the inhibitory environment. Neurons must integrate the signals that they receive from multiple pathways in order to respond to this inhibitory environment in order to promote axons to regenerate. Taking a systems therapeutic approach, we investigated the cannabinoid-1 receptor (CB1R) signaling cascade to stimulating neurite outgrowth and determined that it may be regulated by a much larger signaling network, allowing for many potential points of signal integration. The CB1R signaling cascade involves activation of signal transducer and activator of transcription 3 (STAT3) and cAMP response element-binding protein (CREB), both are transcription factors involved with neurite outgrowth and axonal regeneration. We studied how integration of CB1R and other parallel signaling pathways, in this case the Interleukin-6 receptor (IL-6R) could induce axonal regeneration. We found in primary cortical neurons that combinatorial activation of the CB1R and IL-6R pathways converge on STAT3 activation for promoting neurite outgrowth even in the presence of myelin inhibitors. We also observed that lower dosages of the agonists for CB1R and IL-6R that are normally ineffective individually, in combination promoted neurite outgrowth of cortical neurons. To determine if the combinatorial activation of CB1R and IL-6R can promote *in vivo* axonal regeneration we utilized the rat optic nerve model. Using HU-210 as the agonist for CB1R, and IL-6 which we delivered intra-vitreally immediately after optic nerve crush we determined the extent of axons regenerating with cholera toxin-B (CTB) labeling and GAP-43 staining. We found using sub-optimal concentrations of HU-210 or IL-6 individually did not promote axonal regeneration in the crushed optic nerve, however in combination we observed robust CTB-labeled axons and GAP-43 staining that were significantly past the crush site. Currently we are using electroretinograms (ERGs) to determine if there are physiological improvements detectable in the retinal ganglion cell bodies that could be indicative of the potential axonal regeneration in the injured optic nerve. Our preliminary data suggests that after HU-210 and IL-6 treatment there are improvements in the pattern and flash ERGs. Our combinatorial approach offers us an opportunity to elucidate signaling pathways to integrate and induce axonal regeneration in the injured CNS using lower dosages of agonists and potentially decreasing unwanted side effects.

Title: Microglial depletion reduces neurogenesis in response to QA-induced lesioning in adult zebrafish telencephalon

Authors: *K. SKAGGS[1], D. GOLDMAN[2], J. M. PARENT[3];
[1]Neurol., [2]Biol. Chemistry, Mol. and Behavioral Neurosci. Institutie, Neurosci. Program,
[3]Neurology, Neurosci. Program, Univ. of Michigan, ANN ARBOR, MI

Abstracts: Zebrafish represent an attractive system for the study of neurogenesis following injury because, unlike mammals, they regenerate damaged neurons. We developed a novel brain injury model using quinolinic acid (QA) excitotoxic telencephalic lesioning in adult zebrafish to study neural regeneration. After lesioning, initial cell death is followed by robust inflammation 1-2 days post-injury and a marked increase in proliferation or radial glia-like progenitors that peaks 3-4 days post-injury. The neural progenitors give rise to increased numbers of newborn neurons that migrate to injury and integrate, likely contributing to repair of the lesioned brain. In order to study the role of the early inflammatory response on neurogenesis, we ablated microglia that responded to injury though injection of liposomes containing Clodronate at the time of lesioning. Proliferation and neurogenesis were markedly reduced following Clodronate treatment. These effects persisted over time, resulting in incomplete repair in Clodronate-treated, lesioned brains compared to control liposome-treated, lesioned brains. These results indicate that the early inflammatory response following QA-induced excitotoxic lesioning is an important signaling event that stimulates neurogenesis and repair of adult zebrafish telencephalic brain injury.

Abstracts: The devastating paralysis that occurs following spinal cord injury (SCI) is largely a result of transected central nervous system (CNS) axons failing to regenerate. Previous research has demonstrated that phosphatase and tensin homolog (PTEN) is a significant contributor to regenerative failure, with its deletion within retinal ganglion cells and corticospinal neurons resulting in robust regenerative responses in the optic nerve and corticospinal tract respectively. Here, we assessed whether PTEN deletion would promote axon regeneration in the rubrospinal tract (RST) and whether the age at which PTEN is deleted has an impact on rubrospinal regenerative outcome. Four week (young) and 7-8 month (old) aged floxed PTEN mice were injected with adeno-associated virus serotype 2 expressing Cre and GFP (AAV2-Cre) or GFP alone for control (AAV2-GFP) into the right red nucleus. Four weeks later, mice underwent a left dorsolateral crush at cervical level C4/C5 to fully axotomize the rubrospinal tract. Eight weeks later, mice were sacrificed. While young AAV-Cre injected mice showed rubrospinal axon regeneration up to 1 mm past the injury site, old AAV-Cre injected mice showed only decreased dieback back to the lesion site relative to controls and significantly less axon growth caudal to the lesion site relative to young mice. In analysis of rubrospinal neuron cell bodies within the midbrain, we observed no difference in GFP or phospho-S6 labelling between young and aged AAV-Cre injected mice, suggesting that the decreased regenerative response following ageing is independent of mammalian target of rapamycin (mTOR) signaling. Thus, although PTEN deletion promotes rubrospinal axon regeneration, ageing significantly diminishes the regenerative capacity of PTEN deleted rubrospinal neurons following SCI.

Title: Direct conversion of adult spinal cord-derived oligodendrocyte progenitor cells (OPCs) to spinal motor neurons

Authors: *S. BAZAREK[1], R. A. MARR[1], C. A. BRIGGS[1], G. E. STUTZMANN[1], R. M. HOWARD[2], S. R. WHITTEMORE[2], D. A. PETERSON[1];

Abstracts: The lack of cell replacement following neurological injury limits the regenerative response of the CNS. Progress in understanding the biology of neural stem cells has raised interest in using stem cells for replacing neurons lost to injury or to disease. As existing committed and uncommitted cells in the CNS do not naturally progress to a neuronal fate, it will be necessary to engineer a conversion to a neuronal fate. Advances in cellular reprogramming provide new tools for re-specification of cell fate and provide a potential alternative to cell transplantation, namely the direct *in vivo* conversion of resident CNS cell populations for neuronal replacement. Success in this approach will require the generation of relevant neuronal subtypes. The aim of this study was to evaluate the effect of various neurogenic transcription factors (sox2, mash1, olig2VP16, pax6, and neurogenin2) that are related to cell specification during development on fate induction and subtype specificity on resident glia in the spinal cord. An O4+ Oligodendrocyte Progenitor Cell (OPC) population was enriched from the adult rat spinal cord using Magnetic Activated Cell Sorting (MACS). OPCs are the most abundant cycling population in the adult CNS and their isolation provides an ideal *in vitro* assay for screening neuronal fate determinants. Retroviral-GFP delivery of the single factor, neurogenin2, or the combination of sox2 and mash1 to cultured OPCs resulted in co-expression of GFP with the early neuronal marker, B-III-tubulin at 7 days. Neurogenin2-transduced cells expressed mature neuronal markers, NeuN and MAP2, and cholinergic marker, ChAT, at 7 days. These cells also exhibited typical spinal motor neuron morphology and repetitive action potentials were evoked at 5 weeks post-transduction. In showing that adult-derived OPCs can be directly converted to functional neurons *in vitro*, we provide support for investigating the direct *in vivo* conversion of resident OPCs to a neuronal fate. This approach may provide an alternative therapeutic strategy for neuronal replacement in the adult spinal cord.

Title: N-cadherin function in the adult zebrafish optic nerve regeneration

Authors: S. BHATTARAI[1], R. L. LONDRAVILLE[2], *Q. LIU[3];
[1]Biol., Univ. of Akron, Akron, OH; [2]Biol., [3]Univ. Akron, AKRON, OH

Abstracts: Injured optic nerves in adult mammals have very limited ability to regenerate due to unfavorable extracellular conditions and reduced intrinsic regenerative ability. Unlike mammals, injured optic nerves in fish and amphibians can successfully regenerate. Molecules implicated to promote regeneration include growth promoting factors, transcription factors and cell adhesion molecules such as cadherins. Cadherins are calcium dependent cell adhesion molecules that play important roles in development and maintenance of adult tissues. We previously showed that N-cadherin expression in the adult zebrafish visual system was limited mainly to the germinal zone and outer plexiform layer of the retina, but following an optic nerve crush, its expression became significantly increased in both the retinal ganglion cell layer and the optic nerve for more than two weeks. To determine N-cadheirn function in zebrafish optic nerve regeneration, we blocked N-cadherin expression by electroporating a lissamine-tagged N-cadherin morpholino antisense oligonucleotide (MO) into the fish eye one day after the optic nerve crush, and examined retinal axons regeneration at various time points (e.g. 7 and 14 days). We found that optic nerve regeneration was severely perturbed in these fish compared to fish with a control MO electroporated into the eye. The vast majority of the regenerating optic axons in the N-cad MO treated fish were found between the optic nerve head region and the crush site (immediately behind the eye) 7 days after the optic nerve crush, while the regenerating retinal axons in the control MO treated fish arrived in the optic tectum. Our results suggest that N-cadherin plays an important role in the fish optic nerve regeneration.

Title: Characterization of AAV vectors' potentials to promote long distance optic nerve regeneration, path-finding, and restoration of visual functions after injury

Authors: *B. YUNGHER[1], T. SCHMIDT[3], K. CHEW[3], X. LUO[1], K. LYAPICHEV[1], T.-H. CHOU[2], V. PORCIATTI[2], M. BLACKMORE[4], S. HATTAR[3], K. PARK[1];

Abstracts: Recent studies have demonstrated the effectiveness of several Cre-mediated gene deletions at enhancing axon regeneration in adult retinal ganglion cells (RGCs), though such transgenic manipulations have limited therapeutic relevance and practicability. Given the successes of gene therapy in treating ocular disorders, in the present study we sought to evaluate the potentials of AAV vectors in promoting i) long distance RGC axon regeneration, ii) target-specific guidance of RGC axons to their visual targets, and iii) recovery of visual functions after optic nerve injury. To this end, we use a novel combinatorial approach in which we combine AAV vectors expressing short hairpin RNA against phosphatase and tensin homolog (PTEN) with ciliary neurotrophic factor (CNTF) along with pharmacological elevation of a cyclic adenosine monophosphate (cAMP) analog. We observe the efficacy of this RNA interference both at the suppression of endogenous PTEN expression and at enhancing RGC axon regeneration within the optic nerve of adult mice. Furthermore, combining these three treatments synergistically promotes extensive RGC axon regeneration beyond the optic chiasm and into the brain, an effect dependent on the mammalian target of rapamycin (mTOR) and signal transducer and activator of transcription 3 (STAT3) pathways. Regenerating axons display misguidance at multiple levels, frequently turning and looping in the optic nerve and projecting to non-target areas in the brain. Nevertheless, we find this treatment sufficient to induce axon regeneration into the suprachiasmatic nucleus (SCN), the retino-recipient circadian pacemaker normally innervated by highly-melanopsin expressing intrinsically photosensitive RGCs. The number of axon fibers reaching the SCN is even higher in apoptosis-deficient bcl2-associated X (BAX) knockout mice. Visualization of the retina by optical coherence tomography reveals outer nuclear layer swelling. Photoentrainment of circadian rhythms, as measured by wheel-running activity, does not occur following AAV treatment in wild-type or BAX null mice, demonstrating

the importance of type-specific regeneration and maintenance of retinal physiology, rather than simply total axon numbers regenerating.

Title: Unraveling the therapeutic mechanisms of human umbilical cord tissue-derived cells (hUTC) in retinal degenerative diseases

Authors: ***S. KOH**[1], N. KIM[2], N. DEJENEKA[3], I. HARRIS[3], H. YIN[2], C. EROGLU[1]; [1]Cell Biol., [2]Psychology and Neurosci., Duke Univ., Durham, NC; [3]Janssen Res. & Develop., Spring House, PA

Abstracts: Age-related macular degeneration (AMD) is the leading cause of vision loss in people over the age of 50. Subretinal administration of hUTC to a model of retinal degeneration preserved photoreceptors and visual function; however, the therapeutic mechanism of hUTC has not been defined. Here we characterized the effects of hUTC on functional synapse formation, neuronal survival and outgrowth. Retinal ganglion cells (RGCs), purified from P7 rats,were co-cultured with hUTC or cortical astrocytes (ASCs) as a positive control. A normal human dermal fibroblast (NHDF) cell line was used as negative control. Synapse formation was assessed by immunocytological co-localization of pre- (Bassoon) and post-synaptic (Homer-1) markers and we found that RGC exhibited significant increases on both number and size of synaptic puncta, comparable to astrocytes (positive control). Subsequent electrophysiological recording of the RGCs treated under same conditions revealed that hUTC also increase the amplitude of miniature excitatory postsynaptic currents (mEPSCs). To confirm the effects of co-culture, RGCs were fed with various concentrations of hUTC-conditioned medium (hUCM). Synapse analysis showed that hUCM is sufficient to induce synapse formation in concentration dependent manner, similar to astrocyte-conditioned media (ACM). hUCM also strengthened functional

synapses as shown by increased amplitude and frequency of mEPSCs. Besides its effects on synapse formation, hUCM was sufficient to promote RGC survival in the absence of any other growth factors. hUCM also enhanced RGC neurite outgrowth as demonstrated by significant increase in total process length, number of processes and number of branches. In conclusion, we found that hUTC secrete factors that promote development of functional synapses between purified RGCs *in vitro*. Moreoever, hUTC also support neuronal survival and neurite outgrowth. Our findings suggest that hUTC may affect multiple aspects of retinal cell health and connectivity. The work described was performed under a sponsored research agreement between Duke University and Janssen R&D.

Title: Expression of RhoA in lamprey brain after spinal cord injury

Authors: *K. G. ZHANG[1], J. HU[1], W. RODEMER[1], M. E. SELZER[2,1];
[1]Shriners Hosp. Pediatric Res. Ctr., [2]Neurol., Temple Univ. Sch. of Med., Philadelphia, PA

Abstracts: Disability following spinal cord injury (SCI) is due to failure of axonal regeneration. It is believed that axon growth is inhibited by the presence of several types of inhibitory molecules in CNS, including the chondroitin sulfate proteoglycans (CSPG), myelin-associated glycoprotein (MAG), Nogo and oligodendrocyte-myelin glycoprotein (OMgp). In the lamprey CNS, there are 18 pairs of individually identified reticulospinal neurons with heterogeneous axon regenerative abilities, among which “bad-regenerating” neurons often experience a very delayed form of apoptosis. Previously we reported that the putative CSPG receptors, PTPsigma and LAR, are expressed selectively in the bad-regenerating neurons both in normal lampreys and after SCI,

when those same neurons were also undergoing apoptosis, as indicated by labelling with fluorescently labelled inhibitors of caspase activation (FLICA). Many studies indicate that the intracellular signaling pathways downstream of those inhibitory molecules converge on RhoA. CSPG can activate RhoA via their receptor LAR, and after SCI, activated RhoA has been implicated in both apoptosis and axon growth inhibition. To study the role of RhoA in SCI-induced retrograde neuronal death, we cloned lamprey RhoA, which was highly homologous to mammalian RhoA, and investigated its distribution in lamprey CNS by wholemount *in situ* hybridization (ISH) before and after SCI. RhoA expression was observed in both neurons and glial cells, and increased developmentally in normal lamprey CNS. RhoA was continuously expressed in bad-regenerating neurons and in microglia/macrophages on cord surface after SCI. However, RhoA expression decreased greatly in most reticulospinal neurons after SCI. Moreover, RhoA mRNA expression was correlated with caspase activation in brain at 2 weeks after SCI. The inverse correlation of RhoA expression with the intrinsic regenerative ability and survival post-axotomy is consistent with a role for RhoA signaling in triggering apoptosis and restricting regeneration in lamprey reticulospinal neurons after SCI.

Title: Anisotropic capillary hydrogels with cellular growth factor delivery promote linear axonal growth in the injured spinal cord

Authors: ***M. GÜNTHER**[1], M. MOTSCH[1], N. WEIDNER[1], R. MÜLLER[2], A. BLESCH[1]; [1]Spinal Cord Injury Ctr., Univ. Hosp. Heidelberg, Heidelberg, Germany; [2]Inst. of Physical and Theoretical Chem., Univ. of Regensburg, Regensburg, Germany

Abstracts: Despite recent progress in enhancing axonal growth in the injured spinal cord, the guidance of regenerating axons across an extended lesion site remains a major challenge. To

determine whether axons can be guided in a rostrocaudal direction within a spinal cord lesion site, we implanted alginate-based anisotropic capillary hydrogels seeded with bone marrow stromal cells (BMSCs) into the injured rat spinal cord. Adult female Fischer344 rats underwent a C5 lateral hemisection. Immediately following the lesion, hydrogels (2x2x1.3 mm) seeded with BMSCs (2 µl; 100,000 cells/µl) were implanted into the lesion site. BMSCs were genetically modified to express brain-derived neurotrophic factor (BDNF; 170 ng/ 10^6 cells/ 24 h) or GFP as a control. Four weeks post-lesion, numerous GFP-labeled BMSCs survived inside the scaffold capillaries, providing a cellular matrix for axonal growth. Axons were primarily found in the center of each channel, often in bundles, whereas BMSCs appeared to cover the channel wall. In addition, blood vessels extended into the gels, identified by von Willebrandt factor-labeling. Quantification of the number of axons growing into channels with BDNF- and GFP-expressing cells (n = 5-6 animals/group) demonstrated 3.3 times ($p < 0.01$) higher numbers of β-III-tubulin-labeled axons in BMSC-BDNF seeded hydrogels at 100 µm and 4.2 times ($p < 0.05$) higher numbers at 500 µm inside the hydrogel. Axons were also found in the center of the scaffold (~ 1 mm away from host tissue). Increasing the capillary diameters of hydrogels seeded with BDNF expressing BMSCs from 41 µm to 65 µm did not lead to significant differences in the number of regenerating axons. The orientation of axonal growth in hydrogel capillaries was measured using a new semiautomatic image analysis system and compared to BMSC suspension grafts without hydrogels. In lesions without hydrogels, regenerating axons exhibited random orientations, whereas axons were oriented parallel to the channel walls inside the hydrogels. To examine how far axons can grow into the hydrogel channels and to determine whether axons reach the caudal end of the lesion site, anterograde tracer BDA was injected above the lesion site at level C2/3. The results of this experiment are currently being determined.

Title: Implantable fibrin hydrogels as novel engineered microenvironments that recruit and guide endogenous neural stem cells for cell replacement therapy in the brain

Authors: A. R. CLARK, A. B. CARTER, *E. M. PRICE;
Biol. Sci., Marshall Univ., Huntington, WV

Abstracts: Cell replacement therapy is a promising approach to treat numerous neurodegenerative disorders such as Parkinson's disease, stroke and traumatic brain injury. Unfortunately, direct stem cell transplantation into areas of the brain where new neural cells would be beneficial has proven to be problematic due to issues such as tumor formation and the inability for the implanted cells to integrate into existing circuitry. Our long-term goal is to exploit endogenous adult neural stem cells and redirect migration from their usual destination to new regions of the brain where they will reconstitute lost neural function. The subventricular zone (SVZ) is one source of adult neural stem cells, and their usual function is to continually provide the olfactory bulb with new neurons, which arrive from the SVZ via the rostral migratory stream (RMS). We have engineered cylindrical fibrin hydrogels which contain immobilized neurotrophins, extracellular matrix molecules and aprotinin, and we have implanted these cylinders into one hemisphere of the rat brain with the goal of creating a new migratory path for SVZ-derived neural stem cells. Hydrogel cylinders (0.7 mm dia x 6 mm long) were made with fibrin containing VEGF, NGF, aprotinin and laminin immobilized with the homobifunctional chemical crosslinker disuccinmidyl suberate (DSS). Stereotaxic coordinates were used to implant the cylinder at a location 17 degrees off midline on a path from the RMS to the striatum. Animals were sacrificed 6 weeks following surgery and sections of brain were analyzed via immunohistochemistry with DAPI, doublecortin (Dcx), a marker for immature neurons, and 160 kD Neurofilament (NF 160), a marker for mature neurons. DAPI-labeled cells were found concentrated in the implant region in a pattern that was suggestive of a controlled migratory response to the hydrogel. Dcx labeling demonstrated that migrating neuroblasts (Dcx+) were abundant in the brain region surrounding the cylinder implant region. NF 160 labeled neurons were also observed coincident with Dcx+ cells, indicating that mature neurons, possibly derived from the Dcx+ precursors, were also present in the region of the fibrin hydrogel implant. There was no evidence of undegraded fibrin in any of the samples analyzed. Except for the surface of the brain corresponding to the area of the implant, no overt signs of damage from the procedure were apparent. We are currently evaluating the efficacy of these implants in correcting the 6-OHDA hemi-Parkinson rat model.

Abstracts: The suffering of millions of spinal cord injury (SCI) patients, worldwide, has been the motivation for numerous studies for over a century. Despite extensive success in identifying genes and proteins involved in the complex processes after SCI, no satisfying treatment is available. Our work focuses on understanding the entire complex biochemical processes and their interplay with pathways to unravel the mechanisms leading to regeneration failure, with the goal to find a treatment for SCI. As our central hypothesis is that major functional changes after trauma to the spine are reflected on the proteome level, we perform quantitative proteomics experiments of contused spinal cords at different time points. Therefore, we will present analysis of results, which were generated 1 hour after injury. The results are integrated into a systems biology tool, called Hanalyzer, which was modified to work in the SCI field. For this purpose we extend the tool to draw on information sources for the rat in addition to those for the mouse and human that have been used up to now. The system further implements various ontologies; links molecular functions, biological processes and cellular component to genes, metabolic pathways, and small molecule participants; and retrieves information from various proteinprotein, protein-DNA interaction or metabolic data bases. It also interfaces with the published biomedical literature, extracting facts that are relevant to the biological problem at hand. The comprehension of the complex system behavior and unravel key proteins responsible for regeneration failure holds promise to find a treatment for SCI in the near future.

Title: Creating a migratory stream of transplanted glial restricted progenitors as a therapeutic strategy for spinal cord injury

Authors: *X.-B. YUAN, C. HAAS, I. FISCHER;
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstracts: Transplantation of glial restricted progenitors (GRP) and derived astrocytes is a promising therapeutic strategy for treatment of spinal cord injury, capable of creating a supportive environment for regeneration of injured host axons. Our previous studies have demonstrated that GRP transplantation allows for the regeneration of lesioned, ascending sensory axons into but not out of the graft. Given the permissive nature of GRP, we hypothesized that regenerating axons become trapped within GRP grafts by: 1) encountering an excess of permissive factors within GRP grafts, stalling further regenerative attempts, or 2) forming connections/adhesions with graft-derived cells (e.g., astrocytes or NG2 cells). To address these issues, we targeted GRP migration as a means to enhance axonal regeneration, hypothesizing that by extending the permissive migratory GRP stream we would extend axonal regeneration by: 1) shifting the concentration of the permissive environment or 2) “towing” sensory axons along migrating GRP. We reasoned that during development, gradients of chemotactic factors direct the migration of neural progenitors, and building upon these principles, we examined the effects of related factors on migration of grafted GRP. To screen chemotactic molecules that augment GRP migration, we developed an *in vitro* agarose gradient migration assay and confirmed our results utilizing a standard transwell assay, identifying stromal derived factor-1 (SDF1) and basic fibroblast growth factor (bFGF) as potent pro-migratory agents. In addition, we also discovered that chondroitin sulfated proteoglycans (CSPG) presented a strong inhibitory cue to GRP/astrocyte migration that could be overcome by the CSPG-digesting enzyme, Chondroitinase. Following transplantation into the injured spinal cord, we found that the direction-specific migration of GRP could be significantly enhanced following administration of

lentiviral gradients of chemotactic factors SDF1 and bFGF, as well as CSPG-digesting Chondroitinase. However, the increased migration was not associated with increased regeneration, indicating that other interventions may be needed to prevent connections with graft-derived cells (e.g., targeting LAR receptors) or to increase the regenerative capacity of the sensory axons (e.g., mTOR, SOCS3). These results highlight the ability of GRP grafts to serve as a therapeutic platform and future studies will be directed at identifying additional chemoattractive molecules and evaluating combinatorial strategies for promoting axonal regeneration to reconnect the injured spinal cord. Support by Craig H. Neilsen Foundation 280850 and NIH P01 NS055976.

Title: Limited functional effects of subacute syngenic bone marrow stromal cell transplantation after rat spinal cord injury

Authors: *B. SANDNER, M. CIATIPIS, M. MOTSCH, N. WEIDNER, A. BLESCH;
Spinal Cord Injury Ctr., Univ. Hosp. Heidelberg, Heidelberg, Germany

Abstracts: Cell transplantation might be one means to improve motor, sensory or autonomic recovery after traumatic spinal cord injury (SCI). Among different cell types, bone marrow stromal cells (BMSCs) have received considerable interest due to their potential neuroprotective properties. However, large discrepancies exist in studies published to date due inadequate animal models, a lack of adequate cellular controls, and limited outcome measures. Therefore, we analyzed motor function, bladder recovery and tissue sparing after syngeneic BMSC transplantation in a rat spinal cord contusion injury model. Adult Fischer 344 rats underwent a T9 contusion injury (200kDy) followed by grafting of syngeneic GFP-expressing BMSCs into

the lesion epicenter 3 days post-injury (n=17). Animals receiving a contusion injury and no cellular graft (n=16), or an injury followed by grafts of syngeneic fibroblasts (n=16) served as control. Eight weeks post transplantation, BMSC-grafted animals showed only a minor functional improvement in hindlimb motor function of 1-1.5 points in the BBB open field locomotor rating scale, which was only significant compared to injured control animals without cellular grafts at this time point ($p<0.05$). However, no differences in sensorimotor recovery (number of footfalls) were observed when animals crossed a horizontal ladder. Both cell types survived in the lesion site, but the volume of BMSCs was significantly smaller compared to fibroblast grafts already one week post-grafting ($p<0.05$). Cell survival was further reduced in both groups at the latest assessment, eight weeks post-grafting ($p<0.05$). Eriochrome cyanine staining revealed only minor differences in spared white matter between all three groups, which did not reach significance. Urodynamic measurements of baseline, maximum and intermicturition pressure as well as micturition frequency and micturition volume indicated similar bladder dysfunction in all groups 8 weeks post-injury. Thus subacute grafting of BMSCs has only a minor effect on functional recovery, questioning the rationale for autologous intraspinal BMSC transplantation after SCI.

Title: The immune receptor dectin-1 participates in conditioning injury-induced axonal regeneration of sensory neurons

Authors: ***C. YOON**, K. CARBAJAL, K. BALDWIN, B. SEGAL, R. GIGER;
Univ. of Michigan Med. Sch., Ann Arbor, MI

Abstracts: Under certain circumstances, activation of innate immunity promotes robust regeneration of severed axons following injury to the optic nerve or spinal cord for which, however, the underlying cellular and molecular mechanisms remain to be elucidated. Our lab

recently identified that the interaction of curdlan (a particular from of β-(1,3)glucan) with the pattern recognition receptor dectin-1 on myeloid cells triggers an inflammatory cascade that enables injured retinal ganglion cells (RGC) to extend lengthy axons that grow beyond the lesion site in the adult mouse optic nerve. Curdlan, an FDA approved food supplement, mimics the pro-regenerative effects of zymosan when injected into the vitreous of wildtype mice, but not dectin-1 null mice. In the current study, we hypothesized that dectin-1 participates in the conditioning injury-induced growth response of dorsal root ganglion (DRG) neurons. Our preliminary results show a decrease in macrophage infiltration into DRGs following conditioning injury in dectin-1 null mice compared to wild type controls. Flow cytometric analysis confirmed that following sciatic nerve injury, neutrophil, dendritic cell, and macrophage accumulation in DRGs is reduced. Importantly, conditioning injury-induced neuronal growth of DRG neurons in dectin-1 mutants is reduced compared to wildtype controls: neurite outgrowth, as assessed by NF200 immunolabeling, is significantly decreased in dectin-1 null cultures. Together these findings suggest that dectin-1 participates in immune responses that contribute to conditioning injury-induced axonal growth of sensory neurons. Our current focus is on determining whether dectin-1 is required for conditioning injury-induced growth of severed dorsal column axons in the mouse spinal cord. The long-term goal of this research is to identify the signaling pathways that are activated by the innate immune system to enable CNS axon regeneration following injury or disease.

Title: Unconventional granulocytes are recruited by zymosan and promote central nervous system regeneration

Authors: *K. CARBAJAL[1], K. T. BALDWIN[2], R. J. GIGER[2], B. M. SEGAL[1];
[1]Neurol., [2]Cell & Developmental Biol., Univ. of Michigan, Ann Arbor, MI

Abstracts: Regeneration in the central nervous system (CNS) can be enabled by inflammation, however the underlying molecular mechanism is poorly understood. Intra-ocular injection of

zymosan, a yeast cell-wall extract, following optic nerve crush injury promotes local inflammation in association with robust retinal ganglion cell (RGC) axon growth. We have previously shown that immune cell expression of Dectin-1 and TLR2, pattern recognition receptors (PRRs) that bind components of zymosan, is critical for regeneration in this experimental model. In the present study, we assess the contribution of different leukocyte subsets to zymosan-induced axon regrowth. Flow cytometric analysis of intraocular infiltrates demonstrate that neutrophils are the most prominent cell type early post zymosan injection. To directly determine their pro-regenerative potential, we adoptively transferred zymosan-stimulated, purified neutrophils into the eyes of mice with O.N. crush only and observed robust axon regeneration comparable to positive controls injected intraocularly with zymosan. We next blocked recruitment of neutrophils to the eye following O.N. crush and intraocular zymosan injection with the expectation of thwarting axonal regrowth. Surprisingly, this resulted in a significant increase in regeneration of axons compared to vehicle treated controls. Detailed flow cytometric analysis confirmed blockade of conventional neutrophil recruitment following treatment but also revealed an unexpected enrichment of a subset of unconventional, CCR2+ granulocytes in the intraocular infiltrate. These unconventional granulocytes, which became the dominant population of infiltrating cells following treatment, have features of immature myeloid cells. Our study raises the possibility of using regenerative, CCR2+ granulocytes as a neuroprotective intervention in patients with CNS injury.

Title: Beta-glucan/dectin-1 signaling in immune cells activates the canonical NF-kB pathway to induce long-distance cns axon regeneration

Authors: *K. T. BALDWIN[1], K. S. CARBAJAL[2], B. M. SEGAL[2], R. J. GIGER[1];
[1]Cell and Developmental Biol., [2]Neurol., Univ. of Michigan, Ann Arbor, MI

Abstracts: Following injury to the adult mammalian central nervous system (CNS), severed axons fail to undergo spontaneous regeneration, resulting in permanent neurological deficits. Retro-orbital crush injury to the optic nerve in adult mice is a well-established animal model to study neuronal responses to CNS injury. Intra-ocular injection of zymosan, a yeast cell-wall extract, triggers an inflammatory response in the eye, and enables retinal ganglion cells (RGCs) to extend lengthy axons following optic nerve injury. Despite its relatively common use, the molecular mechanism of zymosan-elicited axonal regeneration is unknown. Here we identify particulate *β*-(1,3)glucan as the active ingredient in zymosan, sufficient to promote RGC axon regeneration. In mice, loss of the pattern recognition receptor *dectin-1*, but not *toll-like receptor-2 (TLR2)* or *complement receptor-3,* greatly attenuates zymosan-mediated RGC regeneration. The combined loss of *dectin-1* and *TLR2* completely blocks the pro-regenerative effects of zymosan, suggesting that these receptors act in a collaborative manner. Dectin-1 is found on retina-resident microglia and dendritic cells, as well as blood-derived myeloid cells which accumulate in the vitreous following intraocular inflammation. In *dectin-1-/-* mice, intraocular *β*-(1,3)glucan fails to induce optic nerve regeneration. Studies with chimeric *dectin-1* mice revealed a requirement for *dectin-1* in both retina-resident cells as well as bone marrow-derived immune cells for *β*-(1,3)glucan-elicited optic nerve regeneration. Ligation of dectin-1 with particulate *β*-(1,3)glucan leads to activation of multiple downstream signaling pathways, including both canonical and noncanonical NF-kB pathways, and the mitogen-activated protein kinase (MAPK) pathway. Studies with mice deficient for *caspase recruitment domain 9 (CARD9)* revealed that dectin-1 signals primarily through the canonical NF-kB pathway to elicit *β*-(1,3)glucan-induced optic nerve axon regeneration. Ongoing studies are focusing on a detailed characterization of myeloid cell types necessary for immune-mediated neuroregeneration, as well as chemokines, cytokines, and growth factors that enable long-distance axonal growth in the injured adult mammalian CNS.

Abstracts: Retrograde endocannabinoid signaling via presynaptic CB_1 cannabinoid receptors controls neurotransmitter release at most synapse types. Despite the specific functions of CB_1 receptors in various forms of synaptic plasticity, the principles characterizing the precise subcellular distribution and density of this GPCR on given axon terminal types are poorly understood. Therefore, in the present study, we employed cell type-specific STORM superresolution microscopy to address the general question of how the nanoscale localization and amount of CB_1 receptors on boutons contribute to synapse-specific properties of cannabinoid signaling. For example, perisomatic and dendritic GABAergic synapses on CA1 pyramidal neurons exhibit striking quantitative differences in the efficacy of exogenous cannabinoids and in endocannabinoid signaling. Thus, we aimed to ascertain in the mouse hippocampus whether axon terminals of two major forms of CB_1-containing GABAergic interneurons, which are specialized to target either the perisomatic or dendritic regions of pyramidal cells, are equipped with a differential nanoscale molecular architecture for cannabinoid signaling. First, we developed a novel methodology based on the combination of whole-cell patch-clamp recording, single-cell biocytin labeling, and STORM superresolution microscopy, which allowed the cell type-specific correlation of physiological and morphological parameters with nanoscale molecular imaging data. By using this approach, we found that presynaptic CB_1 abundance correlated tightly with bouton size as well as axon terminals of perisomatically-projecting interneurons were larger and possessed more CB_1 receptors compared to dendritically-targeting cells. In contrast, the level of bassoon, an integral component of the presynaptic release machinery known to organize voltage-gated calcium channels at the active zone, did not differ between the two axon terminal types. These findings imply that a higher CB_1 receptor/effector ratio may contribute to stronger cannabinoid signaling at perisomatic synapses. Furthermore, chronic Δ^9-tetrahydrocannabinol treatment, which is known to reduce cannabinoid efficacy on

GABA release, resulted in a robust overall decrease in CB_1 levels and increased receptor internalization in axon terminals derived from perisomatically-projecting interneurons. Together, these findings suggest that the number of available CB_1 receptors on the presynaptic plasma membrane critically determines the efficacy of cannabinoid inhibition of neurotransmitter release.

Title: Polyclonal and monoclonal antibody production for CB_1 cannabinoid receptors in FcRn transgenic animals

Authors: *G. Y. BALLA[1], J. CERVENAK[2], C. M. HENSTRIDGE[1], A. ILIÁS[3], E. SZABADITS[1], M. LEDRI[1], S. I. SZABÓ[1], B. DUDOK[1], B. LÁSZLÓ[1], I. KACSKOVICS[2,3], I. KATONA[1];

Abstracts: Antibodies are the best tools to determine the position and density of endogenous proteins in the brain. However, it is often difficult to study low copy number proteins due to limitations in antibody sensitivity and specificity. For example, presynaptic CB_1 cannabinoid receptors are visualized by most conventional antibodies on forebrain GABAergic boutons, but CB_1 expression levels are usually too low to be investigated in a quantitative manner on most other axon terminal types. To overcome this limitation, we used transgenic rabbits and mice overexpressing the neonatal Fc receptor (FcRn) to produce highly sensitive polyclonal and monoclonal antibodies against the mouse CB_1 receptor. Transgenic animals carrying and expressing extra copies of the FcRn exhibit an enhanced immune response. Accordingly, CB_1 antisera obtained from FcRn transgenic rabbits had higher titers and exhibited better dissociation kinetics compared to antisera collected from wild-type rabbits. Moreover, each antisera obtained from FcRn transgenic rabbits (n=3) revealed dense axonal CB_1-immunostaining pattern in wild-type mouse hippocampus. The specificity of this staining pattern was validated in CB_1 knockout animals. In contrast, only one antiserum collected from wild-type rabbits (n=3) could visualize CB_1 receptors. Similarly, we could successfully obtain 10 positive, high affinity anti-CB_1 IgG-expressing clones from FcRn-overexpressing mice, but none from wild-type mice. Immunostaining with monoclonal antibodies generated from these clones also revealed extensive immunolabeling of CB_1-positive GABAergic axons. To further improve the sensitivity of CB_1-immunostaining, the FcRn transgenic rabbit, producing antisera with the best dissociation constant, was further immunized and the last three bleeds were mixed and purified. Immunohistochemistry with this new antibody resulted in unprecedentedly dense CB_1-immunostaining outlining the laminar topography of glutamatergic pathways. Electron microscopic analysis demonstrated that the vast majority of a randomly selected population of excitatory terminals carried CB_1 receptors in the inner molecular layer of dentate gyrus and in the stratum oriens of CA3 subfield. STORM superresolution imaging of CA3 pyramidal cells confirmed this result at the single cell level by visualizing CB_1 in most recurrent collaterals. These findings demonstrate that FcRn-overexpressing transgenic animals are ideal tools to generate highly sensitive and specific antibodies, and were instrumental to obtain new monoclonal and polyclonal antibodies which allow quantitative investigation of CB_1 receptors in the brain.

Title: A new approach for correlated confocal and superresolution microscopy visualizes the distribution of presynaptic CB_1 cannabinoid receptors at the nanoscale

Authors: *L. BARNA[1], B. DUDOK[1], V. MICZÁN[1], S. I. SZABÓ[1], A. HORVÁTH[2], M. MATOLCSI[3], I. KATONA[1];

Abstracts: How synapse-specific differences in signaling protein density determine the qualitative and quantitative properties of synaptic transmission is a fundamental question in neuroscience. However, our understanding of the molecular parameters underlying synaptic processes remains limited due to methodical limitations. Therefore, in the present study, we exploited whole-cell patch-clamp recordings, confocal microscopy and STORM superresolution microscopy to allow the integrated analysis of physiological and morphological properties of a single neuron with quantitative molecular imaging within its axon terminals. Importantly, the whole experimental and analysis process can be carried out in a few days and reveals the localization of synaptic proteins with excellent sensitivity and specificity, ultra-high spatial resolution, and in large sample sizes. We first employed methodical improvements for STORM superresolution imaging in mouse hippocampal sections, which revealed the subcellular distribution of CB_1 cannabinoid receptors with a fluorophore localization precision of 6 nm and 41 nm in the lateral and axial dimensions, respectively. The specificity of CB_1 immunolabeling in STORM images was validated by using CB_1 knockout animals. To make physiological characterization and anatomical classification possible in combination with superresolution imaging, CB_1-positive GABAergic interneurons were filled with biocytin during patch-clamp recording and their morphology was visualized by confocal microscopy. To provide a cellular context for the 3D coordinates of CB_1 localization points obtained by STORM, high magnification confocal microscopy was used to detect biocytin-labeled axon terminals and then CB_1 distribution within the selected axon terminal was imaged by STORM. To facilitate the correlative visualization and analysis of confocal and STORM microscopy data, we also developed a new software with an easy-to-use graphical user interface. A correlation analysis of

confocal and STORM images demonstrated that 3-D STORM provides a reliable quantitative readout of protein abundance in HEK cells and in GABAergic axon terminals. Finally, we applied new algorithms allowing nanoscale measurements of relative CB_1 density and intermolecular distances along the surface of GABAergic axon terminals. Taken together, our new methodology including improvements for brain tissue processing and imaging, as well as new software tools for data analysis represents a powerful approach for cell type-specific nanoscale molecular investigations in association with physiological and anatomical characterization in intact brain circuits.

Title: Corticosterone-endocannabinoid signaling for memory recovery from general anesthesia

Authors: F. WANG[1], L. TONG[1], X. LI[1], R. KINDEN[1], L. XIONG[2], H. DONG[2], *X. ZHANG[1]; [1]Inst. Mental Hlth. Res., Univ. Ottawa, Ottawa, ON, Canada; [2]Dept. of Anesthesiol., Fourth Military Med. Univ., Xi'an, China

Abstracts: The inaugural clinical practice of general anesthesia in 1840's revolutionized medicine by allowing surgery to be performed in a humane manner, and now approximately 234 million of patients each year undergo anesthesia for surgery worldwide. However, how memory recovers from anesthesia remains completely unknown. In the present study, we investigated how contextual fear memory recovers from general anesthesia with the volatile anesthetic isoflurane, a routine anesthetic in both humans and animals. We found that rats received isoflurane anesthesia for 2 h showed an approximate 25% of contextual fear memory recovery at 1 hour, 67% of memory recovery at 4 hour, and a full recovery at 12 hour after cessation of anesthesia. Contextual fear memory recovery at 1 hour after cessation of anesthesia was abolished by pretreatment of rats with the mineralocorticoid receptor (MR) antagonist RU28318 (but not by glucocorticoid receptor antagonist), calcium channel blocker, endocannabinoid

(eCB) 2-arachidonoylglycerol (2-AG) synthesis enzyme inhibitor, and the cannabinoid type-1 receptor (CB_1R) antagonist AM281. The abolishment effects produced by RU28318 and AM281 were mimicked and blocked by gamma-aminobutyric acid (GABA) receptor agonist and antagonist, respectively. All the findings together lead us to propose a corticosteroid-eCB signaling ---- composed of MR activation, calcium influx, 2-AG mobilization, presynaptic CB_1R activation, and GABAergic synaptic disinhibition ---- that drives memory recovery from general anesthesia.

Title: Medial prefrontal cortex endocannabinoid system modulates autonomics response in rats submitted to restraint stress

Authors: ***T. B. MORAES NETO**, A. FASSINI, F. M. A. CORREA, L. B. M. RESSTEL; Dept. of Pharmacol., Univ. of Sao Paulo - Sch. of Med. of Ribeirao Preto, Ribeirao Preto, Brazil

Abstracts: Goals: Acute restraint is an unavoidable stress situation that evokes autonomics changes, characterized by elevated mean arterial pressure (MAP), intense heart rate (HR) increases and decrease in the tail skin temperature. The ventral portion of medial prefrontal cortex (vMPFC), witch is compound by prelimbic (PL) and infralimbic (IL) cortices, is involved with modulation of autonomics responses associated with stress. The vMPFC glutamatergic system is involved with modulation of autonomics responses evoked by acute restraint stress. Moreover, the endocannabinoid CB1 receptors activation reduces the local vMPFC glutamate releases. The mainly endocannabinoid is anandamide (AEA), witch is hydrolyzed by enzyme fatty acid amide hydrolase (FAAH). Therefore, the objective of the present work was to

investigate the involvement of endocannabinoid in the modulation of autonomic responses evoked by restraint stress in rats. Methods: Male Wistar rats (250-270g) had guide cannulae bilaterally implanted in the PL or IL for drug injection. A polyethylene catheter was implanted in the femoral artery for MAP and HR recording. Tail skin temperature was measured using a thermal camera. The animals were submitted to acute restraint, which was initiated by introducing animals into a small plastic cylindrical restraining tube (diameter =6.5cm and length =15cm) and lasted for 60 minutes. The FAAH inhibitor URB597 (100 pmol/ 200 nL) was administrates 10 minutes before the restraint stress. Results: The acute restraint stress was able to increase MAP ($F_{35, 350} = 15.14$, $P<0.001$) and HR ($F_{35, 350} = 16.65$, $P<0.001$), and decrease the tail skin temperature ($F_{17, 180} = 60.99$, $P<0.001$). The microinjection of URB597 (n=6) reduces the pressor (PL: $F_{1, 350} = 16.13$, $P<0.01$; IL: $F_{1, 350} = 16.80$, $P<0.01$) and tachycardiac response (PL: $F_{1, 350} = 6.517$, $P<0.01$; IL: $F_{1, 350} = 6.446$, $P<0.01$), and increases the tail skin temperature drop (PL: $F_{1, 180} = 44.86$, $P<0.01$; IL: $F_{1, 180} = 69.36$, $P<0.01$) when compared with vehicle treated animals (n= 6). Conclusion: The present a result shown that vMPFC endocannabinoid system through AEA has an inhibitory influence in the cardiovascular responses and an excitatory influence on the tail skin temperature responses evoked by restraint stress.

Title: Activation of CB1 cannabinoid receptors stimulate transmitter release in striatopallidal terminals of the rat mouse brain when Gi Protein-Receptor coupling is restricted

Authors: R. CABALLERO-FLORAN[1], L. LOPEZ-SANTIAGO[4], L. ISOM[4], J. ACEVES[2], D. ERLIJ[5], *G. B. FLORAN[3];
[1]Pharmacol., [2]Physiol., [3]CINVESTAV IPN, Mexico DF, Mexico; [4]Pharmacol., Univ. of Michigan Med. Ctr., Ann Arbor, MI; [5]Dept. of Physiol. and Pharmacol., SUNY Dowstate Med. Ctr., Brooklyn, NY

Abstracts: The most widespread neuronal effect of CB1 cannabinoid receptor agonists is inhibition of transmitter release from presynaptic terminals. In a previous study, using neurochemical techniques, we found that the decrease in GABA release produced by activating CB1 cannabinoid receptors in striatopallidal terminals was transformed into stimulation of release by restricting Gi/o protein interactions. In the present experiments we investigated the effect of stimulating the CB1 receptor with the selective cannabinoid type 1 receptor (CB1) agonist arachidonyl-2-chloroethylamide (ACEA) on whole-cell recordings of inhibitory postsynaptic currents (IPSCs) in neurons of the globus pallidus. ACEA reduced IPSC amplitude. The effect was associated with paired-pulse facilitation, indicating a presynaptic action. When Gi/o receptor-protein interactions were limited by treatment with pertussis toxin, the inhibitory effects of ACEA were transformed. ACEA now increased IPSC amplitude instead of reducing it. This effect was associated with paired-pulse depression indicating stimulation of GABA release. Because it has been shown that stimulation of D2 receptors may reduce Gi/o availability we investigated the effects of activation of dopamine D2 receptors (D2Rs) on the response to stimulation of CB1 receptors. Treatment with the selective D2R agonist quinpirole depressed IPSC amplitude and caused paired pulse facilitation. In quinpirole treated slices ACEA increased IPSCs amplitude and depressed the paired-pulse ratio. These results show that when Gi protein-receptor coupling is restricted, activation of CB1 receptors leads to transmitter release stimulation. They also show that increasing D2R activation can transform the inhibitory effects of CB1 receptor stimulation into a stimulatory response. We suggest that this effect is also associated with decreased Gi protein-receptor interactions.

Title: The endocannabinoid 2-arachidonoyl glycerol suppresses seizures by decreasing excitatory synaptic input around the inner molecular layer of the dentate gyrus

Authors: *Y. SUGAYA[1], M. YAMAZAKI[2], K. SAKIMURA[2], M. KANO[1];
[1]Neurophysiol., The Univ. of Tokyo, Tokyo, Japan; [2]Cell. Neurobio., Brain research institute, Niigata Univ., Niigata, Japan

Abstracts: Previous studies revealed that the endocannabinoids in the dentate gyrus and the surrounding structures have protective effect on kainate-induced status epilepticus. However, it is still unclear which of the two major endocannabinoids, anandamide or 2-arachidonoyl glycerol (2-AG), suppresses seizures and how the endocannabinoid signaling changes excitability in the hippocampus during seizures. We have recently demonstrated that 2-AG produced by diacylglycerol lipase α (DGLα) is the endocannabinoid that mediates retrograde synaptic suppression. The present study aimed at elucidating roles of 2-AG in modulating neural circuit activity in the hippocampal dentate gyrus and in the generation of seizure. Under urethane anesthesia (1.75g/kg BW, i.p.), a stimulus electrode was implanted into the angular bundle of adult DGLα knockout mice and their wild-type littermates. A 16-channel silicon probe was implanted into the dentate gyrus of the mice. Afterdischarges were evoked by burst stimuli (20 Hz for 10 seconds) to the perforant path and the current source density during afterdischarges was calculated from the local field potentials. We found that the afterdischarges were significantly longer in DGLα knockout mice than in their wild-type littermates. The afterdischarges in the dentate gyrus consisted of repetitive burst discharges of granule cells with inter-burst interval of about 350 msec. At the start of each burst discharge, sink current around the inner molecular layer (IML) of the dentate gyrus was significantly larger in DGLα knockout mice than in their wild-type littermates. Optogenetic stimulation of excitatory projection fibers to the IML significantly increased the duration of afterdischarges in wild-type mice. These results suggest that 2-AG suppresses the excitatory synaptic input around the IML of the dentate gyrus and shortens afterdischarges. We also investigated the suppressive effect of 2-AG on spontaneouse seizures during kainate-induced epileptogenesis (0.4 μg dissoleved in 100 nl, injected to the dentate gyrus). We found that the blockade of 2-AG hydrolysis by JZL184 (4 mg/kg, i.p.), an inhibitor of monoacylglycerol lipase, significantly reduced the number of spontaneous seizures. By contrast, blockade of 2-AG-mediated signaling by AM251 (4mg/kg, i.p.), a blocker of cannabinoid CB_1 receptor, significantly increased the number of spontaneous seizures and mortality rate. These results indicate that 2-AG mediated signaling strongly suppresses seizures and may be a possible target for the treatment of epilepsy.

Title: Macamides as inhibitors of fatty acid amide hydrolase (FAAH)

Authors: M. ALAMOUDI, M. BOHLKE, T. J. MAHER, *A. J. PINO-FIGUEROA; MCPHS, Boston, MA

Abstracts: Lepidium meyenii (Maca), a Peruvian plant, has been used as a folk medicine for centuries. It has been found that the pentate extract of Maca possesses neuroprotective effect *in vitro* and *in vivo*. Maca contains unique compounds called macamides which are claimed to be responsible for its pharmacological effects. Since there is a structure similarity between macamides and anandamide, the endogenous ligand of the endocannabinoid system, macamides might exert their effects through the endocannabinoid system. Our preliminary results suggested that macamides act as inhibitors of fatty acid amide hydrolase (FAAH), an enzyme that degrades anandamide, and results in the termination of endocannabinoids signaling. The aim of this study was to demonstrate and characterize the FAAH inhibitory effects of the most abundant macamides, N-benzyl-palmitamide, and their derivatives, N-(3-methoxybenzyl)-palmitamide, N-(4-fluorobenzyl)-palmitamide, and N-(4-chlorobenzyl)-palmitamide. An FAAH inhibitory activity assay, which is a fluorescence-based method, was performed to test each compound using concentrations from 1 to 100 μM. Fluorescence was measured at different time points, using a microplate reader at an excitation wavelength of 340-360 nm and an emission wavelength of 450-465 nm, at 37 °C, during 60 minutes after initiation of the enzymatic reaction. The percentage of inhibition of FAAH produced by 100 μM of N-benzyl-palmitamide, N-(3-methoxybenzyl)-palmitamide, N-(4-fluorobenzyl)-palmitamide, and N-(4-chlorobenzyl)-palmitamide was 53.3±1.8%, 47.7±1.3%, 28.0±1.2%, and 43.1±1.6%, respectively (n=3). IC50 values of N-benzyl-palmitamide, N-(3-methoxybenzyl)-palmitamide, N-(4-fluorobenzyl)-palmitamide, and N-(4-chlorobenzyl)-palmitamide were 11.6±1.6 μM, 4.7±0.3 μM, 5.7±0.7 μM, and 7.7±0.6 μM, respectively. The results indicated that all studied macamides inhibit FAAH in a concentration-dependent manner. Macamides by inhibiting FAAH could offer a promising alternative for treatment of many CNS disorders such as pain, inflammation and neurodegenerative diseases.

Title: Neuronal localization of endothelial nitric oxide synthase

Authors: A. CAVIEDES[1], J. BRAVO[1], A. MASSMANN[2], J. FIGUEROA[2], F. NUALART[3], *U. WYNEKEN[1];
[1]Univ. De Los Andes, Santiago, RM, Chile; [2]Wake Forest Univ. Hlth. Sci., Winston-Salem, NC; [3]Ctr. for Advanced Microscopy Bio-Bio, Concepcion, Chile

Abstracts: Nitric oxide (NO) is a pivotal messenger in various brain processes. Its synthesis in the brain has been most commonly been ascribed to neuronal nitric oxide synthase (nNOS), however, the endothelial isoform (eNOS) has also been implicated as a retrograde messenger in cellular plasticity. A better characterization of eNOS localization in neurons and its possible functional consequences has not yet been performed. We thus studied the localization of eNOS by immunocytochemistry of primary hippocampal and cortical neurons and by Western Blots of subcellular fractions, while cell viability was assessed with the Tripan blue test. We show by confocal and super-resolution microscopy that eNOS co-distributes with post-synaptic markers (Shank2) and is localized in spines. Moreover, eNOS is enriched in synaptic membranes and in postsynaptic densities isolated from neuronal cultures and from the rat forebrain. eNOS inhibition in cortical cells has a negative impact on cell survival after excitotoxic stimulation with NMDA. In turn, hippocampal neuronal death depends on nNOS-dependent NO synthesis and eNOS inhibition does not affect neuronal viability. Our results show that eNOS is located at excitatory synapses where it could represent a major source for NO production able to modulate synaptic function and neuronal survival. Title: Slit2 as a β-Catenin-dependent retrograde signal for presynaptic differentiation

Authors: ***A. BARIK**[1], H. WU[1], Y. LU[2], W.-C. XIONG[3], L. MEI[3];
[1]Inst. of Mol. Med. and Genet., [3]Dept. of Neurosci. and Regenerative Med., [2]Georgia Regents Univ., Augusta, GA

Abstracts: Neuromuscular junction (NMJ) formation requires proper interaction between motoneurons and muscle cells. Our earlier work indicated that β-catenin in muscle is critical for motoneuron differentiation, probably via a retrograde mechanism. β-Catenin could regulate cell adhesion by bridging the interaction between cadherin and a-catenin. Alternatively, β-Catenin regulates transcription by associating with TCF/LEF1 transcription factors, a major biological response in the Wnt canonical pathway. To investigate how muscle β-Catenin controls presynaptic differentiation, we generated transgenic mice expressing wild type β-catenin or mutants impaired in either of the two functions. In a set of *in vivo* rescue experiments, we found that the effect of β-Catenin requires the C-terminal transactivation domain (TAD), but not the α-catenin binding motif, suggesting a necessary role of β-Catenin target genes. Analysis of β-Catenin -dependent transcriptome in the muscle led to the identification of Slit2, a factor that has been implicated in axon navigation in the brain. A previous report demonstrated that Slit2 null mice showed NMJ deficits including characteristic mislocation of primary nerve branches in the diaphragms that were observed in muscle β-Catenin mutant mice. We found, first by chromatin immunoprecipitation (ChIP), that β-catenin bound to the 5'-UTR of the Slit2 gene. Second, Slit2 immobilized on beads were able to induce terminal differentiation of motoneurons as well as hippocampal neurons. Finally, we generated transgenic mice that express Slit2 specifically in the muscle. Our data suggest that Slit2 muscle expression was able to diminish presynaptic deficits in β-Catenin mutant mice, providing genetic evidence for a role of Slit2 in NMJ formation. Together, these observations identify Slit2 as a novel retrograde signal of muscle for presynaptic differentiation.

Title: Pathway-specific neuromodulation of striatonigral and striatopallidal neurons in the pathophysiology of motor control

Authors: M. TRUSEL[1], *A. CAVACCINI[1], B. GRECO[1], A. GUIJARRO[2], P. P. SAINTOT[1], M. CEROVIC[3], I. M. MORELLA[4], R. BRAMBILLA[4], R. TONINI[1];
[1]Neurosci. and Brain Technologies, [2]Drug Discovery and Develop., Fondazione Inst. Italiano Di Tecnologia, Genova, Italy; [3]Inst. di Ricerche Farmacologiche Mario Negri, Milano, Italy; [4]Inst. of Exptl. Neurology, Div. of Neuroscience, San Raffaele Scientific Inst. and Univ., Milano, Italy

Abstracts: In the dorsolateral striatum (DLS), complex motor information originating mainly from cortical and midbrain inputs converges on striatal medium spiny neurons (MSNs) of the striatonigral- (direct-dMSNs) and striatopallidal (indirect-iMSNs) pathways. Increasing evidence suggests that these two MSN subpopulations exert opposing control on aspects of motor behavior, including skilled motor learning and drug-induced locomotion. The apt and timely regulation of the relative balance between the activity of dMSNs and iMSNs neurons is, therefore, crucial to execute proper motor patterns. To this purpose, distinct classes of synaptic neuromodulators functionally integrate at corticostriatal synapses of the DLS during complex tasks of motion, hence tuning the coordinated outputs of striatonigral and striatopallidal pathways. However, a direct relationship between pathway-specific modulation of corticostriatal synaptic plasticity and aspects of motor behavior is still missing. We found that long-term synaptic depression (LTD) induced by high-frequency stimulation of layer V of the somatosensory cortex (HFS-LTD) was blocked by inhibition of endocannabinoid (eCB)- and dopamine D2 receptor-mediated signaling at cortical connections to iMSNs, but not to dMSNs in the DLS. HFS-LTD at dMSNs is expressed pre-synaptically and it involves the activation of local neuromodulators. To address whether striatal motor behavior displays similar pathway specificity, we examined how cell-type specific modulation of synaptic plasticity rescues motor deficits in the unilateral 6-hydroxydopamine (6-OHDA) lesioned mouse model of Parkinson's disease (PD). Under our experimental conditions, HFS-LTD was selectively lost at cortical connections to iMSNs of parkinsonian mice, while it was unaffected in striatonigral neurons. The in-vivo pharmacological manipulations of intracellular Ca^{2+} signal in the MSNs exerted a

dichotomous effect as it decreased the excitatory drive to the striatopallidal pathway while it increased the synaptic responsiveness in the striatonigral pathway. This associated with improved skilled-motor behavior in PD mice through a mechanism involving the release of eCBs from striatopallidal neurons, and it enhanced rotational behavior induced by administration of dopaminergic drugs. Our results reveal a direct relationship between neuromodulation of synaptic plasticity in segregated striatal circuits and the pathophysiology of motor control.

Abstracts: Corticotropin releasing hormone (CRH) signaling within the prefrontal cortex (PFC) has been shown to modulate emotional behavior. Herein, we examined the interactions between CRH signaling and endocannabinoid signaling within the PFC to determine if an interaction between these systems in the PFC could be relevant for the regulation of emotional behavior. To this extent, we found that intra-cerebroventricular (icv) administration of CRH resulted in an

increase in the tissue levels of the endocannabinoid ligand 2-arachidonoylglycerol (2-AG) within the PFC. This effect appeared to be mediated by the CRH type 1 receptor (CRHR1) as this effect was recapitulated by icv administration of the CRHR1 agonist cortagine, but not the CRHR2 agonist urocortin II. We then sought to investigate if this relationship maintained under conditions of chronic exposure to corticosterone, which has been shown to upregulate extrahypothalamic levels of CRH. Similar to what has been established within the amygdala, we found that chronic exposure to corticosterone resulted in an upregulation of CRH mRNA within the PFC. This increase in CRH expression in the PFC was accompanied by a significant increase in the tissue content of 2-AG following chronic corticosterone exposure, which was completely reversed by concurrent exposure to the CRHR1 antagonist antalarmin. The role of this interaction with respect to the regulation of emotional behavior is currently under investigation.

Title: Increased NFκB signalling upregulates human PINK1 gene expression

Authors: ***X. DUAN**[1,2], J. TONG[1], Q. XU[1], Y. WU[2], F. CAI[1], W. SONG[1];
[1]Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada; [2]Children's hospital, Chongqing Med. Univ., Chongqing, China

Abstracts: Parkinson’s disease (PD) is one of the major neurodegenerative disorders. However, its etiology and the mechanism underlying its pathogenesis remain elusive. Mitochondrial movement, distribution, and clearance are critical for cells to keep their energy balance and avoid oxidative stress. Mitochondrial malfunction is implicated in PD pathogenesis. Ser/Thr kinase

PINK1, a PD-associated protein, plays an important role in the regulation of mitochondrial movement. The regulation of PINK1 gene expression remains unknown. In the present study, we aimed to understand the transcriptional regulation of PINK1. Firstly, we identified the transcription start site (TSS) of PINK1 using RNA ligase-mediated rapid amplification of cDNA ends (RLM-RACE) strategy. The TSS is located at 94bp upstream of the translation start site (ATG). The 1825bp 5'-flanking region of the human PINK1 gene coding sequence and a series of nested deletions were cloned into the pGL3-Basic vector. The promoter activities of the nested deletions were analyzed by a dual luciferase assay. The region of 104bp (-78 to +26) was identified to be the minimal promoter region with functional transcriptional activity for the PINK1 gene. Secondly, transcriptional activation and gel-shift assay demonstrated that the PINK1 gene promoter contains functional cis-acting NFκB-binding sites. NFκB p65 overexpression led to up-regulation of PINK1 transcription and expression in HEK293 cells and SH-SY5Y cells. Meanwhile, lipopolysaccharide (LPS) treatment significantly increased the PINK1 protein level in SH-SY5Y cells. Taken together, our results clearly suggested that PINK1 expression is tightly regulated at its transcription level and NFκB is a positive regulator for PINK1 expression.

Title: Brain distribution pattern of radiolabel from carbon-14 labeled anandamide

Authors: *K. QIAN, Y. MIAO, S. SONTI, R. DUCLOS, S. J. GATLEY;
Northeastern Univ., Boston, MA

Abstracts: Inhibitors of fatty acid amide hydrolase (FAAH), which inactivates the endocannabinoid anandamide (N-arachidonoylethanolamine), are candidate drugs against pain and inflammation. Mapping FAAH activity in the brain would facilitate evaluation of such drugs. Autoradiography of mouse brain after administration of [H-3]anandamide show a

heterogeneous distribution pattern which was considered to reflect regional FAAH activity (Glaser, Gatley et al. 2006). However, using carbon-14 instead of tritium we found that similar patterns were produced with labeled arachidonic acid and with [C-14-arachidonoyl]anandamide, suggesting that FAAH does not control disposition of radioactivity. To examine regional FAAH activity without the interference of other enzymatic activities related to the metabolism of the fatty acids, we undertook the radiosynthesis of anandamide labeled in the ethanolamine moiety instead of the acyl moiety, and used [C-14]ethanolamine in control experiments. Autoradiography experiments with [C-14-ethanolamine]anandamide showed a heterogeneous pattern of incorporation of radiolabel in the brain, which was distinct from the more homogenous distribution of radioactivity produced with [C-14]ethanolamine. (Abstract#: 639.25, 2012) Radio TLC and HPLC analyses showed that [C-14]ethanolamine was released from anandamide and then converted mainly to phosphatidylethanolamine (PE). In subsequent work we have tested the effects of the FAAH inhibitor URB597 on the regional uptake of radiolabel from anandamide labeled at either the acyl or the ethanolamine moiety. Even though URB597 (3mg/kg) blocked the production of labeled phospholipids (TLC analysis showed 0% radioactivity as phospholipids at 15 minutes after tracer injection); it did not prevent the formation of a heterogeneous pattern at both 15 minute and 100 minute time-points. The heterogeneous pattern changed over time in brains from URB597 treated but not vehicle treated mice. At 100 minutes after tracer injection into URB597 treated mice, there was increased accumulation of radioactivity in hippocampus, and a 40% decrease in total amount of radioactivity, relative to 15 minutes. Our results indicate that un-metabolized anandamide accumulates heterogeneously in different brain parts before it is hydrolyzed, but that FAAH activity does not control the brain distribution pattern of radiolabel from anandamide. We conclude that the change in brain distribution of label over time in URB597 treated mice is determined by a combination ofthe physical and/or biochemical properties of anandamide itself and of its labeled metabolites.

Title: Expression of transient receptor potential ankyrin type 1 in the mouse brain

Authors: *S.-I. HONG, S.-X. MA, J.-Y. HWANG, J.-S. KIM, J.-Y. SEO, S.-Y. LEE, C.-G. JANG;
Dept. of Pharmacol. Sch. of Pharm., Sungkyunkwan Univ., Suwon, Korea, Republic of

Abstracts: Transient receptor potential ankyrin type 1 (TRPA1), responding to noxious cold and pungent compounds, was found in thermosensitive neurons, and hair cells of ear, but little is known about the expressions of the TRPA1 within the brain, specifically cortex, dorsal and ventral hippocampus, caudate putamen, nucleus accumbens, and ventral tegmental area. To address this issue, we used real-time PCR, Western blot analysis, and immunohistochemistry. Real-time PCR and Western blot analysis data showed that TRPA1 mRNA was expressed in the brain. TRPA1 mRNA was highly expressed in the cortex compared to brain other regions. We investigated that whether the location of TRPA1 protein is in the neuronal cell body or neurofilament of axons and dendrite. Double staining of TRPA1 with neuronal nuclei protein (NeuN), a neuronal marker, showed that TRPA1 was co-expressed with NeuN in the brain, especially hippocampus pyramidal region, caudate putamen and nucleus accumbens in which the cell bodies of neurons are located. Further, when combining TRPA1 and microtubule associated protein type 2 (MAP2) staining, a marker of neurofilament, both TRPA1 and MAP2 can be observed in the brain. Taken together, our results suggest that TRPA1 mRNA and protein be expressed in the mouse brain and further, TRPA1 be expressed in the neuronal cell body and neurofilament.

Title: Intense/prolonged sensory stimulation activates neuronal pannexin-1 channels in the mouse brain *in vivo*

Authors: *T. DALKARA[1], B. DÖNMEZ-DEMIR[2], K. KILIC[2], E. EREN-KOCAK[2], Y. GÜRSOY-ÖZDEMIR[2], P. MAGISTRETTI[3], H. KARATAS[2];
[1]Hacettepe Univ. Fac. of Med., Ankara, Turkey; [2]Hacettepe University, Inst. of Neurolog. Sci. and Psychiatry, Ankara, Turkey; [3]Ctr. for Psychiatric Neuroscience, Dept. of Psychiatry, Brain Mind Institute, EPFL, Lausanne, Switzerland

Abstracts: We have recently demonstrated that spreading depolarization (SD) can activate neuronal pannexin-1 channels in the intact mouse brain *in vivo* (Science 2013, 339:1092-1095). The extracellular concentrations of glutamate and potassium substantially increase during SD and may contribute to opening of pannexin-1 channels. One may posit therefore that increases in extracellular glutamate and potassium to supra physiological levels during intense/prolonged synaptic activity may also activate pannexin-1 channels. Here, we tested this hypothesis in the intact mouse barrel cortex *in vivo*. We first identified the barrel cortex area that showed maximum CBF increase during whisker stimulation by laser speckle imaging. We stimulated whiskers with a brush driven by a motor and detected the stimulation parameters that induced a robust CBF increase in this area. We then placed extracranial Ag/AgCl electrodes over the thinned skull to record DC potential changes during whisker stimulation to make sure they do not induce SD, which itself activates pannexin-1 channels. Just before the stimulation, we injected propidium iodide, a membrane impermeable fluorescent dye, intracerebroventricularly to label neurons, whose pannexin-1 channels were activated. Pannexin-1 megachannel opening allows passage of large molecules up to 1 kD, therefore, the influx of small fluorescent dyes are used to monitor their activity. We found that prolonged and intense sensory stimulation caused opening of the neuronal pannexin-1 channels in the barrel cortex and thalamus. This effect was especially striking when glycogen mobilization or lactate transport to neurons were inhibited pharmacologically or by genetic means. During synaptic activity, glycogen in peri-synaptic astrocyte end-feet is used as an immediate energy supply for glutamate and potassium uptake and to fuel post-synaptic membrane pumps by supplying lactate. In conclusion, intense/prolonged sensory stimulation can activate neuronal pannexin-1 channels when energy supply cannot quickly match the increased demand.

Sch. of Convergence Sci. and Technology, Seoul Natl. Univ., Seoul, Korea, Republic of

Abstracts: Itch is an unpleasant sensation that evokes a desire to scratch. Antihistamines are widely used for treating pruritus. However, in many cases, patients who suffer from chronic itch are insensitive to antihistamine treatment. Thus, better therapeutics is needed to treat the histamine-independent itch. Several molecules, cells, and circuitry for itch transmission have been identified. TRPV1 is implicated in mediating histaminergic itch. Mas-related G protein-coupled receptors are itch receptors for non-histaminergic pruritogens, such as chloroquine or SLIGRL. TRPA1 is known to be a downstream target of Mas-related G protein-coupled receptors in mediating itch signaling. Anoctamin 1 (ANO1/TMEM16A) is a Ca2+ activated chloride channel expressed highly in nociceptors. Recently, we found that ANO1 is a heat sensor necessary for mediating acute, inflammation, or nerve-injury induced pain. Because of high expression in nociceptors, ANO1 may be involved in itch signals. Thus, this study aims to determine if ANO1 mediates itch. Using Adv/Ano1fl/fl mice that have a functional ablation of Ano1 mainly in DRG neurons, we determined a functional role of ANO1 in itch. To induce itch, pruritogenic substances were injected into the nape of the neck subcutaneously. Surprisingly, compared to control mice, Adv/Ano1fl/fl displayed a significant reduction in scratching behaviors to chloroquine or SLIGRL injection, but not histamine injection. These results demonstrate that ANO1 possibly mediate histamine-independent itch signaling in sensory neurons. Title: Inhibition of recombinant $GABA_A$ receptor by sulphated neurosteroids - a study of molecular mechanism and elucidation of binding sites

Authors: *D. SACHIDANANDAN, T. AHMED, A. K. BERA;
Biotech., Indian Inst. of Technol. Madras, Chennai, India

Abstracts: γ- amino butyric acid ($GABA_A$) receptor is negatively modulated by two structurally similar neurosteroids, Pregnenolone sulphate (PS) and Dehydroepiandrosterone sulphate (DHEAS). However, the exact binding site and mechanism still remains elusive. Using human $GABA_A$ receptors expressed in HEK293 cells, we performed electrophysiology experiments to study the molecular mechanisms governing neurosteroid mediated GABA-ergic inhibition. We showed that presence γ subunit in $GABA_AR$ enhances the efficacy of DHEAS without altering its binding affinity. Saturating concentrations of DHEAS blocked about 80% of currents mediated by $GABA_AR$, composed of α_1, β_1 and γ_{2S} subunits. The inhibition was only 30% in case of α_1 and β_1 containing $GABA_AR$. IC_{50} of DHEAS was identical with or without γ subunit. In contrast to DHEAS, neither the affinity nor the efficacy of PS was altered by the γ subunit. When Val256 of α_1 was mutated to Ser, the mutant channel became resistant to inhibition by both DHEAS and PS. PS exerted its inhibitory effect by enhancing the desensitization kinetics of $GABA_AR$, possibly by promoting the interaction between M2-M3 linker and extracellular loop 7/ loop 2. Mutant α_1, containing double Cys in loop 2/loop 7 and M2-M3 linker formed disulphide bond twice as much faster, when treated with saturating GABA + PS, compared to GABA alone or GABA + DHEAS. Taken together, we demonstrated that inhibition of $GABA_AR$ by DHEAS and PS follows similar but not identical inhibitory mechanism. For elucidating the neurosteroid binding sites, we built a homology model of $GABA_AR$ based on *C. elegans* Glutamate Gated Chloride Channel (GluCl, PDB i.d.3RHW). The two proteins were aligned using EMBOSS Needle and the structure was built using MODELLER 9.9. The model thus generated was used for docking after refinement and verification with experimental data. Docking was performed with PS and DHEAS on the built model using AUTODOCK. Results suggest that sulphated neurosteroids bind at α (-)/β (+) interface. Residues predicted by docking were mutated to alanine and the mutants subjected to PS and DHEAS concentrations to estimate the IC_{50}. We observed that PS and DHEAS have different binding sites as well, apart from molecular mechanism.

Title: The ClC-2 channel: contribution to neuronal excitability in the thalamocortical network

Authors: *C. E. NITURAD, N. DAMMEIER, U. B. S. HEDRICH, S. MALJEVIC, H. LERCHE;
Neurol. and Epileptology, Hertie Inst. For Clin. Brain Res., Tübingen, Germany

Abstracts: Chloride homeostasis is essential for effective inhibition in the brain. Intracellular chloride accumulation in neurons can lead to an excitatory GABAergic response, emphasizing the importance of effective chloride extrusion mechanisms. The potassium chloride co-transporter 2 (KCC2) provides the major chloride extrusion pathway and a similar role has been proposed for the chloride channel ClC-2. Recently, loss of function mutations of ClC-2 channels were found in leukoencephalopathic patients and none of them was affected by epilepsy. Nevertheless we are interested in verifying and understanding whether the absence of the ClC-2 channels can be considered as susceptibility factor of some epileptic phenotypes. Since previous studies suggested a role of ClC-2 channels in mediating chloride extrusion or in a direct regulation of neuronal excitability by chloride influx, we used ClC-2 knock-out, heterozygous and WT littermates to study the contribution of the ClC-2 channel to chloride homeostasis in thalamocortical brain slices. Chloride currents were recorded using the whole cell patch clamp technique in the thalamic reticular nucleus (NRT), in relay neurons within the ventrobasal complex (VB) of the thalamus and in the cortex. Regarding the distribution pattern of ClC-2, our recordings did not show obvious differences in current amplitudes of NRT inhibitory neurons in WT compared to heterozygous animals. ClC-2 KO mice did not show any chloride currents. However, NRT inhibitory neurons showed decreased firing activities in KO animals in

comparison to the WT, indicating reduced inhibition in thalamocortical networks, the mechanisms of which have to be further explored.

Title: Characterization of Cl^- channel modulators on the currents of TMEM16A and Bestrophin1

Authors: *H. ZHANG[1], Y. LIU[1], H. ZHANG[1], D. HUANG[1], X. DU[1], N. GAMPER[2,1]; [1]Pharmacol., Hebei Med. Univ., Hebei, China; [2]Sch. of Biomed. Sciences, Fac. of Biol. Sci., Univ. of Leeds, Leeds, United Kingdom

Abstracts: The Ca^{2+} activated Cl^- channels (CaCCs) play multitude of important physiological functions including regulation of neuronal excitability. A number of candidate proteins have been proposed to form CaCC, but only two families, the bestrophins and the TMEM16 (ANO) proteins, recapitulate properties of native CaCC in expression systems. In sensory neurons, both bestrophin1and TMEM16A have been suggested to be the molecular basis of CaCC. Studies of endogenous CaCCs are hindered by the lack of information for the profiles of pharmacology modulators of CaCC and a systematic comparison of the effects of these modulators on TMEM16A and bestrophin1 is missing. In the present study, we studied seven Cl^- channel inhibitors: niflumic acid (NFA), NPPB, flufenamic acid (FFA), DIDS, tannic acid, $CaCC_{inh}$-A01 and $T16A_{inh}$-A01 for their effects on TMEM16A and bestrophin-1(Best1) stably expressed in CHO cells using patch clamp technique. Among seven inhibitors studied, NFA showed highest selectivity for TMEM16A (IC_{50} of 7.40 ± 0.95 μM) over Best1 (IC_{50} of 102.19 ± 15.05 μM). In contrast, DIDS displayed a reverse selectivity inhibiting Best1 with IC_{50} of 3.93 ± 0.73 μM and TMEM16A with IC_{50} of 548.86 ± 25.57 μM). $CaCC_{inh}$-A01 was the most efficacious blocker for

both TMEM16A and Best1 channels. $T16A_{inh}$-A01 partially inhibited TMEM16A currents but had no effect on Best1 currents. Tannic acid, NPPB and FFA had variable intermediate effects. We are testing the effects of these modulators on endogenous CaCC of sensory neurons.

Title: The influence of intracellular ATP on rat P2X2a receptor desensitization

Authors: ***M. ROKIC**[1], C. CODDOU[2], E. LEIVA-SALCEDO[1], S. STOJILKOVIC[1]; [1]NIH, Bethesda, MD; [2]Dept. of Biomed. Sciences,, Fac. of Medicine, Univ. Catolica del Norte, Coquimbo, Chile

Abstracts: The activated P2X2 receptor (P2X2R) desensitizes in a calcium-independent and -dependent manner. The former reflects the structure of the C-terminal sequence, whereas the nature and mechanism of the later process are not known. Using the whole-cell recording with potassium as an intracellular ion, and rat P2X2aR expressed in HEK293 cells and bathed in 2 mM calcium-containing medium, here we show that receptor desensitization is facilitated during repetitive agonist application (termed use-dependent desensitization); receptor desensitization was practically abolished in the whole-cell recording in the absence of bath calcium and in perforated patch clamp recording independently of bath calcium concentration. Addition of ATP but not GTP in the pipette solution also abolished bath calcium-dependent receptor desensitization in whole-cell recording, suggesting that a leak of ATP from cytosol to pipette facilitates transition of channels from open to desensitized state. Substitution of intrapipette potassium with cesium facilitated receptor desensitization as well as the addition of 10 mM staurosporine to ATP-containing intracellular solution, indicating the relevance of phosphorylation status of receptors on channel gating. In a search for amino acid residues accounting for effects of ATP, we used three spliced forms of receptors, the V439-Q459 C-terminal deletion mutant, and numerous intracellular single residue mutants. These experiments

excluded the relevance of the V370-Q459 amino acid sequence in calcium-dependent desensitization. Furthermore, no consistent effect was observed with single residue D15N, E17A, and several T354 mutants. On the other hand, six Y16 mutants showed the presence of significant positive correlation between residue volume and desensitization rate. Furthermore, T18V, T18D and T18P mutants desensitized rapidly, whereas the receptor function was rescued by substitution of T18 with arginine or tyrosine. Finally, receptor desensitization was facilitated by substitution of the S363 residue with five other amino acids, but used-dependent desensitization was lost in all mutants. These findings indicate the importance of intracellular ATP in P2X2R function by providing the phosphorylation/dephosphorylation equilibrium and suggest the importance of S363 amino acid residues in use-dependent desensitization, whereas the role of T18 residue in calcium-dependent and -independent desensitization requires further work.

Title: Effects of chronic caffeine administration on brain sodium-potassium atpase activities in streptozotocine-induced diabetic female wistar rats

Authors: *A. O. MAHMUD-IMAMFULANI, O. K. BAMIKOLE, B. V. OWOYELE; Physiol., Univ. of Ilorin, Ilorin, Nigeria

Abstracts: Diabetes mellitus (DM) may affect the morphology and plasticity of the brain, leading to cognitive, memory, and electrophysiological impairment. Streptozotocine-Induced (STZ-induced) diabetes leads to a sustained up-regulation of facilitatory adenosine A2A receptors in the hippocampus. Brain Sodium-Potassium ATPase (Na+/K+ATPase) enhance neuroprotection, memory consolidation and diminishes cognitive deficits. Thus, it has been observed that brain Na+/K+-ATPase activities is reduced in diabetic state in male animals. We therefore aim to determine the effects of caffeine (an adenosine receptor antagonist) on brain Na+/K+ATPase activities in STZ-induced diabetic female rats. Eleven groups of 7 female Wistar rats weighing between 150-200g were used for the study. Groups 1, 2 and 3 were administered

15, 20 and 25 mg/kg caffeine intraperitoneally (i.p) per day respectively for five weeks; groups 4, 5 and 6 were administered 15, 20 and 25 mg/kg caffeine (i.p) per day respectively for five weeks and were maintained on caffeine for three weeks thereafter; groups 7, 8 and 9 were DM rats placed on caffeine immediately after induction of DM at 15, 20 and 25 mg/kg (i.p) per day respectively for 3 weeks; groups 10 and 11 were control and DM respectively that were administered normal saline. DM was induced with 50 mg/kg STZ. At the end of the experiments, rats brains were removed and Na+/K+ATPase activities was determined. The ATpase activity was expressed as μmolPi/mg protein/hour x 10-3. The results showed a significant ($P < 0.05$) decrease in Na+/K+ATPase activities of untreated DM group (250.9 ± 0.26) compared with control group (415.6 ± 0.26). Also groups 1, 2 and 3 pretreated with caffeine showed increase in Na+/K+ATPase activities (1022.0 ± 0.51, 825.0 ± 0.22 and 498.6 ± 0.04 respectively) with significant ($P < 0.05$) observation in groups 1 and 2 when compared with control group. Groups 4 and 6 showed significant ($P < 0.05$) decrease in Na+/K+ATPase activities (280.0 ± 0.40 and 232.4 ± 0.34 respectively) when compared with control and a significant increase in group 5 (374.0 ± 0.34) compared with DM group. DM rats in groups 7, 8 and 9 showed increase in Na+/K+ATPase activities (468.8 ± 0.51, 428.5 ± 0.50 and 259.9 ± 0.20 respectively when compared with diabetic group, with significant increase ($P < 0.05$) in groups 7 and 8. The result shows that Na+/K+ATPase activity is reduced in STZ-induced diabetic female Wistar rats. In conclusion, the findings from this study shows that caffeine at low to moderate doses improves and restores the brain Na+/K+ATPase activities in diabetic rats. Thus moderate caffeine intake could be beneficial to brain functions in diabetic animals and man.

Title: Modulation of p2x7 receptor mediated calcium signaling by pannexin hemichannel

Authors: *V. SIRISHA, A. K. BERA, A. MANI;
biotechnology, IITM, Chennai, India

Abstracts: Pannexins are the members of the family of gap junction proteins in vertebrates, expressed in many organs including brain. In the central nervous system, Pannexin1 (Panx1) participates in both autocrine and paracrine signaling by working as an ATP release channel. It is also involved in calcium signaling by activating P2X7 receptor through the released ATP. A physical interaction between Panx1 and P2X7 receptor (P2X7R) has been reported, though the functional consequences of such interaction have not been studied. In the present study, we demonstrate that over-expression of Panx1 attenuates P2X7R mediated intracellular calcium rise without altering expression of the latter. By sequentially deleting amino acids from the carboxy terminus of Panx1, we identified that the region from amino acid 370 to 406 in the carboxy terminus is responsible for this inhibition. CHO-K1 cells which are known to express endogenous functional P2X7 receptor were transiently transfected with wild type Pannexin1 and Pannexin1 C terminus truncated mutants. Intracellular calcium was measured ratiometrically using Fura2-AM.Endogenous expression of P2X7 was checked by western blotting and Real time PCR after transfecting with Pannexin1 hemi channel.

Title: Angiopoietin-1 inhibits zinc entry through PIP2 hydrolysis-induced ion channel blockage

Authors: ***J. LIM**[1], J.-Y. KOH[1,2];
[1]Neural Injury Res. Lab., [2]Dept. of Neurol., Asan Med. Ctr., Seoul, Korea, Republic of

Abstracts: Release of synaptic zinc and its entry into cortical cells during hypoxic ischemia or seizure result in extensive neuronal death. Hence, neuroprotective measures targeting zinc toxicity may prove useful in reducing acute brain injury. Angiopoietin-1 (Ang1), a potent vascular growth factor that binds to Tie2 and integrins, exhibits substantial protective effect

against various kinds of cytotoxic insults. Thus, we investigated whether Ang1 is able to protect cortical cells against zinc-induced cell death. In our neuron-glia co-culture system, transient exposure to zinc (150 μM) induced necrotic death of approximately 70% of the cells; co-treatment with Ang1 (200 ng/μl) markedly reduced zinc-induced toxicity to 20%. Interestingly, whereas zinc toxicity occurs largely through oxidative stress, Ang1 did not protect cortical cells against direct oxidative stress induced by H_2O_2_rather, fluorescent staining of intracellular zinc revealed that Ang1 dramatically reduced the entry of zinc via ion channels, thereby nullifying the effect of added extracellular zinc ion in the first place. We then tested the hypothesis that Ang1 blocks ion channels by activating phospholipase C (PLC), which induces hydrolysis of phosphatidylinositol 4,5-biphosphate (PIP_2) and ion channel blockage: notably, PLC inhibitor U73122 completely negated Ang1-induced inhibition of zinc entry and the subsequent cytotoxicity. Lastly, the protective action of Ang1 was effectively reversed by anti-integrin α5 antibody and FAK inhibitor PF573228, indicating that binding of Ang1 to α5 integrin and the subsequent activation of FAK signaling pathway is needed for blockage of zinc entry. Taken together, these results demonstrate a potent protective effect of Ang1 against zinc-induced necrotic cortical cell death, and at the same time reveal a novel role of Ang1/integrin pathway in regulating ion channel activity by PLC activation and subsequent PIP_2 hydrolysis. Keywords: zinc, angiopoietin-1, ion channel, phosphatidylinositol 4,5-biphosphate

Title: Software for model-based design of experiments

Authors: *S. G. CARVER[1,2], M. HINES[3];
[1]Mechanical Engin., The Johns Hopkins Univ., Baltimore, MD; [2]Mathematics and Statistics, American Univ., Washington, DC; [3]Yale Univ., New Haven, CT

Abstracts: We have written software to aid in the design of experiments that test hypotheses in the form of models. The models to be tested must include a representation of both the biological

system (e.g. currents and/or cells) and the experimental protocols. The models can have adjustable parameters. A successful experiment will reveal that one of the hypothesized models is substantially more likely than the others to reproduce the experimental data. Our software addresses the question: do the different hypotheses make different enough predictions---different enough to be testable with the planned experimental protocols? With the answer to this question in hand, the experimenter can decide to proceed with the experiment as planned, or alternatively, to reformulate the hypotheses, and/or adjust the protocols. To arrive at the answer, our software computes, with Monte Carlo integration and optimization, (1) the minimum Kullback-Leibler divergence between an assumed model and an alternative model structure, (2) the probability that the Akaike information criterion (AIC) selects each candidate model (based on data simulated from the assumed model), and (3) the number of repetitions of the experiment needed to make the selection correctly, a desired fraction of the time (e.g. 95%). As a last step, our software can analyze experimental (or simulated) data to rank hypotheses and select the best model. Our software requires simulating the models, and computing and optimizing the likelihood that each model produces the data. We compute likelihoods recursively with a Bayesian filter. By restricting our models to partially observed Markov chains (e.g. a patch clamp making single-channel recordings), we eliminate the need for approximation in the computation of the likelihood, and greatly reduce the amount of computation needed. More general models, planned for future work, require such approximations (e.g. based on the extended Kalman filter, or the particle filter). While our model-based design of experiments can be computationally very costly for such models, the computational expense, when attainable, can pay off, if it justifies or rejects an even more costly experiment.

Title: Modulation of acid sensing ion channels by estrogen and quercetin

Authors: *M. MUKHOPADHYAY[1], A. K. BERA[1], S. CHAKRAVARTY[2], P. JHELUM[2]; [1]Biotech., Indian Inst. of Technol., Chennai, India; [2]Indian Inst. of chemical technology, Hyderabad, India

Abstracts: Acid Sensing Ion Channels (ASICs), present on neuronal membranes, are activated by low pH. Activation of ASIC1a during stroke promotes cell death by increasing intracellular calcium. Estrogen has been shown to exhibit neuroprotective properties against several neurological disorders, including stroke. We hypothesize that estrogen mediated neuroprotection involves ASICs. We found that while ASIC1a subtype promotes cell death during ischemia, ASIC2a subtype is neuroprotective. There was significant up-regulation of ASIC2a in female mice, subjected to experimental stroke. This up-regulation was, however, not observed in the ovarectomised mice and male mice, suggesting the possible involvement of estrogen . We also studied the effect of a naturally occurring flavonoid Quercetin on ASIC by performing whole cell patch clamp technique. Quercetin is known to have neuroprotective action. Quercetin inhibits both ASIC1a and ASIC2a mediated currents in sub-micromolar concentration, suggesting that it possibly exerts its activity by targeting ASICs.

Title: Nicotine exposure fragments Golgi and alters the recycling and glycosylation of alpha4beta2-type nicotinic acetylcholine receptors

Authors: *A. P. GOVIND[1], Y. VALLEJO[2], W. GREEN[1,3];
[1]Neurobio., Univ. of Chicago, CHICAGO, IL; [2]Natl. Cancer Inst., Bethesda, MD; [3]Marine Biol. Lab., Woods Hole, MA

Abstracts: Nicotine addiction is initiated by nicotine binding to nicotinic acetylcholine receptors (nAChRs) in brain during chronic exposure. We have characterized how nicotine exposure altered the trafficking and glycosylation of cell-surface alpha4beta2-type nAChRs while new ligand binding sites formed on these nAChRs via the process of nicotine-induced upregulation. Long-term nicotine exposure stimulated surface nAChR endocytosis and recycling and fragmented the Golgi apparatus of the cells and neurons in which they were expressed. Nicotine-induced Golgi fragmentation caused glycosidases to co-localize with recycling nAChRs. As a result, N-linked glycosylation of recycling nAChRs changed from high-mannose to complex-trimmed during nicotine exposure in parallel with their upregulation. During nicotine-induced Golgi fragmentation, nAChR upregulation, surface insertion, recycling and trafficking through the secretory pathway continued in contrast to BrefeldinA-induced Golgi fragmentation where all of these processes were inhibited. Co-exposure of nAChR competitive inhibitors and channel blockers with nicotine did not block the effects of nicotine indicating that nicotine acts independent of surface nAChR activation or desensitization. However, nicotine-induced Golgi fragmentation occurred only in cells and neurons expressing nAChRs. Thus, Golgi fragmentation and likely other nicotine-induced changes are caused by nicotine binding to nAChRs in an intracellular compartment. Altogether, our results suggest novel mechanisms by which membrane-permeable drugs, such as nicotine, act by binding to their intracellular receptors causing Golgi fragmentation and, in turn, the redistribution and modification of receptors at the cell surface.

Title: Pannexin1 mediates astrocyte cell death

Authors: *E. SCEMES[1], D. G. JACKSON[2], J. WANG[2], R. W. KEANE[2], G. P. DAHL[2];
[1]Dept of Neurosci, Albert Einstein Col. of Med., BRONX, NY; [2]Physiol. and Biophysics, Univ. of Miami Sch. of Med., Miami, FL

Abstracts: Elevation of the extracellular concentrations of excitatory neurotransmitters (e.g., glutamate, aspartate, ATP) and ions (mainly K^+) resultant from traumatic brain injury and stroke triggers the progressive and long lasting secondary wave of cell death. This secondary bystander damage (necrosis and apoptosis) results from the activation of caspase and phospholipase pathways in nearby cells. Activation of P2 receptors by elevated ATP is one of the initial signals leading to inflammatory responses and pyroptotic cell killing. Pannexin1 (Panx1) forms plasma membrane channels that are activated directly by extracellular K^+ and, through intracellular signaling cascades, by ATP-sensitive P2 receptors. Interestingly, Panx1 is regulated by its permeant, i.e. the permeant ATP inhibits the channel from the extracellular space. Here we tested the interplay between stimulatory and inhibitory factors on the Panx1 channel in mediating cell death. Using pharmacological, electrophysiological, biochemical and fluorescence imaging techniques, we provide evidence that extracellular K^+ attenuates the inhibition of Panx1 channels by ATP and its analogue BzATP. Increased extracellular K^+ not only attenuated the self-inhibition of Panx1 but also affected the potency of other Panx1 channel inhibitors, notably those affecting the putative binding sites for ATP, thus suggesting that the binding sites of K^+ and BzATP on Panx1 channels overlap as well. Astrocyte cell death (LDH release and caspase-3 activation) induced by elevated K^+ was attenuated by BzATP and prevented in astrocytes deficient in Panx1 but not in $P2X_7$-null astrocytes. Similar to the observations made in an expression system and cell cultures, BzATP also attenuated the K^+-induced activation of Panx1 channels (dye uptake) in neurons and astrocytes from hippocampal slices of wild-type and $P2X_7$-null mice; K^+-induced Panx1 activation was absent in hippocampal slices of Panx1 deficient and double $P2X_7$ and Panx1 null mice. In summary, we provide evidence that Panx1 is a key molecule that orchestrates caspase-dependent cell death in response to elevation of extracellular K^+ and ATP concentrations and that the negative feedback control of ATP on Panx1 channels can be abrogated by elevated extracellular K^+ concentration. During acute injuries to the CNS, the loss of ATP-induced inhibition of Panx1 channels in a K^+-rich environment could be a key factor for hyper-stimulation of the apoptosome in neighboring healthy cells resulting in secondary wave of cell death.

Title: Compound action potential inhibition produced by aroma-oil compounds without TRP activation in the frog sciatic nerve

Authors: S. OHTSUBO, T. FUJITA, A. MATSUSHITA, C.-Y. JIANG, *E. KUMAMOTO; Dept Physiol, Saga Med. Sch., Saga, Japan

Abstracts: Capsaicin, menthol and allyl isothiocyanate, which activate TRPV1, TRPM8 and TRPA1, respectively, inhibited fast-conducting and voltage-gated Na^+-channel blocker tetrodotoxin-sensitive compound action potentials (CAPs) recorded from the frog sciatic nerve without TRP activation. Opioids such as morphine, ethylmorphine and codeine depressed CAPs in a manner dependent on their chemical structures without opioid receptor activation. Similar CAP inhibition was seen between tramadol and mono-*O*-demethyl tramadol and also among various adrenoceptor agonists including dexmedetomidine. We have previously reported that several aroma-oil compounds inhibit CAPs. The present study examined whether the CAP inhibitions are mediated by TRP activation and a detail of how the CAP inhibitions are related to the chemical structures of aroma-oil compounds. The experiment was performed by applying the air-gap method to the frog sciatic nerve. Citral, which activates TRPV1, TRPM8, TRPA1 and TRPV3, attenuated CAP peak amplitudes with the IC_{50} value of 0.48 mM; this action was resistant to a non-selective TRP antagonist ruthenium red. Camphor (TRPV1 and TRPV3 agonist) at 5 mM reduced CAP amplitudes by 33% and (+)-borneol (TRPV3 agonist) inhibited CAPs with the IC_{50} value of 2.0 mM; these actions were insensitive to ruthenium red. Lavender-oil compounds, linalyl acetate and (±)-linalool, reduced CAP amplitudes with the IC_{50} values of 0.49 and 1.7 mM, respectively. -CHO group- (citronellal), -OH group- (citronellol, geraniol, (-)-linalool, (-)-borneol and α-terpineol), -COO- group- (geranyl acetate and bornyl acetate) and oxide group- (rose oxide) containing ones reduced CAP amplitudes with the IC_{50} values of 0.50, 0.38, 0.53, 1.5, 1.8, 1.1, 0.51, 0.65 and 2.0 mM, respectively. On the other hand, myrcene and *p*-cymene at 5 mM reduced CAP amplitudes by 7 and 20%, respectively. Taking into consideration previously-reported data, an efficacy sequence of aroma-oil compounds for the CAP inhibitions was phenols (thymol, carbacrol and eugenol) ≥ aldehydes (citral and citronellal) ≥ esters (bornyl acetate, linalyl acetate and geranyl acetate) > alcohols ((±)-linalool, (-)-linalool, (+)-borneol, (-)-

borneol, α-terpineol, geraniol, citronellol and menthol) > ketones (carbone, menthone and plegone) > oxides (rose oxide and cineole) >> hydrocarbons (*p*-cymene, myrcene and limonene), except for a ketone camphor that was less effective than oxides. These results further confirmed the idea that there is a relationship between nerve conduction inhibitions by aroma-oil compounds and their chemical structures. Such an inhibition was not mediated by TRP activation.

Title: Frog sciatic nerve compound action potential inhibitions by crude medicines contained in daikenchuto and interaction between the inhibitions

Authors: A. MATSUSHITA, *T. FUJITA, S. OHTSUBO, C.-Y. JIANG, E. KUMAMOTO; Dept. Physiol., Fac. Med., Saga Univ., Saga, Japan

Abstracts: We have recently revealed that various plant-derived transient receptor potential channel agonists such as capsaicin, zingerone, menthol, allyl isothiocyanate and cinnamaldehyde inhibit fast-conducting and voltage-gated Na^+-channel blocker tetrodotoxin-sensitive compound action potentials (CAPs) in frog sciatic nerves. A similar inhibitory action was seen by traditional Japanese medicine (Kampo medicine) containing many plant-derived chemicals. Daikenchuto, rikkosan, kikyoto, rikkunshito, shakuyakukanzoto and kakkonto reduced the peak amplitude of the CAP in a concentration-dependent manner. Daikenchuto had a half-maximal inhibitory concentration (IC_{50}) value of 1.1 mg/ml. When compared at a concentration of 2 mg/ml, the extents of the reductions by daikenchuto, rikkosan, kikyoto, rikkunshito, shakuyakukanzoto and kakkonto were 70%, 30%, 25%, 15%, 14% and 12%, respectively. Daikenchuto being the most effective in inhibiting CAPs is composed of three kinds of crude medicine, Japanese pepper, processed ginger and ginseng. The present study examined how the three crude medicines of daikenchuto affect CAPs and whether there is an interaction between the actions of the crude medicines on CAPs. The experiments were performed by applying the air-gap method to the frog sciatic nerve. When each of the crude medicines at 2 mg/ml was

tested, Japanese pepper and processed ginger reduced CAP peak amplitude by 70% and 30%, respectively, while ginseng radix hardly affected CAPs. The inhibitory action of Japanese pepper had the IC_{50} value of 0.77 mg/ml. Ginseng radix (0.6 mg/ml), which had no effect on CAPs, unaffected the inhibitory action on CAPs of processed ginger in a range of 0.2 to 2 mg/ml, but had a tendency to enhance the inhibitions of CAPs by low (< 0.5 mg/ml) but not high (> 0.5 mg/ml) concentrations of Japanese pepper. Processed ginger (1 mg/ml) also had a tendency to increase CAP inhibition by Japanese pepper at low but not high concentrations. These results indicate that two kinds (Japanese pepper and processed ginger) of the crude medicine of daikenchuto have an ability to inhibit CAPs and that there is a positive interaction in nerve conduction inhibition among crude medicines contained in daikenchuto at low but not high concentrations. It is suggested that the pharmacological actions of Kampo medicine may be partly due to nerve conduction inhibition.

Title: Effects of membrane sealing agents poloxamer-188 and citicoline to cortical spreading depression-induced megachannel opening in the brain

Authors: *S. LULE[1], T. YILDIRIM[2], A. EYLEN[2], S. CANKURTARAN-SAYAR[3], K. SAYAR[4], M. UGUR[3], O. UGUR[5], T. DALKARA[1,6], Y. GURSOY-OZDEMIR[1,6];

Pharmacol., [5]Departmant of Pharmacol., Ankara Univ., Ankara, Turkey; [6]Dept. of Neurol., Fac. of Med., Ankara, Turkey

Abstracts: Cortical spreading depression (CSD) is a propagating wave of neuronal and glial depolarization that causes transient neuronal megachannel opening. Poloxamer-188 (P-188) and citicoline are known to seal plasmalemma and protect cells against several types of brain injury, although their mechanism of action is not clear. The aim of this study is to investigate whether P-188 and citicoline could suppress CSD-induced neuronal megachannel opening in the intact male

mouse (Swiss albino) brain and to gain insight to its mechanism of action. Pretreatment with P-188 and citicoline significantly decreased CSD-induced propidium iodide influx to neurons in both cortex (34% and 15%, respectively) and hippocampal dentate gyrus (32% and 22%, respectively), suggesting that these agents can block megachannel opening by either their membrane sealing action or by an unknown mechanism. To gain further insight, we examined whether or not P-188 and citicoline suppress P2X7 megachannel opening in cell cultures. Prolonged stimulation with adenosine tri-phosphate (ATP) induces a non-selective permeability increase due to opening of P2X7-ligand-gated ion channel, allowing molecules as large as 900 Daltons to enter cells. We used human embryonic kidney (HEK) 293 cells transfected with mouse P2X7 receptors (HEK-mP2X7) and a mouse macrophage derived cell line, RAW 264.7 that expresses an endogenous P2X7 receptor. The YO-PRO 1 fluorescence increase was monitored as an indicator of ATP-induced megachannel formation. We have found that neither P-188 nor citicoline had any blocking effect on mP2X7R induced dye uptake. We are currently investigating whether P-188 and citicoline could inhibit dye influx through Pannexin 1 (Panx1) megachannels in cell cultures.

Title: Local corticothalamic feedback via presynaptic GABAa receptors on thalamocortical terminals in rat V1

Authors: *L. WANG[1], M. KLOC[1], A. ERISIR[2], A. MAFFEI[1];
[1]Dept. of Neurobio. & Behavior, SUNY At Stony Brook, Stony Brook, NY; [2]Dept. of Psychology, Univ. of Virginia, Charlottesville, VA

Abstracts: Inhibitory GABAergic transmission plays a fundamental role in neocortical circuit function. Recent work showed that in many areas of the brain GABAa receptors can be located presynaptically and directly modulate the efficacy of synaptic transmission at GABAergic and glutamatergic inputs. However, in neocortical circuits the general assumption is that fast phasic or tonic GABA regulates circuit excitability by acting on postsynaptic GABAa receptors. No evidence regarding the possible presence of presynaptic GABAa receptors in neocortex has been reported. Here we tested the possibility that presynaptic GABAa receptors may be present in neocortical circuits and may play an important role in regulating how cortical circuits are activated by incoming inputs. We combined optogenetic, physiological, immunohistochemical and electron microscopy approaches to demonstrate that in rat primary visual cortex (V1) GABAa receptors containing the α4 subunit are specifically located at thalamocortical (TC) presynaptic terminals and modulate the amplitude of evoked TC currents. No evidence for presynaptic GABAa receptors at recurrent excitatory synapses was observed, indicating a connection-specific role for these receptors. Our results compel a thorough reevaluation of current theories about the functional role of inhibition in neocortex, as changes in the level of inhibition can provide connection-specific corticothalamic feedback through fast presynaptic GABA signaling. Therefore, presynaptic GABAa receptors containing the α4 subunit and located at TC terminals may play an important role in regulating neocortical circuit function under healthy and pathological conditions.

Title: Effects of seizure-inducing munc18-1 mutations on synaptic neurotransmission

Authors: *S. LOGAN[1], A. M. OROCK[2], F. DEAK[1];
[1]Reynolds Oklahoma Ctr. on Aging/Geriatric Med., [2]Oklahoma Ctr. for Neurosci., Univ. of Oklahoma HSC, Oklahoma City, OK

Abstracts: Early infantile epileptic encephalopathy (EIEE), also known as Ohtahara syndrome, is a severe form of epilepsy with pathophysiology manifesting in the first months of life. Patients experience tonic spasms and EEG measurements reveal suppression-burst patterns with poor medical prognosis. Mis-sense point mutations (C180Y, M443R, G544D and V84D) in STXBP1, the gene that encodes the protein munc18-1, have been identified as a probable cause for EIEE. Possible mechanisms for seizure induction by munc18-1 mutants may be through 1) haploinsufficiency whereby reduced stability or expression of the mutants would affect synaptic release; 2) dominant negative effect on wild-type munc18-1; or 3) loss-of-function. The effect of these mutations on synaptic neurotransmission remains to be elucidated. We hypothesized that disease causing munc18-1 point mutants adversely affect synaptic neurotransmission. To address this hypothesis, we virally expressed cerulean-tagged mutants in primary cortical neuronal cultures derived from munc18-1 wild-type (WT; +/+), heterozygotes (HET; +/-) and knock-out (KO; -/-) mouse embryos. Munc18-1 knock-out neurons die within 7 days *in vitro* (DIV) and synaptic transmission is severely impaired. Overexpression of C180Y mutant in KO neurons rescued neuronal survival and synaptic transmission albeit to a lower extent than tagged wild-type overexpression. GFP overexpression did not rescue KO neuronal survival. Using live imaging and FM1-43 staining methodology we measured synaptic release in the transduced neurons. Overexpression of C180Y mutant partially rescued synaptic release in munc18-1 knock-out neurons, albeit to a lower extent than the WT-expressing neurons (~20% of fluorescence lost within 15 seconds). This release rate is comparable to Munc18-1 heterozygote knock-out (20-30%) neurons. Control wild-type neurons have a typical ~40% of fluorescence drop in 15s of destaining. Furthermore, KO neurons expressing C180Y mutant also had a smaller recycling pool (7111 ±492 fluorescence units) compared to WT neurons (9961 ±1973, $p<0.039$). We conclude that the C180Y is a loss of function mutation of munc18 and full restoration of synaptic release is not necessary to prevent neurodegeneration by the munc18 protein. Characterization of the functional consequence of these mutants may lead to therapeutic interventions for patients with munc18 mutations and EIEE pathophysiology.

Title: Kv3 channel clustering in presynaptic boutons of cerebellar interneurons imparts local control of spike duration between release sites

Authors: *M. J. ROWAN, J. M. CHRISTIE;
Max Planck Florida Inst., Jupiter, FL

Abstracts: Compartmentalized control of electrical excitability including local shaping of action potentials (APs) is a key functional feature in the dendrites and myelinated axons of projection neurons. However, the capacity for local control of APs in the neurites of inhibitory interneurons remains relatively unexplored. We examined for localized control of AP waveform in unmyelinated axons of molecular layer interneurons (MLIs) in the cerebellum, a cell type that drives precisely timed inhibition from *en passant* bouton release sites onto postsynaptic targets. Using two-photon (2P) voltage-sensitive dye imaging to measure APs from multiple axonal locations, we find that the rate of AP repolarization is faster at boutons as compared to connecting axon shafts. In addition, AP repolarization rates of adjacent boutons display considerable variation. Together, these results demonstrate a highly-localized AP topography within small axonal regions (<15μm). Morphological perturbation failed to alter APs in boutons indicating that axon geometry alone does not account for these observed differences. Instead, our results point to Kv channel clustering at boutons as the key determinant of compartmentalized AP shaping within axons. This was experimentally validated using tight-seal patch-clamp recordings from intact boutons and axon shafts (not bleb endings) to measure Kv channel-mediated currents. Peak conductance density was substantially greater in boutons compared to axon shafts. Using targeted 2P photolysis of a caged Kv channel blocker at individual boutons, we ascertained the spatial extent over which Kv-mediated conductances govern AP repolarization. Uncaging was sufficient to locally broaden APs, however, broadening was constrained to the target bouton leaving neighboring boutons largely unaffected. Pharmacological manipulations revealed an essential role for Kv3-type channels in local AP shaping likely owing to their unique biophysical properties. As spike-width directs the magnitude of AP-evoked Ca^{2+} influx, release probability at individual boutons is likely informed by the specific expression and dynamic regulation of the Kv3 channels at independent boutons, thereby tuning neurotransmission at individual synapses.

Title: Neurones in the spinal cord of the mouse innervating the external urethral sphincter: Its identification and quantitative analysis of their presynaptic inputs

Authors: ***Y. MERICAN**, R. M. ICHIYAMA, S. A. DEUCHARS, J. DEUCHARS;
Univ. of Leeds, Leeds, United Kingdom

Abstracts: One of the most common and distressing problems in the elderly is poor sphincter control resulting in involuntary passing of urine. The external urethral sphincter, which serves as the muscle of continence, is innervated by the pudendal nerve which carries signal from the Onuf's nucleus in the spinal cord. In ageing, we hypothesise that there is an altered balance of excitatory and inhibitory influences on these motoneurones in the Onuf's nucleus. This is supported by a previous study that showed the urethral sphincter architecture and volume is unaltered in ageing (Russell et. al., 1996). In this study, we investigated the Onuf's nucleus homologue known as the dorsolateral nucleus (DLN) in young mice, followed by analysis of the type and number of presynaptic terminals to the DLN motoneurones. Twelve wild-type mice C57BL6 female mice (age 3 month) were used. For identification of the motoneurones innervating the external urethral sphincter, the sphincteric muscles of 6 mice were injected with cholera-toxin Bchain (2 µl in 1% saline) under Fluothane anaesthesia. 3 days later, the animals were anaesthetised with 80mg/kg pentobarbitone IP, perfused with 4% paraformaldehyde (PFA) and spinal cords were sectioned at 50µm using a vibrating microtome and processed with cholera-toxin immunohistochemistry. Using this retrograde tracing method, the motoneurones innervating the external urethral sphincter were traced and verified to be located in the ventral horn of the sixth lumbar to first sacral segments of the spinal cord. The remaining six mice were perfused and processed as above. The sectioned spinal cords from 3 mice were processed for the choline acethyl transferase (ChAT) using peroxidase immunohistochemistry. The DLN is easily identified based on the location of the ChAT peroxidase immunoreactivity. The mean length of the nucleus was 0.65 ± 0.2 mm, and the mean number of dorsolateral motoneurones was 38.5 ± 1.5 per spinal cord. Sectioned spinal cords from another 3 mice were processed for triple

labelling immunofluorescence with ChAT, glutamic acid decarboxylase (GAD67) and glycine transporter (GlyT2). Images obtained by confocal microscopy were analysed quantitatively using method by Chang & Martin (2009), and revealed that there were 2.0 (± 0.7), 4.4 (± 0.6) and 3.2 ± (0.8) of ChAT-, GAD67- and GlyT2-immunopositive boutons respectively per 100 μm membrane perimeter of motoneurones in the DLN. This initial result are important as baseline findings will be compared to the findings in aged mice to determine if there are age-related changes in the presynaptic inputs to the DLN motoneurones.

Title: Time resolved cryo-electron tomography of stimulated synaptosomes

Authors: *S. ASANO, U. DITTMANN, Z. KOCHOVSKI, V. LUCIC, W. BAUMEISTER; Max Planck Inst. of Biochem., Martinsried, Germany

Abstracts: Within the presynaptic terminal, synaptic vesicles are embedded inside a dense filamentous protein network known as the presynaptic cytomatrix. Earlier cryo-electron tomography studies of fully-hydrated, vitrified synapses showed significant differences in the cytomatrix at the active zone after prolonged stimulation. Here we used a newly developed setup capable of stimulating synapses 10-100 ms before vitrification. Quantitative analysis of stimulated synapses showed differences in synaptic vesicle distribution and cytomatrix organization which depends on stimulation protocol.

Title: Presynaptic calcium channel - vesicle release site relationships probed using measurements of synaptic latency

Authors: A. E. HOMAN[1], J. MA[2], M. DITTRICH[2], *S. D. MERINEY[3];
[1]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Pittsburgh Supercomputing Ctr., Carnegie Mellon Univ., Pittsburgh, PA; [3]Univ. Pittsburgh, Pittsburgh, PA

Abstracts: The organization of presynaptic active zones (AZs) can have a considerable impact on neurotransmission at synapses. The spatial relationship between voltage-gated calcium channels (VGCCs) and synaptic vesicle release sites has been demonstrated to influence release dynamics. Synaptic latency, the time delay from the arrival of the presynaptic action potential to the start of the postsynaptic response, provides a measure of the spatial relationship between VGCCs and release sites. We used the frog neuromuscular junction (NMJ) as a model synapse, and experimental manipulations designed to alter VGCC - synaptic vesicle release site relationships, to study variability in synaptic latency between synapses. Frog NMJs contain hundreds of AZs that are highly organized with respect to presynaptic VGCCs and docked synaptic vesicles. Previous studies suggest that there are 20-40 VGCCs in each AZ that open with low probability during a presynaptic action potential. Further, it has been hypothesized that each synaptic vesicle fusion event is triggered predominately by the calcium flux through a single open VGCC, with significant, but minor contributions from neighboring VGCCs. Using a combination of extracellular macropatch recordings positioned on top of nerve terminals and intracellular recordings from postsynaptic cells, we have characterized synaptic latency at these synapses. In control terminals, synaptic latency ranged from 0.29 ms to 0.51 ms with a mean of 0.43 ms, indicating that there is inherent variability between synapses under normal conditions. This distribution was shifted considerably following exposure to low extracellular calcium (0.5mM Ca2+) with synaptic latencies spanning from 0.29 ms to 2.8 ms with a mean of 0.60 ms, an average increase of approximately 100-200µs. Conversely, application of 400 nM conotoxin-GVIA decreased synaptic latency by approximately 100µs. These data support that on average, release at the frog NMJ is largely due to the flux of calcium through a single channel, with some contribution from other nearby channels. However, we also observed that the change in latency

induced by these experimental conditions was not consistent across synapses, suggesting that not all release sites are similarly organized. To aid in the interpretation of these findings we used spatially realistic MCell computer modeling to investigate the effect of VGCC number, location and organization in the AZ on release and facilitation. Our physiological and computer modeling data suggest that different synapses may have variability in their calcium channel-vesicle release site organization, and this has an impact on neurotransmission.

Title: Adenosine receptors and muscarinic receptors cooperate in acetylcholine release modulation on neuromuscular synapse

Authors: ***N. GARCIA**, M. PRIEGO, M. M. SANTAFÉ, T. OBIS, M. TOMÀS, M. A. LANUZA, N. ORTIZ, E. HURTADO, L. NADAL, J. M. TOMÀS;
Univ. Rovira i Virgili, Reus, Spain

Abstracts: In the neuromuscular synapse, presynaptic muscarinic ACh autoreceptors (mAChR) and purinergic adenosine autoreceptors (AR) directly couple ACh release and adenosine (ADO) secretion, respectively to regulate the nerve ending release mechanism itself. We show by immunocytochemistry that adenosine receptors subtypes (A1R, A2AR, A2BR and A3R) are present in the motor nerve terminals at the neuromuscular junctions (NMJs). Preliminary data from our group show that in resting neuromuscular preparations with fully preserved neurotransmission machinery (μ-CgTx-GIIIB paralyzed muscles), the presence of unselective AR agonist (adenosine 0.3-25μM) or antagonist (8-SPT, 100μM) does not change evoked ACh release. However, A1R can reduce spontaneous quantal leak of ACh and the collaboration of A1R and A2AR may protect synaptic function by reducing depression during repetitive activity. The present study is designed to analyse: 1) the effect of adenosine deaminase (ADA), ADO, 2-

chloroadenosine (CADO) and 8SPT in depression induction during electrically stimulated muscles (40-100Hz) and 2) to detect the AR and mAChR interaction in transmitter release modulation. Result indicates that: i) in basal conditions, endogenous ADO reduces the efficacy of the unsincronised spontaneous ACh release mechanism; ii) some colaborative work between different AR subtypes may reduce synaptic depression at moderate activity level (40Hz); iii) at high activity levels (100Hz), endogenous ADO production in the synaptic cleft could attain sufficient amount to interactuate with A1R receptors to protect for depression; iv) when using the non metabolizable 2-chloroadenosine (CADO) agonist, both quantal content and depression reduction occurs, and A1R seems mainly involved; v) there exist and absolute mutual dependence of AR and muscarinic acetylcholine receptors (mAChR) on the modulation of evoked and spontaneous ACh release in basal conditions and in experimental conditions with CADO stimulation; vi) the purinergic and muscarinic mechanism cooperate in the control of depression by sharing a common pathway though the purinergic control seems more powerful that the muscarinic one because depression can be additionally increased with 8SPT after a first increase in depression by muscarinic block with atropine.

Title: Loss of laminin-α4 leads to decreased functional capacity in neurotransmission at maturing neuromuscular junctions

Authors: *K. K. CHAND[1], K. M. LEE[1], B. L. PATTON[2], P. G. NOAKES[1,3], N. A. LAVIDIS[1]; [1]Sch. of Biomed. Sci., The Univ. of Queensland, Brisbane, Australia; [2]Sch. of Med. Fac., Oregon Hlth. & Sci. Univ., Portland, OR; [3]Queensland Brain Inst., Brisbane, Australia

Abstracts: Synaptic basal lamina such as laminin-421 (α4β2γ1), play an integral role in the organization of the neuromuscular junction (NMJ). Laminins interact with other synaptic

molecules to ensure precise alignment of pre- and postsynaptic structures. Targeted mutation of the *lama4* gene does not alter formation of active zones (AZs) and junctional folds, though disruptions in the precise alignment of AZs and postsynaptic folds are seen in the NMJs of laminin-α4 deficient mice (*lama4*$^{-/-}$) when compared to wild-type mice (WT). The laminin-α4 chain is suggested to play an instructive role in the placement of postsynaptic specializations such as acetylcholine receptors (AChRs). In the present study we compared neurotransmission at developing (postnatal day 8, P8), mature (postnatal day 18, P18) and young adult (postnatal day 30, P30) NMJs of *lama4*$^{-/-}$ and WT mice. Mice were bred and maintained on a C57BL/6-129SvJ genetic background. We functionally examined the diaphragm, a mixed type I and type IIA fiber muscle; and, *extensor digitorum longus*, a type IIB fiber muscle in *lama4*$^{-/-}$ NMJs (n=6 for each muscle at all ages and both genotypes). Utilizing intracellular electrophysiology we recorded end-plate potentials (EPPs) and miniature end-plate potentials (MEPPs). Early perturbations in neurotransmission were observed at P8, and became more evident by P18 with no significant progression to P30 at *lama4*$^{-/-}$ NMJs. At all ages investigated *lama4*$^{-/-}$ NMJs displayed higher intermittence of transmitter release (P8, $p<0.05$; P18 and P30, $p<0.01$) when compared to WT. MEPP amplitude was significantly increased in *lama4*$^{-/-}$ at P8 ($p<0.05$), P18 ($p<0.01$) and, P30 ($p<0.01$) in comparison to WT. The decay time of MEPPs was increased in *lama4*$^{-/-}$ when compared to WT NMJs for both fiber types. Immunohistochemical studies demonstrated normal distribution of pre- and postsynaptic densities. At the ages investigated we observed no change in the number of AZs at *lama4*$^{-/-}$ NMJs.The present study observed greater intermittence of transmitter release at *lama4*$^{-/-}$ NMJs, as well as decreases in the probability of release and quantal content at *lama4*$^{-/-}$ NMJs. These findings suggest a possible interaction between laminin-α4 and vesicular associated proteins at the AZ, as loss of laminin-α4 has been shown in this study to decrease the probability of transmitter release. Furthermore, the increase in MEPP amplitude and decay time indicates a down regulation of acetylcholine esterase. This is suggested to be a compensatory mechanism for the misalignment of AZs to AChRs seen at *lama4*$^{-/-}$ NMJs.

Title: Locating synaptic calcium channels

Authors: *S. A. MERRILL, S. WATANABE, E. HUJBER, J. R. RICHARDS, E. M. JORGENSEN;
Biol., Univ. of Utah, Salt Lake City, UT

Abstracts: Neurotransmission occurs when calcium triggers exocytosis of synaptic vesicles primed at release sites. The number, position and activity of nearby calcium channels determine the perdurance of free calcium at a release site. However, calcium entry through multiple sources within a synapse has been studied only indirectly. To understand the synapse we must identify the location of calcium channels in relation to synaptic vesicles, fusion proteins, and subcellular structures such as the dense projection. Mammals contain at least 10 genes that encode thousands of unique calcium channel isoforms. In *C. elegans unc-68* (RyR), *egl-19* (L-type), and *unc-2* (N-type) channels are each encoded by a single gene and contribute the calcium for synaptic vesicle exocytosis at neuromuscular junctions. First, we are transgenically attaching to each channel an enzymatic tag that covalently binds organic fluorophores suitable for correlative imaging by super-resolution fluorescence and electron microscopy (nano-fEM). Additionally, each channel will be imaged by biplane 3D super-resolution fluorescence microscopy to determine the colocalization of calcium channels with other synaptic proteins at nanometer resolution. Finally, we will test the contributions of the vesicle priming proteins *unc-13*, *unc-10* (RIM), and *rimb-1* (RIM-binding protein) to localizing each synaptic calcium channel and its adjoining vesicles.

Title: Nanodomain coupling of P/Q-type Ca2+ channels with truncated C-terminus of the alpha1A subunit to the release of synaptic vesicles at a central synapse in the Leaner (tgla/la) mouse

Authors: *Y. YANG[1,2], M. J. FEDCHYSHYN[1,2], T. M. EPPS[1,3], O. C. SNEAD[1,3], L. C. ABBOTT[4], L.-Y. WANG[1,2];
[1]The Hosp. For Sick Children, Toronto, ON, Canada; [2]Physiol., [3]Med. & Biomed. Sci., Univ. of Toronto, Toronto, ON, Canada; [4]Med. & Biomed. Sci., The Texas A&M Univ., College Station, TX

Abstracts: Emerging evidence suggests that the C-terminus of alpha1A or alpha1B subunit of voltage-gated Ca2+ channels (VGCCs) plays a crucial role in interacting with synaptic proteins RIM and RIM-BP and tethering synaptic vesicles (SVs) for efficient fusion at central synapses. However, whether such an interaction is essentially indispensable for fast synchronous release remains elusive. To address this question, we take advantage of the leaner mouse (tgla/la) in which a spontaneous missense mutation proximal to S6 transmembrane domain gives rise to a truncation of the C-terminus of alpha1A subunit, leading to impaired function of P/Q-type VGCCs and severely ataxic and epileptic behavioral phenotypes. By performing single or paired recordings from pre- and post-synaptic compartments of the mature calyx of Held synapse, we find that in contrast to the wild-type nerve terminal where Omega-agatoxin sensitive P/Q-type VGCCs exclusively mediate transmitter release, mutant P/Q-type channels contribute to a fraction of synchronous release in the tgla/la synapse and the loss-of-function mutation is compensated by Omega-conotoxin sensitive N-type VGCCs. After blocking N-type VGCCs, surprisingly we reveal that diffusion of a slow Ca2+ buffer EGTA (10 mM) into the calyx has little effect on transmitter release mediated by mutant P/Q-type channels. Further measurements of the input (presynaptic Ca2+ currents)-output (excitatory postsynaptic currents) relationship demonstrate that the "Ca2+ channel/ domain cooperativity" in the tgla/la synapses is comparable to that in the WT synapses. Collectively, these results indicate that mutant P/Q-type VGCCs lacking its functional C-terminus can form "nanodomain" release modality and effectively engage SVs in neurotransmission. We therefore suggest that the interaction between the C-terminus of alpha1 subunits and RIM/RIM-BP is not necessary for tethering SVs to the vicinity of VGCCs in the active zone to promote nanodomain coupling of Ca2+ influx to release of neurotransmitters.

Title: The novel protein kinase C epsilon isoform at the adult neuromuscular synapse: Location, synaptic activity-related expression, phosphorylation function and coupling to ACh release

Authors: *M. A. LANUZA, E. HURTADO, N. BESALDUCH, T. OBIS, L. NADAL, N. GARCIA, M. M. SANTAFE, M. PRIEGO, M. TOMAS, J. TOMAS;
Univ. Rovira i Virgili, Reus, Spain

Abstracts: nPKCε is a major isoform in the novel PKC family. Although it has been increasingly implicated in neural functions and associated neurogenic diseases, the role of nPKCε in neurons is still not well understood. Recent studies provide evidence that nPKCε could regulate distinct aspects of neural functions, including neurotransmitter release and signal transduction. Moreover, to date, no reports have been published on the localization and function of the nPKCε at the paradigmatic neuromuscular junction (NMJ). Here, we have examined the distribution of the nPKCε in the adult NMJ cell components, its synaptic activity-related expression changes, its regulation by muscle contraction and its possible involvement in ACh release. Furthermore, we have investigated the relation between skeletal muscle contraction, the tyrosine kinase receptor B (TrkB) signaling and the presynaptic expression of nPKCε at the adult rat NMJ. We use immunohistochemistry and confocal microscopy to demonstrate that the novel isoform nPKCε is exclusively located in the motor nerve terminals on the NMJ. We also report by electrophysiological techniques and using a nPKCε-specific translocation inhibitor peptide (εV1-2) that nPKCε is decisively involved in ACh release potentiation induced by phorbol esters like PMA. Moreover, results also show that synaptic activity-induced muscle contraction enhances nPKCε expression, and its catalytic function in phosphorylating the substrate MARCKS through TrkB activity. Together, these results provide a mechanistic insight into how synaptic activity-induced muscle contraction could regulate the presynaptic action of the PKC isoforms in neurotransmission and suggest that muscle contraction is an important regulatory step in TrkB receptor signaling at the NMJ.

Title: A novel mechanism controlling reclustering of synaptic vesicles in *Drosophila* synapses

Authors: Å. M. E. WINTHER, K. A. REES, O. VORONTSOVA, E. SOPOVA, A. PECHSTEIN, W. JIAO, G. ARPINO, *O. SHUPLIAKOV;
Karolinska Institutet, Stockholm, Sweden

Abstracts: Synapsins are synaptic vesicle (SV) associated proteins that modulate neurotransmitter release and control the organization of SVs in adult nerve terminals and during development. Here we demonstrate that at *Drosophila* neuromuscular junctions (NMJs) the scaffolding protein Dap160, the ortholog of mammalian intersectins, controls synapsin localization during the synaptic vesicle cycle. We report that the SH3A-B domain region of Dap160 is essential for the synapsin binding and the remaining SH3 domains facilitate the interaction between the proteins. During synaptic activity synapsin is broadly dispersed throughout the axon in mutants expressing *dap160* lacking the SH3A-B domain region, while in control it is restricted to the nerve terminal. At the subcellular level the nerve terminals in the mutant revealed delayed reclustering of SV at release sites. Numerous small SV clusters were still present within synaptic boutons subjected to intense stimulation whereas control boutons completely recovered their morphology rapidly. Abnormal clustering of vesicles was also observed in NMJs from *synapsin* null mutant. Synapsin expression and delivery to nerve terminals remained unchanged in mutants expressing *dap160* lacking the synapsin-interacting SH3 domains and Dap160 level in *synapsin* null boutons was not altered, implying that for both Dap160 and synapsin additional interactions are involved in their delivery to presynaptic boutons during development. In summary, our results uncover a novel role for Dap160/intersectin interaction in targeting synapsin back to SVs and facilitating reclustering of SVs at the active zone during synaptic activity.

Title: The localization of ATR (ataxia telangiectasia and Rad3-related) in synaptic vesicles - A super-resolution study

Authors: *A. CHENG[1], T. ZHAO[2], M. LOY[2], K. HERRUP[1,3];
[1]Div. of Life Sci., [2]Dept. of Physics, HKUST, Kowloon, Hong Kong; [3]Rutgers Univ., Piscataway, NJ

Abstracts: ATR (ataxia telangiectasia and Rad3-related), is a PI3-kinase involved in DNA single-strand break repair. Mutations that lower the activity of ATR are responsible for Seckel syndrome, a devastating CNS developmental disorder. In addition to its expected nuclear localization, ATR is found in the neuronal cytoplasm where it physically associates with the homologous PI3-kinase, ATM (ataxia telangiectasia mutated) as well as with VAMP2 (synaptobrevin) and synapsin-I. Cytoplasmic ATM has been localized to vesicular structures in the neuronal cytoplasm; a detailed analysis of ATR localization has not been done. We have now used super-resolution microscopy to gain further insight into the localization and cytoplasmic function of cytoplasmic ATR. We used stochastic optical reconstruction microscopy (STORM), a new technique of optical microscopy that allowed us to achieve two-color labeling of ATR at 20 nm resolution. Antibodies to ATR clearly label vesicular structures in DIV15 neurons. The identity of these structures as vesicles was confirmed by double immunostaining with the CgA vesicular cargo protein. While proving the identity of the labeled structures as vesicles, this finding also emphasizes that ATR is found not only on neurotransmitter containing synaptic vesicles, but also on dense core vesicles, the precursors of nascent synaptic active zones in neurons. Bassoon, an active zone localized protein, is associated with dense core vesicles *in vivo*; and double labeling with ATR and Bassoon showed significant co-localization. Curiously, we

also found ATR co-localized with MAP2 as well as with PSD95, opening the possibility that ATR is located on both sides of the synapse. This is consistent with reports that some potential ATR targets (with [S/T]Q motifs) are localized in dendritic spines on the post-synaptic side of the synapse. We are exploring the hypothesis that ATR is responsible for phosphorylation of [S/T]Q substrates at sites within the dendritic spine itself while its sister kinase, ATM, is localized to and mainly regulates substrates in cytoplasm.

Title: Enrichment of GABARAP relative to LC3 in the axonal initial segments of neurons

Authors: *M. KOIKE[1], I. TANIDA[2], T. NANAO[1], N. TADA[1], J. IWATA[1], T. UENO[1], E. KOMINAMI[1], Y. UCHIYAMA[1];
[1]Juntendo Univ. Sch. Med., Tokyo, Japan; [2]Natl. Inst. of Infectious Dis., Tokyo, Japan

Abstracts: GABAA receptor-associated protein (GABARAP) was initially identified as a protein that interacts with GABAA receptor. Although LC3 (microtubule-associated protein 1 light chain 3), a GABARAP homolog, has been localized in the dendrites and cell bodies of neurons under normal conditions, the subcellular distribution of GABARAP in neurons remains unclear. Subcellular fractionation indicated that endogenous GABARAP was localized to the

microsome-enriched and synaptic vesicle-enriched fractions of mouse brain as GABARAP-I, an unlipidated form. To investigate the distribution of GABARAP in neurons, we generated GFP-GABARAP transgenic mice. Using these transgenic mice, we investigated the intracellular distribution of GFP-GABARAP in hippocampal pyramidal neurons and cerebellar Purkinje cells by comparing its distribution with that of endogenous LC3. Immunohistochemistry in these transgenic mice showed that positive signals for GFP-GABARAP were widely distributed in neurons in various brain regions, including the hippocampus and cerebellum. Interestingly, intense diffuse and/or fibrillary expression of GFP-GABARAP was detected along the axonal initial segments (AIS) of hippocampal pyramidal neurons and cerebellar Purkinje cells, in addition to the cell bodies and dendrites of these neurons. In contrast, only slight amounts of LC3 were detected along the AIS of these neurons, while diffuse and/or fibrillary staining for LC3 was mainly detected in their cell bodies and dendrites. These results indicated that, compared with LC3, GABARAP is enriched in the AIS, in addition to the cell bodies and dendrites, of these hippocampal pyramidal neurons and cerebellar Purkinje cells.

Title: Comparison of different slice angles in preservation of major hippocampal pathways in the mouse

Authors: ***G. XIONG**[1], B. JOHNSON[1], C. SMITH[1], A. S. COHEN[1,2];
[1]Neurol., Children's Hosp Philadelphia, Philadelphia, PA; [2]Neurosurg., Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA

Abstracts: The hippocampus plays a critical role in higher cognitive function and has been implicated in numerous neuropathologies. Electrophysiological recording on live slices is one of

the most powerful tools for investigating hippocampal cellular and network activity. In general, three types [frontal, transverse and hippocampal-entorhinal cortex (HEC)] of live slices have been widely used to study the major hippocampal pathways i.e., perforant path (PP), mossy fiber (MF) and Shaffer collateral (SC). In the present study, we focused on intrahippocampal fiber preservation in slices generated by sectioning through different planes. The postmortem neural tract tracer DiI was used to label afferent pathway fibers in slices from fixed mouse brains. Laser scanning confocal microscopy was adopted for imaging DiI-labeled fibers. Our data demonstrate that PP fibers are well preserved in HEC slices, MFs in both HEC and transverse slices, and SCs in all three types of slices. To verify our morphological data, we compared HEC and frontal slices by recording field potentials in stratum lucidum of area CA3 while stimulating in the dentate granule cell (DGC) layer. Using HEC slices, we were consistently able to evoke DGC stimulated mossy fiber responses. By contrast, DGC-evoked potentials in frontal slices required higher stimulation current and could only be recorded in a fraction of slices. The present study provides an anatomical correlate for choosing the most apt slice angle for subsequent physiological experiments.

Title: Pancreatic islet beta cells employ synaptic cleft proteins and synaptogenic mechanisms to establish insulin secretory function

Authors: *S. D. CHESSLER, C. ZHANG, M. R. MIRBOLOOKI;
Med., UC Irvine Sch. of Med., Irvine, CA

Abstracts: In fruit files and other primitive animals, specialized neurons in the brain function as the equivalent of the mammalian insulin-secreting pancreatic islet beta cells. This and a variety of other evidence suggest that pancreatic beta cells--although endodermal--are evolutionarily

descended from central nervous system neurons. The parallels between the developmental and functional biology of neurons and beta cells are striking. We are interested in the architecture of the beta-cell insulin secretory apparatus, which is remarkably similar to that of the synaptic machinery for neurotransmitter release. We hypothesize that the explosion of new knowledge in the neurobiology field regarding the role of transcellular protein interactions in synaptogenesis and maintenance of synaptic function will yield important insights into beta-cell maturation and function. Our working model of transcellular beta-cell interactions is depicted in the figure. Neurexin-containing pre-synaptic-like microdomains (red) on the beta cell surface are opposed to neuroligin-2-containing post-synaptic-like microdomains (yellow). We have found that neuroligin and neurexin are expressed by beta cells and engage in transcellular interactions promoting insulin secretion. Neurexin, as shown, interacts directly with the submembrane exocytic machinery, promoting its assembly. Here we ask whether interactions involving CADM1 (SynCAM) similarly enhance beta cell function. Co-culture of beta cells with COS-7 cells expressing CADM1 revealed that transcellular interactions involving CADM1 enhance insulin secretion. As with neuroligin, while CADM1 binding interactions in coculture experiments increased insulin secretion, perturbation of levels of the protein in INS-1 beta cells had differing effects. CADM1 overexpression impaired insulin secretion, while CADM1 gene silencing enhanced secretion. CADM transcript levels decreased in response to increased glucose concentrations. These results indicate a significant role for CADM interactions in the establishment of beta-cell function.

Title: The importance of the organization of presynaptic calcium channels and synaptic vesicle release sites in plasticity and disease

Authors: J. MA[1], T. TARR[2], S. D. MERINEY[2], *M. DITTRICH[1];
[1]Pittsburgh Supercomputing Ctr., Carnegie Mellon Univ., Pittsburgh, PA; [2]Univ. of Pittsburgh, Pittsburgh, PA

Abstracts: Over the last decade, there has been mounting evidence that the function of neuromuscular synapses may be regulated by structural changes at the level of single-vesicle release sites consisting of a synaptic vesicle and a small number of closely associated voltage gated calcium channels (VGCCs). To shed additional light onto the mechanisms behind these structure-function relationships, we have used electrophysiological recordings, calcium imaging, and MCell computer modeling to study how differences in active zone (AZ) structure at the mouse and frog neuromuscular junction (NMJ) can explain their functional properties. We hypothesize that the arrangement of single-vesicle release sites into the different AZ organizations observed in frog and mouse is sufficient to explain major functional differences between the two NMJs (Tarr et al. 2013). Physiologically and structurally, the frog and mouse NMJ differ considerably. The frog NMJ shows significant paired-pulse facilitation (PPF) and tetanic potentiation (TP). On the other hand, mouse NMJs show virtually no PPF and TP. Structurally, the frog NMJ AZs consist of a long linear double row of VGCCs flanked laterally by two rows of 25-30 synaptic vesicles. In contrast, AZs at the mouse NMJ consist of a short row of ~ 2 synaptic vesicles running between two short linear rows of VGCCs. We have previously developed a spatially realistic MCell computer model of the frog NMJ, which predicts experimentally measured vesicle release both under single and multiple stimulus paradigms. Based on this model we were able to show that re-arranging the basic single vesicle release sites from a frog NMJ into a mouse NMJ organization allowed us to predict the observed differences between frog and mouse NMJ physiology. Further, our modeling studies allowed us to gain detailed insight into the underlying mechanisms at the single vesicle release site that relate structure to function in these systems. Our results suggest that facilitation at NMJs can be tuned by defined structural changes at the sub-AZ level. Our approach can also be applied to studies of AZ changes induced by Lambert-Eaton myasthenic syndrome (LEMS), an autoimmune disease characterized by an attack on presynaptic VGCCs that reduces their number and disrupts AZ structural organization. In mice passively transferred with LEMS, there is a dramatic increase in tetanic potentiation. Using experimental comparisons with acute pharmacologic block of

VGCCs, we are using our modeling approach to predict how changes in VGCC number and/or spatial relationships with docked synaptic vesicles impact synaptic function at these synapses.

Title: Assayable markers of presynaptic neuronal function suitable for high-throughput screening using fixable FM-dyes

Authors: *M. NIEDRINGHAUS[1,2], A. M. TAYLOR[1,2,3];
[1]UNC/NCSU Joint Dept. of Biomed. Engin., [2]Neurosci. Ctr., [3]Carolina Inst. of Developmental Disabilities, Univ. of North Carolina, Chapel Hill, NC

Abstracts: The development of high-throughput screening (HTS) techniques has advanced the field of drug discovery, particularly in oncology, however these techniques have found only limited success identifying potential therapies for neurological conditions. A significant limiting step is a lack of assays suitable for HTS that measure neuronal function. For example, while many non-neuronal screens utilize experimental endpoints such as inhibition of cellular growth or cell death, neural disease states are often characterized by more subtle changes (e.g. changes in vesicular pool size/distribution and release). In addition, as localized, presynaptic physiology is increasingly implicated in neural disease, functional assays specific to presynaptic effects of compounds are needed. We speculated that fixable styryl (FM) dye use in presynaptic screens would be advantageous as they are employable in all disease-model species, they provide an optical readout, and they can be employed in parallel over a large number of screens. FM dyes are readily loaded into presynaptic vesicles during either chemical or electrical stimulation. This pool of FM-labeled vesicles has been suggested to represent the recycling vesicle pool. Here, we demonstrate the potential for FM dye in assays of presynaptic function that are compatible with

HTS. We also examine disease-induced presynaptic changes in isolation from the postsynaptic compartment using FM dyes. We propose a FM dye-based assay for HTS by chemically inducing endocytosis of fixable FM dyes using a very short loading/fixing protocol. We found a significant decrease in the size of the FM-loaded vesicular pool in Fragile X Disease (FX) in both human and mouse neurons. This difference is consistent with other anatomical studies and could, in part, represent known differences in kinetics of vesicular release (i.e. an increase in "kiss and run" vs. full fusion exocytosis). While we demonstrate assayable differences in vesicle pools labeled with fixable FM-dye in FX neurons, changes in the vesicle pools have been shown in other diseases including epilepsy and schizophrenia, suggesting these protocols could be used in screening for a large variety of neurological disorders. Equally compelling, FM dye loading is altered by certain physiological states (such as LTD) so there exists the potential for even broader usage in functional HTS.

Title: Chronic social isolation reduces excitatory synaptic inputs in medial prefrontal cortex

Authors: *K. YAMAMURO[1], H. YOSHINO[1], Y. OGAWA[2], M. MAKINODAN[1], C. GABRIEL[3], T. KISHIMOTO[1];
[1]Dept. of Psychiatry, Nara Med. Univ., Kashinara City, Japan; [2]Dept. of Physiol. 1, Nara Med. Univ., Kashinara City, Japan; [3]Dept. of Neurology, Boston Children's Hospital, Harvard Med. Sch., Boston, MA

Abstracts: Social experiences are necessary for the development of forebrain function and the maturation of medial prefrontal cortex (mPFC). Rearing mice in post-weaning social isolation produces behavioral and neurochemical alterations similar to those observed in psychiatric disorders such as schizophrenia and autism. However it is not well-known about electrophysiological changes in neural circuit of mPFC induced by social isolation. In the present study, we examined the change of excitatory synaptic inputs into layer 5 pyramidal cells in

mouse PFC produced by isolation rearing, with whole-cell patch clamp recording. Mice pups were divided into two groups at weaning and reared in isolation (housed one per cage) or reared in a group (housed four or five per cage) for 6 weeks. We found that the spontaneous excitatory postsynaptic current (sEPSC) frequency and miniature excitatory postsynaptic current (mEPSC) frequency were significantly lower in isolated mice than in grouped mice. There was no significant difference in sEPSC amplitude and mEPSC amplitude between both mice. These results show that chronic social isolation reduces excitatory synaptic inputs on layer 5 pyramidal cells of mouse mPFC and suggest that social experience have an impact on neural circuit development of mPFC.

Title: Analysis of Rab3 structure as related to its function in active zone formation at the *Drosophila* neuromuscular junction

Authors: S. CHEN, H. K. GENDELMAN, J. P. ROCHE, P. ALSHARIF, *E. GRAF;
Dept. of Biol., Amherst Col., Amherst, MA

Abstracts: The complement of presynaptic release machinery proteins at individual release sites controls the efficacy of vesicle release at each site. The small GTPase Rab3 was previously identified as playing a novel role that controls the localization of release machinery proteins to the release sites of the *Drosophila* neuromuscular junction (NMJ). In the rab3 mutant, key components of the presynaptic release machine, including Bruchpilot (Brp), Ca2+ channels, and T-bars, are enriched at a subset of active zones, leaving the remaining release sites devoid of such proteins and structures. However, the mechanism by which Rab3 performs this function is not understood. To clarify the mechanisms of Rab3 function at the *Drosophila* NMJ, we have employed a structure-function analysis to determine the structural requirements of Rab3 for its localization to the axon terminal and function at the NMJ to regulate active zone development.

Utilizing GTP-binding defective mutations of Rab3, we find that GTP binding is required for Rab3 to localize to NMJs and control Brp distribution across active zones. Although GTP-binding defective mutants are not trafficked appropriately to NMJs, strong expression in a wild type background results in a dominant negative effect that phenocopies the rab3 mutant in a hypomorphic manner. Conversely, mutations that disrupt GTP hydrolysis do not disrupt Rab3 localization or function, resulting in NMJs that are similar to wild type. However, average Brp puncta size is reduced in comparison to wild type when GTP-hydrolysis-defective mutants are expressed in either rab3 mutant or wild type backgrounds, suggesting that the constitutively active mutation may result in a gain-of-function synaptic phenotype. We further show that the protein-binding "switch" regions of Rab3 are required for controlling proper Brp distribution and analyze the requirement of specific residues within the "switch" regions. Mutations associated with the effector-binding N-terminal CDR region also prevent rescue of the rab3 mutant phenotype, whereas mutations in two other CDR regions do not affect Rab3 function. Finally, while mutations that disrupt the membrane association properties of Rab3 do not prevent the transport of Rab3 to the NMJ, we find that membrane association is required for controlling Brp distribution, consistent with a model by which Rab3 may control release machinery localization to active zones via a vesicle docking mechanism.

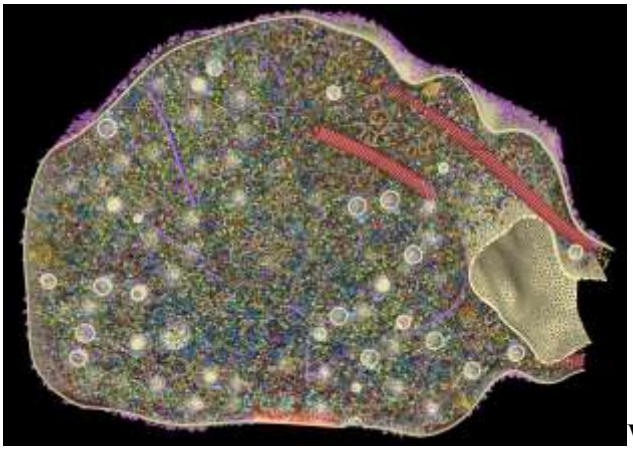
Title: The molecular organization of the synaptic bouton

Authors: *S. TRUCKENBRODT[1], B. G. WILHELM[1], S. MANDAD[2], K. KRÖHNERT[1], C. SCHÄFER[1], B. RAMMNER[1], S. J. KOO[3], G. A. CLAßEN[3], M. KRAUSS[3], V. HAUCKE[3], H. URLAUB[2], S. O. RIZZOLI[1];
[1]Univ. of Göttingen Med. Ctr., Göttingen, Germany; [2]Max-Planck-Institute for Biophysical Chem., Göttingen, Germany; [3]Dept. of Mol. Pharmacol. and Cell Biol., Leibniz-Institute for Mol. Pharmacol., Berlin, Germany

Abstracts:



We present here the 3D model of a synaptic bouton, comprising >300,000 individual proteins as absolute copy numbers of 62 different proteins essential to synaptic vesicle recycling, in their average subcellular localisation. We obtained this model via an integrative approach, using quantitative Western blotting to determine protein copy numbers, electron microscopy to measure organelle numbers, morphology and distribution, and super-resolution fluorescence microscopy to localise the proteins within the synaptic bouton. Using quantitative mass spectrometry, we determined the copy numbers of an additional >1100 different proteins. The model we obtained shows that copy numbers of proteins involved in the same step of synaptic vesicle recycling correlate closely, while copy numbers vary over more than three orders of magnitude between steps. Synaptic vesicle exocytosis is amply provided for, with more than 20,000 copies of each exocytotic SNARE protein per synaptic bouton. Proteins involved in synaptic vesicle endocytosis, on the other hand, are far less abundant (~1000-4000 copies each) and sufficient for simultaneous recycling of only ~7-11% of all vesicles present in the average synaptic bouton. The model thus points to a hitherto unknown level of quantitative regulation in cellular trafficking pathways and provides a reference source for research on synaptic biology.

Title: The differential gene and isoform expression levels contribute to the functional diversity of Neurexin-3

Authors: *J. N. AOTO[1], C. FÖLDY[1], D. MARTINELLI[2], K. TABUCHI[4], R. MALENKA[3], T. SÜDHOF[1,5];
[1]Mol. and Cell. Physiol., Stanford Univ. Sch. of Med., Stanford, CA; [2]Mol. and Cell. Physiol., [3]Dept. of Psychiatry, Stanford Univ., Stanford, CA; [4]Shishu Univ., Nagano, Japan; [5]Howard Hughes Med. Inst., Chevy Chase, MD

Abstracts: Neurexins were initially discovered over 25 years ago as the endogenous presynaptic receptor for Black Widow spider venom; however, their functional roles in regulating synaptic transmission remains poorly understood. Neurexins are expressed from three genes (*Nrxn1-3*), each giving rise to a larger alpha and shorter beta mRNA transcript. Moreover each neurexin mRNA transcript can undergo alternative splicing at up to 6 conserved splice sites (SS1-SS6), of which, SS4 has been biochemically demonstrated to regulate binding to most known postsynaptic ligands. The diversity of neurexin gene and isoform expression has posed a

significant hurdle in the synaptic characterization of neurexin function. To systematically address these issues, we here utilize three neurexin-3 mutants - 1.) a constitutive neurexin-3[[Unsupported Character - Symbol Font ]] KO; 2.) a conditional neurexin-3[[Unsupported Character - Symbol Font ]][[Unsupported Character - Symbol Font ]][[Unsupported Character - Symbol Font ]] KO; and 3.) a conditional neurexin-3 SS4 mutant where the SS4 insert is constitutively included, but can be conditionally excluded – to interrogate the synaptic function of neurexin-3. Furthermore, we quantitatively assessed mRNA levels of *Nrxn1*, *Nrxn2* and *Nrxn3* and their SS4 isoforms in single neurons and identified two brain regions – the hippocampus where, antithetical to the other two neurexins, *Nrxn3* primarily lacks an insert at SS4, and the olfactory bulb where GABAergic granule cells express a reduced complement of neurexin gene products. We found that at synapses in the hippocampus, neurexin-3 SS4 isoforms play a central role in transsynaptically regulating basal and activity-dependent postsynaptic AMPA-receptor stability while at GABAergic synapses in olfactory bulb cultures, the neurexin-3 intracellular domain is required to maintain presynaptic release probability. Taken together, our systematic analysis revealed distinct synaptic functions of neurexin-3 and highlights the importance of evaluating region specific and cell-type specific expression patterns of neurexins.

Title: Tomographic analysis of clustering and bridging filaments organized for the release of synaptic vesicles in hippocampal synapses

Authors: *A. A. COLE, X. CHEN, T. S. REESE;
Structural Neurobio. Section, NINDS, Bethesda, MD

Abstracts: Continuous synaptic transmission depends on movement of synaptic vesicles through the presynaptic vesicle cloud to contact the active zone. However, the molecular organization of

the presynaptic terminal is not well understood. Here we used EM tomography of high pressure frozen and freeze substituted dissociated rat hippocampal neurons to render a comprehensive picture of the connections between synaptic vesicles. Long filaments with complex, modular morphology - modular clustering filaments - cluster vesicles throughout the presynaptic vesicle cloud. A smaller bridging filament joins vesicles into pairs and triplets in the cloud. Along the active zone membrane, unique filaments ground vesicles to the active zone membrane. Small clusters of small irregular filaments, presumably representing SNARE complexes, cradle vesicles that contact the active zone membrane. A larger membrane bound modular clustering filament - active zone clustering filament - anchors multiple synaptic vesicles to the active zone membrane. In the synaptic vesicle cloud, a network of modular clustering filaments embraces ~ 80% of synaptic vesicles, including grounded vesicles. Each vesicle in this network has multiple bridging filament associations. Clustering filaments provide a complex network orthogonal to the active zone, favorable for trafficking synaptic vesicles toward the active zone, while bridging filaments do not show preferential orientation but provide a comprehensive network, congealing all vesicles into one cloud. Active zone clustering filaments are distributed throughout the active zone membrane and seem to be a key mechanism binding the vesicle cloud to the active zone. Small irregular active zone bound filaments extend less than 30 nm into the presynaptic terminal. These results provided a mechanical scheme for maintaining vesicle clouds and moving the vesicles to active zones for ultimate release, providing for trafficking of presynaptic vesicles in response to activity.

Title: Control of a slow phase of synaptic transmission at a retinal ribbon synapse

Authors: J.-B. KE[1], L. S. MORTENSEN[2], K. REIM[2], J.-S. RHEE[2], N. BROSE[2], *J. H. SINGER[1];

[1]Biol., Univ. of Maryland, College Park, MD; [2]Max Planck Inst. for Exptl. Med., Göttingen, Germany

Abstracts: Signaling between rod bipolar (RB) and AII amacrine cells in the mammalian retina is a critical component of rod-mediated (i.e., night) vision, and the RB->AII synapse has been the subject of much investigation owing both to its central role in night vision and to its accessibility as a model ribbon synapse. The presynaptic ribbon-type active zone (AZ) contains a small pool of readily-releasable vesicles, exocytosis from which can be driven by the opening of single Ca channels. Thus, it was thought that highly localized presynaptic [Ca2+] changes were the primary determinant of transmission at this synapse. Recently, though, it was demonstrated that ribbon AZ-independent release from a unique vesicle pool in RB terminals activated postsynaptic AMPARs on AIIs. This form of release developed slowly, was driven by global changes in intraterminal [Ca2+], and appeared to draw on a unique vesicle pool. Here, we examined this "delayed release" at RB->AII synapses in an *in vitro* mouse retinal slice preparation. First, we demonstrated that delayed release was unaffected by genetic deletion of complexin 3, an accessory AZ protein that binds to the core exocytotic complex and increases the efficiency with which Ca2+ evokes exocytosis. As the initial, transient component of release, which, presumably, is driven by [Ca2+] changes localized to the AZ, was reduced in complexin 3 knockout mice, this finding supports the conclusion that delayed release resulted from an elevated global [Ca2+] acting on a unique vesicle pool. Next, we assessed delayed release without altering intracellular Ca2+ handling in the RB. The light-gated ion channel, channelrhodopsin2, was expressed in RBs, and transmission from unperturbed RBs was evoked by stimulating RBs in with blue-green light. Exocytosis from RB terminals was assessed by recording evoked EPSCs from postsynaptic AIIs. Depolarizing the RB for > 100 ms elicited EPSCs with initial transient and secondary, delayed components. The delayed components were enhanced substantially by blocking inhibition to the RB terminal, indicating that feedback and feedforward inhibition act primarily on slow signaling from RBs. Delayed release was potentiated strongly by the calmodulin (CaM)-dependent phosphodiesterase (PDE) inhibitors IBMX and MPPX, indicating that Ca2+ accumulation in the terminal likely acts through a CaM-PDE to regulate the availability of vesicles in the ribbon-independent pool that contributes to delayed release. In total, our data support the hypothesis that the RB axon terminal contains a pool of vesicles distinct from the readily-releasable pool and modulated independently.

Title: Loss of laminin-α4 accelerates aging of the neuromuscular junction

Authors: *K. LEE[1], K. K. CHAND[1], B. L. PATTON[3], N. A. LAVIDIS[1], P. G. NOAKES[1,2];
[1]Sch. of Biomed. Sci., [2]Queensland Brain Inst., The Univ. of Queensland, Brisbane, Australia;
[3]Sch. of Med. Fac., Oregon Hlth. and Sci. Univ., Portland, OR

Abstracts: Laminin-α4 is involved in the alignment of pre- and postsynaptic apparatuses at the neuromuscular junction (NMJ). Laminins-α4, -β2 and -γ1 form the laminin-421 heterotrimer, a key component of the synaptic basal lamina. Loss of critical basal lamina components may result in structural and functional changes at the NMJ. Mutation of laminin-α4 gene results in morphological abnormalities that resemble changes seen in aged wild-type mice. Here, we compared neurotransmission properties of wild-type (WT) and laminin-α4 deficient (*lama4*$^{-/-}$) NMJs at 3 months (3mnth), 6 months (6mnth) and 12 months (12mnth) of age. Mice were bred and maintained on a C57BL/6-129SvJ genetic background. We functionally examined the diaphragm muscle using intra- and extracellular electrophysiological recordings of evoked and spontaneous transmitter release. The diaphragm and innervating nerve were dissected from WT and *lama4*$^{-/-}$ mice at each age group (n=6 for 3mnth and 6mnth; n=4 for 12mnth for each genotype). Immunohistochemistry studies were conducted to investigate the colocalization and distribution of active zone markers to postsynaptic acetylcholine receptors. Our results demonstrated aberrations in neurotransmission at *lama4*$^{-/-}$ NMJs that persist throughout aging. The NMJs of *lama4*$^{-/-}$ displayed a higher number of stimuli that failed to evoke neurotransmitter release at 3mnth and 6mnth in comparison to age-matched WT NMJs ($p<0.01$ for 3mnth; $p<0.05$ for 6mnth; $p>0.05$ for 12mnth). Analysis of spontaneous transmitter release displayed a decrease in frequency ($p<0.0001$ for 3mnth; $p<0.001$ for 6mnth and 12mnth) and slower rise time ($p<0.0001$ for 3mnth; $p<0.01$ for 6mnth and 12mnth) at *lama4*$^{-/-}$ NMJs. Spontaneous amplitude also increased in *lama4*$^{-/-}$ NMJs at 3mnth ($p<0.001$) and 6mnth ($p<0.01$). Evoked transmitter release displayed slower rise time ($p<0.001$ for 3mnth; $p<0.0001$ for 6mnth) at *lama4*$^{-/-}$ NMJs. Immunohistochemical studies demonstrated morphological changes at *lama4*$^{-/-}$ NMJs that are characteristic of aged NMJs. Motor function in these *lama4*$^{-/-}$ mice is not compromised despite the abnormalities observed in our present studies due to the NMJ possessing a large safety factor. Our findings demonstrate that loss of laminin-α4 results in early perturbations in neurotransmission normally observed at aged NMJs. These findings suggest that laminin-α4 may play a role in the maintenance of the NMJ during aging.

Title: Microtubule-dependent trafficking of synaptic vesicle "superpool" in cultured giant synapse

Authors: *L. GUILLAUD, D. DIMITROV, T. TAKAHASHI;
Okinawa Inst. of Sci. and Technol. Grad. Univ., Onna-Son, Okinawa, Japan

Abstracts: We previously visualized and analyzed synaptic vesicle movements in cultured calyx of Held synapses and demonstrated that, within this large presynaptic terminal, synaptic vesicles show different motions that could be categorized into 3 pools with respect to their dynamic properties. It has already been reported at various synapses that a small fraction of synaptic vesicles (synaptic vesicle "superpool") can move between adjacent synaptic boutons (inter-synaptic trafficking). Here we report that 10-15% of synaptic vesicles in the calyx-type presynaptic terminals likewise move between synaptic swellings (inter-swelling trafficking) with a high velocity and directional movements, and that inter-swelling trafficking is significantly disrupted by the microtubule depolymerizing drug nocodazole. We also found that the presynaptic terminal was enriched with de-tyrosinated microtubules that invaded into and interconnected presynaptic swellings. The kinesin KIF1A also co-localized with a subset of synaptic vesicles both within the pre-synaptic swellings and digit-like processes of calyceal terminals. These results suggest that the fast moving synaptic vesicle "superpool" in the calyceal terminal depends on microtubule/kinesin based transport between presynaptic swellings.

Title: Control of antero- and retrograde mitochondrial transport in *Drosophila* motor axons

Authors: *M. BABIC[1], B. W. HUNTER[2], G. J. RUSSO[3], A. J. WELLINGTON[2], K. E. ZINSMAIER[2];

Abstracts: Microtubule-based transport of mitochondria into dendrites and axons is critical for normal synaptic function. In axons, kinesin motors drive anterograde transport of mitochondria while retrograde transport is driven by dynein. However, the mechanisms controlling the selective use of these motors remain poorly understood. The mitochondrial GTPase Miro is required for mitochondrial transport in axons and dendrites. Here, we show that the activity of *Drosophila* Miro's N-terminal GTPase domain controls antero- and retrograde transport of mitochondria in axons. Rendering the domain inactive by introducing the mutation T25N inhibited anterograde transport and depleted larval *Drosophila* motor axons of mitochondria. Conversely, rendering the domain constitutively active by introducing the mutation A20V caused a pronounced accumulation of mitochondria at axon terminals, and facilitated anterograde transport while suppressing retrograde transport. In mammals, kinesin and dynein are linked to mitochondrial Miro through the adaptor proteins TRAK1 and 2. We show that the only *Drosophila* homolog of TRAK1/2, Milton, facilitates not only kinesin- but also dynein-driven transport in axons. Milton expresses four different protein isoforms (A-D) generated by alternative mRNA splicing. Acute overexpression of Milton-A accumulates mitochondria at axon terminals within a few hours, while Milton-B depletes axons of mitochondria and accumulates them in the cell body. We are currently testing how Miro's N-terminal GTPase may control the selective use of Milton-A and -B and thereby antero- and retrograde axonal transport of mitochondria.

Title: The trade-off between the capacity to sustain neurotransmitter release and presynaptic energy efficiency

Authors: *Z. LU[1], A. CHOUHAN[2], A. ROSSANO[3], G. MACLEOD[1];
[1]Biol. Sci., Florida Atlantic Univ., Jupiter, FL; [2]Baylor Col. of Med., Houston, TX; [3]Univ. of Texas Hlth. Sci. Ctr. At San Antonio, San Antonio, TX

Abstracts: Synapses, building blocks for neural information processing, spend most of the energy in the brain. Given that large synaptic energy demand contrast with relative limited energy supply, it is advantageous for the synapse to adopt energy-efficient mechanisms in neurotransmission. We proposed that optimization of energy efficiency is widespread among different nerve terminals. Therefore, we further hypothesize that energy efficiency is the same amongst synapses. Here, we estimated energy efficiency in two *Drosophila* glutamatergic nerve terminals using electrophysiology recordings and calcium imaging. Surprisingly, presynaptic energy efficiencies are not the same. Energy efficiencies differ between these functionally differentiated nerves terminals innervating the same postsynaptic target. The nerve terminal with larger capacity for neurotransmitter release is less efficient. Furthermore, our simulation results indicate that calcium entry per active zone plays an important role in coordinating neurotransmitter release and energy use. In conclusion, our findings suggest a trade-off between the capacity to sustain neurotransmitter release and presynaptic energy efficiency.

Title: Dynamic phosphorylation of synaptic and extrasynaptic AMPA receptors in the rat striatum and prefrontal cortex in response to amphetamine

Authors: *B. XUE, L. MAO, J. WANG;
Dept. of Basic Med. Sci., UMKC Sch. of Med., Kansas City, MO

Abstracts: The α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor is sensitive to psychostimulants. Chronic stimulant administration induces plastic changes in AMPA receptors in the mesolimbic and mesocortical circuitry, which contributes to the enduring remodeling of excitatory transmission in relation to the addictive properties of drugs of abuse. Phosphorylation of AMPA receptors has been shown to be regulated by stimulants, although the specific AMPA receptor population at synaptic sites is less studied for their responses to stimulants. In this study, we used a pre-validated fractionation procedure to enrich AMPA receptors from synaptic and extrasynaptic pools to investigate the effect of the stimulant amphetamine on phosphorylation of AMPA receptors at these distinctive subsynaptic sites in the adult rat striatum and prefrontal cortex (PFC) *in vivo*. We found that amphetamine at a single, behaviorally active dose induced a marked increase in GluA1 phosphorylation at serine 845 (S845) in the striatum. The amphetamine-stimulated S845 phosphorylation occurred at both synaptic and extrasynaptic sites and was a time-related event as the response returned to the normal level by 4 h after amphetamine injection. In contrast to S845, phosphorylation of GluA1 at serine 831 (S831) remained stable in response to amphetamine at both synaptic and extrasynaptic sites. Similar results were observed in the PFC. No significant change in total levels of GluA1 was seen after amphetamine administration. These results demonstrate a dynamic and serine residue-specific upregulation of GluA1 AMPA receptor phosphorylation in the synaptic and extrasynaptic compartments of striatal and cortical neurons in response to stimulant exposure.

Title: Neural bases for the excitatory control of VTA dopamine neurons by the ventral subiculum

Authors: *C. GLANGETAS[1], G. R. FOIS[2], M. JALABERT[3], C. HERRY[4], M. DIANA[2], S. CAILLÉ[5], F. GEORGES[1];
[1]IINS UMR CNRS 5297, Bordeaux, France; [2]Dept. of Chem. Pharmacol., Sassari, Italy; [3]INMED, Marseille, France; [4]INSERM CRI U862, Bordeaux, France; [5]CNRS UMR 5287, Bordeaux, France

Abstracts: The hippocampal formation including the ventral subiculum (vSUB) and the ventral CA1 area is a brain region that is involved in context-dependent processes, and also is considered as a regulator of emotion. The ventral tegmental area (VTA) plays a role in the acquisition of learned appetitive behaviors and in the development of drug addiction. It is now well accepted that the vSUB activates the dopamine (DA) system, however, the long term effect of the vSUB stimulation on VTA DA neurons activity is still unclear. First, we used electrophysiological approaches in anesthetized rats to demonstrate that Delta-bursts stimulation (DBS) protocols in the vSUB induces *in vivo* potentiation of VTA DA neurons activity 24 h after. This potentiation was still present 5 days after DBS protocols in the vSUB. To better understand the mechanism by which the vSUB activates VTA DA neurons, we decided then to use low frequency stimulation (that do not elicit plasticity) in the vSUB and observed the impact on VTA DA neurons activity. This low stimulation of vSUB has an excitatory effect on the tonic activity of VTA DA neurons. Futhermore, this electrical stimulation of the vSUB evoked both excitatory and inhibitory responses of VTA DA neurons. Moreover, we have previously shown that the bed nucleus of the stria terminalis (BNST) stimulation increases VTA dopamine neuron activity and that the BNST receives excitatory inputs from the vSUB. Interestingly, we demonstrated that DBS protocols in the vSUB induced *in vivo* NMDA long-term potentiation (LTP) in BNST neurons. By infusing locally in the BNST glutamatergic receptors antagonist, we showed that the BNST relays the excitatory drive between the vSUB and VTA. All together, these results strongly suggest that the NMDA long-term potentiation that occurs in the BNST induced by the DBS protocols in the vSUB is crucial for the hyperactivity of VTA DA neurons.

Title: *In vivo* homeostatic plasticity in BNST neurons

Authors: *F. E. GEORGES[1], G. FOIS[2], M. JALABERT[3], D. GIRARD[1], M. DIANA[2], C. GLANGETAS[1];
[1]IINS-CNRS 5297, BORDEAUX, France; [2]Dept of Chem. & Pharm., Sassari, Italy; [3]INMED, Marseille, France

Abstracts: The anteroposterior part of the bed nucleus of the stria terminalis (BNST) plays a critical role in anxiety and learning reward related behaviors. It is clearly established that the BNST projects to the paraventricular nucleus of the hypothalamus, important regulatory center of the HPA axis but also to the ventral tegmental area, key structure in motivational rewarding related behaviors. The BNST receives massive glutamatergic afferents from the ventral subiculum (vSUB) and the infralimbic cortex (ILCx) which are strategic areas that integrate/encode contextual and emotional informations. We have previously demonstrated that ILCx and the vSUB exert a strong excitatory influence on BNST neurons. However, it is unknown how synaptic transmission and plasticity evoked by the stimulation of the vSUB will affect the responses of the ILCx inputs at the level of individual BNST neurons. We first combine anatomical and *in vivo* electrophysiological approaches to demonstrate that the majority of the BNST neurons were under monosynaptic excitatory influence of both, ILCx and vSUB inputs. Using Delta-bursts stimulation (DBS) protocols in the vSUB, we were able to induce *in vivo* NMDA long-term potentiation (LTP) at vSUB-BNST synapses and long-term depression (LTD) at ILCx-BNST synapses. In conclusion, we demonstrated that an individual BNST neuron: 1) integrate both informations coming from ILCx and vSUB and 2) displays homeostatic plasticity after DBS. Together, these data show that synaptic scaling occur *in vivo* in the BNST suggesting that the BNST is uniquely positioned to process both emotional- and context-dependent informations arising from the ILCx and the vSUB.

Title: Modelling the spatiotemporal dynamics of adenosine in neural tissue

Authors: ***A. NEWTON**, M. J. WALL, M. J. E. RICHARDSON;
Univ. of Warwick, Coventry, United Kingdom

Abstracts: The neuromodulator adenosine is involved in both physiological and pathological activity, such as sleep, epilepsy and stroke. However, the complex processes underlying the release, transport and clearance of adenosine from tissue, and their interactions, are poorly quantified. Using parameters taken from an extensive search of the literature, we present the first detailed model of the spatiotemporal dynamics of adenosine in tissue. The mechanisms included in our model are: diffusion and breakdown by adenosine deaminase (ADA) in the extracellular space, transport between the extracellular and intracellular space by equilibrative nucleoside transporters (ENT), neuronal breakdown by ADA and glial metabolism, involving both 5'-nucleotidase and adenosine kinase. The literature search allowed us to estimate the range of the available parameters as well as identifying aspects of the purine transport and metabolism that have yet to be experimentally quantified. These unknown parameters comprise: the kinetics of adenylate kinase and the affinity of ENTs for inosine. A hierarchy of models is considered, starting with extracellular metabolism only, then including neurons, or glia, or both. Analysis of these models determines that the concentration following local adenosine release is primarily determined by diffusion through the tortuous extracellular space and that parameters suggest that neuronal uptake should be the dominant clearance mechanism. We apply the model to the rat neocortex and compare our model to the experimentally measured response of purine biosensors, which measure both adenosine and its breakdown products inosine and hypoxanthine. The model predicts the range of influence of an isolated adenosine source, characterised as the maximum distance where the amplitude of an EPSP would be halved due to the activation of A1 receptors, the most abundant class of adenosine receptors in the neocortex. The greatest influences on this

effective range are: the tortuous diffusion coefficient, extracellular volume fraction and the basal adenosine tone.

Title: Rapid PACAP-induced plasticity at autonomic synapses requires nAChR-dependent NOS1 activation and AKAP-mediated PKA targeting

Authors: *J. F. MARGIOTTA[1], S. S. JAYAKAR[2], P. C. PUGH[3], E. R. STARR[1]; [1]Neurosciences, UT Col. of Med. & Life Sci., TOLEDO, OH; [2]Neurobio., Harvard Med. Sch., Boston, MA; [3]Psychiatry & Behav Neurobio., Univ. of Alabama, Birmingham, AL

Abstracts: Pituitary adenylate cyclase activating polypeptide (PACAP) engages a selective G-protein coupled receptor (PAC_1R) to enhance quantal acetylcholine (ACh) release from ciliary ganglion neuron terminals within minutes *via* neuronal nitric oxide synthase (NOS1) and cyclic AMP/protein kinase A (PKA) dependent processes. Here, we examined how PACAP stimulates NOS1-dependent NO production and targets resultant PKA-dependent outcomes to synapses. Scavenging extracellular NO blocked PACAP-induced plasticity supporting a retrograde (post- to presynaptic) NO action on transmitter release. Live-cell NO imaging revealed that PACAP stimulates NO production by mechanisms requiring NOS1, PKA and Ca^{2+} influx. Ca^{2+}-permeable nicotinic ACh receptors composed of α7 subunits (α7-nAChRs) that are potentiated by PKA-dependent PACAP/PAC_1R signaling, are required for PACAP-induced NOS1-dependent NO production and synaptic plasticity since both outcomes were blocked following their selective inhibition. Co-precipitation studies revealed that NOS1 associates with α7-nAChRs, many of which are perisynaptic, as well as with heteromeric α3*-nAChRs that generate the bulk of synaptic activity. Such an arrangement would facilitate NO production at perisynaptic and adjacent postsynaptic sites to regulate focal ACh release from juxtaposed presynaptic terminals. These PKA-dependent outcomes of PACAP/PAC_1R signaling are localized to synaptic membrane components by PKA anchoring proteins (AKAPs). PKA regulatory-subunit

overlay assays identified five AKAPs in CG lysates, including the prominent neuronal subtype, AKAP5 (AKAP79/150). Moreover PACAP-induced synaptic plasticity was selectively blocked by inhibiting PKA regulatory-subunit binding to AKAPs. Taken together, our findings indicate that PACAP/PAC_1R signaling rapidly coordinates nAChR, NOS1 and AKAP activities to induce targeted, retrograde plasticity at autonomic synapses. Such coordination has broad relevance for understanding the control of autonomic synapses and consequent visceral functions.

Title: Direct evidence of altered neuronal excitability due to electric field stimulation

Authors: ***B. LAFON**, A. RAHMAN, M. BIKSON, L. C. PARRA;
City Col. of New York, New York, NY

Abstracts: Transcranial direct current stimulation (tDCS) is gaining importance both in clinical as well as basic neuroscience research. tDCS generates weak electric fields in the brain of ~1 mV/mm per mA of current applied. This causes an incremental passive membrane polarization in pyramidal cells of up to 0.1mV. This incremental polarization has been shown to acutely affect spike timing, increase firing rate, and synaptic efficacy. Moreover, plastic changes elicited by electric fields have been assessed in terms of synaptic efficacy. However, neuronal excitability for a constant synaptic input has not been concurrently documented yet in-vitro. We hypothesized that due to membrane polarization the synaptic input required for firing will be affected, therefore modulating the neuronal input-output (I/O) function. Simultaneous recording of the fEPSP (synaptic input) and the population spike (neuronal output) were performed in the CA1 region of rat hippocampal slices. Measurements were taken in three conditions: control, positive and negative fields. Our results indicate that DC stimulation which depolarizes the soma advances and amplifies neuronal firing for a given synaptic input. The latter is seen as a leftward shift of the threshold of the I/O curve. We built computational models to test two alternative hypotheses: 1) single cell effect - increased output results from an increased drive within a cell

due to the potential gradient induced by the electric fields, 2) network effect - increase output results from a differential effect of fields on the timing of excitatory and inhibitory neurons. Irrespective of the precise mechanism, the increased spiking activity of a neuronal population observed here can have important implications for the effect of fields during acute stimulation as well as plastic mechanisms.

Title: Robust and novel modulation of synaptic excitability in the Hippocampus via endogenous free iron

Authors: ***R. S. WHITE**, A. BHATTACHARYA, Y. CHEN, G. CARLSON, S. KIM; Psychiatry, Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA

Abstracts: We identified a novel signaling cascade in neurons whereby stimulation of glutamate-NMDA receptors activates Dexras1, inducing iron movement into the neurons via an iron channel, DMT1. This led us to demonstrate that Dexras1-mediated iron influx plays a crucial role in NMDA excitotoxicity. This suggested that free iron may also have a role in normal neurophysiological processes. We investigated whether chelating iron with membrane permeable iron specific chelator, pyridoxal isonicotinoyl hydrazone (PIH), affects hippocampal activity and excitability. PIH application induced an increase in the frequency of spontaneous events (Control=0.9 +/- 0.09; 100μM PIH= 1.6 +/- 0.19Hz) and produced a 47% increase in evoked synaptic excitability following PIH treatment. To investigate if this generated differences in circuit activity we utilized voltage sensitive dye imaging of hippocampal slices and found an increase in both amplitude and tau of decay of the schaffer evoked EPSP following PIH treatment. When NMDA receptor activity is blocked by AP5 this increase in VSDi response and

sEPSCs frequency in PIH is abolished. However when AMPA receptor activity is blocked with DNQX, PIH still causes an increase in evoked VSDi response in CA1 (+35.2% n=5). To identify the localization of free iron, hippocampal slices were imaged using an iron sensitive fluorescent dye Calcien-AM. After PIH application, CA1 had the greatest change in fluorescence showing that chelatable iron was present and at higher concentration than in the dentate gyrus or CA3. To test if the Dexras1/DMT1 pathway was active in mediating this iron dependent synaptic modulation, we investigated the role of dexras1 in the PIH dependent increase in synaptic excitability. Recording and imaging from the hippocampi of dexras1 KO mice showed a complete lack of all PIH-dependent response. Similar results were found in the DMT1 blocker ebselen. The lack of iron in the ACSF bathing the slices indicated that there must be an internal source of iron in the neurons. We found that collapsing the lysosomal proton gradient with NH4Cl significantly reduced free iron, suggesting that lysosomes are releasing iron into the intracellular space causing changes in NMDA mediated excitability. Linking the dexras1/DMT1 pathway to the lysosome, immunoblotting different subcellular fractions for our showed Dexras1 in the lysosomal fraction along with the lysosomal protein, LAMP-2, along with ACBD3, a scaffolding protein, which forms a complex of Dexras1 and the DMT1 iron channel. These data reveal a novel mechanism that demonstrates an active role of iron in modulating synaptic excitability.

Title: Waves of noradrenaline and corticosterone after stress differentially affect glutamatergic transmission in the mouse basolateral amygdala

Authors: *H. KARST, M. JOËLS;
Dept. Translational Neuroscience, Brain Ctr. Rudolf Magnus, Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

Abstracts: stress-related information and restoring homeostasis. The amygdala, including the basolateral amygdala (BLA), is the main brain structure for emotional and fear regulation. It was

shown1 that both After stress, the brain is exposed to waves of stress hormones which are important for encoding of Isoproterenol (ISO), a β-adrenoceptor agonist, and corticosterone (Cort) are necessary to strengthen the consolidation of fear-related information after stress. In the BLA, mineralocorticoid (MR) and glucocorticoid receptors (GR) are expressed. MRs and GRs generally affect properties of neurons via genomic pathways, but more recently rapid non-genomic actions through membrane-located MRs and GRs were demonstrated2. Application of 100 nM corticosterone was reported to cause an increase of the BLA mEPSC frequency, reflecting an increased release probability of glutamate. The mEPSC amplitude was not affected. Remarkably, a second surge of corticosterone 1-4 hours later resulted in a rapid reduction of the mEPSC frequency. We now show that this metaplastic mode of action requires a delay of ~60 minutes between the first and second corticosterone application. We furthermore show that ISO also rapidly increases BLA glutamatergic transmission. Surprisingly however, this gradually reverses in a decrease in mEPSC frequency, indicating that ISO also affects transmission via a genomic pathway. Co-application of ISO and Cort has a mixed synergistic and additional effect on the mEPSC frequency. Under normal physiological circumstances the brain first experiences a wave of NA after a stressful event, followed by a gradual increase in the Cort level. When Cort was administered after ISO, we found that Cort decreases the mEPSC frequency. Our final step was to mimic the physiological situation by exposing brain slices to consecutive waves of ISO and Cort. We mimicked an arousing event, a mildly stressful and a severely stressful event, by varying the ISO and Cort concentrations. We observed that low to moderate concetrations cause a brief increase in mEPSC frequency followed by a prolonged suppression. With very high concentrations -mimicking severe stress- BLA glutamatergic transmission remained at a very high level for hours. The latter may relate to the inappropriately strong encoding of emotional aspects after traumatic events. 1 Roozendaal et al. (2006) Proc Natl Acad Sci USA 103, 6741-6 2 Karst et al. Title: Compartment-specific modulation of GABAergic inputs by TRPV1 channels in the dentate gyrus

Authors: *A. E. CHAVEZ[1], V. M. HERNANDEZ[2], A. RODENAS-RUANO[1], S. CHAN[2], P. E. CASTILLO[1];
[1]Dominick P Purpura Dept Neurosci., Albert Einstein Col. Medici, BRONX, NY; [2]Dept. of Physiology, Feinberg Sch. of Medicine, Northwestern Univ., Chicago, IL

Abstracts: The transient receptor potential TRPV1 or vanilloid receptor is a nonselective cation channel mainly found in nociceptive neurons of the peripheral nervous system. TRPV1 has also been reported in different brain regions, where its activation depresses excitatory synaptic transmission. However, whether TRPV1 could regulate inhibitory synapses in the brain remains unknown. Here, using a combination of pharmacology, electrophysiology and *in vivo* knockdown strategies, we show that activation of TRPV1 channels by capsaicin (2 μM) or by the endocannabinoid anandamide (30 μM) depresses somatic but not dendritic inhibitory transmission in both rat and mouse dentate gyrus. These effects on somatic GABAergic transmission were completely abolished in TRPV1 knockout mice and were also eliminated by two different TRPV1 shRNAs expressed in dentate granule cells (DGCs), strongly supporting a functional role for TRPV1 in modulating GABAergic synaptic function in the dentate gyrus. Moreover, the TRPV1-mediated depression of inhibition was not associated with changes in paired-pulse ratio and coefficient of variation, suggesting that TRPV1 does not affect GABA release but modulates postsynaptic function. To directly test this possibility, we monitored GABAergic responses elicited by brief puffs of GABA, a manipulation that shortcuts transmitter release. GABA-evoked responses elicited in the soma (i.e. stratum granulosum moleculare), but not in dendrites (i.e. middle third of the molecular layer) of DGCs, were significantly depressed by capsaicin (2 μM). In addition, we found that TRPV1-mediated effects require postsynaptic Ca2+ rise, activation of calcineurin, and are likely mediated by a clathrin-dependent internalization of GABAA receptors. Altogether our findings reveal a novel form of compartment-specific regulation of synaptic transmission, whereby activation of TRPV1 channels depresses inhibitory synaptic inputs presumably by targeting postsynaptic GABAA receptor number. Such specific regulation of GABAergic transmission along the somato-dendritic axis may have important functional consequences in controlling DGC output.

Title: Protein phosphatase 2A mediates adenosine A1 receptor-induced GluA1 AMPA receptor internalization and persistent synaptic depression in rat hippocampus

Authors: *F. S. CAYABYAB, J. STOCKWELL, Z. CHEN, Z. MING, A. GARGOUM; Dept. of Physiol., Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstracts: The adenosine A1 receptor (A1R) plays an essential role in synaptic depression induced by increased extracellular adenosine surges seen in neuronal insults such as hypoxia or ischemia. We recently showed that A1 receptor-induced synaptic depression was mediated postsynaptically by inducing GluA1- and GluA2-containing AMPA receptor internalization. The GluA1 AMPA receptor subunit contains two major regulatory C-terminal serine phosphorylation sites, Ser831 and Ser845, which are known to be involved in GluA1 surface expression and synaptic trafficking. We have shown that dephosphorylation of these two regulatory sites accompanies GluA1 internalization, and that it involves A1R-induced protein phosphatase activity through protein phosphatase 2A (PP2A). Previous data shows pharmacological inhibition of PP2A reduces APSD and GluA1 internalization, but the drugs used are not easily translated into an *in vivo* stroke model. We further explored this A1 receptor - PP2A - GluA1 signaling complex using a Tat peptide interference strategy. We designed a new peptide, called Tat-YD peptide, which is expected to prevent PP2A activation. We hypothesized that GluA1 internalization would be inhibited after Tat-YD treatment. Using fEPSP electrophysiology experiments on rat hippocampal slices, we found that Tat-YD peptide perfusion onto naive hippocampal slices increased fEPSP slope by approximately 20%, indicating that PP2A inhibition increases the surface levels of GluA1. Accordingly, our biochemistry data showed that Tat-YD incubation increased surface GluA1 in hippocampal slices. Adenosine A1 receptor activation by a selective agonist CPA induced both AMPA receptor internalization and adenosine-induced persistent synaptic depression (APSD), which are both reduced by pre-incubation of slices in Tat-YD peptide. The levels of phosphorylation of GluA1-Ser831 and

GluA1-Ser845 were increased by Tat-YD alone, and were not reduced below baseline levels after prolonged CPA treatment. Together, these results indicate that adenosine A1 receptors recruit PP2A to downregulate AMPA receptor trafficking, thereby enhancing APSD. Targeting PP2A to prevent excessive APSD represents a novel approach to promote neuroprotection during cerebral ischemic damage.

Title: Species differences in the BNST-VTA pathway: Comparative anatomical and electrophysiological analysis

Authors: *J. KAUFLING[1], D. GIRARD[1], M. MAITRE[2], F. GEORGES[1];
[1]Dept. of Neurosciences, Interdisciplinary Inst. for Neurosci., Bordeaux, France; [2]Ctr. de Recherche Inserm U862, Borbeaux, France

Abstracts: The Bed Nucleus of the Stria Terminalis (BNST) is a forebrain region mostly GABAergic (GABA) with a significant component of glutamatergic (GLU) neurons. Recent optogenetic findings from experiments performed in mice confirm the main conclusion of our original work performed in rats: the BNST exert an excitatory influence onto VTA dopaminergic (DA) neurons activity. However, the neuronal circuit implicated in this excitatory influence remains a matter of debate. Our hypothesis is to test if there are any differences between mice and rats in evoked responses of VTA DA neurons induce by stimulation of monosynaptic inputs of the BNST. Using a combination of *in vivo* electrophysiological, neuroanatomical tracing and laser capture approaches we reevaluate in rats and mice the BNST influence on VTA DA neurons activity. First, we characterize in rat the molecular phenotype of the BNST neurons projecting to the VTA. We found that this projection is multiple and complex in terms of neurotransmitter: expression of GABA markers and GLU markers (vGlut2 and vGlut3). Then VTA injections of a classic retrograde tracer, the B sub-unit of the choleric toxin (CTB) reveal a

stronger BNST VTA projection in mice than in rats. Finally, electrical stimulations of the BNST during VTA DA neurons recording in rats and mice demonstrate that an excitatory monosynaptic BNST VTA connection is more important in rats than in mice. All this data, illustrate anatomically but also functionally, a significant difference between rats and mice in the BNST VTA DA pathway. More generally, this study correlating previous research highlights the awareness of the animal model use for the interpretation and the generalization of research data.

Title: Platelet activating factor enhances presynaptic vesicle release

Authors: *J. W. HAMMOND, S.-M. LU, H. A. GELBARD;
Ctr. for Neural Develop. and Dis., Univ. of Rochester, Rochester, NY

Abstracts: Platelet activating factor (PAF) is a potent, inflammatory phospholipid that can also alter synaptic strength. During neuroinflammation, PAF levels are chronically high and PAF directly contributes to neuronal injury as PAF receptor (PAFR) antagonism has been shown to be neuroprotective in mouse models of HIV-1 associated neurocognitive disorders, seizure, trauma, stroke, and multiple sclerosis. Yet, there is much about the mechanisms of PAF signaling at the synapse that we do not understand. We show that the PAF receptor is peri-synaptically localized in mixed cultures of primary hippocampal neurons. Using FM dye or pHluorin tagged synaptophysin to label synaptic vesicle recycling, we show that PAF treatment enhances presynaptic vesicle release. Specifically PAF increases the size of the primed, readily releasable pool (FM dye = 42% increase; pHluorin = 32% increase). PAF also activates previously silent presynaptic terminals. During neuroinflammation, inflammatory leukocytes infiltrate synapses in response to chemotactic stimuli and are capable of secreting PAF in supra-physiologic levels. Thus, our data suggest that PAF-enhanced neurotransmitter release in the presence of physiologic levels of stimulation likely places synapses in a high activity state where they are vulnerable to excitotoxic injury and energy failure.

Title: tDCS current intensity on immediate early gene induction *in vivo*

Authors: ***J. WAGNER**[1,2], R. JANKARD[2];
[1]Wright State Univ., Dayton, OH; [2]Wright Patterson Air Force Base, Fairborn, OH

Abstracts: Transcranial direct current stimulation (tDCS) sends a weak polarizing current across the brain that can modulate human behavior. It is unknown how tDCS modulates the brain and affects behavior, therefore we examined some of the underlying biological processes that could be induced in response to tDCS. In this study, we utilize a rodent tDCS model to discern which gene transcripts are modulated by tDCS. Immediate early genes (IEGs) are induced in response to neuronal activating stimuli, so we chose two IEGs, cFos and zif268, as candidates to assess the effects of tDCS. Our results show that tDCS induces neuronal activation, as indicated by the induction of cFos and zif268. Of interest, the magnitude of IEG induction was dependent upon the current intensity used during stimulation with the highest current intensity yielding the largest IEG induction being observed. These results indicate that the scale of neuronal activation is dependent upon the current intensity utilized during stimulation. Also, the fold change of the IEG's reached its greatest under the stimulation site and decreases as the area become more distal, suggesting a gradient of IEG induction across brain regions. Our study has shown tDCS modulates the biological activity of the brain and that the impact of tDCS on immediate early gene induction is dependent on the current intensity dose. Thus, the induction of immediate early genes by tDCS is a mechanism by which tDCS can affect neuronal activity and may thereby modulate behavior.

Title: PACAP induces acute and sustained synaptic plasticity by distinct cellular mechanisms

Authors: *E. R. STARR, J. F. MARGIOTTA;
Neurosciences, UT Col. of Med. & Life Sci., Toledo, OH

Abstracts: Neuropeptide generated signals alter synaptic components and properties. Pituitary adenylate cyclase activating polypeptide (PACAP) is found at synapses throughout the nervous system. In autonomic ciliary ganglion (CG) neurons, PACAP engages a selective G-protein coupled receptor (PAC_1R), activating signal cascades that rapidly influence synaptic components. Minutes after PACAP application, PAC_1R signaling enhances cholinergic synaptic output, increasing the frequency and amplitude of spontaneous nAChR-mediated excitatory postsynaptic currents (sEPSCs). We previously found that this acute plasticity results from enhanced ACh release from presynaptic terminals without affecting postsynaptic quantal size, and show at an accompanying poster that it arises from coordinated, membrane-localized activation of neuronal nitric oxide synthase (NOS1), and consequent retrograde NO-enhanced ACh release. In addition to these actions, brief PACAP exposure activates transcription and alters expression of genes relevant to synaptic function. Consistent with these actions, PACAP induces synaptic plasticity that persists long after the brief exposure. Specifically, 2 d after 15 min treatment with PACAP, sEPSC frequencies and amplitudes remain elevated compared to controls. While this sustained plasticity resembles that immediately following acute PACAP exposure, we now report that its correlates reflect different cellular mechanisms. First, while sEPSC frequencies 2 d after 15 min PACAP treatment are similar to those immediately after PACAP exposure, sEPSC amplitudes are increased even further. Second, the sustained changes are accompanied by increased postsynaptic quantal size as determined from elevated miniature nAChR-mediated EPSC (mEPSC) amplitudes, and elevated mEPSC frequencies, neither of which are seen immediately after PACAP exposure. Third, the sustained synaptic plasticity is independent of NOS1 since it is unaffected by blocking NOS1 and subsequent production of NO with L-NAME during the initial 15 min PACAP treatment. These findings indicate that PACAP has short- and long-term consequences that, respectively, produce acute and sustained synaptic plasticity by different mechanisms. Experiments are underway to determine how the sustained

plasticity arises by probing its dependence on processes downstream from local membrane signaling such as PAC_1R trafficking and gene transcription. Since PACAP is widely distributed and can also modulate GABAergic and glutamatergic synaptic transmission, uncovering the basis for its ability to induce sustained plasticity could have broad relevance throughout the nervous system.

Title: Calcium channel subtypes on glutamatergic presynaptic terminal projecting to rat hippocampal CA3 neurons

Authors: *M.-C. SHIN, K. NONAKA, M. YOSHIMURA, N. AKAIKE;
Kumamoto Hlth. Sci. Univ., Kumamoto City, Kumamoto Pref., Japan

Abstracts: High-voltage-activated (HVA) Ca2+ channels on presynaptic nerve terminals (boutons) are known to play an important role in neurotransmitter release. Ca2+ flows into the presynaptic terminals through the HVA Ca2+channels bind to various Ca2+-binding proteins at presynaptic transmitter release sites which then triggers exocytosis of neurotransmitter. HVA Ca2+ channel subtypes triggering glutamate release from nerve terminals projecting to rat hippocampal CA3 pyramidal neurons were studied. Single CA3 neurons were mechanically isolated with adherent nerve terminals, namely the ‘synaptic bouton preparation’, and spontaneous glutamatergic excitatory synaptic potentials (sEPSCs) and EPSCs evoked by focal electrical stimuli of a single presynaptic glutamatergic bouton (eEPSCs) were recorded using conventional whole-cell patch recordings. In the synaptic bouton preparation, 30μM nifedipine (L-type selective antagonist), 100nM ω-cg-GVIA (N-type selective antagonist), and 100nM ω-Ag-IVA (P/Q-type selective antagonist) reduced the sEPSC frequency, without altering the mean sEPSC amplitude. However, 100nM SNX-482 (R-type selective antagonist) and 300μM efonidipine (T-type selective antagonist) had no significant effect on the frequency and amplitude of glutamatergic sEPSCs. In the single bouton focal stimulation recordings, not only 30μM nifedipine, 100nM ω-cg-GVIA, 100nM ω-Ag-IVA, but also 100nM SNX-482 increased failure rate (Rf) of glutamatergic eEPSCs, without altering the mean eEPSC amplitude. 300μM

efonidipine had no significant effect on the Rf and amplitude of glutamatergic eEPSCs. Overall, our results suggest that the dominant control of glutamate release depends on Ca2+ entry through L-, N-, P/Q- and R-type Ca2+ channels that ubiquitously populate hippocampal CA3 glutamate release sites.

Title: Melanin-Concentrating Hormone modulates excitatory transmission at the hippocampal synapses by acting on astrocytes

Authors: *L. LE BARILLIER, M. ROSIER, G. MALLERET, P.-A. SALIN;
CRNL Univ. Claude Bernard, LYON, France

Abstracts: The hypothalamic neuropeptide Melanin Concentrating Hormone (MCH) plays an important role in several homeostatic functions as sleep regulation and enhances memory retention in hippocampus-dependent learning tasks in rodents. As we showed that glutamatergic transmission was impaired in mice lacking MCH-receptor-1 gene, we investigated how MCH could modulate excitatory transmission at Schaffer collaterals-CA1 synapse in mice hippocampal slices. We found that application of MCH induced a depression of the synaptic response. Changes in paired-pulse facilitation ratio as well as in $1/CV^2$ suggested that MCH modulates glutamatergic transmission by acting on neurotransmitter release. MCH induced depression was suppressed by adenosine receptor A1 antagonist and inhibitors of ectonucleotidases which degrades ATP in adenosine in extracellular space. As astrocytes are the major source of ATP in the brain, we hypothesized that MCH modulating effects on glutamatergic transmission could be relayed by astrocytes. It has been shown that P2Y1 and mGlur5 play a critical role in ATP release by astrocytes. In agreement with our hypothesis, the selective P2Y1 and mGluR5 antagonists inhibited the MCH induced depression. Moreover, in presence fluoroacetate which selectively inactivates astrocytes, the MCH induced depression was totally blocked. All this results suggest that MCH decreases hippocampal glutamatergic transmission by activating astrocytes which triggers release of ATP. Since recent studies pointed out that astrocytes are

essential to synaptic plasticity, our work suggests a new cellular mechanism by which MCH could facilitate memory consolidation.

Title: Presynaptic adenosine A2A-receptor mediated pathway acts as a counteragent of calcineurin-based downregulation of L-type calcium channel activity in mouse neuromuscular junctions

Authors: ***E. TARASOVA**, A. GAYDUKOV, O. BALEZINA;
Dept. of Human and Animal Physiol., Fac. of Biology, Moscow State Lomonosov Univers, Moscow, Russian Federation

Abstracts: It is well known that L-type voltage-gated calcium channels are present in mouse neuromuscular junctions (NMJs) but do not contribute to acetylcholine (ACh) release. In our previous work we demonstrated that in mouse NMJs the activity of L-type calcium channels is hindered by calcineurin which acts presynaptically as a downregulator of evoked neurotransmitter release. Calcineurin inhibitor cyclosporine A (CsA) increased evoked synaptic transmission by 30%. The goal of our present study was to reveal a possible pathway of L-type channel upregulation despite of the presence of functionally active calcineurin. In central neurons the activation of adenosine A2A-receptors (A2AR) leads to phosphorylation of L-type calcium channels by PKA and thereby enhances calcium influx. Presynaptic adenosine A2AR are also present in NMJs, but their involvement in secretion regulation is rather under question. Therefore we decided to focus on the interaction of calcineurin and the molecular cascade triggered by A2AR. Experiments were conducted on «dissected» mouse diaphragm preparations using standard microelectrode technique of biopotential registration. We registered both spontaneous and evoked activity of NMJs in form of miniature end plate potentials (mEPP) and end plate potentials (EPP) respectively. PKA inhibitor H-89 (1μM) had no effect on evoked synaptic transmission. Nevertheless, preliminary H-89 application fully prevented the increase of

EPP quantal content caused by following CsA (1 μM) treatment. So, PKA seems to be involved in L-type channel regulation reciprocally to calcineurin. Application of A2AR blocker ZM241385 (1 nM) did not alter neither spontaneous nor evoked ACh secretion. But in the presence of ZM241385(1 nM) CsA (1 μM) failed to enhance evoked transmission, similarly to the effects of H-89(1 μM) . Presynaptic A2AR agonist CGS-21680(1 μM) produced a rise of EPP quantal content by nearly 20%. The data obtained suggests that the cascade of molecular events starting from A2AR activation and calcineurin act antagonistically and have the same target - L-type calcium channels. Interestingly, when L-type calcium channels were already activated by calcineurin inhibition and transmission was facilitated, applying CGS-21680 (1 μM) did not lead to any additional changes in the EPP quantal content. Thus, we showed that the presynaptic pathway involving A2A-receptors and PKA is able to counteract with calcineurin in its influence on L-type calcium channels.

Title: Regulation of spontaneous synaptic transmission by extracellular calcium at excitatory synapses onto hippocampal CA1 pyramidal cells

Authors: W. E. BABIEC[1], R. GUGLIETTA[2], S. A. JAMI[3], *T. J. O'DELL[1];
[1]Dept Physiol, David Geffen Sch. Med. UCLA, LOS ANGELES, CA; [2]Interdepartmental Ph.D. Program for Neurosci. at UCLA, [3]Molecular, Cellular, and Integrative Physiol. Ph.D. Program, UCLA, Los Angeles, CA

Abstracts: Schaffer collateral (SC) fiber synapses onto pyramidal cells (PCs) in the CA1 region of the dorsal and ventral hippocampus exhibit striking differences in both short-term and long-term plasticity. Importantly, evoked and spontaneous synaptic transmission may involve distinct

molecular mechanisms, pools of presynaptic vesicles, postsynaptic receptors. Thus, we examined evoked and spontaneous transmission at excitatory synapses onto CA1 PCs in the dorsal and ventral hippocampus to determine whether the properties of spontaneous transmitter release also differ along the septotemporal axis of the hippocampus. Paired-pulse facilitation of SC fEPSPs was significantly smaller and the block of NMDA receptor-mediated excitatory posesynaptic currents (EPSCs) by the use-dependent blocker MK-801 was significantly faster in ventral PCs, suggesting that the probability of transmitter release is higher at SC fiber synapses in the ventral hippocampus. In contrast, the frequency and amplitude of spontaneous miniature EPSCs (mEPSCs) were identical in dorsal and ventral PCs, suggesting that spontaneous excitatory transmission is similar in these two regions. Blocking voltage-gated calcium channels (VGCCs) with Cd^{2+} had no effect on mEPSC frequency in dorsal and ventral PCs, suggesting that spontaneous release in both regions is not due to stochastic openings of presynaptic VGCCs. However, increasing extracellular Ca^{2+} (from 2 to 4 mM) significantly enhanced mEPSC frequency in dorsal PCs ($p < 0.001$) but had no effect on mEPSC frequency in ventral PCs ($p = 0.996$). Elevating extracellular Mg^{2+} (from 2 to 4 mM) also enhanced mEPSC frequency in dorsal PCs ($p < 0.05$) with no effect on mEPSC frequency in ventral PCs ($p = 0.52$). Both Ca^{2+} and Mg^{2+} are agonists of the calcium-sensing receptor (CaSR), a G protein coupled receptor that regulates spontaneous transmission at synapses onto cortical neurons (PMC3097128). Consistent with a role for the CaSR in regulating spontaneous release, bath application of the CaSR agonist spermine induced a 5-fold increase in mEPSC frequency in dorsal PCs but increased mEPSC frequency only 2-fold in ventral PCs. Together our results suggest that the CaSR may have a key role in regulating spontaneous synaptic transmission. Moreover, alterations in CaSR expression and/or signaling may provide a mechanism that maintains a constant level of spontaneous transmitter release at excitatory synapses onto CA1 PCs along the septotemporal axis of the hippocampus at physiological levels of Ca^{2+} and Mg^{2+} despite different probabilities of evoked transmitter release at these synapses.

Title: *In vitro* exposure to nicotinic agonists modulates the function of NMDA receptors present on glutamatergic and GABAergic nerve endings in rat nucleus accumbens

Authors: ***M. MARCHI**[1], S. ZAPPETTINI[2], M. GRILLI[1], G. OLIVERO[1], J. CHEN[1], C. PADOLECCHIA[1], A. PITTALUGA[1];

Abstracts: We provide functional evidence supporting the presence on rat Nucleus Accumbens (NAc) glutamatergic terminals of N-methyl-D-aspartic acid (NMDA) receptors co-localized with nicotinic acetylcholine receptors (nAChRs). We have previously shown that brief pretreatment *in vitro* with nicotine for few minutes decreased the NMDA-induced dopamine release from NAc nerve terminals, indicating that the recruitment of nAChRs dynamically and negatively regulates NMDA receptors through the selective internalization of glutamate N2B-NMDA receptors. This reduction was completely counteracted when dopaminergic synaptosomes were pretreated with nicotine plus mecamylamine or in presence of the selective antagonist DHβE indicating that the changes of the NMDA-dependent dopamine release reported was dependent to the activation of a β2* nAChR subtype. Conversely we here show that the *in vitro* short-term pre-exposure of glutamatergic synaptosomes to α7 nAChR agonists caused a significant potentiation of the 100 μM NMDA-evoked [3H]D-Aspartate overflow possibly throughout the selective externalization of glutamate N2A-NMDA receptors . The brief pretreatment *in vitro* with β2* nAChR agonists did not modify the NMDA-evoked [3H]D-Aspartate overflow. The pre-exposure of GABAergic synaptosomes to α7 nAChR or β2* nAChR agonists did not modify the NMDA-evoked [3H]GABA overflow. Our result show that at the nerve terminal level, nicotinic agents may not only induce neurotransmitter release but, throughout the interaction with other co-existing receptors may also exert functional modulatory role on the functions of co-localized receptors. These mechanisms of adaptation should be relevant to understand the interplay between nAChR and NMDAR in the processes of neuronal plasticity as well as in the mechanisms of learning and memory

Title: Fetal application of HDAC inhibitors facilitates the elongation of Purkinje cell dendrites and the network formation in rat cerebellar cortex

Authors: *S. YOSHIDA[1], N. HOZUMI[2], D. KATSUMATA[1], T. ABE[1], Y. FUETA[3], S. UENO[3], Y. SEKINO[4];
[1]Dept. Envrn. and Life Sci., [2]Dept. Electrical Electronic Info. Eng., Toyohashi Univ. Technol., Toyohashi, Japan; [3]Univ. Occup. and Envrn. Hlth., Kitakyushu, Japan; [4]Natl. Inst. of Hlth. Sci., Tokyo, Japan

Abstracts: Valproate (VPA), the popular anticonvulsant and mood stabilizer, is known as an inducer of autism. It has many kinds of physiological properties, including the inhibition of histone deacetylase (HDAC). Recently we reported VPA application to rat fetus caused developmental changes in cerebellar cortex. In treated cerebellum, the dendrites of Purkinje cells were elongated earlier than in vehicles. Using the enzyme-linked photo assay device, it was observed that some neurotransmitter releases were changed. However it was unclear whether theses effects derived from HDAC inhibition or not. In this study, we report the effects of two other HDAC inhibitors on cerebellar development and compare them with the effect of VPA. The HDACs are classified into three main groups, Class I to III. VPA is possible to inhibit Class I HDACs. Suberoylanilide hydroxamic acid, SAHA, is major anticancer drug, and possible to inhibit Class I and II. Trichostatin A, TSA, is also Class I inhibitor. VPA application to embryonic day 16 p.o. increased GABA release even from early developing periods, and changed its spatial pattern of release. Furthermore, purinergic stimulation of the inhibitory input to Purkinje cells primarily mediated by activation of P_2X receptors, and the inhibitor of ATP-degrading enzymes suggested endogenous ATP would be released 2 weeks later after birth in developing cerebellar cortex. Recently, we developed a new ATP imaging system with ATP requiring redox enzyme, and observed distribution and transition of ATP release in the developing cerebellar cortex. ATP was released to 100 μM glutamate stimulation and observed in the lower molecular layer and granular layer. The ATP release was increased drastically at postnatal day 10 (P10), and decreased gradually to P14. Both VPA and SAHA facilitated these ATP release earlier than vehicle. Purkinje cells in the VPA-applied rat elongated their dendrites all over the molecular layer even in P12. SAHA-applied rat also elongated the dendrites of Purkinje cells earlier, however, the effects was less than VPA-applied ones. The effects of TSA application were observable but slight. These three HDAC inhibitors were categorized as same class, but have different organic structures. VPA belongs to the aliphatic acid compounds, while SAHA and TSA belong to hydroxamic acids. Their physiological spectrum would be different,

however, all of them promoted the corresponding neuronal differentiation. We suggest that some factors induced by the function of HDAC inhibitors would be conditioned the developmental schedule of Purkinje cells.

Title: Regulation of histone H3 phosphorylation at K27me3S28 in response to amphetamine and haloperidol

Authors: ***G. FISONE**[1], A. BONITO-OLIVA[1], E. SÖDERSTEN[1], X. HU[1], G. SPIGOLON[1], J. CABOCHE[2], K. HANSEN[3];
[1]Karolinska Inst., Stockholm, Sweden; [2]Univ. Pierre et Marie Curie, Paris, France; [3]BRIC, Copenhagen, Denmark

Abstracts: Psychostimulant and antipsychotic drugs act on striatal GABAergic medium spiny neurons (MSNs), promoting adenylyl cyclase activity and cAMP/PKA signaling, and leading to phosphorylation of the dopamine- and cAMP-regulated phosphoprotein of 32 kDa (DARPP-32). Psychostimulant drugs (e.g. amphetamine) mainly target the striatonigral MSNs of the direct pathway, expressing dopamine D1 receptors. In contrast, antipsychotic drugs (e.g. haloperidol) preferentially bind to dopamine D2 receptors, expressed in the striatopallidal MSNs of the indirect pathway. Administration of these drugs is associated to chromatin modifications, which ultimately lead to changes in gene transcriptions implicated in synaptic plasticity and long-term behavioral responses. Both amphetamine and haloperidol have been shown to increase histone H3 phosphorylation at Ser10, whereas nothing is known about their effects on Ser28. Recent evidence indicates that histone H3 phosphorylation at Ser28 (H3S28p) in the context of K27 trimethylation (H3K27me3) leads to displacement of gene repressor complexes containing Polycomb group proteins, followed by transcriptional activation. Here, we investigated changes in H3K27me3S28 phosphorylation using an antibody recognizing the occurrence of the two

concomitant modifications on histone H3. We found that amphetamine and haloperidol increase H3K27me3S28p levels specifically in the MSNs of the direct and indirect pathway, respectively, and that these effects depend on DARPP-32. Moreover, we show that the H3K27me3S28p increase induced by amphetamine requires the mitogen-and stress-activated kinase 1 (MSK1). In contrast, MSK1 does not appear to be necessary for haloperidol-mediated H3K27me3 phosphorylation. These results unveil a novel mechanism potentially implicated in the ability of psychostimulants and antipsychotics to modify gene expression in distinct neuronal populations.

Title: Distinct populations of synaptic vesicles in dopamine neurons

Authors: ***H. GU**[1], L. IACOVITTI[2], Q. ZHANG[1,2];
[1]Pharmacol., Vanderbilt Univ., Nashville, TN; [2]Dept. of Neurosci., Thomas Jefferson Univ., Philadelphia, PA

Abstracts: Dopamine (DA) neurons in midbrain are essential for motor control, reward learning and cognition. However, it became clear that DA is not the only neurotransmitter release from axonal terminals of DA neurons. Some of those neurons reportedly co-release glutamate (Glu) and/or GABA alongside DA. First, vesicular Glu transporter 2 (VGluT2) has been found in those neurons and vesicular monoamine transporter (VMAT) reportedly transports GABA into Synaptic vesicles (SV). Second, EPSCs and IPSCs directly triggered by the activation of DA terminals have been observed in neurons having monosynaptic contact with DA neurons. Third,

conditional knockout of VGluT2 only in DA neurons lead to altered locomotor response and enhanced reward learning. Given DA neurons ability to release different neurotransmitters, it becomes important to address if their release is executed distinctly or not and how so. One way to achieve differentiated control of release is spatial segregation, i.e. release from different synapses or different SV. Existing evidence suggested that the former is unlikely as the synaptic location and kinetics of the co-release were quite similar. The latter is also unlikely for GABA given VMAT co-transports GABA and DA into the same SV. However, the limitations of optical or electronic microscopy make it hard to separate different vesicular transporters and same SV with different contents. Using single vesicle tracking enabled by quantum dots (Qdots), we observed some intriguing features of SV in DA neurons. First, there was a subpopulation of Qdot-labeled vesicles located close to but not within the presynaptic boutons marked by FM dyes. Second, those vesicles exhibited an activity-triggered motion towards presynaptic terminals prior to release. Third, the probability and kinetics of release for those vesicles resembled reserve pool vesicles. Furthermore, we utilized physiological and pharmacological interventions to probe the mechanisms governing the traffic of this sub-population of vesicles. We observed that their mobility was associated with stimulation strength, basal calcium concentration and actin but not microtubule. Hypothesizing that this subpopulation of vesicles may be associated with Glu or GABA transmission from DA neurons, we have been performing super-resolution imaging to investigate if there were distinct vesicular transporters and neurotransmitters in those vesicles and how that correlated with the localization of those vesicles. This line of study will be beneficial to dissect out the molecular regulators that contribute to the diversity of synaptic transmission unique to DA neurons in CNS.

Title: Estrogen treatment offsets IPSC frequency reduction and calcium buffering elevation in basal forebrain neurons of reproductively senescent F344 female rats

Authors: *D. A. MURCHISON, A. FINCHER, S. BAKE, D. W. DUBOIS, J. C. DAMBORSKY, W. H. GRIFFITH;
Dept. of Neurosci. and Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr., Bryan, TX

Abstracts: Despite evidence of the beneficial effects of estrogens in animal models, outcomes of estrogen treatments in aged humans have been equivocal. Our lab has been investigating neuronal estrogenic signaling in a rat model of reproductive aging, with the goal of identifying mechanisms that could be targeted therapeutically. We examined the properties of spontaneous inhibitory post-synaptic currents (sIPSCs), cellular Ca2+ buffering and mRNA expression in acutely dissociated neurons from the medial septum/diagonal band of F344 rats in the following age groups: young (2-6 mo) males and females (diestrus), aged males (20-21 mo), reproductively senescent (RS, acyclic) females (15-21 mo), and RS females that were ovariectomized (OVX), including those that received 3-week estrogen treatment (OVX+E). Previously, we used whole-cell voltage-clamp in a reduced synaptic preparation to show a significant decrease in frequency of sIPSCs onto basal forebrain (BF) cholinergic neurons in aged males that could be mimicked in young males by adding exogenous Ca2+ buffer to the presynaptic terminals (J Neurophysiol 2014, 111:273). We have now found a parallel reduction in the IPSC frequency of RS OVX compared to young females and this reduction is eliminated in RS OVX+E rats. Because we hypothesize that reduced synaptic transmission in aged males is mediated by increased Ca2+ buffering, we assessed the buffering in the somatic compartment of BF cholinergic neurons by loading the cells with fura-2 AM and evoking Ca2+ transients by focal stimulation with an elevated K+ solution (20 mM). Different stimulus intensities were obtained by varying the duration and these were graphed against the amplitude of the evoked transients to create a buffering curve, the slope of which represents relative Ca2+ buffering. We confirmed the previously reported increase in Ca2+ buffering with age for males with the buffering slope changing significantly ($p<0.01$) from a mean (± SE) of 22.6 ± 2.3 (n=25) in young to 14.5 ± 1.7 (n=26) in aged (less slope indicates greater buffering). A similar significant ($p< 0.03$) change occurs in RS and OVX females and is alleviated by estrogen treatment. The slopes in females were: 25.0 ± 3.3 (n=36) for young, 13.6 ± 1.0 (n=16) for RS, 13.1 ± 1.8 (n=16) for RS OVX and 39.2 ± 5.9 (n=19) for RS OVX+E. Also, a single-cell RT-PCR survey showed reduced frequency of detection for choline acetyltransferase and G-protein coupled estrogen receptor sequences in RS OVX relative to young and RS OVX+E females. These results are consistent with the hypothesis that age and hormonal status alter Ca2+ buffering, synaptic transmission and gene expression.

Abstracts: The mammalian central nervous system is driven by a delicate balance between excitatory and inhibitory neurotransmission that is established during embryonic development and the first years of life. Impair to establish this balance can lead to the development of neurological diseases such as epilepsy, schizophrenia, and autism. Neurotrophins, especially the Brain-derived neurotrophic factor (BDNF), have been shown to play an important role in the establishment of this balance by regulating the migration, maturation and synaptic transmission of GABAergic system. However, little is known about how BDNF is able to regulate such variety of processes in the GABAergic system. To gain insight into the molecular mechanisms by which BDNF induces enhancement of GABAergic neurotransmission, initially we evaluated the role of TrkB postsynaptically by silencing the receptor on glutamatergic neurons. The results obtained showed that a reduction in the expression of TrkB receptor postsynaptically induces changes in miniature inhibitory synaptic currents (mIPSCs) in addition to modify the expression of Gephyrin and the enzyme GAD65. These results suggest that TrkB postsynaptically is necessary not only for maintaining the inhibitory postsynaptic density but also for regulating the expression of enzymes involve in the synthesis of GABA.

Title: Apparent receptor kinetics analyses of EPSPs evoked by ipsilateral pericentral canal stimulation in spinal cord motoneurons *in vitro*

Authors: W. QIN, C. ZHENG, B.-A. WANG, *M.-Y. WANG;
Cell Electrophysiol Lab., Wannan Med. Col., Wuhu, Anhui 241002, China

Abstracts: Our previous study has shown that apparent receptor kinetics is suitable to analyze the transmitter-receptor binding kinetics of excitatory postsynaptic potentials (EPSPs) evoked by the ipsilateral ventrolateral funiculus (iVLF) in spinal cord motoneurons (MNs) *in vitro* (*Acta Physiol Sin* 2014, 66: 129). To explore the apparent receptor kinetics properties of synaptic transmission from ipsilateral pericentral canal (iPCC) to MNs, the intracellular recordings were performed in MNs of spinal cord slices isolated from neonatal rats (8-14 days old). Electrical stimulation at threshold intensity (T) of iPCC induced mainly EPSPs (iPCC-EPSPs) in 18 MNs and their apparent receptor kinetics parameters, apparent association and dissociation rate constant (K_1 and K_2) and apparent equilibrium dissociation constant (K_T), were estimated to be 0.790±0.613 $T^{-1}\cdot ms^{-1}$ (Mean±SD), 0.078±0.055 ms^{-1}, 0.249±0.464 T, which were not significantly different from those parameters of iVLF-EPSPs recorded in the same MNs ($P>0.05$). However, as compared to a negative linear correlation of K_2 ($r=-0.972$, $P<0.05$) and K_T (-0.953, $P<0.05$) of iVLF-EPSPs in 5 MNs with the stimulation intensity at 1T-1.3T, K_2 and K_T of iPCC-EPSPs in 6 MNs presented dramatic decrease with stimulation intensity from 1T to 1.1T, and were negatively correlated with the intensity of stimulation at 1.1T-1.5T, with linear correlation coefficients of -0.952 ($P<0.05$) and -0.970 ($P<0.05$), respectively. Although the amplitude and area under curve of iPCC-EPSPs and iVLF-EPSPs were both increased by pretreatment of bicuculline (30 μmol/L) and strychnine (1 μmol/L) each for 15 min in 6 MNs ($P<0.01$ or $P<0.05$), APV (30 μmol/L) and DNQX (1 μmol/L) almost completely nullified iVLF-EPSPs ($P<0.01$ or $P<0.05$) and only partially inhibited iPCC-EPSPs ($P<0.01$). These preliminary results suggest that iPCC-EPSPs may be mediated by more heterogeneous transmitter-receptor

mechanisms in addition to glutamate-NMDA and AMPA receptors than iVLF-EPSPs in spinal cord MNs.

Title: Potentiation of synaptic transmission in mouse neuromuscular junctions by ATP

Authors: ***P. O. BOGATCHEVA**, O. P. BALEZINA;
Moscow State Univ., Moscow, Russian Federation

Abstracts: In neuromuscular junctions ATP is known to be a co-mediator of acetylcholine (ACh). It is released from peripheral motor nerve endings along with ACh and then undergoes fast hydrolysis by ectonucleotidases in synaptic cleft. ATP acts both on its pre- and postsynaptic receptors of P2X and P2Y types and its most well-known effect is autoregulatory decrease of synaptic transmission via metabotropic P2Y receptors. Whether this effect is preserved during prolonged presence of ATP in synaptic cleft is unknown. In this study possible pre- and postsynaptic effects of ATP accumulation in synaptic cleft of neuromuscular junctions due to ectonucleotidases inhibition and tonic application of exogenous ATP were investigated. Data presented were obtained from the fast-twitch extensor digitorum longus muscle of adult mice using standard single microelectrode technique. Spontaneous miniature endplate potentials (MEPPs) and evoked endplate potentials (EPPs) were recorded; amplitude, time course and quantal content were analyzed. In mouse neuromuscular junctions, wide range purine receptor blocker suramin (10 and 100 μM) enhanced quantal content of low frequency (0,3 Hz) EPPs by 19 and 37%, respectively, but did not influence the time course of MEPPs or EPPs. The data obtained corresponds well with the literature showing that the primary effect of endogenous ATP is downregulation of evoked transmitter release. Ectonucleotidase inhibitor ARL 67156 (50 μM) did not alter the amplitude of MEPPs and the quantal content of low frequency EPPs, but significantly prolonged their time course by 25%. During long time high frequency (50 Hz, 1 s) rhythmic nerve stimulation, ARL 67156 caused an increase in the amplitude of EPPs by 33% and

time course of MEPPs and EPPs by 20%. The quantal content of EPPs remained unchanged, suggesting postsynaptic mechanisms of neurotransmission potentiation. Non-hydrolyzable ATP analogue γ-S-ATP (10 μM) significantly increased the amplitude and prolonged the time course of synaptic potentials (both MEPPs and EPPs) by 28% and 25%, respectively. Hence, exogenous non-hydrolyzable ATP analogue shows pronounced postsynaptic potentiating effects in motor synapses. These could be due to increased opening frequency of muscle nicotinic ACh receptors and/or increased input resistance of muscle fibers caused by blockade of chloride leak channels. Based on the data obtained we propose that regulatory effects of ATP on neuromuscular transmission strongly depend on its accumulation level in synaptic cleft which differs with patterns of synaptic activity.

Title: O-GlcNAcylation dampens hyperexcitability in hippocampus during acute epileptoform activity

Authors: L. T. STEWART[1], K. WANG[1], J. C. CHATHAM[2], *L. L. MCMAHON[1];
[1]Dept Cell, Developmental, and Integrative Biol., UAB, BIRMINGHAM, AL; [2]Pathology, Univ. of Alabama at Birmingham, Birmingham, AL

Abstracts: Epilepsy and associated seizure disorders are characterized by the spontaneous induction of hypersynchronous neuronal activity in various circuits in the brain. These periods of increased excitability have detrimental effects on both acute and long-term synaptic function. O-GlcNAcylation is a dynamic posttranslational modification involving O-linked addition of β-N-acetylglucosamine (GlcNAc) to serine/threonine residues on nucleocytoplasmic and membrane proteins. Hippocampal neurons express high levels of OGT and OGA, enzymes that add and remove O-GlcNAc moieties, respectively. Our lab recently reported that acutely increasing O-GlcNAcylation using Thiamet-G (TMG) to block OGA, or glucosamine (GlcN) to provide increased substrate to OGT, induces LTD at CA3-CA1 hippocampal synapses. Here, we

investigated the impact of hyperexcitability on hippocampal basal protein O-GlcNAc levels and tested the hypothesis that increasing O-GlcNAcylation can dampen circuit hyperexcitability using *in vitro* and *in vivo* models of seizure activity. Using acute hippocampal slices from adult rats, hyperexcitability induced via pharmacological blockade of GABAARs with picrotoxin (100 μM) significantly decreased global protein O-GlcNAcylation in area CA1. In pilocarpine treated rats experiencing recurrent seizures 30 days post-injection, basal protein O-GlcNAc levels were also significantly decreased compared to sham. Moreover, in resected human brain tissue from epileptic patients, O-GlcNAc levels were decreased in epileptic tissue compared to marginally resected tissue. Given the findings that hyperexcitability decreases protein O-GlcNAcylation, we next tested whether pharmacologically increasing O-GlcNAc levels could depress hyperexciability. Using hippocampal slice electrophysiology at CA3-CA1 synapses, we found that hyperexcitability induced by picrotoxin could be significantly reduced by increasing O-GlcNAcylation levels in hippocampus using a combination of GlcN and TMG. Finally, EEG recordings were carried out in adult mice to examine the anticonvulsant effects of increasing O-GlcNAcylation using the pentylenetetrazole (PTZ) seizure model. We found a significant reduction in total spike number in mice pretreated with GlcN/TMG compared to vehicle. Collectively these findings suggest that increasing protein O-GlcNAcylation is a viable therapeutic strategy to treat epilepsy and seizure disorders.

Title: Expression of long-term memory after training with inedible food in *Aplysia*: Modification of fast synaptic connections from buccal ganglia mechanoafferents to B4, but not to B31/B32

Authors: *S. TAM[1,2];
[1]BAR ILAN UNIVERSITY, MOSHAV BEIT ARIF, Israel; [2]Gonda Multidisciplinary Brain Res. Ctr., Bar Ilan Univ., Ramat Gan, Israel

Abstracts: Training *Aplysia* with an inedible food causes changes in behavior, which animals remember 24 hours later. Long-term memory is expressed by changes in motor patterning, as

well as by a decrease in time to stop responding to the inedible food. Molecular correlates oflong-term memory have been found in the buccal ganglia, which have primarily a motor function in organizing consummatory feeding behaviors. The molecular changes are expressed in the S1 and S2 mechanoafferent clusters that innervate the interior of the buccal mass. These neurons monosynaptically and polysynaptically contact additional buccal ganglia neurons, including the B31/B32 neurons, which decide on the initiation of a consummatory feeding movement, and the B4/B5 neurons, whose firing biases motor activity toward rejection-like patterns. We examined whether monosynaptic connections from the mechanoafferents to B31/B32 and B4/B5 are changed after training leading to long-term memory. Connections were sampled in buccal ganglia removed from *Aplysia* 24 hrs after 2 training sessions with inedible foods, which were separated by 24 hrs. We found no significant changes in synaptic connections to B31/B32, indicating that the decrease in the likelihood to respond to food when memory is expressed is unlikely to arise from a change in the properties of synapses from mechanoafferents to B31/B32. However, there were significant changes in the synaptic connections from the mechanoafferents to B4.Fast monosynaptic connections from S1 neurons to B4 were increased, whereas fast monosynaptic connections from S2 neurons to B4 were decreased. These findings indicate that plasticity from mechanoafferents to B4 is likely to contribute to the changes in motor activity that are expressed as part of long-term memory. The data suggest that different aspects of memory are expressed at different neural sites, with changes in motor activity being expressed in the buccal ganglia. Changes in the likelihood to respond to food are likely to be expressed elsewhere, perhaps in cerebral ganglion neurons that recruit B31/B32.

Title: Vesicular glutamate transporters at corticothalamic synapses contribute to short-term plasticity and visual attention

Authors: *B. GRANSETH[1], S. H. LINDSTROM[2];
[1]Linkoping Univ., Linkoping, Sweden; [2]Linkoping university, Linkoping, Sweden

Abstracts: Vesicular glutamate transporters (VGluTs) are essential for most excitatory signaling in the central nervous system (CNS), and evidence suggests that the presynaptic function(s) of the VGluTs extend beyond loading glutamate into presynaptic vesicles. Two isoforms are used by glutamatergic synapses, VGluT1 and VGluT2. VGluT1 tends to be expressed at synapses with low release probability (Pr) and short-term facilitation, while VGluT2 expressing synapses tend to have high Pr and short-term depression. Relay cells in the lateral geniculate nucleus (LGN) receive glutamatergic input from two sources. The driving input, from retinal ganglion cells, has been shown to have high Pr and short-term depression. In contrast, modulatory input from the corticothalamic (CT) neurons has low Pr and strong short-term facilitation. Anatomical data suggests that CT neurons express VGluT1 while retinal ganglion cells express VGlut2; however, this dichotomy has not been fully established. In this study we aim to determine how much of the CT input to relay cells is mediated by VGluT1, examine the effect of reduced VGluT1 expression on CT short-term facilitation, and determine if these functional changes are reiterated in a behavioral measure of visual attention. To examine the role of VGluT1 at CT synapses, we performed whole-cell patch-clamp recordings of LGN relay cells in brain slices from wild-type (WT), VGluT1+/-, and VGluT1-/- mice. Visual learning and attention were assessed in WT and VGluT1+/- mice using a paired visual discrimination task and the 5-Choice Serial Reaction Time Task (5CSRTT). Our results showed that relay cells in VGluT1-/- mice lack CT input, while retinal input is largely unchanged. We conclude that CT input uses exclusively VGluT1, while retinal input is primarily mediated by VGluT2. Previous studies with VGluT1+/- mice have demonstrated that VGluT1 protein levels are half that observed in WT mice and this reduced expression alters the distribution of synaptic vesicles. In agreement with this finding, our results suggest that short-term facilitation is reduced at CT synapses in VGluT1+/- mice. Behavioral testing showed that VGluT1+/- mice had no deficit in learning a complex visual discrimination. Thus their ability to process visual information seems intact. However, the 5CSRTT revealed deficits in visual attention and inhibitory control, suggesting that the alterations in CT short-term facilitation produced by reduced VGluT1 expression may be important in these processes.

Title: Compartmentalized calcium microdomains in large mossy fiber terminals gates short-term facilitation at mossy fiber to CA3 pyramidal cell synapses

Authors: *S. CHAMBERLAND[1], A. EVSTRATOVA[2], K. TÓTH[2];
[1]Cell. and Mol. Neurosci., CRULRG, Quebec, QC, Canada; [2]IUSMQ, Quebec, QC, Canada

Abstracts: Presynaptic terminals can be composed of several active zones, each supported by assigned pools of vesicles. The properties of synaptic transmission strongly depend on the location of the calcium sensors in relation to the source of calcium influx in the terminals. Spatial dynamics of calcium in individual presynaptic terminals will dictate the release of vesicles at specific release sites. However, the spatial compartmentalization of calcium signaling and its consequences on short-term synaptic facilitation remain largely unexplored. We performed whole-cell patch-clamp recordings from CA3 pyramidal cells in acute mouse hippocampal slices. Mossy fiber (MF)-mediated EPSCs were evoked by electrical minimal stimulation. The spatial dynamics of calcium elevations in mossy fiber boutons was probed using random-access two-photon microscopy (RAMP) in combination with single granule cell recordings. RAMP calcium imaging in individual large mossy fiber terminals revealed spatially-heterogeneous calcium elevations associated with one action potential evoked at the soma of granule cells in 2.5 mM [Ca2+]. Accordingly, a significant increase in the standard error of calcium elevations recorded simultaneously at multiple sites within the same bouton was observed. In this condition, coefficient of variation analysis suggested that short-term facilitation at MF-CA3 was supported by an increase in the number of release sites (N). Variance-mean analysis showed that a significant increase in N contributes to synaptic transmission in 2.5 mM [Ca2+]. Therefore, the increase in N could be promoted by heterogeneous calcium microdomains observed in single mossy fiber boutons. Two-photon glutamate uncaging confirmed that short-term facilitation was of presynaptic origin. Contrasting with the increase in N observed in 2.5 mM [Ca2+], synchronization of multivesicular release was observed during trains of facilitating EPSCs recorded in 1.2 mM [Ca2+]. Indeed, covariance analysis revealed a gradual augmentation in quantal size (Q) during trains of EPSCs and the low-affinity glutamate receptor antagonist γ-DGG showed an increase in cleft glutamate concentration. The synchronization of multivesicular

release was partially dependent on intracellular calcium stores. Our findings show that the compartmentalized spatial profile of calcium elevations in large mossy fiber gates the recruitment of additional release sites. Thus, synchronization of multivesicular release acts in combination with the recruitment of additional release sites to increase glutamate release during burst activity and expands the dynamic range of mossy fibers information transfer.

Title: Differential synaptically-evoked spiking of two subgroups of NPY interneurons in the stratum radiatum of hippocampal CA1

Authors: *Q. LI, A. F. BARTLEY, L. E. DOBRUNZ;
Neurobio. Dept., Univ. of Alabama At Birimgham, Birmingham, AL

Abstracts: Neuropeptide Y (NPY) is a widely expressed peptide in the brain that has anti-epileptic and anti-anxiety properties. NPY is released by a subset of GABAergic interneurons that also express nitric oxide, enabling these cells to regulate brain circuits through multiple means. It is therefore important to understand the mechanisms that regulate firing of NPY interneurons, including their excitatory inputs. In the CA1 region of hippocampus, NPY interneurons are very abundant, even more so than parvalbumin basket cells. NPY interneurons are widely distributed in stratum radiatum (SR) of CA1, where they could potentially receive feed-forward inputs from Schaffer collateral (SC) or temporoammonic (TA) afferents. However, little is known about synaptically-evoked firing of SR NPY cells in response to feed-forward inputs. In this study, we examined physiological properties, morphology and biochemical

properties of NPY interneurons in the SR of CA1. Our data shows that excitatory inputs from the SC pathway can drive firing of NPY interneurons in SR. SC stimulation onto NPY cells elicits two forms of short-term plasticity: most NPY cells express paired-pulse facilitation (SC-PPF) while a subset has paired-pulse depression (SC-PPD). The SC-PPF cells and SC-PPD cells also show differences in their intrinsic excitability and synaptically evoked spiking. The firing probability of SC-PPF cells increases during high frequency SC stimulation, while that of SC-PPD cells decreases. Both types of NPY cells receive facilitating input from the TA pathway in stratum lacunosum-moleculare (SLM) that also drives spiking, suggesting that the two major inputs to CA1 are both important for NPY cell firing. Morphological reconstruction of NPY cells in SR revealed that SC-PPD cells are more abundant close to the pyramidal layer, whereas SC-PPF cells are evenly distributed across SR. SC-PPD cells have axons primarily in SR, while SC-PPF interneurons also target their axons to SLM. Together, these data suggest that these two subgroups may represent two distinct classes of NPY cells in SR. Two main classifications of NPY interneurons have been previously described: ivy cells located in stratum pyramidale and SR, and neurogliaform cells in SLM. Based on location and morphology, the SC-PPD cells show similarities to ivy cells. Single cell PCR will be used to test whether the SC-PPD and SC-PPF cells correspond to ivy and neurogliaform cells or instead depict new NPY subtypes in SR. Our data indicate that NPY cells in SR are heterogeneous, and that they may be differentially recruited by feed-forward stimulation of the SC pathway, enabling them to have different effects on CA1 circuit function.

Title: *In vivo* analysis of synaptic function in CA3 microcircuits using optogenetics

Authors: ***S. ZUCCA**[1,2], M. GRIGUOLI[2], C. MULLE[2];
[1]Wickens Unit, Okinawa Inst. of Sci. and Technol., Kunigamigun, Japan; [2]Interdisciplinary Inst. for Neuroscience, Univ. of Bordeaux, CNRS UMR 5297, Bordeaux, France

Abstracts: In the hippocampus synaptic transmission between the dentate gyrus and CA3 region is mediated by the axons of granule cells (GCs), the so-called mossy fibers (MFs). MFs to CA3 pyramidal cell (CA3-PCs) synapses are particularly distinctive for their low basal release probability and prominent activity-dependent short-term synaptic plasticity, including pronounced paired-pulse facilitation, and frequency facilitation. The reliability of monosynaptic glutamatergic transmission at MFs-CA3 synapses is highly sensitive to the firing frequency of GCs, and this indicates that MFs synapses are "conditional detonators", making short term plasticity a crucial component for GCs-CA3 spike transfer. Despite a large body of information from computational studies and *in vitro* preparations, the functional consequences of short term plasticity on the operation of CA3 circuits in the intact brain are still elusive. To address this question we used an optogenetic approach *in vivo* to selectively target and control the activity of GCs while performing electrophysiological recordings in anesthetized mice. We injected a Cre-inducible recombinant AAV vector containing a mutated variant of ChR2 (AAV-DIO-ChR2(H134R)-EYFP) in mice expressing Cre-recombinase in POMC neurons in the dentate gyrus of the hippocampus. To test the functionality of ChR2 we first performed whole cell recordings from ChR2+ granule cells in acute brain slices. Brief pulses of blue light (0.5-1 ms; 470 nm) reliably induce action potentials at different frequencies of stimulation (up to 40 Hz), and short term plasticity of excitatory postsynaptic currents in CA3-PCs. To examine the functional properties of MFs-CA3 synapses *in vivo* in the anesthetized mice, we implanted an optical fiber in the dentate gyrus to deliver optical stimulation at 0.05 Hz (1-5 ms, 470 nm) and record fEPSP responses in the CA3 region. Gradual increase of frequency of stimulation over a range of frequencies (1, 3, 10 Hz) produced a clear potentiation of fEPSP slope compared to baseline values. To better understand the impact of frequency facilitation relative to the output of CA3 targets we performed juxta-cellular recordings from CA3 neurons. We found that light stimulation of ChR2+ GCs *in vivo* reliably discharged CA3 interneurons but only rarely discharged CA3-PCs, suggesting that a fine tuning of inhibition/excitation balance may be critical for the transfer of information between GCs to CA3. Further studies at the single cell level will allow us to better characterize the mechanisms of short term facilitation occurring at MFs-CA3 synapses *in vivo* and gain new insights on the role of conditional detonators of MFs in the CA3 network.

Title: PKC is a calcium sensor for short-term synaptic plasticity

Authors: *D. FIORAVANTE[1,2], Y. CHU[2], A. P. H. DE JONG[2], M. LEITGES[3], P. KAESER[2], W. REGEHR[2];

Abstracts: In presynaptic boutons, calcium (Ca^{2+}) triggers both neurotransmitter release and short-term synaptic plasticity. Whereas synaptotagmins are known to mediate vesicle fusion through binding of high local Ca^{2+} to their C2 domains, the proteins that sense smaller global Ca^{2+} increases to produce short-term plasticity have remained elusive. Here we identify a Ca^{2+} sensor for post-tetanic potentiation (PTP), a form of plasticity thought to underlie short-term memory. We find that at the functionally mature calyx of Held synapse the Ca^{2+}-dependent protein kinase C isoforms α and β are necessary for PTP, and expression of PKCβ in PKCαβ double knockout mice rescues PTP. Disruption of Ca^{2+} binding to the PKCβ C2 domain specifically prevents PTP without impairing other PKCβ-dependent forms of synaptic enhancement. We conclude that different C2-domain-containing presynaptic proteins are engaged by different Ca^{2+} signals, and that Ca^{2+} increases evoked by tetanic stimulation are sensed by PKCβ to produce PTP.

Title: The role of presenilin in presynaptic plasticity at hippocampal mossy fiber synapses revealed by an optogenetic approach

Authors: *C. MULLE, J. RUMI, G. BARTHET;
Interdisciplinary Inst. For Neuroscience, Univ. Bordeaux, Bordeaux, France

Abstracts: Presenilin (PS), the catalytic subunit of the intramembrane protease gamma-secretase, cleaves various synaptic proteins including APP and N-cadherin but the role of these processings in synaptic function is not known. Importantly, more than 150 missense mutations have been found on PS1 gene which cause the early-onset form of familial Alzheimer's disease (FAD) and decrease the proteolytic activity of PS. PS regulates presynaptic plasticity by an unknown mechanism. Here we provide new understanding to the role of PS in presynaptic forms of short-term plasticity. We have examined the role of PS1 and PS2 at synapses between dentate gyrus (DG) granule cells and CA3 pyramidal neurons of the hippocampus which are characterized by short-term presynaptic plasticity with a high dynamic range, endowing these synapses with detonator properties essential for information transfer and memory encoding. We have developed new optogenetic tools which specifically target the DG, combining specific expression of a channelrhodopsin with cell-specific genetic manipulation. We have generated a bicistronic lentiviral tool to co-express the variant of channelrhodopsin ChIEF together with a transgene of interest separated by a 2A-peptide specifically targeted to DG cells via the use of a DG specific promoter cloned for the first time. Stereotaxic injection of this virus lead to co-expression of ChIEF and Cre recombinase to knock-down PS1 gene in PS1-floxed mice. We have performed electrophysiological recordings (field EPSP and whole-cell patch clamp) in a slice preparation. Light activation of DG cells triggered synaptic responses in CA3 pyramidal cells which only originated from DG cells lacking PS1. This approach has allowed to characterize the role of PS1 in different forms of presynaptic short term plasticity. We have also shown that PS-dependent control of presynaptic function and plasticity depends on the fragment CTFbeta of APP, a main substrate of gamma-secretase, which accumulates in absence of PS1. This optogenetic approach combined with cell-specific genetic manipulation of presynaptic DG cells offers great potential for understanding the presynaptic mechanisms of action of PS and its consequences in terms of hippocampal circuit acitivity and memory encoding, in the context of Alzheimer's disease.

Title: Characterization of the heterosynaptic interaction of the septal and crossed entorhinal projections to the dentate gyrus after unilateral entorhinal cortex lesion in rats: A time course study

Authors: N. A. UPRIGHT, E. L. KRAUSE, G. R. SMITH, M. K. MOSES-HAMPTON, P. G. LAKHMANI, *J. J. RAMIREZ;
Psychology Dept and Neurosci. Program, Davidson Col., DAVIDSON, NC

Abstracts: Axonal sprouting has been investigated following various forms of damage to the CNS, including Alzheimer's disease, stroke, and traumatic brain injury. Alzheimer's disease is known to involve a marked degeneration of the entorhinal cortex (EC). A significant number of entorhinal projections to the hippocampus terminate in the ipsilateral dentate gyrus (DG); however, a small number of fibers project to the contralateral DG forming the crossed temporodentate (CTD) pathway. Following a unilateral EC lesion in the rat, the glutamatergic CTD and the acetylcholinesterase-containing, cholinergic septal input to the DG, termed the septodentate (SD) pathway, have been shown to undergo axonal sprouting. Lesion-induced, CTD sprouting results in greater synaptic efficacy as early as 6 days postlesion relative to the normal CTD. The present study explored whether, relative to CTD stimulation alone, paired stimulation of the SD pathway followed by CTD stimulation would affect the response of the DG at 6, 8, 12, or 90 days postlesion. Male, Sprague-Dawley rats were given either unilateral entorhinal lesions or sham operations, which consisted of a craniotomy over the entorhinal area. Stimulating electrodes were placed in the medial septum and in the intact, contralateral EC 6, 8, 12, or 90 days after a unilateral entorhinal lesion or sham operation. Evoked, field excitatory postsynaptic potentials (fEPSPs) were recorded in the DG ipsilateral to the lesioned EC. The paired-pulse paradigm involves stimulation of an initial input, termed the "conditioning pulse," followed by a

second input, termed the "test pulse." In the heterosynaptic paired-pulse stimulation portion of this study, SD stimulation preceded CTD stimulation at a range of interpulse intervals (IPIs; from 30 to 500 ms). Relative to control cases, unilateral EC lesions significantly increased the fEPSPs produced by CTD stimulation alone at all the time points we examined. In contrast, compared to CTD stimulation alone, pairing SD with CTD stimulation significantly depressed the amplitude of the fEPSPs across IPIs at 8, 12, and 90 days postlesion. Stimulation of the CTD alone rarely produced granule cell discharge (i.e., population spikes) at the time points we explored; however, paired stimulation of the SD and CTD produced granule cell discharge in a significant number of cases at the 90-day time point with a response profile similar to that observed after paired stimulation of the SD and the perforant path in intact cases. Thus, heterosynaptic stimulation in which the septal input and crossed entorhinal input are paired following entorhinal lesions significantly affects DG responsivity.

Title: Prolonged ketamine exposure increases synaptic plasticity in the anterior cingulate cortex of neonatal rats

Authors: S. KOKANE[1], J. PERISH[1], R. WANG[1], A. WOMACK[1], R. STEVENS[1], X. ZOU[1], *Q. LIN[2];
[1]Psychology, Univ. of Texas at Arlington, Arlington, TX; [2]Psychology, Univ. of Texas At Arlington, Arlington, TX

Abstracts: Prolonged exposure to ketamine, a commonly used pediatric anesthetic, has been reported in animal studies to induce widespread neuroapoptosis in many parts of the neonatal brain. The hippocampus and anterior cingulate cortex (ACC), which are the two main brain areas involved in learning and memory, show maximal neuronal loss due to ketamine exposure. Increasing evidence shows that neuroapoptosis eventually leads to cognitive and memory

deficits. Ketamine is a non-competitive N-methyl D-aspartate receptor (NMDAR) antagonist. One of the molecular mechanisms, by which ketamine induces neurotoxic insult, suggests that a glutamate storm caused by the compensatory up-regulation of NMDARs after ketamine withdrawal results in increased Ca^{2+} influx that triggers downstream pro-apoptotic cascades. We hypothesize that this is mediated by alterations in the synaptic strength. To examine this hypothesis, we performed whole-cell patch-clamp recordings from ACC neurons of neonatal Sprague-Dawley rat brain slices after ketamine withdrawal. Ketamine was administered at postnatal days 4-7 (subcutaneous injections, 20 mg/kg given 6 times at 2 hour intervals). Both evoked and spontaneous postsynaptic current activities mediated by NMDARs were sampled at 2, 4, 6, and 8 h after ketamine withdrawal by recording evoked and miniature excitatory postsynaptic currents (eEPSCs and mEPSCs). We observed that both eEPSCs and mEPSCs were significantly increased beginning at 4 h until 8 h after ketamine withdrawal. This trend of altered current activity was significantly different than that seen in the saline administered group where the current activity remained unchanged at basal levels over the time course. Thus, these data provide strong pathophysiological evidence to indicate that ketamine exposure-induced neurotoxic insult is initiated by increasing enhancement of excitatory synaptic plasticity.

Title: Effect of synaptic activity on the replenishment of resting pool

Authors: ***M. I. GLAVINOVIC**, L. BUI;
Physiol., McGill Univ., Montreal, QC, Canada

Abstracts: The synaptic activity at room temperature renders the replenishment of the readily releasable pool (RRP) slower (Bui & Glavinovic, Cogn. Neurodyn. 7, 105, 2013). Vesicular dynamics of the excitatory synapses of rat hippocampus is thus time dependent. Given that the replenishment rate of the RRP is also Ca++-independent and is largely unaffected by compounds

that speed-up or slow down vesicular trafficking, the replenishment of the RRP does not appear to be associated with a significant vesicular movement (Bui & Glavinovic, Cogn. Neurodyn. 8, 99, 2014). The replenishment dynamics of the resting pool (RP) is far less known and its biophysical mechanism is far less understood. To start with we do not know: a) how large the RP is, b) how fast its replenishment is, whether it changes with synaptic activity and if so how fast, c) whether it is Ca++-dependent, and d) whether vesicular trafficking plays a significant role in its replenishment. We characterize the dynamics of the vesicular storage and release system and its changes during stimulation using model-fitting. Experiments were done on rat hippocampal pyramidal neurons in slices at room temperature using standard whole cell clamp recording, and patterned stimulation of Schaffer collaterals. The optimal values of all parameters of the storage and release system of presynaptic cells were calculated by minimizing the difference between the measured output (the amplitudes of the evoked excitatory post-synaptic currents) and the estimated output (calculated from the estimated parameters). The replenishment of the RP is much slower (>100 times) than that of the RRP. Interestingly, the replenishment coupling into the RP surpasses the replenishment coupling into RRP, but because the RP size is >1000 times that of the RRP, this renders the replenishment of the RP 'only' ~100 times slower than that of the RRP. During prolonged high frequency stimulation the replenishment rate of the RP decreases, and though it is slow, its decrease during stimulation is fast. This study provides much needed information about the replenishment dynamics of the resting pool, and the findings suggest that the replenishment is probably not associated with a significant vesicular movement.

Title: Presynaptic Ca2+ dynamics in the mature calyx of Held synapse with morphological heterogeneity

Authors: *A. FEKETE, L.-Y. WANG;
Program in Neurosci. and Mental Hlth., The Hosp. for Sick Children, Toronto, ON, Canada

Abstracts: The morphology of the mature calyx of Held synapses becomes highly heterogeneous with different levels of segmentation, namely varying number of stems, stalks and swellings. The morphological variability at maturity strongly correlates with the differences in quantal parameters, forms of STP and fidelity of spiking (Grande and Wang, 2011). In this study, we have examined Ca2+ dynamics in different types of mature calyces and distinct compartments of the same calyx (P16-23). We applied two-photon laser scanning microscopy of high- and low-affinity Ca2+-indicators (50 μM Fluo-4 / Fluo-4FF) and the morphological tracer Alexa 594 (15-30 μM). Action potentials are evoked by stimulating axons either with a bipolar electrode after removing the loading pipette or directly by a patch electrode in current-clamp mode. We delivered trains of APs with different frequencies (2x100/200/300 Hz, Δt=500 ms) or single APs to determine the spatiotemporal profile of Ca2+ transients mediated solely by P/Q-type Ca2+ channels in the presynaptic terminal in slices from both WT and Cacna1aCitrine knock-in mice (citrine-tagged α1A subunit encoding P/Q-Ca2+ channel). We found Ca2+ transients in every morphological subtype of the calyces and throughout the entire calyceal arborization including the swellings, stems and stalks. The size of the Ca2+ transients varied with the size of the compartment, being the most robust in the smallest compartments (swellings). Application of potassium channel blocker (TEA,1 mM) increased the Ca2+ transients in the different calyx subtypes and compartments, suggesting that APs can successfully propagate into distinct compartments and recruit increasing number of calcium channels to boost Ca2+ transients. Our data implicate the heterogeneity of presynaptic Ca2+ transients as a mechanistic link underpinning different quantal properties and short-term synaptic plasticity at the mature calyx of Held synapses with distinct morphological complexity.

Title: The NMDA receptor-mediated spontaneous EPSCs are sensitive to constitutively- active ghrelin receptors in the hippocampus

Authors: *M. ISOKAWA;
Dept. of Biomedicine, Univ. Texas-Brownsville, BROWNSVILLE, TX

Abstracts: Increasing evidence points a stomach hormone, ghrelin, may have numerous physiological functions in the brain in addition to its primary role in stimulating hypothalamic orexigenic neurons. Intra-hippocampal ghrelin improved memory retention, increased dendritic spines, and facilitated spine synapse formation, suggesting that ghrelin appears to modulate molecular and cellular signaling events involved in memory acquisition and consolidation. The ghrelin receptor, GHSR1a, is expressed highly in the hippocampus, which further supports the involvement of ghrelin signaling in synaptic transmission and plasticity in the hippocampus. We previously reported that a low concentration of ghrelin (25-100 nM) enhanced the NMDA receptor-mediated EPSCs (NMDAR-EPSCs) in the CA1 pyramidal cells that were isolated with a whole-cell patch electrode containing Cs methanesulfonate in the bath-presence of picrotoxin ($GABA_A$ receptor antagonist) and NBQX (AMPA receptor antagonist). Involvement of GHSR1a was characterized using the receptor antagonists L-Dys3-GHSR-6 (1 microM) and Substance-P analogue (1 microM), which negated the effect of ghrelin in a reversible manner. GHSR1a displays a high degree of ligand-independent signaling activity. In the present study, we tested if constitutive activation of GHSR1a was involved in the NMDA receptor-mediated synaptic transmission in the hippocampus. In the absence of exogenous ghrelin in the hippocampal slice culture, we found that the antagonist of GHSR1a reduced the peak amplitude of NMDAR-EPSCs suggesting that constitutively-active GHSR1a may determine the magnitude of the NMDAR-mediated synaptic transmission. In addition, the amplitude of spontaneously occurring EPSCs (sEPSCs mediated by the NMDAR), in particular, those with the amplitude greater than 100 pA were sensitive to the application of GHSR1a antagonists. The generation of NMDA spikes, which are spontaneously-generated local electrical signals at dendritic branches where NMDA receptors are highly localized, was also reduced by the GHSR1a antagonists. These findings suggest that hippocampal CA1 pyramidal neurons are likely to be under constant modulation by GHSR1a signaling in synaptic activities, and this modulation occurs, to some extent, independent of the availability of the endogenous ligand. Title: Differences in short-term modulation of excitatory synaptic responses in stratum radiatum and stratum lacunosum moleculare in mouse hippocampus

Authors: D. PEKALA, *M. RAASTAD;
Dept Physiol, Emory Univ. Sch. of Med., Atlanta, GA

Abstracts: We investigated short-term modulation of synaptic strength in two layers of the CA1 field of hippocampi from 8-9 weeks old mice. We used four stimuli with 25 ms intervals and an additional stimulus with 100 ms interval, giving synaptic peak amplitudes A1 - A5. Experiments were made with 300 um transverse slices, 36 °C, standard Ringer's solution with 2 mM Ca2+. APV (50 uM) was added to reduce postsynaptic modulation of synaptic strength. When the five-pulse trains were repeated once a minute facilitation (A2/A1) was larger in str. lacunosum moleculare (SLM, 2.22 ± 0.13%) than in str. radiatum (SR, 1.52 ± 0.04%). When the test-trains were repeated at higher rate (1 Hz) A1 increased and approached A2, i.e facilitation was reduced, to 0.92 ± 0.03 and 1.12 ± 0.02 in SLM and SR respectively. A1 increased relatively similarly in SLM and SR during these 1 Hz repetitions to 243 ± 0.22% and 209 ± 18% in SR and SLM, respectively. However, a striking difference between SLM and SR appeared in the change of the other synaptic amplitudes in the five-pulse train (A2 - A5): A2 - A5 were slightly reduced in SLM (to 87 ± 3%) but increased in SR (to 136 ± 9%) of their original value. By subtracting from A1 these changes, that seemed to be general to all the five synaptic responses in the train, even larger differences in the change of A1 were detected: A1 in SR grew to 173 ± 0.09% while A1 in SLM grew to 274 ± 0.19% of their original amplitudes. These differences between short-term changes in synaptic responses in SLM and SR are likely to reflect different mechanisms for control of transmitter release. Blockers of GABAa receptors did not eliminate the difference between SR and SLM synaptic responses, but other modulating receptors are not ruled out.

Title: Mechanism of metabotropic glutamate receptor 5-dependent long-term depression induced by cathodal direct-current stimulation in mouse primary motor cortex

Authors: *Y. SUN[1,2], J. LIPTON[1,3], M. SAHIN[1], A. ROTENBERG[1];
[1]Dept. of Neurol. and the F.M. Kirby Neurobio. Ctr., Boston Children's Hosp., Boston, MA;
[2]Program in Neurosci., [3]Div. of Sleep Med., Harvard Med. Sch., Boston, MA

Abstracts: Transcranial direct-current stimulation (tDCS) is a method for focal noninvasive cortical stimulation where low-amplitude direct current is conducted to the brain via scalp electrodes. Extensive data indicate that anodal tDCS leads to enhanced cortical excitation and cathodal tDCS leads to depressed cortical excitation, similar to long-term potentiation (LTP) and long-term depression (LTD), respectively. However, the mechanisms underlying the tDCS effect are poorly understood. A recent study reported that anodal tDCS induced brain-derived neurotrophic factor (BDNF)-dependent LTP in mouse primary motor cortex (M1) and improves BDNF-dependent motor skill learning in humans. In the present study, we tested whether and to what extent a range of DCS settings modulates cortical field excitatory postsynaptic potential. We demonstrate that cathodal DCS applied to mouse M1 slices induced a LTD (DCS-LTD), which depends on the intensity, duration, and relative orientation of the DC current vector and the vector of the neuronal structures. Partial attenuation of the magnitude of DCS-LTD was observed by applying the antagonists of NMDA (D-2-amino-5-phosphonopentanoate, D-AP5) and $GABA_A$ receptors ([R-(*R**,*S**)]-6-(5,6,7,8-Tetrahydro-6-methyl-1,3-dioxolo[4,5-*g*]isoquinolin-5-yl)furo[3,4-*e*]-1,3benzodioxol-8(6*H*)-one, Bicuculline). However, bath application of 2-chloro-4-((2,5-dimethyl-1-(4-(trifluoromethoxy)phenyl)-1H-imidazol-4yl)ethynyl)pyridine (CTEP), a potent inhibitor of mGluR5, blocked the DCS-LTD. Meanwhile, the positive allosteric modulator of mGluR5, 3-cyano-N-(1,3-diphenyl-1H-pyrazol-5-yl)benzamide (CDPPB) enhanced the transient effect by short DCS application which otherwise did not lead to a durable depression of M1 excitability. Given that mGluR-dependent LTD requires mTOR pathway-dependent translation of dendritic mRNA, we queried the expression ratio of phosphorylated ribosomal protein S6 (S6)/total S6 (P-S6/S6) as a gauge of relative mTOR pathway activity in M1 slices during DCS-LTD. We observed a significant increase in P-S6/S6 ratio in stimulated compared to unstimulated controls. Our findings suggest that mGluR5 activation is critical for the DCS-LTD and mTOR pathway activation is involved during this after-effect in M1 slices. We will further investigate the signaling pathways that couple mGluR5 activation to translation initiation pathways (such as mTOR signaling) during DCS-LTD. Our study may implicate cathodal DCS as a potential treatment of neurologic conditions in which mGluR5 signaling and/or mGluR-mediated synaptic plasticity are impaired, such as tuberous sclerosis complex.

Title: The roles of IP_3R in LTD induction in visual cortex

Authors: ***D. KALIKULOV**, M. J. FRIEDLANDER;
Virginia Tech. Carilion Res. Inst., Roanoke, VA

Abstracts: We evaluated the contributions of inositol trisphosphate receptors (IP_3R) to the induction of long-term synaptic depression (LTD) in layer 2/3 pyramidal neurons in guinea pig (ages P6-P12) visual cortex in response to three induction paradigms: i) low frequency afferent stimulation (LFS), ii) bath application of (S)-3,5-Dihydroxypenylglycine hydrate (DHPG - agonist of mGluR), and iii) pairing of presynaptic activity induced by stimulation of afferent fibers and postsynaptic spiking activity induced by current injection into the postsynaptic neuron at a fixed temporal delay. In the LFS group, a net LTD was induced (-16±4%; n=17), while individual cells either underwent statistically significant LTD or no significant change (NC). Inhibition of IP_3Rs with xestospongin C (1.0μM, -17±6%, n=11) in the LFS group did not alter the likelihood or magnitude of LTD, while inhibition of NMDARs with bath applied D-AP5 (DL-2-Amino-5-phosphonopentanoic acid) prevented the induction of LFS induced LTD (50 μM d-AP5; +0.3±3%; n=14). Bath application of the mGluR agonist DHPG (100 uM) also resulted in a net LTD (-24±5%; n=6). In contrast to the LFS group, inhibition of IP_3Rs with xestospongin C (1.0μM) reduced the magnitude of LTD induced (from -24%± 5%; n=6 to -11±5%; n=4). Pre-postsynaptic pairing resulted in a range of plasticity outcomes at the individual cell level from LTD to NC to LTP with a net LTP (+9±5%; n=30). Inhibition of IP_3Rs (1.0μM xestospongin C) in the pre- postsynaptic pairing group resulted in a significant change in the plasticity outcome ($p \leq 0.05$; t-test) with a net LTP (+31±9%, n=25) with individual cells undergoing only LTP or NC and no cells in this group undergoing LTD. These findings demonstrate that IP_3R activation is not necessary for LFS induced LTD, while both chemically and pairing induced LTD require IP_3R activation.

Title: Chemical LTD mediated changes in synaptic AMPA receptors is associated to changes in postsynaptic density scaffold proteins

Authors: *J. RODRIGUEZ-ALVAREZ[1], W. CHEN[2], D. SIEDLECKI[2], V. JIMENEZ[2], A. OTXOA DE AMEZAGA[2], C. A. SAURA[2], A. J. MINANO-MOLINA[2];
[1]Inst. De Neurociencies/ UAB, Barcelona, Spain; [2]Inst. de Neurociencies and Dpt. Bioquímica i Biología Molecular, Univ. Autònoma de Barcelona, Cerdanyola del Vallès, Spain

Abstracts: Excitatory synaptic transmission is tightly regulated by total number and activation of AMPA receptors (AMPAR) present at the synapse. Synaptic AMPARs localization is closely related with NMDA receptor (NMDAR) activity. Current evidences suggests that AMPARs are inserted into the postsynaptic membrane during LTP and could be removed from the membrane during LTD. Dephosphorylation of GluA1 at Ser845 and enhanced endocytosis could be critical events in the modulation of LTD. Moreover, changes in scaffold proteins from the postsynaptic density (PSD) could be also related to AMPAR regulation in LTD. In the present study we have analyzed the effect of chemical LTD (cLTD) on AMPAR and AKAP150 levels in cultured cortical neurons. cLTD reduces surface expression of GluA1 and GluA2 AMPAR subunits and GluA1 phosphorylation at Ser845. Moreover cLTD induces concomitant changes in AKAP79/150 and PSD95 protein levels that are dependent on calcineurin (CaN) and proteosome activation since pharmacological inhibition of CaN or proteosome activity revert cLTD-mediated changes in AKAP79/150 and PSD95. Since PSD95 and AKAP79/150 are synaptic proteins that has been proposed to function as a signaling scaffold that regulates phosphorylation, channel

activity, and endosomal trafficking of AMPAR, the cLTD-mediated changes in these proteins could be related to a deregulation of synaptic AMPA receptors in LTD.

Title: The BDNF pro-peptide is a novel facilitator of hippocampal LTD, and its biological action is altered by the common BDNF polymorphism Val66Met

(AIST), Ikeda, Osaka, Japan; [6]Lab. of Functional Neuroscience, Nara Inst. of Sci. and Technol. (NAIST), Ikoma, Nara, Japan

Abstracts: Most growth factors are initially synthesized as precursors and subsequently processed into their mature form by proteolytic cleavage, resulting in removal of a pro-peptide. These events take place in the secretory pathway and in extracellular spaces. The biological roles of pro-peptides are not as well understood as those of the mature forms. Given that mature and pro-peptide forms are produced simultaneously, pro-peptides may physiologically serve important functions. In this study, we aimed to elucidate the biological roles of the pro-peptide of brain-derived neurotrophic factor (BDNF). Mature BDNF promotes neuronal growth of developing neurons, and also modulates synaptic plasticity in the adult brain. Here, we demonstrate that the BDNF pro-peptide directly facilitates hippocampal long-term depression (LTD) in a manner that requires the activation of N-methyl-D-aspartate (NMDA) receptor

subunit 2 (NR2B)-containing NMDARs and p75NTR activity. Moreover, NMDA-induced alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor endocytosis is enhanced by the BDNF pro-peptide, and this mechanism of AMPA receptor (AMPAR) trafficking is elicited by the pro-peptide itself. Thus, the BDNF pro-peptide, a previously functionally unknown ligand, is involved in synaptic plasticity that controls a mechanism responsible for promoting LTD. In a common polymorphism in the BDNF gene, Val66Met, methionine replaces valine at position 66 of the BDNF pro-domain and it was reported that this BDNF polymorphism affects human memory function. This genetic variant affects the biological activity of the BDNF pro-peptide. In contrast to the wild-type pro-peptide, the Met-BDNF pro-peptide markedly inhibits LTD and NMDA-induced AMPAR trafficking. Moreover, the binding of the mutant pro-peptide to p75NTR is much weaker than that of the wild-type. Thus, the Val66Met polymorphism has a functional impact on the BDNF pro-peptide. Finally, we show that the BDNF pro-peptide can bind mature BDNF but not other neurotrophins, and that this heterodimer complex is stabilized by the amino-acid substitution in the Val66Met variant. Our findings thus provide new insight into the effects of a naturally occurred human BDNF polymorphism, Val66Met.

Title: Distinct roles of neurabin and spinophilin in the targeting and regulation of protein phosphatase 1 in AMPA receptor trafficking and LTD induction

Authors: *H. YANG, V, J. GAO, X. HU, H. XIA;
Neurosci., LSU Hlth. Sci. Ctr., New Orleans, LA

Abstracts: Protein phosphatase-1 (PP1) plays an important role in the induction threshold of long term potentiation (LTP) and depression (LTD) which contributes to PP1's constraint role in learning and memory. PP1's promoting function in LTD induction requires both PP1's enzymatic activity and its proper anchoring to synaptic spines. We have shown previously that neurabin, a major synaptic scaffolding protein, targets PP1 to synapses for LTD induction. We now discovered that PP1 targeted by spinophilin, a close homologue of neurabin and another major synaptic PP1 anchoring protein, does not play a role in LTD induction, suggesting the privileged role of neurabin in nano-domain targeting of PP1 in spines for LTD induction. Moreover, we found that protein kinase A (PKA) can significantly weaken neurabin-PP1 interaction in neurons, via phosphorylation of neurabin at serine 461, a phosphorylation site which is immediately adjacent to PP1 binding motif and not conserved in spinophilin. Finally, we found that expression of neurabin phosphorylation mimicking mutant, neurabin (S461E), blocked AMPA receptor endocytosis and LTD induction. Our study thus elucidated the critical importance of nano-domain targeting of PP1 within synaptic spines and its regulation in LTD induction.

Title: Control of hippocampal to medial prefrontal cortex signalling by long-term depression of NMDA receptor mediated transmission

Authors: ***P. J. BANKS**, A. BURROUGHS, Z. I. BASHIR;
Physiol. & Pharmacol., Univ. of Bristol, Bristol, United Kingdom

Abstracts: The hippocampus is connected to the medial prefrontal cortex (mPFC) by a long-range monosynaptic glutamatergic projection which is known to undergo activity-dependent modification. This connection has been shown to be involved in numerous cognitive processes including learning and memory. It has been shown in mouse that this synaptic connection can be studied in modified coronal mPFC slices *in vitro* using conventional electrophysiological means.

Here we demonstrate that this slice preparation is possible in rat brain and study plasticity of this synapse, focussing on NMDAR mediated transmission. We show that activation of G-protein coupled receptors induces long-term depression (LTD) of pharmacologically isolated NMDAR-mediated transmission in the hippocampal-prefrontal pathway: bath application of D2-like dopamine receptor agonist quinpirole potently reduces NMDAR transmission for at least 1 hour. Similar effects were observed following application of DHPG, carbachol and mAChR1 agonist AF102B. Interestingly, we discovered that delivery of 300 stimuli at 5 Hz induces LTD selectively of NMDAR-, but not of AMPAR-mediated transmission. However, this activity-dependent LTD was not blocked by antagonists of muscarinic or mGlu receptors or by inhibition of NMDA receptors during the 5 Hz stimulation (by hyperpolarisation to -100 mV or by temporary wash in of AP5). Given the prominent role of dopamine in synaptic plasticity and learning and memory in mPFC we then investigated whether this transmitter may be involved in activity-dependent NMDAR-LTD. Interestingly we show that the antagonism of D2-like receptors, but not D1-like receptors, blocked induction of LTD. NMDARs have been shown to play a highly significant role in the temporal summation of short bursts of synaptic stimuli. We demonstrate that this is also the case in the hippocampal-mPFC connection: NMDAR attenuation by bath application of AP5 or induction of NMDAR-LTD considerably reduced temporal summation of synaptic stimuli in a frequency-dependent manner, reducing or abolishing spiking in those cells which had previously fired action potentials. These results demonstrate that dopamine-dependent plasticity of NMDA receptors can profoundly alter input-output characteristics of hippocampal to prefrontal transmission - this may be important for learning and memory and other cognitive processes such as working memory in which this synapse is involved.

Title: A myosin va mouse mutation acting as a dominant negative disrupts glutamate scaffolding in the hippocampus and abnormal behavior

Authors: *S. PANDIAN, Y. MURATA, J.-P. ZHAO, M. CONSTANTINE-PATON;
McGovern Inst. for Brain Res., MIT, Cambridge, MA

Abstracts: MyosinVa (MyoVA), a vesicular cargo-binding actin motor, is abundant in vertebrates and critical for survival. Elimination of *myo5a* causes early death in mice. Human *myo5a* mutations cause neurological dysfunction, mental retardation and hypomelanation and death in infancy or childhood (Griscelli et al., 1978 and Elejalde et al., 1979). The mouse line Flailer (Flr) expresses, only in brain, a truncated cargo-binding domain of MyoVA. When present in a 1:1 ratio *flr* and *myo5a* genes, cause early seizures, mild ataxia, (Jones et al., 2000) and, in visual neurons (Yoshii et al., 2013), defective long-term synaptic depression (LTD). We now show defective LTD in hippocampal CA1, reductions in hippocampal synaptosome proteins necessary for scaffolding glutamate receptors, and abnormal pup vocalizations and, as adults, repetitive grooming, anxiety, asocial, and defective memory behaviors. Thus, Flr is similar to Tsc1 and PTEN mouse mutants, where LTD loss has been associated with similar neuropsychiatric disorders (Bateup et al., 2011 Takeuchi et al., 2013). However, *flr* is an additional gene whose site-specific removal may identify specific pathways involved in abnormal behaviors in mice, and perhaps, in humans as well.

Title: How plasticity of inhibitory transmission in area CA2 modulates CA1 activity

Authors: *K. NASRALLAH, R. A. PISKOROWSKI, V. CHEVALEYRE;
CNRS UMR8118, Paris, France

Abstracts: The hippocampus is a region of critical importance for memory formation and learning. For decades, studies have focused on a linear model of information transfer to explain hippocampal function: the classical trisynaptic pathway which successively recruits the

enthorinal cortex (EC), the dentate gyrus (DG), CA3 pyramidal neurons (PNs) and CA1 PNs. However, this trisynaptic cortico-hippocampal loop in which area CA2 is excluded is not sufficient to explain hippocampal function. Furthermore, very recent studies have revealed a role of CA2 area in certain forms of memory. However, the understanding of CA2 function is just emerging. CA2 PNs are connected by CA3 input, and like CA3 PNs, they project to area CA1. In area CA2, a strong feed-forward inhibition (FFI) controls the Schaffer collateral (SC) synaptic drive onto CA2 PNs and prevents their activation by CA3 PNs. Furthermore, inhibitory transmission from parvalbumin-positive interneurons onto CA2 PNs expresses a delta-opioid-mediated long-term depression (I-LTD). Therefore, we examined whether I-LTD in area CA2 can increase the SC synaptic drive onto CA2 PNs and permit the recruitment of CA2 PNs by CA3 PNs. Our results show that the inhibitory synapses that express the delta-opioid-mediated I-LTD participate to the control of the SC synaptic drive onto CA2 PNs. This I-LTD allows a long-lasting increase in the SC synaptic drive onto CA2 PNs which is sufficient to allow CA2 PNs to fire action potentials in response to CA3 inputs activation, even though synaptic transmission at the SC-CA2 excitatory synapses do not express long-term potentiation. Because area CA1 is connected by both CA2 and CA3, we examine how the SC synaptic drive onto CA1 PNs could be changed by the recruitment of CA2 PNs by CA3 PNs after induction of I-LTD in area CA2. By combining pharmacology, optogenetics and electrophysiology, we show how the delta-opioid-mediated I-LTD in area CA2 directly contributes to CA1 activity.

Title: Bidirectional structural changes driven by protein synthesis-dependent activity at individual spines

Authors: ***Y. RAMIRO**, I. ISRAELY;
Champalimaud Neurosci. Programme, Champalimaud Ctr. For the Unknown, Lisbon, Portugal

Abstracts: Dendritic spines are highly dynamic structures whose morphology and lifespan are modified as a response to synaptic efficacy changes. Structural modifications in response to different forms of activity may underlie the long term encoding of information within neural circuits. Long lasting changes in synaptic efficacy require new protein synthesis, and during synaptic potentiation, lead to long lasting growth of spines. Synaptic tagging and capture between individual inputs allows for the cooperative expression of long lasting plasticity and growth, by sharing new proteins. However, when multiple spines are stimulated closely together in time, they compete for the expression of plasticity, and individual spines oscillate between growth and shrinkage. While the relationship between spine volume and current amplitude are directly correlated, little is known about whether this spine shrinkage represents a true decrease in synaptic efficacy. Here, we determine what are the structural correlates of synaptic depression when new proteins are available. LTD that is mediated by metabotropic glutamate receptors, mGluR-LTD, is known to be long lasting and requires new protein synthesis. We showed that the global induction of mGluR-LTD induces robust shrinkage and elimination of spines, requires new protein synthesis and synaptic activity, occurs at spines of various sizes, and lasts for up to 24 hours. However, it is unknown whether this form of depression can occur at individual synapses, and if there are structural correlates. Using 2-photon imaging and glutamate uncaging in hippocampal neurons, we induce mGluR-LTD at individual inputs, and examine the functional and structural consequences. We test if depression induced at multiple spines within a domain leads to competition that depends on protein availability. Finally, we see how different forms of plasticity interact between spines, to determine the learning rules for bidirectional changes in structure and function. We extend these findings by the use of mouse genetics to manipulate signaling pathways, such as mGluR5 KOs, or levels of available proteins, such as in Fragile X models. Thus, we hope to gain an understanding of how activity can effect long lasting structural remodeling of neural circuits.

Title: Role of microtubule-dependent transport in synaptic plasticity

Authors: *A. LARIO[1], J. D. PETERESEN[2,3], D. CHOQUET[2,3], J. A. ESTEBAN[1];
[1]Ctr. De Biología Mol. Severo Ochoa. CSIC - UAM, Madrid, Spain; [2]Univ. Bordeaux, Inst. Interdisciplinaire de Neurosciences, UMR 5297, F-33000, Bordeaux, France; [3]CNRS, Inst. Interdisciplinaire de Neurosciences, UMR 5297, F-33000, Bordeaux, France

Abstracts: The majority of excitatory synapses are located at dendritic spines. Consequently, these are considered key compartments where the machinery for synaptic plasticity will operate. During synaptic plasticity expression, spines alter their morphology and structure, and neurotransmitter receptor trafficking events take place. These phenomena have been related to actin cytoskeleton changes, but recently, microtubules (MT) have been shown to enter the spine in an activity-dependent manner. Therefore, in this study we have evaluated the relevance of the MTcytoskeleton during specific forms of synaptic plasticity. Specifically, we have investigated whether molecular transport along MT participates in neurotransmitter receptor trafficking associated to synaptic plasticity. To address this question, we carried out a series of electrophysiological, molecular and imaging experiments on CA1 excitatory synapses from hippocampal slices. We will present our recent findings suggesting that there is a bidirectional influence between synaptic plasticity and MT dynamics. More precisely, we found that NMDA-receptor dependent LTD is decreased when MT associated transport is impaired. In conclusion, this work pretends to shed some light into the interplay between cytoskeletal elements and the regulation of synaptic strength.

Title: Rab11Fip5, a Rab11 adaptor, is selectively required for hippocampal LTD

Authors: *T. BACAJ[1], M. AHMAD[4,2], S. JURADO[5,2], R. C. MALENKA[2], T. C. SUDHOF[3]; [1]Mol. and Cell. Physiol., [2]Dept. of Psychiatry and Behavioral Sci., [3]HHMI & Mol. and Cell. Physiol., Stanford Univ., Stanford, CA; [4]Dept. of Cell Biol., Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK; [5]Dept. of Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstracts: Postsynaptic AMPA-type glutamate receptors (AMPARs) are among the major determinants of synaptic strength, and can be trafficked into and out of synapses. Neuronal activity regulates AMPAR trafficking during synaptic plasticity to induce long-term changes in synaptic strength, including long-term potentiation (LTP) and long-term depression (LTD). Rab family GTPases regulate most membrane trafficking in eukaryotic cells and, particularly, Rab11 and its effectors are implicated in mediating postsynaptic AMPAR insertion during LTP. To explore the synaptic function of Rab11Fip5, a major neuronal Rab11 effector and a candidate autism-spectrum disorder gene, we performed shRNA-mediated knock-down and genetic knock-out (KO) studies. Surprisingly, we observed robust shRNA-induced synaptic phenotypes that were rescued by a Rab11Fip5 cDNA, but that were nevertheless not observed in conditional KO neurons. Both in cultured neurons and acute slices, KO of Rab11Fip5 had no significant effect on basic parameters of synaptic transmission, indicating that Rab11Fip5 is not required for fundamental synaptic operations such as neurotransmitter release or postsynaptic AMPAR insertion. KO of Rab11Fip5 did, however, abolish hippocampal LTD as measured both in acute slices or using a chemical LTD protocol in cultured neurons, but did not affect hippocampal LTP. The Rab11Fip5 KO mice performed normally in several behavioral tasks, including fear conditioning, but showed enhanced contextual fear extinction. These are the first findings to suggest a requirement for Rab11Fip5, and presumably Rab11, during LTD.

Title: Effects of BRAG1 X-Linked Intellectual Disability mutations on synaptic function

Authors: *A. N. PETERSEN, J. C. BROWN, N. Z. GERGES;
Cell Biology, Neurobio. & Anat., Med. Col. of Wisconsin, Milwaukee, WI

Abstracts: Brefeldin-A-Resistant Arf-GEF 1 (BRAG1) is a post-synaptic protein with a critical role in regulating synaptic transmission and plasticity. BRAG1 is involved in the insertion of recycling GluA2-containing α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPARs) as well as the activity-dependent removal of AMPARs underlying long-term depression (LTD). Mutations of BRAG1 have been identified which result in X-linked Intellectual Disability (XLID). Several of these mutations (R758Q, Q801P, and R863W) are located within the Sec7 domain, which is responsible for BRAG1's guanine nucleotide exchange factor (GEF) activity. An additional mutation (R359C) is found in the IQ motif, a calmodulin binding site. Mutations of both the Sec7 and IQ regions have been shown to reduce the GEF activity of BRAG1, which was found to be required for LTD. However, the effect of these mutations on synaptic function is unknown. In this study we have expressed mutations of BRAG1 in CA1 pyramidal neurons to determine their effects on synaptic transmission and plasticity. We find that the XLID-causing mutations disrupt synaptic function and differentially impact the roles of BRAG1 in AMPAR regulation.

Title: Calcium threshold shift enables frequency-independent control of plasticity by an instructive signal

Authors: *H. TITLEY[1], C. PIOCHON[1], Y. ELGERSMA[2], C. HANSEL[1];
[1]Dept. of Neurobio., Univ. of Chicago, Chicago, IL; [2]Dept. of Neurosci., Erasmus Med. Ctr., Rotterdam, Netherlands

Abstracts: At glutamatergic synapses both long-term potentiation (LTP) and depression (LTD) can be induced at the same synaptic activation frequency, under control of instructive signals that modulate local calcium transients. Synapses maintain the ability to potentiate or depress over a wide frequency range, but it remains unknown how threshold-controlled synaptic plasticity operates when variations of frequency alone cause differences in calcium transient profiles. We addressed this problem at cerebellar parallel fiber - Purkinje cell synapses, which can undergo LTD or LTP in response to 1Hz- as well as 100Hz-stimulation. High-frequency stimulation elicits dramatically larger spine calcium transients than low-frequency stimulation but, regardless of activation frequency, climbing fiber co-activation provides an instructive signal that further enhances calcium transients and promotes LTD. This frequency-independence of the instructive signal requires a threshold shift that results from inhibitory autophosphorylation of calcium/calmodulin-dependent kinase II (CaMKII) at Thr305/306, enabling plasticity control based on relative, not absolute, calcium thresholds.

Title: Co-regulation of synaptic plasticity, learning and memory in the mouse hippocampus by D2 dopamine receptor and dopamine transporter

Authors: *J. ROCCHETTI, C. FASANO, E. GUMA, G. DAL BO, E. ISINGRINI, S. EL MESTIKAWY, T. WONG, B. GIROS;
Neurosci., Douglas Res. Ctr., Verdun, QC, Canada

Abstracts: Converging evidences link a dysfunction in mesocorticolimbic dopamine (DA) signaling in cognitive processes to the pathophysiology of mental disorders like schizophrenia. Endogenous levels of DA modulate synaptic plasticity and memory in the rodent hippocampus (HP) but the function of the mesohippocampal DA pathway is not fully understood. We reported that genetic deletion of DA D2 receptors (D2R) or D2R blockade by antipsychotics in the mouse HP induce profound impairments in learning and memory and long-term depression (LTD) in CA1 due to a lack of presynaptic D2R activity (Rocchetti et al, Biol. Psychiatry, 2014, PMID: 24742619). However, antipsychotics action on positive symptoms of schizophrenic individuals is based on the hypothesis that the DA system and D2R are overactivated. A clarification of the antipsychotic effects in mouse models with preexisting DA hyperactivity in the HP is therefore needed. In DAT KO mice, a model of persistent endogenous hyperdopaminergia, LTD is absent in CA1 and mice exhibit impaired behavioral flexibility in the Morris watermaze (MWM). Both deficits are rescued by the antipsychotic haloperidol. To precise the impact of endogenous DA elevation on HP synaptic plasticity, we studied the effect of GBR12935, a DAT blocker on CA1 long-term potentiation (LTP) and LTD *in vitro* in C57BL/6J mice. Recordings in temporal CA1 in presence of GBR (30nM) resulted in no change of LTP. However GBR application blocked LTD expression. Co-application of GBR and sulpiride conversely rescued significant LTD. To assess the behavioral consequences of acute and subchronic elevation of endogenous DA in the HP, we implanted bilateral canulae in the temporal CA1 subfield of naïve mice and tested their memory abilities in the MWM and recognition tasks following chronic injections of GBR. Daily infusion before training resulted in a deficit at the learning phase in the spatial MWM. However, treated mice remembered the platform location during the probe. Mice treated with GBR also exhibited a clear deficit in the novel object recognition test (NORT) and the object novel place preference test (ONPP) after 2 weeks of infusion, but not after acute injection. We are now attempting to rescue recognition memory in the GBR chronically infused animals with an antipsychotic treatment. Altogether, this ongoing study enforces the belief that a modulation of both DAT and D2R activities trigger homeostatic DA changes in the mouse HP function. It could also provide some explanations for reported discordant findings concerning the role of DA in learning and memory and adds new dimensions to this neurotransmitter's involvement in the pathophysiology of mental disorders.

Title: Neurotensin induces presynaptic, calcineurin-dependent LTD of dopamine D2 autoreceptor-mediated neurotransmission in midbrain dopamine neurons

Authors: *E. PICCART[1], N. A. COURTNEY[2], C. P. FORD[2], M. J. BECKSTEAD[1]; [1]UTHSCSA, San Antonio, TX; [2]Dept. of Physiol. and Biophysics, Case Western Reserve Univ. Sch. of Med., Cleveland, OH

Abstracts: Increased dopaminergic signaling is a hallmark of severe mesencephalic pathologies, including schizophrenia and psychostimulant abuse. Application of the modulatory peptide neurotensin to midbrain dopamine neurons transiently increases activity by decreasing dopamine D2 autoreceptor function. However, it is not known how neurotensin affects dendritic dopaminergic neurotransmission that strongly determines dopamine neuron activity. Here, we performed patch-clamp electrophysiology and fast-scan cyclic voltammetry in mouse brain slices to determine the effects of neurotensin on dopamine autoreceptor-mediated signaling. Neurotensin application produced two distinct effects: a transient depression of postsynaptic dopamine autoreceptor signaling and a persistent long-term depression (LTD-DA) of D2 autoreceptor-mediated inhibitory postsynaptic currents (IPSCs). This LTD-DA required activation of the type 2 neurotensin receptor and protein phosphatase calcineurin. NT application increased the paired pulse ratio and reduced somatodendritic dopamine release, suggesting that neurotensin-induced LTD-DA is expressed presynaptically. Surprisingly, we observed that stimulation-induced LTD-DA (which we reported previously) was also dependent on the type 2 neurotensin receptor and calcineurin. The fact that electrically-induced LTDDA is blocked by postsynaptic calcium chelation, in combination with present data, suggests that endogenous neurotensin may act as a retrograde messenger to decrease presynaptic dopamine release. The current research thus provides a mechanism through which increased neurotensin release can produce a long-lasting increase in membrane excitability of midbrain dopamine neurons.

Title: Nicotinic modulation of striatal synaptic transmission and plasticity in the dorsolateral striatum of rat

Authors: *A. LOTFI, L. ADERMARK;
Psychiatry and Neurochemistry, Univ. of Gothenburg, Gothenburg, Sweden

Abstracts: The ability to change behaviour likely depends on the selective strengthening and weakening of brain synapses, and this complexity and adaptability of neuronal communication is necessary for integrative and higher functions of the brain. Nicotine has repeatedly been shown to enhance cognitive performance in humans and laboratory animals and appears to decrease the threshold for induction of synaptic plasticity in the hippocampus. Thus, nicotine may either strengthen cell processes normally involved in learning or recruit additional processes. The aim for this study was to define the role of nicotine in modulating neurotransmission and endocannabinoid-mediated plasticity in the dorsolateral part of the striatum. *In vitro* electrophysiology was performed on acutely isolated brain slices containing the striatum and the overlaying cortex from juvenile rats (p23-28). Administration of nicotine (0.5-10 μM) depressed striatal neurotransmission in a dose-dependent manner that involved activation of nicotinic acetylcholine receptors (nAChRs), N-Methyl-D-aspartate receptors (NMDA), glycine receptors and gamma-aminobutyric acid (GABA) receptors, but not dopamine D2 receptors. Endocannabinoid-mediated long-term depression, induced by high frequency stimulation, was facilitated in slices pre-treated with nicotine, while short-term depression induced by the cannabinoid 1 receptor agonist WIN55,212-2 (1 μM) was not, suggesting that nicotine promotes endocannabinoid signalling at a level that is upstream from the presynaptic terminal. The data presented here indicates that nicotine enhances endocannabinoid-mediated plasticity by altering striatal microcircuitry and shifting the threshold for endocannabinoid production and release, which could be important for the cognitive enhancing properties of nicotine.

Title: Replication of chronic intermittent ethanol-induced metaplasticity in C57Bl6/J DRD1a-TdTomato medium spiny neurons in the nucleus accumbens shell

Authors: *R. RENTERIA, III[1], T. R. BUSKE[2], R. MORRISETT[2];
[1]UT Austin - Inst. For Neurosci., Austin, TX; [2]Col. of Pharm., Univ. of Texas at Austin, Austin, TX

Abstracts: The purpose of this study was to determine the effects of *in vivo* ethanol exposure on the expression of plasticity in D1 and D2 dopamine receptor expressing medium spiny neurons (MSNs) in the nucleus accumbens (NAc) shell. The output of the nucleus accumbens can be divided into two distinct pathways: the direct and indirect pathways. Medium spiny neurons of the direct pathway express D1 dopamine receptors and project primarily to the VTA. In the indirect pathway, MSNs express D2 dopamine receptor and project to the ventral pallidum. To distinguish the two subtypes of MSNs in the nucleus accumbens we used DRD1a-TdTomato mice that have been back crossed onto C57BL6/J. The use of the transgenic mice allows us to identify MSNs that express D1 dopamine receptors (D1+) and those that do not (D1-). Our previous work in C57BL6/J has shown that the expression of LTD induced by low frequency stimulation is blocked by acute ethanol, while *in vivo* chronic intermittent ethanol (CIE) exposure with the same stimulation protocol results in long term potentiation (LTP). In this study we used whole cell patch clamp electrophysiology to measure excitatory post synaptic currents (EPSCs) in D1+ and D1- MSNs in the NAc shell. Plasticity was induced by pairing low frequency stimulation with post synaptic depolarization. In ethanol naïve mice, D1+ MSNs express LTD while D1- MSNs do not. Mice were treated with 16 hours of ethanol vapor for 4 consecutive days. In slices prepared from ethanol treated mice, D1+ MSNs express LTP. The expression of LTP in D1+ MSNs is accompanied by an increase in the frequency of spontaneous EPSCs as well as an increase in action potential firing in response to fixed current injections. D1- MSNs from ethanol treated mice express LTD and have a decrease in the frequency of spontaneous EPSCs as well as an increase in paired pulse ratio. The reversal in plasticity in D1+

MSNs and the expression of LTD in D1- MSNs may constitute an important neuroadaptation necessary for the expression of alcohol related behaviors.

Title: Endocannabinoid LTD at Nucleus Tractus Solitarius excitatory synapses depends on the nutritional status

Authors: A. KHLAIFIA, *F. J. TELL;
CRN2M, CNRS UMR 7286, Marseille, France

Abstracts: Presynaptic long-term depression (LTD) of synapse efficacy generally requires coordinated activity between presynaptic and post-synaptic neurons and a retrograde signal synthesized by the postsynaptic cell in an activity-dependentmanner. In this study, we examined LTD in the rat nucleus tractus solitarii (NTS), a brainstem nucleus that relays homeostatic information from the internal body to the brain. We found that coactivation of N-methyl-D-aspartate receptors (NMDARs) and type 1cannabinoid receptors (CB 1 Rs) induces LTD at the first central excitatory synapse between visceral fibers and NTS neurons.This LTD is presynaptically expressed. However, neither postsynaptic activation of NMDARs nor postsynaptic calcium influx are required for its induction. Direct activation of NMDARs triggers cannabinoid-dependent LTD. In addition, LTD is unaffected by blocking 2-arachidonyl-glycerol synthesis, but its induction threshold is lowered by preventing fatty acid degradation. Altogether, our data suggest that LTD in NTS neurons may be entirely expressed at the presynaptic level by local anandamide synthesis. Ongoing experiments indicates that this form of LTD depends on the nutritional status. Fasting impairs LTD induction while refeeding restores it. We are currently investigating the mechanisms involved in such regulation.

Title: ATP consumption in molecular reactions of neuronal signaling

Authors: *N. RASUMOV, E. DE SCHUTTER;
Okinawa Inst. of Sci. and Technol. 1919-1, Tancha Onna-Son, Japan

Abstracts: The human brain consumes 10^6 times less energy than the currently fastest supper computer [1], while maintaining a comparable performance in many demanding task [2]. These energetic efficiency has been suggested to result from primitive computations on a molecular level [3]. However, while the importance of ion channels on energy efficiency has been the primary focus of research [4], most computations occur at the molecular level prior to the amplification step and prior to the information transmission. We calculate the amount of energy consumed by such computations and compare their structural and functional properties. As a starting point, we chose the molecular reactions involved in long term depression and using our stochastic model [5] estimate the molecular energy consumption. To compare our feedback loop we investigate the energy consumption of millions of feedback loops in molecular signaling. For the first time we are able to go beyond the current size limit of 15 steps [6] and detect feedback loops with hundreds of molecular reactions. We find that the number of ATPs consumed is related with size of positive feedback loop. We conclude that the energy consumed by the long term depression is only marginally above the physical limit of storing information and above its silicon equivalent of Random Access Memory. Hence, this study provides the first systematic attempt to investigate the energy consumption of information-storing molecular computations and points towards energy efficient motifs for synthetic biology. Title: Ca^{2+}/Calmodulin promotes postsynaptic release of PSD-95 by preventing palmitoylation

Authors: *L. MATT[1], Y. ZHANG[2], T. PATRIARCHI[1], D. K. PARK[1], D. CHOWDHURY[1], Z. A. MALIK[1], J. B. AMES[2], J. W. HELL[1];
[1]Sch. of Medicine, Dept. of Pharmacol., [2]Dept. of Chem., Univ. of California Davis, Davis, CA

Abstracts: Postsynaptic density protein-95 (PSD-95) is essential for anchoring AMPA and NMDA receptors to the glutamatergic postsynapse. It is rapidly relocated from dendritic spines following Ca^{2+} influx through NMDA receptors. Using pull-down and protein interaction studies we identified Ca^{2+}/Calmodulin (CaM) binding to residues 1-13 of the PSD-95 N-terminus. A structural model based on NMR data predicts that the first 16 residues of PSD-95 assume an alpha-helical conformation upon CaM binding and that CaM tightly interacts with Tyr12 of PSD-95 blocking access to the palmitoylation sites at Cys3 and Cys5. Confirming the model's prediction, rapid de-pamitoylation of PSD-95 following NMDA-treatment of acute forebrain slices is prevented by CaM inhibitors. Furthermore, mutating Tyr12 of PSD-95 to Glu (Y12E)

results in a CaM binding-deficient protein, which is no longer de-palmitoylated upon stimulation. Glutamate stimulation of cultured neurons leads to a rapid relocation of overexpressed wildtype PSD-95 from dendritic spines. This re-location is not observed for the CaM binding-deficient Y12E mutant. Interestingly, after stimulation, the concentration of Y12E PSD-95 in synaptic spines is even increased. In summary we find that the block of PSD-95 palmitoylation by CaM binding promotes the Ca^{2+}-induced dissociation of PSD-95 from the postsynaptic membrane. We believe that this increase in PSD-95 mobility contributes significantly to postsynaptic plasticity after NMDA receptor activation and Ca^{2+} influx by increasing structural flexibility.

Title: Predictive and reactive precision grip force control in individuals with autism

Authors: *Z. WANG, G. MAGNON, R. GREENE, J. SWEENEY, M. MOSCONI;
Dept. of Psychiatry, UT Southwestern Med. Ctr., Dallas, TX

Abstracts: Sensorimotor abnormalities are present in the majority of individuals with autism spectrum disorders (ASD). The control processes and neurological substrates underlying these dysfunctions are not well understood. Here, we examined predictive and reactive visuomotor force production in 31 individuals with ASD and 21 healthy controls matched on age, sex and handedness. Participants pressed on opposing load cells with their thumb and index finger and received visual feedback in the form of a horizontal line that moved upwards on a monitor in front of them when they increased their force level. Participants were instructed to press on the load cells so that the horizontal line reached the level of a parallel, static target line. Each participant completed trials in which the target force level was set to 15%, 45% or 85% of their maximum force. Predictive control was examined by measuring the accuracy of initial (i.e.,

primary) responses completed prior to visual feedback being processed. Reactive control was examined by measuring the accuracy of participants' force level after making corrective adjustments to reach the target force level subsequent to the primary response. There were no differences in the accuracy of primary responses or the number of corrective adjustments made following the primary response for individuals with ASD and healthy controls. But, after completing their corrective adjustments, individuals with ASD overshot targets at 15% MVC compared to controls, and undershot targets at 85% MVC. Individuals with ASD also took longer to complete their corrective adjustments at 15% MVC. There were no differences in the peak rate of force increase during the primary response or during the total force increase phase. These results indicate that individuals with ASD are unable to precisely adjust their force output to task demands due to deficits making reactive adjustments to force levels based on visual feedback. Given that they applied the same number of corrective pulses as healthy controls, ASD participants appear to be able to perceive and utilize online visual feedback. However, they either fail to map their compensatory motor commands to the perceived performance error, or they are not able to execute the corrective motor commands as accurately and efficiently as healthy individuals. This reactive precision grip force control impairment in ASD is similar to the profile of grip force imprecision reported in multiple studies of patients with cerebellar disease. These findings thus provide new evidence for visuomotor alterations in ASD consistent with functional disturbances of the cerebellum.

Title: RBM8a regulates anxiety and social behaviors

Authors: *C. MCSWEENEY[1], A. ALACHKAR[2], P. D. HULLIHEN[1], D. ZOU[1], Y. ZHOU[1], F. DONG[1], D. DENG[1], Y. MAO[1];
[1]Penn State Univ., State College, PA; [2]Univ. of California Irvine, Irvine, CA

Abstracts: Nonsense-mediated mRNA decay (NMD) is an RNA surveillance mechanism that ensures the degradation of mRNAs carrying premature termination codons (PTCs). This mechanism relies on several factors, which form a tetramer known as the exon junction complex (EJC). Mutations in multiple EJC factors have been reported to cause X-linked mental retardation and autism (Tarpey et al., 2009; Laumonnier et al., 2010; Addington et al., 2010). This strongly indicates a potential role for NMD in the pathogenesis of autism. Various behavioral assays can be used to assess behaviors typically associated with neuropsychiatric disease. These tests include the open field test (anxiety), social interaction task (social preference), and contextual fear conditioning (learning and memory). Due to multiple papers associating core NMD factors with autism and mental retardation, we suspect that RBM8a (an EJC factor) may be involved in autism. In order to probe how RBM8a affects mouse behavior, WT mice were injected with RBM8a overexpression lentivirus or RBM8a shRNA lentivirus, targeted to the dentate (bilateral) and assessed on a variety of behavioral tasks. RBM8a overexpression and knockdown mice were found to exhibit an anxious phenotype when tested in the open field ($p<0.05$ for both groups). In the social interaction task, RBM8a overexpression mice were found to have impaired social interaction, while RBM8a knockdown mice exhibited enhanced social interaction ($p<0.05$ for both groups). In addition, RBM8a knockdown mice showed deficits in learning and memory in the contextual fear conditioning task ($p< 0.05$). The behaviors found to be altered in RBM8a overexpression and knockdown mice parallel those seen in autism (anxiety, sociability, learning and memory). Further dissection of the behavioral phenotypes associated with these mice, in addition to investigating the molecular mechanisms that cause these phenotypes may provide insights into causes of autism and mental retardation.

Abstracts: Is well know that children with Autism Spectrum Disorders (ASD) show alterations related with social interaction, affective regulation, language, stereotyped and anxious behaviors, between others. Most ASD therapies are based on behavioral treatment and those has shown to be effective specially in stereotyped, anxious behaviors and affective regulation. However it is important to considerer new alternative therapies, which can ameliorate symptoms observed in ASD. Moreover It has been shown that yoga has great benefits for mental and physical health, like cognition improvement in dementia patients, improve on anticipatory responses, upturn in adaptative skills, reduction of depressive symptoms and betterment in Attention Deficit Hiperactive Disorder. The aim of this study assess if yoga reduces symptoms related to ASD in children. Our sample includes eight children between 3 to 9 years old who practice yoga sessions ones a week per one hour in the National Rehabilitation Intitute of Mexico. Parents were asked to answer a check list related to changes in ADS symptoms in their sons and daughters . Parents refered changes after yoga sessions in following instructions, social interaction and language, these results highlights that yoga benefits ASD patients and shows that could be a complementary treatment in ASD symptoms. Nevertheless it is necessary to apply different evaluation methods that contributed with a deep analisys of the changes in ASD and yoga practice.

Title: Using HRV, skin conductance, and neurofeedback training thresholds to quantify progress in children diagnosed with ASD

Authors: *H. COURELLIS[1], A. COURELLI[1], E. FRIEDRICH[2], J. A. PINEDA[2];
[1]Bioengineering, [2]Cognitive Sci., UCSD, La Jolla, CA

Abstracts: Neurofeedback training (NFT) has been shown to elicit behavioral improvement in pediatric patients diagnosed with Autism Spectrum Disorder (ASD). A typical NFT schedule is comprised of multiple 45-min sessions that aim to suppress mu-brainwaves, 8-13 Hz rhythms specific to the sensorimotor cortex. As NFT training progresses, monitoring the outcomes of individual trainees is essential because it can contribute to the customization of the NFT protocol for each patient. A set of physiological measures that can quantify NFT progress includes Heart rate Variability (HRV), skin conductance, and the power of mu, beta, and theta bands present in EEG. HRV has been shown to predict mental effort in Brain-Computer Interface (BCI) activities, while tonic skin conductance is associated with attention tasks in a social context (e.g., during interaction with others). Pediatric patients diagnosed with ASD between 6 and 17 years of age participated in a series of NFT sessions. NFT was implemented through a BCI in which each participant interacted with the computer in a "video game" like scenario. Activity was rewarded if the "player" maintained their mu, theta, and beta brainwave power within specific ranges, which were progressively adjusted to increase the difficulty of the game and, consequently, increase the rigor of the training. The training was designed to downregulate beta and theta power and to upregulate mu power. Each session lasted for approximately one hour and EEG brain activity was recorded from one electrode over the right sensorimotor cortex (C4). During a period of five minutes before and five minutes after each NFT session, the participant's heart rate (electrodes placed at left wrist and neck) and skin conductance (electrodes placed at the pointer and ring finger of the left hand) were also recorded. The acquired data was analyzed and mu, theta, and beta training thresholds, the high frequency power of the HRV power spectrum, and the amplitude of tonic and phasic skin conductance were tabulated. In a number of cases, as the training progressed, the high frequency power of HRV showed a noticeable increase in pre- and the post- assessments, suggesting that the performance in social cognition of the participants (as implemented by the "video game") had improved. This observation was supported by the amplitude of the tonic skin conductance which was significantly elevated after the training. Finally, thresholds leading to successful upregulation for mu and downregulation for beta and theta brainwaves corroborated the level of progress that was achieved.

Title: The role of dietary polyunsaturated fatty acids in the pathogenesis and treatment of autism spectrum disorders

Authors: K. VAN ELST[1], J. E. MERKENS[1], H. BRUINING[1,2], B. BIRTOLI[3], C. TERREAUX[3], J. BUITELAAR[4], *G. M. RAMAKERS[5], M. J. H. KAS[1];
[1]Translational Neurosci., Brain Ctr. Rudolf Magnus, Utrecht, Netherlands; [2]Dept. of Psychiatry - UMC Utrecht, Utrecht, Netherlands; [3]Vifor Pharma, Villars-sur-Glâne, Switzerland; [4]Donders Inst. for Brain, Cognition and Behavior, Dept. of Cognitive Neuroscience, Radboud Univ. Nijmegen Med. Ctr., Nijmegen, Netherlands; [5]Neurosci. and Pharmacol., Rudolf Magnus Inst. of Neuroscience, UMC Utrecht, Utrecht, Netherlands

Abstracts: The last decades have shown a spectacular rise in the autism spectrum disorders (ASD) prevalence that cannot solely be explained by known factors such as broader diagnostic criteria, diagnostic accretion or higher parental age. Further, environmental factors, including dietary composition, may also play a role in ASD pathogenesis. The rise in ASD seems to parallel changes in the diet. The replacement of cholesterol by omega-6 (n-6) polyunsaturated fatty acids (PUFAs) resulted in a drastically disturbed ratio of n-6/n-3. It has been shown that depletion of omega-3 (n-3) PUFAs, especially during early life, induces aberrant developmental changes in brain connectivity, synaptogenesis, behavior and cognition. We reasoned that the recent changes in fatty acid composition may be contributing to the etiology of neurodevelopmental conditions such as, among others, ASD. To investigate this, a longitudinal behavioral and neurodevelopmental study in 2 mouse inbred strains, C57BL/6J and BTBR T+ Itpr3tf/J, has been performed. The animals received a dietary supplementation or depletion of n-3 PUFAs in chow, thereby decreasing or increasing the n-6/n-3 PUFA ratios, respectively. Diets were given to the mothers prior to pregnancy and were continued throughout life. The effects of the different diets were measured in various ways: firstly, by assessing animal behaviors inside and outside the ASD behavioral domains of repetitive and social behavior by applying an extensive longitudinal behavioral test battery. Secondly, by taking blood samples at different developmental stages and parallel to the test battery, to determine the PUFA peripheral concentrations over time. The diets had the expected effect on PUFA blood concentrations in

mice, as blood sample PUFA ratios were in the same directions as in the diets. Preliminary findings indicated that n-3 PUFAs have a positive effect on behavioral outcome related to the autistic domain of repetitive behavior and on the cognitive domain during early life. Currently, changes in brain morphology and composition as a function of dietary exposure are under investigation. This study puts forward the interesting possibility of applying dietary intervention in the understanding and treatment of behavioral domains related to neurodevelopmental disorders, such as ASD.

Title: Behavioral characterization of internal models and predictive mechanisms in autism

Authors: *C. EGO[1,2], L. BOHOMME[3], J.-J. ORBAN DE XIVRY[1,2], D. DA FONSECA[3], P. LEFÈVRE[1,2], G. S. MASSON[3], C. DERUELLE[3];
[1]ICTEAM, Univ. catholique de Louvain, Louvain-la-Neuve, Belgium; [2]Inst. of Neurosci. (IoNS), Univ. catholique de Louvain, Brussels, Belgium; [3]Inst. de Neurosciences de la Timone, CNRS & Aix-Marseille Univ., Marseille, France

Abstracts: Autism spectrum disorder (ASD) is a group of complex disorders of brain development characterized by difficulties in social interaction, verbal and nonverbal communication and repetitive behaviors. Previous studies reported that autism might also be characterized by a dysfunction in the ability to build prediction, a critical cognitive skill for both behavioral and social functions. Eye movements are useful to study prediction abilities. In the present study, we investigated the integrity of predictive mechanisms in autistic children during ocular tracking of moving objects that were temporarily blanked. Eye movements were recorded in 27 subjects aged from 11 to 21 years old. Among them, 18 suffer from Asperger's syndrome and 9 are aged-matched control subjects. Subjects were instructed to pursue a 0.5 deg red dot at the center of a moving bird stimulus. After an initial fixation and gap period, the target started to move towards the center of the screen at constant velocity. After 600ms, the target was blanked for 800ms and reappeared for 600ms. The target velocity (20 deg/s) and direction (right or left) were kept constant over the 20 trials of each of the 4 blocks to allow subjects to learn the target trajectory. During target blanking, pursuit eye velocity first decayed similarly for both groups. After a few trials, control subjects learned the timing of target reappearance and were able to increase eye velocity in anticipation of target reappearance. ASD subjects did not exhibit this predictive reacceleration, suggesting that they were not able to learn such timing. In all subjects, we observed some variability of the pursuit response during the blanking period. In control subjects, this variability was well compensated by the saccadic system, resulting in a negative correlation between pursuit and saccadic eye displacements during blanking. This negative correlation is a signature of internal models as it occurs in the absence of visual signals. Interestingly, this correlation tended to be weaker in ASD subjects suggesting that internal models might be altered in these subjects. In conclusion, our results suggest that ASD subjects have impaired predictive mechanisms and less reliable internal models.

Title: Social deficits in ASD are linked with greater task-driven neural synchrony under naturalistic conditions

Authors: *K. JASMIN[1,2], S. J. GOTTS[1], Y. XU[3], N. ABDULSABUR[3], S. LIU[3], J. E. INGEHOLM[1], I. W. EISENBERG[1], B. ORIONZI[1], A. R. BRAUN[3], A. MARTIN[1]; [1]NIMH/NIH, Bethesda, MD; [2]Inst. of Cognitive Neurosci., UCL, London, United Kingdom; [3]NIDCD/NIH, Bethesda, MD

Abstracts: A defining feature of autism spectrum disorders (ASD) is difficulty in social situations. However, previous functional brain imaging studies of ASD have relied on pre-recorded visual or auditory stimuli. These studies typically show attenuated brain responses to social stimuli relative to typically developed (TD) controls.. Similarly, rest-state studies typically show weaker correlations between brain regions in ASDs, especially in social areas. Whether the brains of ASD people show less correlation in a naturalistic social context has not been tested. We recruited 18 high-functioning males with ASD age 14-30 and 20 typically developed age and IQ-matched controls (TDs) for an ecologically valid social task: Subjects engaged in free, spontaneous conversations with an experimenter while they were scanned with functional magnetic resonance imaging (fMRI). Both parties could see and hear each other through MR-safe headphones and microphones. We used PCA to isolate and remove large BOLD fluctuations caused by speech-related movement. Cardiac pulse, respiration, head motion parameters, ventricles and localized white matter signals were also regressed from the data to markedly reduce noise while preserving task-related BOLD fluctuations. Across task runs, we correlated each voxel's time series with the mean of all gray-matter voxels in the brain. Correlation maps were then compared by group with an independent samples t-test. This analysis also controlled for degree of motion and percent time spent speaking (Speaking Time; ST), although neither measure differed significantly between groups. During conversation, activity across voxels in ASD brains was overall more highly correlated than for TDs. Increased synchrony was particularly prominent in the right hemisphere for ASDs, while the TDs' correlation maps were predominantly left-lateralized. Our result cannot be explained by differences in speaking time between groups, as ST was well-matched between groups (ASD=47%, TD=48%). Moreover, the ASD subjects who spoke the least showed higher levels of task-driven synchrony and more severe autistic symptoms. In contrast to studies showing links between decreased whole-brain correlation at rest and autism symptomatology, here we demonstrated a reversed pattern during live social interaction: the brains of people with ASDs showed increased task-driven neural synchrony compared to TDs. Moreover, greater synchrony was associated more severe autistic symptomatology. Our results suggest that ASD brains are less differentiated than TD brains, and therefore recruit a more bilateral, spatially distributed set of areas to perform real-world social tasks.

Title: Investigations in neuronal receptors expression in the animal model of autism based on the early blockade of GRPR: Potential role in the behavioral impairments observed in ASD

Authors: *J. PRESTI TORRES[1,2], M.-C. AUDET[3,2], J. JAMES[2], P. KENT[2], Z. MERALI[2]; [1]PUCRS, Porto Alegre, Brazil; [2]Inst. of Mental Hlth. Reseach, Univ. of Ottawa, Ottawa, ON, Canada; [3]Dept. of Neurosci., Carleton Univ., Ottawa, ON, Canada

Abstracts: Autism spectrum disorder (ASD) is a neurodevelopmental disorder defined by impairments in social interaction and social communication, as well as restricted interests and activities. In addition to environmental factors that have been linked to ASD, dysfunction of serotonin processes during early brain development has been suggested to play a role in its etiology. Hyperserotonemia during neurodevelopment was reported to modulate a number of molecular events associated with social interaction impairments and anxiety. Preclinical and human genetic studies have suggested that gastrin-releasing peptide receptor (GRPR) may be associated with this disorder. In this vein, our group has previously shown that pharmacological blockade of the GRPR during the neonatal period in rats produced behavioral features reminiscent of ASD at different stages of development. Importantly, administration of the atypical antipsychotic clozapine reversed the social interaction deficits elicited by neonatal blockade of GRPR, suggesting that social disturbances elicited in this model could be mediated by dopamine and/or serotonin dysfunction.. Here we evaluated the effects of neonatal blockade of the GRPR on social interactions and on the mRNA expression of serotonin receptors in the medial prefrontal cortex (mPFC) of rats at the juvenile stage. Male Wistar rats received intraperitoneal injections of the GRPR antagonist, RC-3095, or of a saline vehicle on postnatal days (PND) 1-10. One set of rats was tested for social interaction on PND30. For the determination of mRNA expression of serotonin receptors in mPFC, a second set of rats

submitted to the same treatment was sacrificed and brain tissue was collected on PND32 Pharmacological blockade of the GRPR during neurodevelopment significantly decreased patterns of social interaction, such as following, sniffing, and play fighting behaviours. As well, this treatment increased the prefrontal expression of serotonin receptors, 5-HT2C, but failed to alter that of other serotonin receptors. This data supports the idea that the social interaction deficits elicited by early blockade of the GRPR may be related to alterations in the serotonin system. Further investigations are needed to characterize alterations in the expression of additional brain receptors that could be related to ASD symptomatology.

Title: Intrinsic motivation and theory of mind in adolescents with autism

Authors: *M. FIRESTEIN[1], P. F. GERHARDT[2], H. HOCH[3];
[1]Psychiatry, Columbia Univ., New York, NY; [2]JPG Autism Consulting, New York, NY;
[3]Psychology, Barnard Col., New York, NY

Abstracts: Numerous studies have suggested that theory of mind (ToM), a cognitive process by which an individual is able to recognize that others have their own internal mental states that are different than his or her own, is delayed or impaired in individuals with autism. The ability to understand that these internal mental states direct behavior is a crucial skill needed for forming social relationships with others. Thus, it is possible that the social behavior deficits associated with autism may be partly the result of an inability to employ ToM. The purpose of this study was to investigate how intrinsic motivation affects the ability of adolescents with autism to employ ToM during a false-belief task. Specifically, we were interested in manipulating the content of the task, so that the task itself, as opposed to a consequential reward, would be motivating enough to increase the adolescent's attention and desire to engage in the task. Participants (n=4, mean age=14 years) were tested on three conditions of the Sally-Anne Task. Performance on the "standard condition" of the Sally-Anne Task was recorded and compared to performance on two novel, modified versions of the task. These modified conditions were

identical to the standard condition, except that they incorporated personalized and intrinsically motivating objects and people in order to examine how performance might vary depending on the content of the task. In our modified "familiar person condition" neutral dolls were replaced with personalized hand-made dolls of each participant's close friends. In our "intrinsically motivating object condition" we replaced the neutral hidden object (a marble) with each participant's preferred object (e.g. M&Ms). None of the participants passed the false-belief question in the standard condition. Of the four participants, two passed the false-belief question in the familiar person condition and three passed the false-belief question in the intrinsically motivating object condition. We have demonstrated that by including personalized, intrinsically motivating stimuli into the Sally-Anne Task, three adolescents with autism were able to pass this false-belief task and thus demonstrate ToM. The implications of these findings not only provide novel insight into ToM abilities in individuals with autism, but also suggest potential educational techniques that may be advantageous for this clinical population.

Title: What eye movements reveal about the reliability of the Autism-Spectrum Quotient

Authors: ***J. L. STEVENSON**[1], K. R. HART[2], K. A. WILLIAMS[3], L. S. MULLER[3];
[1]Psychology, [2]Mathematics and Computer Sci., [3]Neurosci., Ursinus Col., Collegeville, PA

Abstracts: The Autism-Spectrum Quotient (AQ) is a 50-item self-report questionnaire that assesses the number of autistic characteristics in adults. Participants respond to statements about autistic characteristics (e.g., I prefer to do things the same way over and over again) using a 4-point Likert scale (i.e., definitely disagree, slightly disagree, slightly agree, or definitely agree). While the AQ was designed to be a screening questionnaire for individuals on the autism spectrum, a growing body of research uses the AQ to characterize neurotypical individuals as either having a high degree of autistic traits or a low degree of autistic traits. The current study investigated the reliability of the AQ in a neurotypical sample. Thirty-six undergraduate students (M = 19.00 years, SD = 0.79; 23 females, 13 males) completed two computerized versions of the AQ. The first version was completed online (M = 111.44, SD = 19.35) and the second was

completed in the laboratory (M = 108.75, SD = 17.80) while participants' eye-movements were monitored using a Tobii T60 eye-tracker. Analyses focused on the five subscales of the AQ: attention switching, communication, attention to detail, imagination, and social skill. Regardless of subscale, male participants displayed a significantly greater change in AQ subscale scores than female participants ($F(1, 34) = 5.61$, $p = .024$; male: 95% CI: 0.48 - 2.29; female: 95% CI: -0.62 - 0.74). A 2 x 5 mixed-design ANOVA was conducted to investigate the effects of gender and subscale on the time spent fixating on the selected option (corrected for the time spent fixating on all possible options). There was a significant interaction between gender and subscale ($F(4, 136) = 3.65$, $p = .007$). Males tended to spend more time than females fixating on their selected response option for the attention to detail subscale ($p = .06$), whereas females tended to spend more time than males fixating on their selected response option for the social skill subscale ($p = .06$). Additional analyses examining the relation between eye movement patterns and consistency of AQ scores will be presented. These results have the potential to shed insight on the reliability of AQ subscale scores for neurotypical males and females. Furthermore, these results could inform research on whether AQ scores in the neurotypical population reflect state or trait characteristics.

Title: Autistic behavior in adolescent Fmr1 knockout mice - With parallels to the valproate rat model of autism

Authors: E. SORENSEN[1], T. BANKE[2], F. BERTELSEN[1,3], J. SCHEEL-KRUGER[1], A. MOLLER[1,3], *K. DRASBEK[1];
[1]CFIN/MINDLab, [2]Dept. of Biomedicine, Aarhus Univ., Aarhus C, Denmark; [3]PET-Centre, Aarhus Univ. Hosp., Aarhus C, Denmark

Abstracts: The prevalence of the currently incurable developmental disabilities, known as autism spectrum disorders (ASDs), has been increasing during the past years. This steep rise in the prevalence of ASDs is foreseen to continue in the next decade thereby necessitating a better understanding of the background of ASDs, hopefully leading to the development of effective treatment strategies. Animal models present valuable tools in uncovering the etiology of ASDs as well as platforms for testing novel intervention strategies. The aim of this study is to evaluate and compare a genetic and a pharmacologic animal model of ASDs. The Fmr1 knockout (KO) mouse model is a monogenic animal model that mimics the fragile X syndrome (FXS). This model exhibits developmental abnormalities affecting cognitive functions including learning disabilities, anxiety, and hyperactivity, which are all symptoms related to autism. About one third of human FXS cases exhibit ASDs. In parallel, we will study the valproate (VPA) rat model of autism that is induced by VPA exposure during embryogenesis. As presented previously by our group, daily injections of clinically relevant doses of VPA in pregnant rats cause several autistic features in the offspring, including a 60 % reduction in play behavior during adolescence. In the human clinic, alterations in play behavior are one of the first signs seen in autistic children. Using a C57BL/6 mouse background, autistic behavior in adolescent (5-9 weeks) Fmr1 KO mice is studied using a battery of behavioral tests. Firstly, anxiety level was assessed using the marble burying test. It showed that Fmr1 KO mice had a lowered anxiety level as they buried less marbles than wildtype mice. Currently, we are establishing tests for social interaction and preference for social novelty (3-chamber test) and recognition memory (novel object recognition test). It is generally accepted that autism has a largely genetic etiology, but environmental factors also have a significant effect, which is utilized in the VPA rat model of autism. Most behavioral tests are originally developed in rats and the relatively high anxiety level seen in the C57BL/6 mouse can potentially interfere with the mice's performance when testing for sociability and memory functions. Therefore, anxiety must be extensively studied and conditions should be optimized to reduce stress and anxiety during testing. Until now, most behavioral research in the Fmr1 KO mouse has focused on adult mice. In humans, autistic symptoms appear very early in life. Therefore, to be valid as an animal model of autism, the Fmr1 KO mouse should have autistic behavior in adolescence.

Abstracts: Benzyl Butyl Phthalate (BBP) is an industrial plasticizer that has an unknown action in the central nervous system. Phthalates have recently been associated with behavioral actions that are linked to their endocrine disrupting properties. The purpose of this study was to investigate the behavioral, anatomical and molecular effects of indirect perinatal BBP exposure in offspring of BBP treated pregnant dams. We administered BBP (10.0 μg/ml) in sweetened food pellets to pregnant dams until pups were weaned at post natal day 23. In Experiment 1, offspring were sacrificed at PND23 and we found a significant decrease in anogenital length and a decrease in body weights in both male and female exposed offspring, suggesting BBP exposure s an leads to reproductive abnormalities. Further analysis showed no migrational or lamination deficits in the hippocampus or cortex of exposed male offspring, but nickel staining with MAP2 of the hippocampus demonstrated unusual blunting of axons. In Experiment 2, offspring were sacrificed at PND65 and we found an increase in serum levels of 17β-Estradiol in male offspring suggesting BBP can invoke changes in the endocrine system. BBP exposed offspring have a decrease freezing response in tests of fear conditioning and no gross motor changes. Lastly, we found altered protein levels associated with normal neuronal development, synaptic plasticity and dendritic morphology in the amygdala, dorsal and ventral hippocampus. MeCP2 and Ube3a were found to be dysregulated in exposed offspring are also targets of investigation in Autism Spectrum Disorders. Our studies suggest that indirect perinatal BBP exposure to offspring disrupts normal learning and social behavior. These effects could be related to alterations in brain development. These findings indicate a compelling need for evaluation of acceptable levels of exposure to phthalates present in the environment.

Title: Altered amygdala-cortical gray-matter structural covariance in males with autism spectrum disorder

Authors: *Y. C. CHEN[1], ,. Y. LIN[2], J. O. S. GOH[3], S. S. F. GAU[2];
[1]Dept. of Psychiatry, Natl. Taiwan university Hosp. & Col. of Med., Natl. Taiwan Univ., Taipei, Taiwan; [2]Dept. of Psychiatry, Natl. Taiwan Univ. Hosp. and Col. of Med., Taipei, Taiwan; [3]Grad. Inst. of Brain and Mind Sciences, Natl. Taiwan Univ. Col. of Med., Taipei, Taiwan

Abstracts: Inter-regional covariation of brain structural volumetry has been suggested to reflect systemic neurodevelopmental architectural processes. In autism spectrum disorder (ASD), several pathophysiological brain structural abnormalities are involved across various regions. In particular, aberrant morphometry of the amygdala underpins social-emotional impairment in ASD. How brain systems structurally covary with the amygdala in ASD remains unclear. In this study, we compared how amygdala morphometry relates to various structural indices across cortical regions between ASD and typically developing (TD) individuals. We hypothesized that to the extent that aberrant amygdala structure captures systemic neurodevelopmental disorders in ASD, positive associations should be observed across various cortical areas. By contrast, in TD, amygdala structure should be less associated with the morphometry of other cortical regions. Structural MRI (3T) images of 117 males with ASD (mean age±SD, 14.6±4.4 years) and 108 TD males (mean age±SD, 15.0±5.9 years), with age ranging from 7 to 30 years. Volume-based

morphometry analysis was implemented using Freesurfer ver. 5.2.0, which parcellated gray matter into various brain regions including cortical areas and amygdala for each participant. Multiple regression models were then used to assess the differences in covariance between the amygdala and cortical volumes between ASD and TD males, controlling for age, intelligence and intracranial volume. All imaging results were corrected for multiple comparisons by Monte Carlo simulation ($p<0.05$). In the TD group, the volume of the left amygdala positively correlated only with left entorhinal gyrus volume. In the ASD group, right amygdala volume positively correlated with bilateral rostral middle frontal, the left superior frontal, left superior parietal, and right lateral occipital areas. In direct group comparisons, co-varying relationships between the left superior parietal gyrus-left amygdala pair, alongside the left rostral middle frontal gyrus-right amygdala and the superior parietal lobule-right amygdala pairs, was significantly greater in ASD than TD males. In general, amygdala-cortical structural correlations were more widespread and positive in ASD, while the relationships were reduced or even negative in the TD group. Our findings point to a systemic pattern of neuropathological gray matter development across various brain regions in ASD that is distinct from more heterogeneous inter-regional morphometry in TD individuals.

Title: Over-expression of Tbx1 or COMT in the mouse hippocampus partially recapitulates behavioral phenotypes of 22q11.2 duplication

Authors: ***S. BOKU**[1], T. IZUMI[1], T. TAKAHASHI[1], G. KANG[1], A. HISHIMOTO[1], A. NISHI[1], S. KATO[2], K. KOBAYASHI[2], K. TANIGAKI[3], T. HIRAMOTO[1], N. HIROI[1]; [1]Psychiatry and Behavioral Sci., Albert Einstein Col. of Med., Bronx, NY; [2]Fukushima Med. Univ., Fukushima, Japan; [3]Shiga Med. Res. Inst., Moriyama, Japan

Abstracts: Duplication of human chromosome 22q11.2 is associated with high rates of autism spectrum disorders (ASDs) and intellectual disability (ID). Because the duplicated region

contains more than 30 genes, specific 22q11.2 genes that contribute to these neuropsychiatric disorders are not understood in humans. We tested the hypothesis that over-expression of two 22q11.2 genes, the transcription factor Tbx1 and catechol-O-methyl-transferase (COMT), in the hippocampus contributes to behavioral phenotypes relevant to these disorders in mice. Because our own analysis showed that Tbx1 is enriched in postnatal and adult neural progenitor cells and Comt mRNA is present in postnatal neural progenitor cells, we designed a lentiviral vector that carried Tbx1 or COMT, together with enhanced green fluorescent protein (EGFP), under murine stem cell virus (MSCV) promoter. These vectors were infused into the hippocampus of C57BL/6J mice and mice were tested 10 days later for social interaction, anxiety-related behavior in the elevated plus maze, working memory in spontaneous alternation and motor activity and thigmotaxis in an inescapable open field. The vectors preferentially infected postnatal neural progenitor cells in the hippocampal dentate gyrus, as evidenced by colocalization of nestin and EGFP of the vector. Tbx1 over-expression increased social interaction, reduced anxiety-related behavior and impaired working memory at 2 months of age; it had no effect on thigmotaxis or motor activity. Over-expression of COMT impaired working memory and elevated basal levels of anxiety-related behaviors and thigmotaxis at 2 months, but not 1 month of age; it had little effect on other behaviors. Our data suggest that 1) Tbx1 over-expression in postnatal neural progenitor cells in the hippocampus contributes to working memory deficits but paradoxically opposes social interaction deficits associated with 22q11.2 duplication and 2) COMT over-expression selectively impairs working memory and elevates anxiety-related along developmental trajectory. Our data suggest that a dose elevation of these two 22q11.2 genes induces distinct behavioral phenotypes related to ASDs and ID during postnatal development.

Title: Sensory and social reinforcement monitor for identification of an autism-like phenotype in rats

Authors: *J. B. RICHARDS[1], J. PERON[2], R. WANG[3], D. R. LLOYD[4], R.-Y. SHEN[4], S. HAJ-DAHMANE[4];
[1]Res. Inst. On Addictions, BUFFALO, NY; [2]Ctr. for Assistive Technol., [3]Res. Institue on Addictions, [4]Res. Inst. on Addictions, State Univ. of New York at Buffalo, Buffalo, NY

Abstracts: Stereotyped behavior and impaired social interaction are core diagnostic features of autistic spectrum disorder (ASD). It has been hypothesized that sensory reinforcement underlies the occurrence of repetitive stereotyped behaviors that are characteristic of ASD. In rats an established measure of sensory reinforcement is responding to produce a light onset. Rats display a large variety of social approach behaviors. Here we described a novel operant methodology designed to compare the relative frequency of responding for sensory and social stimuli. Rats emit separate (but topographically equivalent) responses to gain access to a stimulus rat (social reinforcer) or light onset (sensory reinforcer). We hypothesize that this methodology can measure an ASD-like phenotype in rats. An ASD-like phenotype would be indicated by high levels of responding for light onset and low levels of responding for access to a conspecific. The figure illustrates the apparatus that we used to measure choice between a social reinforcer (a rat), a sensory reinforcer (light onset) and a control (empty compartment). The three holes in the center compartment are blocked by metal flaps that can be locked down by electromagnets to control access to the social and sensory stimuli. Turning off the electromagnet releases the flap and allows access. Infrared sensors monitor snout pokes. During testing access to sensory and social reinforcers is contingent upon snout poking according to concurrent Variable Interval 2 min schedules of reinforcement. Six rats were tested with light alone, stimulus rat alone, or with concurrent light and stimulus rat. Dependent measures were the number pokes and the duration of contact with response contingent stimuli while the blocking flap was released. Rats responded at higher rates into the holes associated with sensory and social stimuli than control holes. These results demonstrate that the methodology asses the effects of social and sensory stimuli presented both alone and simultaneously in rats.

Title: Hyper-fear memory formation is associated with hyper-plasticity in the amygdala in the VPA rat model of autism and hypo-fear memory formation is associated with hypo-plasticity in the amygdala in the MAM model of schizophrenia

Authors: *D. LA MENDOLA, V. DELATTRE, H. MARKRAM, K. MARKRAM;
EPFL, Lausanne, Switzerland

Abstracts: Autism and schizophrenia are two neurodevelopmental disorders associated with changes in cognition and emotion as well as impaired social abilities. Animal models of both disorders can be induced during gestation by injection of valproic acid (VPA) or methylazoxymethanol (MAM), respectively. Offspring exposed to either these drugs exhibit substantial neuroanatomical, behavioral and electrophysiological symptoms of autism and schizophrenia. In this study we compared rat models of autism (VPA) and schizophrenia (MAM) on a social interaction task and in a fear conditioning paradigm. We observed that both VPA- and MAM-treated offspring exhibited reduced social interactions, but that fear conditioned memories were increased in the autism model, whereas they were decreased in the schizophrenia model. Fear memory formation is mediated by the amygdala, and we hypothesized that the amygdala is differentially affected in the two rat models of autism and schizophrenia. We then compared long-term potentiation (LTP) in the amygdala in both rat models, VPA and MAM, using the patch-clamp technique paired with extracellular stimulation in acute brain slices *in vitro*. We report significantly increased LTP in the VPA rat model of autism and significantly decreased LTP in the MAM rat model of schizophrenia. In the VPA rat model of autism, the observed amygdaloid hyper-plasticity agrees with the hyper-fear memory formation, whereas the amygaloid hypo-plasticity agrees with the hypo-fear memory formation in the MAM model of schizophrenia. The speculate that autism and schizophrenia may lie on opposite extremes of one neurophysiological spectrum, that in both cases leads to similar apparent symptoms, such as social withdrawal, but might be caused by opposite neurophysiological activity patterns in the amygdala.

Title: Transfer of remote emotional information in a mouse model of autism

Authors: *K. Z. MEYZA, T. NIKOLAJEW, K. KONDRAKIEWICZ, K. ZIEGART, A. PUSCIAN, E. KNAPSKA;
Nencki Inst. of Exptl. Biol., Warsaw, Poland

Abstracts: Autism spectrum disorder (ASD) is a behaviorally defined neurodevelopmental disorder diagnosed by two major clusters of symptoms: 1. deficits in social communication and social interaction, and 2. restricted, repetitive patterns of behavior (DSM-V 299.0). The first set is responsible for the lack of empathy observed in autistic patients. Even though empathy is considered a human-specific trait, growing evidence suggests that it is possible to develop animal models of this phenomenon. Here we used a behavioral paradigm developed initially for rats (Knapska et al. 2006, 2009) to test empathy-like behavior in highly social c57BL/6J (B6) mice and a well-defined mouse model of ASD, the BTBR T+tf/J (BTBR) mice. The animals were housed in same-strain pairs for 4 weeks prior to the onset of the experiment and habituated (for at least 10 days) to being handled, transported and to a brief separation (10 min each day). On the test day, one of the mice (Demonstrator) was removed from the cage, moved to the conditioning chamber and either left undisturbed or subjected to a fear conditioning training. The other mouse (Observer) was left undisturbed in the home cage. After the animals were reunited in their home cage, their behavior was recorded for 10 minutes. The behavior of the Observers exposed to stressed Demonstrators was strikingly different in B6 and BTBR mice. B6 mice increased the number and duration of contacts, the number of nose-to-nose and nose-to-anogenital sniffs and the number and duration of digging episodes as compared with same-strain Observers exposed to non-stressed Demonstrators. BTBR mice on the other hand reduced the duration of contacts and nose-to-anogenital sniffing and dug less in response to a stressed Demonstrator as compared to a non-stressed one. In order to look for neuronal correlates of these striking behavioral differences we evaluated the expression of c-Fos protein in the medial prefrontal cortex, amygdala and the ventral hippocampus of these mice. While prelimbic and infralimbic medial prefrontal cortex and

the basolateral and central (lateral part) nuclei of the amygdala proved to be involved in empathic behavior, medial and cortical amygdala and the ventral hippocampus did not.

Title: Effects of a ketogenic diet in BTBR mice using a novel test-retest protocol in the 3-chamber sociability test

Authors: *D. N. RUSKIN, J. H. ALTSCHULER, H. S. REUMAN, S. A. MASINO; Trinity Col., HARTFORD, CT

Abstracts: Sociability can be impaired or abnormal in psychiatric/neurological conditions such as autism, schizophrenia, neurofibromatosis type I and brain injury. Treatments that could aid social functioning would be of great benefit. Mouse models exist for many of these conditions, and there are several ways to assess sociability. For instance, play behavior and ultrasonic vocalization can be studied in juveniles, and a common test for sociability in adults is the 3-chamber test. The relevant apparatus has one center and two side chambers. After a side preference assessment phase, a stranger mouse (novel to the test mouse) is contained in a small enclosure in one side chamber, the opposite side chamber contains an empty enclosure, and the test mouse is allowed to wander among the three chambers. Normal mice prefer to be social and spend more time in the side with the mouse. In contrast, on average, mice with impaired sociability, such as the BTBR mouse model of autism, are asocial and do not have a preference. However, a group of BTBR mice may contain individuals that are social and others that are

antisocial (preference for the empty chamber). To understand the reliability of sociability over time we performed a retest implementation of the 3-chamber test. Mice (either the social control strain CD-1 or the autism model strain BTBR) underwent a 3-chamber test at five weeks of age. Mice were retested at eight weeks of age, with different stranger mice in the small enclosure (to maintain social novelty). In addition, between tests some BTBR mice were fed a Ketogenic diet, a metabolic therapy we have shown enhances sociability in this test in this mouse strain (Ruskin et al 2013 PLOS ONE). We found that CD-1 mice were stably social over the two tests, and BTBR mice on their normal chow diet were stably asocial (no preference as a group) over the two tests. Notably, the Ketogenic diet-fed BTBR mice, confirmed to be asocial as a group in the first test, were significantly social in the second test, confirming the benefits of the ketogenic diet. In addition, if analysis was restricted to the BTBR mice that preferred to spend time in the empty chamber, the ketogenic diet also significantly enhanced sociability in this population of identified antisocial animals. This test-retest implementation might have several useful applications, including reducing animal use, identifying social and antisocial subpopulations before further experimentation, and assessing reversibility of experimental treatments. It may have particular utility in environmental models of animal autism, in which environmental insults early in development may produce inconsistent effects on adult sociability.

Title: Effect of GABAAR subtype-selective positive allosteric modulators in the BTBR mouse model of autism

Authors: *R. F. YOSHIMURA, M. B. TRAN, D. J. HOGENKAMP, R. J. EGUSQUIZA, T. K. GEE, K. W. GEE;
Pharmacol., Univ. of California, Irvine, Irvine, CA

Abstracts: Autism spectrum disorder (ASD) is characterized by core behavioral symptoms including deficits in social interaction, communication and repetitive/stereotypical behavior. ASD has significant comorbidities with epilepsy, cognitive impairment and anxiety which suggest the potential involvement of the γ-aminobutyric acid-A receptor (GABAAR). In support of this, studies on ASD patients have reported a downregulation in the enzymatic synthesis of GABA and a selective reduction in GABAAR expression. Amelioration of this deficit in inhibitory neurotransmission could be a promising pharmacological target for the treatment of ASD. The BTBR mouse strain is characterized by a behavioral phenotype with core deficits similar to that of ASD patients. BTBR mice show decreased sociability in the three-chamber social approach paradigm and increased repetitive behavior in the self-grooming paradigm, both of which are reversed using the mGluR5 negative allosteric modulator, GRN-529. We have tested the beta-subunit subtype-selective GABAAR positive allosteric modulator, 2-261, in both the social approach and self-grooming behavioral paradigms and compared it to GRN-529. The data from these studies provide encouragement that novel treatments for ASD can be developed from GABAAR subtype-selective positive allosteric modulators.

Abstracts: Cognitive control encompasses a range of abilities that allow for flexible allocation of mental resources and direction of behavior depending on one’s current goals. Previous research has shown that cognitive control impairments play a large role in the pathology of

Autism Spectrum Disorders (ASD), which are characterized by social and communication deficits, as well as general mental inflexibility. The current study aimed to further elucidate the role of cognitive control in late childhood and ASD by using a social and non-social conflict adaptation task. Thirty-seven children with ASD and thirty-two typically developing (TD) ages 7 to 15 completed the tasks. Participants were asked to respond to a target word (LEFT or RIGHT) in the presence of task-irrelevant stimuli (an arrow or face with averted gaze) that were congruent or incongruent with the target word. Trials on both tasks were embedded in blocks that varied by percent of incongruent trials, placing demands on either moment-to-moment control (25% incongruent trials) or task-set maintenance (75% incongruent trials). Participants' parents also filled out questionnaires regarding the child's executive and social behaviors, including the Behavior Rating Inventory of Executive Function (BRIEF) and Social Responsiveness Scale (SRS). Accuracy was calculated using the percent of Incongruent trials correctly answered. Accuracy was analyzed separately for the two block types using Group x Task repeated measures ANOVAs. As predicted, ASD participants were more error prone than their TD counterparts on both tasks during the Moment-to-Moment Adjustment blocks, $F(1,67) = 4.81$, p .05. Furthermore, performance on Moment-to-Moment Adjustment blocks for the Arrows task negatively correlated with parent ratings on the BRIEF, $r(59) = -.38$, $p < .05$, and its subscales for Inhibit, $r(59) = -.36$, $p < .05$, Shift, $r(59) = -.25$, $p = .05$, and Emotional Control, $r(59) = -.31$, $p < .01$, as well as the SRS subscales for Social Awareness, $r(62) = -.27$, $p < .05$, and Autistic Mannerisms, $r(62) = -.25$, $p < .05$, suggesting that worse cognitive control skills in daily life were related to greater difficulty making fast adjustments to conflicting non-social stimuli. Performance on Task-Set Maintenance blocks for the Faces task negatively correlated with the BRIEF subscales for Emotional Control, $r(59) = -.34$, $p < .05$, and Monitor, $r(59) = -.26$ $p < .05$, and SRS subscales for Social Awareness, $r(62) = -.25$, $p < .05$, Social Communication, $r(62) = -.29$, $p < .05$, and Autistic Mannerisms, $r(62) = -.25$, $p < .05$, suggesting that worse social skills were related to greater difficulty maintaining a task set with social stimuli.

Title: Impact of virtual stimulation on motor skills of autistic children

Authors: *C. N. CRESPO CORTÉS[1], P. SAFT[2], G. A. CORIA-AVILA[2], L. I. GARCIA[2], M. E. HERNANDEZ[2], J. MANZO[2];
[1]Univ. Veracruzana, Veracruz, Mexico; [2]Ctr. de Investigaciones Cerebrales, Univ. Veracruzana, Xalapa, Mexico

Abstracts: Previous studies showed the benefits of virtual stimulation for motor deficits. In autism, some children have motor problems, including low muscle tone. Thus, there is a huge effort to face this challenge. Present work stimulated the movement of 10 autistic children between 4 and 12 years old with a similar diagnosis of autism, from the Child Rehabilitation Center of Veracruz, Mexico. We used the Wii-Nintendo video game to stimulate the subjects with the "Wii sports" for 10 weeks, twice a week, 20 minutes each session. The sports used on the screen were two pairs, two with a fixed target (boxing and bowling), and two with a target in motion (tennis and baseball). At first the facilitator played the games to catch the attention and stimulate the subjects to imitate the movements and to play by themselves. Data collection was made by direct observation and organized in eleven categories according to movements observed in subjects per session. Results indicated that attention was poor at the first four tests. Starting at the fifth test a long attention was observed in all subjects until the end of the study. The fifth session represented also the time when subjects took the remote without any assistance. At session 1 only 30% of subjects could mimic de movement, however at session 7, 90% of the kids were capable to mimic the specific movement for a sport. At session 1 only 10% pressed the A button of the remote, but at session 6 all the individuals press button A to start the game. And this learning remained until the end. Pressing button B was a more complex concept, because the button is not visible, however at the 9th session, 70% of subjects used it. At the beginning no subject could make a movement toward the target, however starting at the 6th session 70% of the kids made a movement toward a target. Subjects became more skilled in sports with a fixed target. Data showed that autistic children are sensitive to virtual stimulation and responds to it following a two-week stimulation, and the acquisition of the skill remains for a long term. Thus, virtual stimulation not only enhanced the motor skill of the subjects but also the process of learning and memory of what is the goal of a challenge. Our hypothesis is that fixed target were more stimulating, and preferred by the subjects, because they can direct a movement to a target, but following a target is a more complex task to achieve. However, we suggest that they will be able to follow targets with further stimulation.

Title: Animals reared in impoverished conditions are slower to habituate to the reinforcing effects of sensory reinforcers

Authors: *R. WANG, J. B. RICHARDS, D. R. LLOYD, S. HAJ-DAHMANE, R.-Y. SHEN; Res. Inst. on Addictions, SUNY at Buffalo, Buffalo, NY

Abstracts: Background Restricted, repetitive and stereotyped patterns of behavior are one of three core diagnostic features of autistic disorder. It has been hypothesized that stereotyped behavior is maintained by sensory reinforcement (Often referred to as automatic reinforcement). Stereotyped behaviors such as “rocking” are displayed to some degree by most individuals. Autistic individuals have more frequent and persistent stereotyped behaviors. We hypothesize that increased frequency and persistence of stereotypy in autism disorder is due to a failure of normally occurring habituation of reinforcer effectiveness. We (Lloyd et al., 2012) have previously reported that habituation modulates responding for a sensory reinforcer (light onset). This research examined how environmental factors can modulate habituation in responding for sensory reinforcers (light onset). Rats were reared in impoverished (IC), enriched (EC), and social (SC) conditions after weaning. Dishabituation challenges were used to rule out motor and/or sensory fatigue explanations of within-session declines in responding. Method EC (n=10), IC (n=16), and SC (n=10) rats were placed into dark test chambers for 1-hour/day. Entries into 2 snout poke holes were counted. During test sessions 1-10 snout poking had no programmed effect. Beginning with test session 11, light onset (5 s) was made contingent upon responding into one of the 2 snout poke holes (active). Dishabituation challenges were performed by presentation of a loud warbling tone and by altering the location of the response-contingent light onset. Results EC rats habituated much more rapidly than SC and IC rats, and responding was higher in SC and IC rats during all phases of the study. Tests of dishabituation produced robust dishabituation in SC and IC rats, and produced smaller inconsistent effects in EC rats. Conclusion The results indicate that the reinforcing effects of sensory stimuli habituate more rapidly in EC than in IC and SC rats, resulting in less stereotypy. The dishabituation challenges

indicate that these differences are not due to adaptation or sensory fatigue. Therefore, enriched environment could be effective in reducing stereotypy in individuals with autistic disorder.

Title: Behavioral motor deficits in juvenile mice induced by unilateral cerebellar haemorrhage and inflammation

Authors: ***S. TREMBLAY**, D. GOLDOWITZ;
CMMT, Vancouver, BC, Canada

Abstracts: Background: Extreme preterm infants are exposed to multiple stressors during their postnatal development including perinatal cerebellar haemorrhage (CBH) and postnatal infection, two major risk factors for neurodevelopmental impairments. In order to understand how cerebellar development is altered by those insults, we developed an animal model using a cerebellar haemorrhagic insult combined with an early or late inflammatory event in mice pups. Methods: Unilateral intraparenchymal CBH was induced by using local injection of bacterial collagenase (0.15U) at postnatal day 1 (P1) combined with intraperitoneal lipopolysaccharide (LPS) injection (300µg/kg) concomitantly (early inflammatory state, EIS) or at P5 (late inflammatory state, LIS). Mice were behaviourally tested on a modified mouse neurological exam every day until P15 and cerebellar tissues were collected at P2 and P15. At P15, tests were performed to further assess locomotor activity, motor coordination and muscular strength. Results: Unilateral cerebellar haemorrhages induced at P1 delays forelimb grasp acquisition in neonatal mouse pups by 24-48 hours and increases locomotor activity in P15 mice during open-field recording (1357±287 vs 2583±562sec, p=0.048). Early inflammatory state induction also

leads to comparable delay in neonatal forelimb grasp acquisition followed by a significant decrease in grip strength (0.036±0.002 vs 0.027±0.003kg, p=0.037) and muscular strength measured by the inverted screen task in juvenile mice (18.4±2.1 vs 8.6±1.9sec, p=0.003). However, late inflammatory state did not induce any significant neonatal or juvenile behavioural impairment. Combined model of cerebellar haemorrhage with either an early or late inflammatory state did not worsen juvenile muscular strength or motor function. Preliminary histological data looking at 24 hours after the haemorrhagic event combined or not with inflammation shows an increase in total microglial cells in the single and double insult models in both hemispheres along with a greater increase of microglial cells in the ipsilateral white matter area in relation with cerebellar haemorrhage. Conclusions: Early insults in the developing neonatal brain alters juvenile motor milestones in a mouse model of cerebellar haemorrhage combined with early systemic inflammatory stress. This new model will allow us to measure short and long-term impact of combined early insults on cerebellar development, their impact on neurobehavior and test neuroprotective strategies to improve extremely preterm infant neurodevelopmental outcomes.

Title: The role of mTOR signaling in parvalbumin interneuron function

Authors: *A. KOEPPEN-BABCOCK;
Psychiatry, Children's Hosp. of Philadelphia, Philadelphia, PA

Abstracts: Mutations in phosphatase and tensin homolog on chromosome ten (Pten), a tumor suppressor gene that inhibits the mammalian target of rapamycin (MTOR) pathway, have been linked with a subset of autistic patients that exhibit spontaneous seizures and macrocephaly. Recent studies using Nse-Cre conditional Pten knockouts found that haplo-insufficient mice had significant decreases in cytochrome c oxidase activity and increased mtDNA mutations. Because of this increase in mitochondrial stress, GABAergic parvalbumin interneurons, which are fast

spiking and non-accommodating, should be particularly vulnerable to these effects due to their high metabolic needs. To test this idea, PTEN-loxP mice have been crossed to Lhx6-Cre, in which Cre is mainly expressed in PV and SST- interneuron subgroups of the cerebral cortex and striatum. Both knockout and haplo-insufficient mice have larger parvalbumin interneurons in the cortex, hippocampus, and striatum at P21. No apoptosis was observed at P15 or P21. Experiments to measure the electrophysiological activity of parvalbumin interneurons, to quantify the accumulation of mitochondrial mutations, and to examine social behavior of the haplo-insufficient mice are ongoing.

Title: Diagnostic prediction in autism using random forest and classification trees of functional connectivities

Authors: *C. P. CHEN[1], A. JAHEDI[2], R. MUELLER[3];
[1]Computat. Sci. Res. Ctr., [2]Mathematics and Statistics, [3]San Diego State Univ., San Diego, CA

Abstracts: Although autism spectrum disorder (ASD) is considered a neurological disorder, there are no established brain biomarkers. Supervised machine learning approaches to diagnostic classification are ideally suited to reveal potentially complex patterns of biomarkers. We used Random Forest, Classification and Regression Trees on resting state functional connectivity MRI data. While the Random Forest procedure identifies the variables (connections) most informative for diagnostic prediction, interpretation of the interaction between these informative variables requires Classification and Regression Trees (CART). Methods We used resting state fMRI data from 252 low-motion participants (126 ASD, 126 TD) from the Autism Brain Imaging Data Exchange (ABIDE), matched on age, nonverbal IQ, and head motion. FMRI data were motion corrected, aligned to high-resolution anatomical, standardized to the MNI152 template, and blurred to a 6mm global full-width-at-half-maximum. Six rigid-body motion parameters, time

series from white matter and ventricles, and derivatives were modeled as nuisance regressors. Time points with motion >.25mm (and their neighbors) were censored. We chose 220 regions of interest (ROIs) from Power et al. (2011), using 10mm spheres to extract an average signal from each. For each ROI pair, a feature was defined as functional connectivity (time series correlation; 24090 total features). We used the top features selected from binary classification and modeled their interaction. Random forest is a multivariate machine learning method that uses an ensemble of classification trees and aggregates their results, capitalizing on linear and non-linear interactions of features. CART is a decision tree technique for dataset segmentation that provides rules applied to new datasets for prediction. Results RF achieved a peak 91% accuracy with 100 informative features. To reduce complexity, we selected 20 most informative features (83% accuracy) for the CART model. Prominent among these were somatosensory/motor and salience network ROIs, accompanied by ventral attention, default mode, and subcortical ROIs. Conclusions While RF machine learning achieved high diagnostic classification accuracy with features involving >100 ROIs, CART - albeit at a lower accuracy - allowed for improved interpretation of findings with respect to most informative regions and their complex interactions. The pivotal role of ROIs in somatosensory, motor, and salience networks adds novel evidence to the growing literature on these systems in ASD.

Title: Differences in neuronal activation and gene expression in the fragile X mouse

Authors: ***T. D. ROGERS**, C. G. FORSBERG, J. VEENSTRA-VANDERWEELE; Vanderbilt Univ., Nashville, TN

Abstracts: Abnormal social behavior is a core symptom of autism spectrum disorders (ASD) and fragile X syndrome (FXS). Interestingly, previous studies have demonstrated an association of amygdala activation with both social approach and social avoidance behavior. Further, both functional and structural neuroimaging studies have implicated the amygdala and prefrontal

cortex (PFC) in ASD. It is currently unclear whether molecular changes occurring in the amygdala and PFC could mediate altered social behavior observed in ASD and FXS. We used the Fmr1 knockout (KO) mouse, which displays altered social behavior, to further investigate this relationship. To determine the impact of a loss of Fmr1 expression on neuronal activation patterns, we used immediate early gene activation (cFos) immunohistochemistry and compared neuronal activation patterns in different brain regions across conditions and genotypes following exposure to a sociability task. The presentation of a novel mouse, as compared to the presentation of a novel item, elicited increased levels of activation in the lateral amygdala (LA) and medial amygdala (MA) and decreased levels of activation in the PFC in wildtype animals ($p < 0.05$). Fmr1 KO mice displayed hyperactivation in LA and MA and hypoactivation in PFC ($p < 0.05$) across both behavioral conditions as compared to littermate controls ($p < 0.01$). Additionally, levels of activation in the LA and MA were negatively correlated with those of the PFC ($p < 0.001$ and $p < 0.005$, respectively), while LA and MA activation levels were positively correlated ($p < 0.005$). In order to identify molecular changes that might mediate altered patterns of neuronal activation and abnormal social behavior, we used RNA sequencing to examine differential gene expression in LA, MA, and PFC of mice from each condition and genotype. An analysis of the interaction between condition and genotype indicated that genes that might affect neurotransmission, such as Th, Gad1, and Oxtr, were differentially expressed in the amygdala ($p < 0.05$). This analysis also indicated that multiple autism candidate genes, including Reln, Sema5a, and Met, were significantly differentially expressed ($p < 0.05$). Real-time PCR is currently underway to confirm the differential expression of genes of interest. The current findings indicate that the amygdala and PFC display differences in neuronal activation and gene expression following exposure to social stimuli as compared to non-social stimuli. Differences in gene expression in these two brain areas in response to social challenge may suggest a mechanism for changes in the neuronal activation patterns and altered behavioral responses in Fmr1 KO mice.

Title: Choroid plexus target-based therapy in rats with chronic hydrocephalus: Use of an aquaporin-1 antibody treatment

Authors: H. L. PHILLIPS[1], S. SURASH[2], M. G. LUCIANO[3], J. CROSS[1], *J. R. HOLLERMAN[1];
[1]Psychology/Neuroscience, Allegheny Col., MEADVILLE, PA; [2]Nuffield Hlth., Newcastle upon Tyne, United Kingdom; [3]Pediatrics and Neurocognitive, Cleveland Clinic, Main Campus, Cleveland, OH

Abstracts: Hydrocephalus is characterized by an excessive accumulation of cerebrospinal fluid (CSF) in the ventricular system, which causes a swelling of the lateral, 3rd and 4th ventricles, also referred to as ventriculomegaly. Current treatments for the disorder include procedures such as implantation of a shunt system or a 3rd ventriculostomy. These options are invasive and tend to fail within three to five years, resulting in multiple surgeries in a patient's life. Aquaporin-1 (AQP1), a water channel showing high expression on the apical surface of the choroid plexus has shown to play an important role in CSF formation. Previous research has predicted that an AQP1 antibody could serve as a potential adjunct therapy in treating patients with hydrocephalus. The aim of the present study was to analyze whether an AQP1 antibody treatment in the right lateral ventricle of a hydrocephalic rat model could improve the common physiological and behavioral deficits characterized by the disorder. Anatomical analysis and immunohistochemistry (IHC) was used to assess uptake of the antibody as well as effects on ventricle size. IHC was also used to assess possible uptake of antibody in another AQP1 expressing organ, the kidney. Behavioral changes were measured with the Morris water maze and the object preference test. Results showed that animals treated with an AQP1 antibody in the right lateral ventricle expressed positive staining, indicating antibody uptake, as well as significantly smaller right and left ventricles nearest the pump implant compared to saline treatment animals. There was no positive staining of the antibody in the kidneys. Behavioral improvements in memory and cognition tasks across the 14-day treatment were observed. This study indicates a viable relationship between AQP1 antibody therapy and improvement in behavioral and physiological symptoms of hydrocephalus.

Title: Evaluation of ganaxolone in B6 mice and the BTBR mouse model of autism

Authors: *T. M. KAZDOBA[1,5], D. ZOLKOWSKA[2], M. A. ROGAWSKI[2], R. J. HAGERMAN[3], J. N. CRAWLEY[4];
[2]Dept. of Neurol., [3]3MIND Inst. and Dept. of Pediatrics, [4]MIND Inst. and Dept. of Psychiatry and Behavioral Sci., [1]Univ. of California, Davis, Sacramento, CA; [5]MIND Inst. and Dept. of Psychiatry and Behavioral Sci., Univ. of California Davis, Sacramento, CA

Abstracts: Excitatory and inhibitory neurotransmission abnormalities, particularly reduced GABAergic inhibition and fewer inhibitory interneurons, are hypothesized to contribute to the symptoms of autism spectrum disorder. BTBR T+ Itpr3tf/J (BTBR) is an inbred strain of mice that models idiopathic autism. BTBR exhibit deficits in social approach, reciprocal social interactions and associated ultrasonic vocalizations, high repetitive self-grooming, and cognitive deficits. Recently, BTBR mice were reported to show reduced spontaneous GABAergic neurotransmission, and low doses of benzodiazepines rescued sociability deficits in BTBR (Han et al., 2014), suggesting that positive allosteric modulators (PAMs) of $GABA_A$ receptors may improve certain aspects of the autism phenotype. Ganaxolone, a synthetic neurosteroid that acts as a PAM at synaptic and extrasynaptic $GABA_A$ receptors, displays anticonvulsant properties in rodent models of seizure and epilepsy, and has an anxiolytic-like profile in the elevated plus maze (Reddy and Rogawski, 2012). Here we evaluated ganaxolone in BTBR mice and in the control social strain C57BL/6J (B6) to determine whether this PAM of $GABA_A$ receptors affects mouse behaviors relevant to diagnostic and associated symptoms of autism. Acute ganaxolone treatment was assessed for its effects on sociability in the three-chambered social approach task, and for its impact on male-female reciprocal social interactions and concomitant vocalizations, spontaneous repetitive self-grooming, and marble burying and digging. In addition, we assessed anxiety-related behaviors in the elevated plus maze and light↔dark exploration test, and exploratory locomotor activity in a novel open field. Evaluation of novel treatments in the BTBR mouse model, particularly those targeting GABA neurotransmission, may lead to the preclinical identification of compounds that show clinical promise for ameliorating the core symptoms of autism.

Title: Social deficits with the Neurofibromatosis type 1 mutation, a role for the extracellular signal-regulated kinase (ERK) pathway

Authors: *D. H. ARENDT[1,2], C. BERNABE[3], L. FEDERICI[3,4], S. FITZ[2], W. D. CLAPP[5,6], A. I. MOLOSH[2,4], P. L. JOHNSON[3,7], A. SHEKHAR[2,7,4,8];
[2]Psychiatry, [3]Anat. and Cell Biol., [4]Stark Neurosciences Res. Inst., [5]Pediatrics, [6]Microbiology&Immunology, [7]Clin. and Translation Sci. Inst., [8]Pharmacol. and Toxicology, [1]IU Sch. of Med., Indianapolis, IN

Abstracts: Neurofibromatosis type 1 (NF1) is a genetic disorder that affects approximately 1 in 3500 individuals and often presents with social and cognitive disabilities. In the past, we have shown that Nf1 knockout mice exhibit deficits in longterm social memory coupled with increased phosphorylation of ERK in Nf1 neuronal cultures. Despite the social deficits, the Nf1 deletion does not impair the animal's ability to distinguish a novel and familiar object. When the P21-activated kinase 1 (Pak1) gene, which also regulates the ERK pathway, was co-deleted with Nf1 (Nf1/Pak1), social deficits seen with a single Nf1 deletion were rescued. Since phosphorylation of ERK is a common feature of both these regulatory genes (Nf1 and Pak1) we further investigated this pathway as it related to social memory. For this work we focused on the amygdala as a range of preclinical and fMRI data have implicated this area in social recognition and memory. Furthermore, our previous work has shown that projection neurons within the basolateral amygdala (BLA) have enhanced miniature inhibitory post-synaptic currents and decreased long-term potentiation in Nf1 knockout mice. Therefore, we hypothesized that acute inhibition of Pak1 with an inhibitor (IPA3) in the BLA would rescue the deficits seen in the Nf1 knockout mice similar to the Nf1/Pak1 co-deletion as we have previously demonstrated. Social memory was tested by utilizing a standard three chamber test for mice. While Nf1 knockout animals did display increased short term preference to the novel mouse with Pir3.5, they did not show a long term social preference. However, when IPA3 (but not Pir3.5, its inactive enantiomer) was administered, long term social memory was restored in NF1 knockouts as

measured by an elevation in contact time with the novel partner. Finally, pharmacologically enhanced levels of pERK within the BLA of WT animals were attenuated with the application of IPA3, further confirming its ability to block ERK phosphorylation. This study adds to a growing body of evidence that ERK activation plays a Key role in social memory. Elucidating this exact mechanism may be critical in treating disorders that present with social deficits.

Title: Purinergic P2X4 knockout mice exhibit altered expression of dopaminergic proteins. Implications of P2X4 receptors in multiple neurological disorders

Authors: ***S. KHOJA**[1], L. ASATRYAN[2], M. W. JAKOWEC[3], D. L. DAVIES[2];
[1]Pharmacol. and Pharmaceut. Sci., [2]Clin. Pharm. and Pharmaceut. Econ. and Policy, [3]Neurol., USC, Los Angeles, CA

Abstracts: Purinergic ionotropic P2X receptors (P2XRs) are homo- and heterotrimeric cation permeable channels activated by extracellular adenosine-5'-triphosphate (ATP). Of the seven subunits of P2XRs, P2X4 receptors (P2X4Rs) are the most abundant in the central nervous system. P2X4Rs have been implicated in regulation of various functions including neuroendocrine functions and hippocampal synaptic plasticity. P2X4Rs have been reported to interact with other major neurotransmitter systems including the GABAergic, glutamatergic and dopaminergic systems. Presently, there is a paucity of information regarding the the role of P2X4Rs in pathophysiology of neuropsychiatric disorders. Using a series of behavioral tests, we reported that P2X4R KO mice exhibit deficits in sensorimotor gating and socio-communication compared to wildtype (WT) mice. Such behavioral deficits are relevant to various neurological disorders including autism spectrum disorders, schizophrenia, and bipolar disorder. In addition, male P2X4R KO mice exhibit higher intake of and preference for ethanol compared to WT mice suggesting that P2X4Rs may contribute to regulation of ethanol intake and play a role in

pathophysiology of alcohol addiction. Furthermore, we reported significant changes in expression of multiple subunits of glutamate ionotropic receptors including α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPARs) and N-Methyl-D-aspartate receptors (NMDARs) and of $GABA_A$ receptors in P2X4R KO mice. The current study tests the hypothesis that dysregulated dopamine function may contribute to behavioral deficits in P2X4R KO mice. We measured expression of tyrosine hydroxylase (TH), dopamine transporter (DAT), dopamine D1 and D2 receptors (D1Rs and D2Rs) and dopamine and cAMP regulated phosphoprotein of 32kDa (DARPP-32) in dorsal and ventral striatum, midbrain and prefrontal cortex of P2X4R KO mice using western blotting. P2X4R KO mice exhibited reduced expression of TH in dorsal, ventral striatum and midbrain compared to WT mice. In addition, there was significant increase in expression of DAT in ventral striatum of P2X4R KO mice compared to WT mice. Further, we found significant increase in expression of D2Rs in midbrain in P2X4R KO mice. Taken together, these findings suggest potential association between P2X4Rs and dopamine neurotransmission. Perturbation of this cross talk may be one of the underlying mechanisms for the behavioral deficits in P2X4R KO mice. Overall, these findings suggest that P2X4Rs may have a role in pathophysiology of severe neuropsychiatric disorders through regulation of dopamine function.

Title: Behavioral consequences of disrupted MET signaling

Authors: *B. L. THOMPSON[1], W. RODRIGUEZ[2], P. LEVITT[2];
[1]Cell and Neurobio., Univ. of Southern California, Los Angeles, CA; [2]Childrens Hosp. of Los Angeles, Los Angeles, CA

Abstracts: Our laboratory discovered that the gene encoding the receptor tyrosine kinase, *MET*, contributes to autism risk. These studies utilized genetically modified mouse lines to dissect the roles of *Met* in the neurobiological underpinnings of neurodevelopmental disorders to test our

hypothesis that disruption of Met signaling during development has functional consequences on the maturation of cortical circuits and specific behaviors that are altered in autism. We generated two conditional mouse lines in which *Met* is deleted from select populations: 1) $Met^{fx/fx}/Emx1^{cre}$ (deleted from all cells arising from the dorsal pallium) and 2) $Met^{fx/fx}/Nestin^{cre}$ (deleted from all neural cells). A battery of behavioral tests was performed to assess cognitive, emotional, and social disturbances that are observed in multiple neurodevelopmental disorders, including autism spectrum disorders, and that, are in part sub-served by circuits that express Met. Multiple cohorts of mice were tested in early adulthood on rotarod, activity chamber, elevated plus maze, spontaneous alternation in the t-maze, olfactory dishabituation, social novelty preference, marble burying, contextual fear conditioning, and direct social interaction with simultaneous USV recordings. We found that the null $Met^{fx/+}/Emx1^{cre}$ mice display significant hypoactivity in the activity chamber and in the t-maze despite normal performance on the rotarod. Additionally, these animals show a deficit in spontaneous alternation. These mice show normal anxiety, olfactory dishabituation, social novelty preference, contextual fear conditioning, and marble burying. In comparison, the null $Met^{fx/fx}/Nestin^{cre}$ mice display deficits in contextual fear conditioning, and a weak deficit in sociability in the social novelty preference task. These mice show normal performance on rotarod and activity chamber, anxiety, spontaneous alternation, olfactory dishabituation, and marble burying. These data suggest a complex contribution of Met in the development of social, emotional, and cognitive behavior. The impact of disrupting developmental Met expression is dependent upon the circuit-specific deletion pattern. The null $Met^{fx/fx}/Nestin^{cre}$ mice (*Met* deleted from every cortical cell) show behavioral phenotypes consistent with autism. In contrast, the null $Met^{fx/+}/Emx1^{cre}$ mice (*Met* deleted from cells arising from the dorsal pallium) show a different behavioral repertoire, with decreased exploratory behavior and memory. Future studies will determine the impact of environmental interactions with the deletion of Met from the $Met^{fx/fx}/Nestin^{cre}$ mice on further social, emotional, and cognitive behaviors.

Title: Haploinsufficiency of the autism-linked gene Protocadherin 10 causes male-specific behavioral deficits

Authors: H. SCHOCH[1], *S. L. FERRI[1], A. S. KREIBICH[2], H. C. DOW[2], S. HIRANO[3], R. T. SCHULZ[4], E. S. BRODKIN[2], E. ABEL[1];
[1]Biol., [2]Psychiatry, Univ. of Pennsylvania, Philadelphia, PA; [3]Cell Biol., Kansai Med. Univ., Osaka, Japan; [4]Ctr. for Autism Res., Children's Hosp. of Philadelphia, Philadelphia, PA

Abstracts: Boys are five times as likely to be affected by autism spectrum disorders (ASD) as girls, but the genetic and hormonal contributions of this sex difference are not clear. The gene PCDH10 has been linked to ASD in human studies. Its product, the calcium-dependent adhesion molecule Pcdh10, plays an important role in pruning of excitatory synapses in the brain. Pcdh10 is expressed in several brain areas associated with cognition and social behavior. Mice heterozygous for a deletion of Pcdh10 (Pcdh10+/- mice) display reduced sociability in the Social Approach Test and impairment in fear conditioning tasks. Remarkably, these impairments were present exclusively in males. Pcdh10+/-mice showed no deficits in locomotor activity in the rotarod test, no deficits in olfactory acuity or discrimination to social or non-social odorants in the olfactory habituation-dishabituation task, and no alternation in nonsocial anxiety-related behaviors in the elevated zero maze or open field test. Here, we explore the role of gonadal hormones in mediating sex-specific behavioral deficits in Pcdh10+/- mice.

Title: A touchscreen version of delayed non-match to position (DNMTP) in inbred mice

Authors: *P. T. LEACH[1], J. N. CRAWLEY[2];
[1]Psychiatry, MIND Institute, Univ. of California Davis Sch., Sacramento, CA; [2]Psychiatry, MIND Institute, Univ. of California Davis Sch. of Med., Sacramento, CA

Abstracts: Mouse models of neurodevelopmental disorders with intellectual impairments have been extensively characterized, but more challenging cognitive phenotyping analyses are needed, especially on complex working memory tasks. Touchscreen operant chambers may be useful for the further characterization of mouse models of neurodevelopmental disorders, particularly those characterized by more subtle cognitive deficits. Here we demonstrate effective methods for conducting delayed non-matching to position in touchscreen chambers. To confirm high baselines that will enable detection of deficits in mutant mouse models, the task was first validated in two inbred strains of mice, C57BL/6J and FVB/AntJ, which display good cognitive abilities in other tasks, and are frequently used as the genetic background for targeted mutations. Briefly, mice were trained to press the touchscreen in a random spatial position, indicated by an illuminated square. When a nose poke occurs in the food magazine at the rear of the chamber, the illuminated square appears in the initially presented position and in a novel position. Successful non-matches to position, i.e., pressing on the novel position, are rewarded with 20 µl strawberry Ensure milkshake. Unsuccessful choices are followed by a timeout and a correction trial. After reaching the criterion of 80% correct responses for 2 days, delays of 1, 3, and 10 seconds are introduced. FVB mastered the non-match rule in an average of ~25 days, and demonstrated delay-dependent performance in this touchscreen task.

Title: Shank3+/- mice exhibit probabilistic learning deficits, but not altered repetitive behaviors

Authors: A. SYED[1], D. A. AMODEO[3], J. A. SWEENEY[4], *M. E. RAGOZZINO[2];
[1]Psychology, [2]Univ. Illinois Chicago, CHICAGO, IL; [3]Psychology, Univ. of Illinois at Chicago, Chicago, IL; [4]Psychiatry, Univ. of Texas Southwestern, Dallas, TX

Abstracts: The Shank3 gene codes for a post-synaptic scaffolding protein found at glutamatergic synapses. Alterations in the Shank3 gene have been repeatedly linked to autism spectrum disorder (ASD) including 22q13 deletion syndrome in which autistic behaviors are exhibited. One of the core features observed in ASD is an "insistence on sameness" or behavioral inflexibility. While Shank3 null mutant mice exhibit reversal learning deficits, it is unclear whether Shank3 heterozygote mice also display behavioral inflexibility. In a recent study, we found that individuals with ASD acquire a two-choice spatial discrimination with probabilistic reinforcement as quickly as controls, but were impaired during reversal learning. The present experiment examined whether Shank3+/- mice exhibit learning and/or reversal learning deficits with probabilistic reinforcement. In addition, mice were tested for repetitive grooming and marble burying behavior to determine whether Shank3+/- may display other repetitive behaviors. Shank3+/- and B6 mice were tested in a spatial discrimination task using a 80/20 probabilistic reinforcement procedure. In the spatial discrimination, mice were tested on acquisition and reversal learning across two consecutive days. Mice learned to obtain a cereal reinforcement from the "correct" spatial location (reinforced on 80% of trials) compared with the "incorrect" spatial location (reinforced on 20% of trials). The learning criterion in both phases was choosing the 'correct' location on 6 consecutive trials. For grooming behavior, mice were individually placed in a clear plastic cage and the cumulative time spent grooming all body regions across 10 min was recorded. For marble burying, 20 glass marbles were placed on top of 3 cm of clean woodchip bedding in a clear plastic cage. Mice were allowed to explore the container and marbles for 30 min. Marbles were considered buried if $\geq 2/3$ of the surface area was covered in woodchip bedding. In the spatial discrimination test, Shank3+/- mice exhibited an initial learning deficit, as well as a reversal learning deficit suggesting that there is a basic learning impairment when feedback is provided in a probabilistic manner. Shank3+/- mice more frequently shifted back to the incorrect choice when mice were not reinforced for a correct response. In contrast, Shank3+/- mice did not exhibit increased grooming or marble burying behavior. Because Shank3 mutations associated with ASD and 22q13 deletion syndrome are heterozygous, studying the Shank3+/- mouse can be useful for understanding the pathophysiology related to certain ASD features.

Title: Mutant DISC1 produces smaller Purkinje cells and impairs recognition memory and social behavior in adult mice

Authors: *A. V. SHEVELKIN[1,2], B. N. ABAZYAN[2], G. L. RUDOW[3], J. C. TRONCOSO[3], C. A. ROSS[2], M. V. PLETNIKOV[2,4];
[1]P.K.Anokhin Inst. Norm Physiol, Moscow, Russian Federation; [2]Departments of Psychiatry and Behavioral Sci., [3]Pathology, [4]Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstracts: Disrupted-In-Schizophrenia-1(DISC1) and its variants have been associated with neurodevelopmental disorders, including schizophrenia and autism spectrum disorders (ASD). Purkinje cells (PC) express DISC1. We generated a mouse model of inducible and selective expression of mutant DISC1 in PC. Here, we sought to analyze the brain and behavioral alterations in this transgenic mouse model. We evaluated volume of the cerebellum and PC in mice at postnatal (P) day 21 and assessed behavioral phenotype in male and female mice of 3-7 months of age using a series of tests relevant to schizophrenia and ASD, including novelty-induced activity, elevated plus maze, Y maze, object and place recognition, fear conditioning and rotarod. We found a significant decrease in Purkinje cells size. Neither total number of PC nor volume of the cerebellum were significantly altered in mutant DISC1 mice. No cellular markers of inflammation were observed in mutant mice. Neurobehavioral phenotyping showed abnormal social interaction, hyperactivity in open field and deficient novel object recognition in male mice. We observed no group differences in elevated plus maze, spontaneous alteration or spatial recognition in Y maze. Electrophysiological analysis of PC activity is in progress. Our findings indicate that mutant DISC1 affects PC morphology and produces cognitive and social abnormalities in adult mice. This may have the potential to advance our knowledge of the role for DISC1 in maturation and function of the cerebellum related to neurodevelopmental disorders.

Title: Autism-associated insertion mutation in shank3 results in impaired behavior and synaptic transmission

Authors: *M. KOUSER[1], H. E. SPEED[1], J. M. REIMERS[1], Z. XUAN[1], C. F. OCHOA[1], C. M. POWELL[1,2];
[1]Neurol. and Neurotherapeutics, [2]Psychiatry, Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstracts: Deletion and other loss-of-function mutations of SHANK3 have been strongly implicated in autism. SHANK3 deletions and mutations have also been linked with Phelan-McDermid Syndrome associated with autism and intellectual disability. At least 3 different Shank3 mutant mice have been published to date, each deleting one or more exons. We have created a novel genetic animal model of an autism-associated SHANK3 insertion mutation in exon 21 with high molecular construct validity. We hypothesize that this autism-associated Shank3 genetic model will result in reduced Shank3 levels and will lead to behavioral abnormalities and functional changes in excitatory synaptic transmission. This autism-associated exon 21 point mutation results in loss of predominant higher molecular weight isoforms of Shank3 protein similar to exon 21 deletion mutation. We find alterations in multiple behaviors including motor coordination and response to novelty, among others, testing littermate, sex-matched progeny of heterozygous by heterozygous matings. We also report abnormalities in hippocampal synaptic transmission and plasticity. In summary, our novel, Shank3 point mutant mouse model of autism provides high construct validity for autism and provides valuable insights into the role of Shank3 in synaptic function and behavior.

Title: Male-specific deficits in reinforcement learning, motivation, striatal volume, and white-matter integrity in the 16p11.2del/+ mouse model of autism

Authors: N. M. GRISSOM[1], S. MCKEE[1], J. LIDSKY-EVERSON[1], H. SCHOCH[2], R. HAVEKES[2], M. KUMAR[3], S. PICKUP[3], V. KUMAR[4], H. POPTANI[3], T. NICKL-JOCKSCHAT[4], T. M. REYES[1], *T. G. ABEL[2];

[4]Psychiatry, Univ. Hosp. Aachen (Universitätsklinikum Aachen), Aachen, Germany

Abstracts: One prominent theory conceptualizing autism spectrum disorders (ASD) focuses on deficits in "social motivation", positing that developmental deficits in reward mechanisms directly impede social learning, resulting in the array of social skill deficits that characterize ASD. Understanding the value of rewards and learning to associate actions with their outcomes is supported by striatal circuitry, including nucleus accumbens and dorsal striatum. We have tested motivation and reward-based learning in 16p11.2del/+ mice, which model one of the most common copy number variations associated with ASD. A mouse model of 16p11.2 hemideletion on a mixed 129/b6 background (the chr7qF3 deficient mouse) has previously been generated (Horev et al, PNAS 2011). Adult male and female 16p11.2del/+ mice were tested for operant learning and motivation using mouse operant 9-hole chambers with a sweetened liquid reinforcer. Compared to wildtype mice, 16p11.2del/+ male, but not female, mice have early impairments in the ability to associate a response with a reward as measured by Fixed Ratio responding. Once fully trained on the fixed ratio task, animals were probed with a Progressive Ratio schedule, which assesses motivation to continue responding as task demands become more challenging. 16p11.2del/+ males demonstrated significantly reduced progressive ratio responding, indicating deficits in motivation to seek reward, while female 16p11.2del/+ were unaffected. Importantly, sucrose preference when given freely in home cage was unaltered in 16p11.2del/+ mice, indicating that mechanisms of reward preference are unaffected. These animals do not display deficits in hearing seen in a model of 16p11.2 hemideletion on a pure b6 background, which might confound changes in striatal function. A separate cohort of animals were perfused and the brains were imaged for structural MRI analysis to assess striatal volume, and Diffusion Tensor Imaging (DTI) to assess white matter integrity. Male del/+ animals had significantly reduced dorsal striatum volume compared to wildtype males, while no differences were observed in females. DTI revealed that the corpus callosum and external capsule were

reduced in integrity, while the fornix was increased in integrity, in male del/+, suggesting diminished corticostriatal connectivity and enhanced hippocampal connectivity. These data indicate that fundamental mechanisms of goal-directed behavior, likely mediated by dorsal striatum, are altered in 16p11.2del/+ male mice while sparing females. These findings provide strong support for the idea that sex differences in reward and motivation are involved in the pathophysiology of ASD.

Title: GABA-B receptor agonist r-baclofen reverses social deficits and reduces repetitive behavior in two mouse models of autism

Authors: *J. L. SILVERMAN, M. C. PRIDE, J. E. HAYES, K. R. PUHGER, J. N. CRAWLEY;
UC Davis Sch. of Med., Sacramento, CA

Abstracts: Autism spectrum disorder (ASD) is diagnosed by two core behavioral criteria, unusual reciprocal social interactions and communication, and repetitive behaviors with restricted interests. Excitatory/inhibitory imbalance is a prominent hypothesis for the etiology of autism. Reductions in excitatory glutamatergic neurotransmission with antagonists and negative modulators, and increases in inhibitory neurotransmission with GABAergic agonists and positive modulators, have reversed abnormalities in mouse models of ASD and Fragile X syndrome on synaptic plasticity, spine morphology, seizures and behavioral phenotypes (Kreuger and Bear, 2011; Silverman et al., 2013; Vorstman et al., 2014). Initial clinical trials with STX209 (Arbaclofen) yielded variable but promising results on the ABC-Social Avoidance, Vineland II-Socialization, Social Responsiveness and ABC-irritability scales (Berry-Kravis et al., 2012; Erickson et al., 2014). We tested the hypothesis that activation of the GABAB receptor with the

commercially available r-baclofen enantiomer, but not the less potent s-baclofen enantiomer, would rescue ASD-relevant phenotypes in the BTBR and C58/J inbred strain mouse models of ASD. BTBR display well-replicated deficits in sociability and long bouts of repetitive self-grooming. C58/J exhibit high levels of stereotyped vertical jumping. Two independent cohorts of BTBR showed improved social approach following acute r-baclofen treatment. Both BTBR and C58 showed reductions in repetitive behaviors after r-baclofen. These data support further investigations of the GABAB agonist target, in other preclinical models and in further clinical studies, to evaluate the benefits of enhancing inhibitory synaptic transmission to treat the core diagnostic symptoms of autism.

Title: Axonal localization of Ca2+-dependent activator protein for secretion 2 is critical for subcellular locality of brain-derived neurotrophic factor and neurotrophin-3 release affecting proper development of postnatal mouse cerebellum

Authors: *T. SADAKATA;
Advanced Scientific Res. Leaders Develop. Unit, Gunma Univ., Maebashi, Japan

Abstracts: Ca2+-dependent activator protein for secretion 2 (CAPS2) is a protein that is essential for enhanced release of brain-derived neurotrophic factor (BDNF) and neurotrophin-3 (NT-3) from cerebellar granule cells. We previously identified dex3, a rare alternative splice variant of CAPS2, which is overrepresented in patients with autism and is missing an exon 3 critical for axonal localization. We recently reported that a mouse model CAPS2αex3/αex3 expressing dex3 showed autistic-like behavioral phenotypes including impaired social interaction and cognition, and increased anxiety in an unfamiliar environment. Here, we verified impairment in axonal, but not somato-dendritic, localization of dex3 protein in cerebellar granule cells and demonstrated cellular and physiological phenotypes in postnatal cerebellum of CAPS2αex3/αex3 mice. Interestingly, both BDNF and NT-3 were markedly reduced in axons of cerebellar granule cells, resulting in a significant decrease in their release. As a result, dex3 mice showed developmental deficits in dendritic arborization of Purkinje cells, vermian lobulation and fissurization, and granule cell precursor proliferation. Paired-pulse facilitation at parallel fiber-Purkinje cell synapses was also impaired. Together, our results indicate that CAPS2 plays an important role in subcellular locality (axonal vs. somato-dendritic) of enhanced BDNF and NT-3 release, which is indispensable for proper development of postnatal cerebellum.

Abstracts: Autism spectrum disorders (ASD) are heterogeneous neurodevelopmental disorders characterized by deficits in social communication and restricted interests and repetitive behaviors. Abnormalities in language development, mental retardation and epilepsy are often observed in ASD children and, conversely, several forms of epilepsy also display ASD. Given the high comorbidity between ASD and epilepsy, the possibility of a common genetic basis for both diseases has been proposed. Synapsins (Syns) are a family of synaptic vesicle phosphoproteins encoded by the SynI, SynII and SynIII genes. The Syn gene family is a good candidate for the synaptic epilepsy/ASD pathway, as Syns regulate synaptic transmission and plasticity with distinct roles in excitatory and inhibitory neurons and SynI and II mutations have been recently associated with ASD in humans. Mice lacking SynI or SynII genes experience epileptic seizures starting at 2-3 months of age and display social and mild cognitive impairments and repetitive behaviours also before the onset of seizures. Aim of our study was to analyze whether deletion of SynI, SynII or SynIII gene in mice causes motor and social communication deficits during infancy and adulthood. During the first two postnatal weeks, we recorded spontaneous locomotor activity and ultrasonic vocalizations in pups in response to social separation, while, at adulthood, we evaluated social behaviors and ultrasonic vocalizations emitted by male mice in interaction with wild-type females in estrous. Moreover, we used Magnetic Resonance Imaging (MRI) to map in the three mutant lines regional gray matter volume and white matter fractional anisotropy (FA), two imaging readouts that have been extensively used in ASD patient populations. Our results showed different phenotypes in the three Syn mutant lines. Deficits in spontaneous behaviors and ultrasonic vocalizations measured during the first two postnatal weeks of age and social investigation and vocal patterns at adulthood were detected in SynI and SynII mutant mice. By contrast, SynIII mice did not show deficits at either infancy or adulthood. MRI did not reveal volumetric or FA alterations in SynII and III mutants, whereas significant increases in FA in callosal and frontal areas were observed in SynI-/-. Overall, motor and social communication deficits observed in SynI-/- and Syn II-/- mice support the view that these genes are involved in the expression of autistic-like behavioral traits and identify these mutant lines as useful experimental models of ASD and epilepsy.

Abstracts: In the human brain, there are two major functional domains. One has been conserved in all mammals through evolution and governs fundamental functions such as reward, emotion and memory; the other is unique to primates, and is acquired through the enlargement of the cerebral cortex governing special functions such as tool use, language, and self-consciousness. Thus, to properly understand these brain functions, we need appropriate animal models for studying each function. Animal models that are used to analyze brain functions are different in each case. In the former, a reductive approach is adopted based on gene manipulation using models such as genetically-modified fish and rodents, while in the latter, the main approach is psychological and involves complex behavior analysis using non-human primates such as macaque monkeys. Many researchers believed that the complementary nature of genetic engineering technologies in rodent and fish models and cognitive neuroscience techniques in primate research would lead to progress in this research field. However, due to lack of appropriate animal models that can be analyzed in both aspects of the brain's functions, contact points between these two approaches have been limited. The development of genetically engineered non-human primates has attracted attention for its potential to connect the two research fields. Recently, we succeeded in creating the world's first transgenic primate using marmosets. This technological breakthrough provides a potential paradigm shift by enabling researchers to analyze both the brain functional domains using various model marmosets. Currently, we are developing a technique for creating knockout marmosets using zinc finger nuclease (ZFN) technology. By combining this technique with the development of cognitive information for marmoset brain analysis, innovative MRI imaging technology and marmoset genetic analysis tools, we aim to create and analyze marmoset models suitable for research on autism spectrum disorders (ASD), to understand the pathogenesis, and to contribute to new therapeutic strategies to treat ASD.

Title: Is erbb4 a susceptibility gene for autism spectrum disorders endophenotype? an association study in korean population

Authors: *R.-S. WOO[1], S. KIM[2];
[1]Anat. and Neurosci., [2]Sch. of Medicine, Eulji Univ., Daejeon, Korea, Republic of

Abstracts: Background: Autism spectrum disorder (ASD) and schizophrenia are major complex psychiatric disorders, and there are several reports concerning the influence of candidate genes and polymorphisms common to both conditions on pathogenesis and behavioral phenotype. **Methods:** To assess whether the *ERBB4* gene, which is a strong candidate gene for schizophrenia, could also be implicated in the vulnerability to ASD, we conducted a family based association study between three common single nucleotide polymorphisms (SNPs) in the *ERBB4* gene (rs7598440, rs839523, rs707284) and 250 Korean ASD multiplex families using the family-based association test (FBAT) program (n = 959). **Results:** It did not reveal any genetic association between SNPs/haplotype in *ERBB* and ASD affection. However, when ASD phenotypes were analyzed using clinical assessment tools, three polymorphisms were associated with scores obtained using the Autism Spectrum Quotient-Children's Version (AQ-C) (dominant model; rs7598440 $p = 0.003$, rs839523 $p = 0.001$, rs707284 $p = 0.002$). Furthermore, the rs7598440(C)-rs839523(A)-rs707284(A) haplotype revealed an association with AQ-C scores (FDR $p = 0.003$ under the dominant model). The rs7598440(C)-rs839523(A)-rs707284(A) "risk" haplotype dominant group demonstrated higher scores for the AQ-C (52.53 ± 27.21 [n = 181]) than the rs7598440(T)-rs839523(G)-rs707284(G) haplotype recessive group (43.20 ± 26.13 [n = 66]) ($p = 0.017$). **Conclusions:** This study suggests a possible association between *ERBB4* variants and the Korean ASD endophenotype.

Title: Early-onset parkinsonism and psychiatric disorder in a patient with missense mutation in the C-terminal tail of DAT

Authors: *F. H. HENRIKSEN[1], T. SKJØRRINGE[2], N. V. ARENDS[1], S. YASMEEN[2], K. ERREGER[3], H. J. G. MATTHIES[3], A. GALLI[3], L. E. HJERMIND[4], L. B. MØLLER[2], U. GETHER[1];

Physiol. & Biophysics, Vanderbilt Univ., Nashville, TN; [4]Danish Dementia Res. Centre, Clin. of Neurogenetics, Dept. of Neurol., Copenhagen Univ. Hosp., Copenhagen, Denmark

Abstracts: Dopamine disturbances are critical in the pathophysiology of Parkinson's disease and have also been implicated in a spectrum of psychiatric disorders including ADHD, schizophrenia, autism, and addiction. The sodium-coupled dopamine transporter (DAT) controls dopamine homeostasis, but its contribution to disease remains poorly understood. We have recently described an adult patient with compromising missense mutations in the DAT gene, who suffered from early onset parkinsonism and ADHD. Here, we present an unrelated patient that carries a missense mutation in the C-terminal PDZ binding domain of DAT and who suffers from early-onset parkinsonism and a complex psychiatric disorder. We have previously reported that the PDZ binding domain of DAT is critical for striatal targeting of DAT *in vivo*, but not for surface expression in heterologous cells. Consistently the missense mutation carried by the patient generates only modest changes in DAT function, when expressed in heterologous cells, as supported by 20-30% reduction in dopamine uptake capacity (~75% of WT DAT), and a corresponding reduction in surface expression and amphetamine induced efflux. Interestingly, a SPECT scan of the patient shows clear bilateral reduction of DAT ligand binding. The

identification of an independent patient with a missense mutation in the DAT gene and concurrent early-onset parkinsonism and neuropsychiatric disorder supports that abnormal DAT function may constitute a risk factor for psychiatric disorders and possibly also for early-onset parkinsonism.

Title: 16p11.2 deletion syndrome mice display ultrasonic vocalization deficits during social interactions

Authors: *M. YANG[1], E. J. MAHRT[2], F. C. LEWIS[1], G. M. FOLEY[1], T. PORTMANN[3], R. E. DOLMETSCH[3,4], C. V. PORTFORS[2], J. N. CRAWLEY[1];
[1]MIND Institute, UC Davis, Sacramento, CA; [2]Sch. of Biol. Sciences,, Washington State Univ., Vancouver, WA; [3]Dept. of Neurobio., Stanford Univ. Sch. of Med., Palo Alto, CA; [4]Novartis Inst. for Biomed. Res., Cambridge, MA

Abstracts: Deletions and duplications at the chromosome 16p11.2 region are variably associated with speech delay, autism spectrum disorder, schizophrenia and cognitive impairments. Social communication deficits are a primary diagnostic symptom of autism. Here we investigated

ultrasonic vocalizations in young adult male 16p11.2 deletion mice during a novel three-phase male-female social interaction test to evaluate responses to the presence and absence of a social partner. Strikingly fewer vocalizations were discovered in most 16p11.2 heterozygous deletion males (+/-) during Phase 1, the first exposure to an unfamiliar estrus female, as compared to wildtype littermates (+/+), replicated in two independent cohorts of subject mice. During Phase 2, when the female was removed, +/+ mice emitted calls, but fewer than during Phase 1, while +/- mice called minimally. Sensory and motor abnormalities were detected in +/-, including higher nociceptive thresholds and a complete absence of acoustic startle responses, along with stereotyped jumping and backflipping in a small percentage of individuals. Hearing loss in all +/- was confirmed by lack of auditory brainstem responses to low 8-32 kHz and high 50-100 kHz frequencies. However, these sensory and motor phenotypes could not directly explain the low vocalization rates in +/-, since both genotypes reduced their calling when the female was removed, and +/- subsequently displayed normal abilities to emit vocalizations during their Phase 3 re-exposure to the female. Together these findings support the concept that vocalizations represent a response to social cues, and that 16p11.2 deletion mice are deficient in their initial USV responses to social cues.

Title: In search of biomarkers and treatment for a subpopulation of autism spectrum disorder (ASD) with high serotonin (sASD)

Authors: K. CHEN[1,2], Y. CHENG[3,1], C.-S. CHEN[4,1], C.-Y. YANG[5,1,6], *J. C. SHIH[7,1]; [1]USC-Taiwan Ctr. for Translational Res., Los Angeles, CA; [2]Dept. of Pharmacol. and Pharmaceut. Sci., USC, Los Angeles, CA; [3]Inst. of Neuroscience, Natl. Yang-Ming Univ. and Dept. of Rehabilitation, Natl. Yang-Ming Univ. Hosp., Taipei, Taiwan; [4]Grad. Inst. of Systems

Biol. and Bioinformatics, Natl. Central Univ., Taipei, Taiwan; [5]Dept. of Educ. and Research, Taipei City Hosp., Taipei, Taiwan; [6]Inst. of Microbiology and Immunology, Natl. Yang-Ming Univ., Taipei, Taiwan; [7]Univ. Southern California, LOS ANGELES, CA

Abstracts: MAOA KO mice display high serotonin (5-HT) levels, particularly during early developmental stages. We have shown that MAOA KO mice exhibit behavioral hallmarks of autism spectrum disorder (ASD), such as sociocommunication impairments, stereotypical responses, and behavioral inflexibility; They also displayed neuropathological alterations, including reduced thickness of the corpus callosum, increased dendritic arborization of pyramidal neurons in the prefrontal cortex and disrupted microarchitecture of the cerebellum, similar to ASD (Bortolato, 2012). Thus, MAOA KO mice are useful animal model of sASD. More importantly we found that reducing 5-HT at P1 to P7, rescued the autistic like behaviors seen in MAO A KO mice. This result suggests the early treatment of sASD may cure the sASD before the symptoms appeared (Bortolato, 2013). In order to identify biomarkers of sASD and comorbid anxiety, we probed MAO A KO mouse serum with human proteome microarray to analyze the serum autoantibody. We found that Up-regulated autoantibodies include SLCA18 (glycine), LSP1(lymphocyte specific protein) TWF2 (neurite development), PTS (SNP in autism, catalyzes synthesis of BH4 , the co-factor for 5-HT and DA synthesis); Down-regulated autoantibodies include 5-HTR2c (SR1), GPR119,TGM1, CAMKA1, ADH6, DTK2B, EPS8, Sox5, Ogfr and ICT1. Recently, we identified two families in Taiwan with sASD. Their plasma serotonin levels were significantly higher (36.51 ± 1.84 ng/mL) than controls (0.14 ± 1.52 ng/mL). Interestingly, the subjects with sASD showed reduced emotional mismatch negativity when we measured the electrophysiological index of anxiety with the presentation of emotionally (neutrally, angrily, fearfully) spoken meaningless syllables dada in a passive auditory oddball paradigm (Fan & Cheng, 2014). The molecular basis of this autistic family includes the altered genes and autoantibodies are currently studied, will be discussed and compared with the data found in MAO A KO mice. This new information will shed lights on the potential treatment and diagnosis of this subpopulation of ASD (sASD).

Title: Genetic abnormalities in autistic disorder

Authors: *D. AHUJA[1], C. SMILEY[2], P. NUNI[2];
[1]Univ. Of Vermont/ Genesys Diagnostics, East Lyme, CT; [2]Genesys Diagnostics, East Lyme, CT

Abstracts: Background: Autism is a highly heritable complex neurodevelopmental disorder characterized by distinct impairments of cognitive function, social interactions and speech development. Mutations in different set of genes may be involved in different autistic individuals. By identifying genetic markers inherited with autism in family studies, the actual mutations that increase the risk for autism may be identified. **Method:** Lymphoblast cell lines from a family of 5 members with autistic fraternal twin brothers were cultured and processed for chromosomal studies and fluorescence in-situ hybridization (FISH) studies to investigate if the autistic twins had any genetic abnormalities and if the unaffected parents and other siblings were carriers of the same genetic abnormality. Lymphoblast cell lines were maintained in culture in PB-Max media. After 72hrs of culture, 50µl of Colcemid was added to arrest the cells in metaphase stage. Then cultures were harvested and fixed following Genesys Diagnostic's harvesting protocol. Cells were dropped and stained using GTG banding technique. Cytogenetic analysis was done by using Ikaros (Metasystems) software system. In order to further investigate the abnormality, FISH procedure was carried out by following the Genesys laboratory protocol. Chromosome enumeration DNA probe Cep-9 and probes for Prader-Willi (PW) and Angelman (AS) syndromes, located on chromosome 15 (bands 15q11-13) (Cytocell) were applied and cells were scored by fluorescent microscopy. Isis software system was used to capture the Images. **Results:** With karyotyping, it was observed that the mother, father, a normal sister were found to be chromosomally normal. The autism affected twins had very low level of mosaicism of trisomy 9, in 2/50 and 3/50 metaphases, respectively. The scoring of aneuploidy by interphase FISH with the chromosome enumeration DNA probe Cep 9 confirmed low level of mosaicism (3.4%) for an extra signal for CEP9, consistent with trisomy 9. However, FISH for the loci at 15q11-13 for AS and PW syndromes showed normal diploid signal patterns for AS and PW in the affected twins. **Conclusions:** Low level of chromosomal mosaicism in twins with autism suggests that low-level mosaicism can have clinical manifestation. Most cytogenetic studies in autism are performed by array CGH techniques, which are less efficient for mosaicism studies.

Abstracts: Behavioral and cognitive impairments observed in autism spectrum disorder (ASD) are thought to arise from abnormal neuronal connectivity in the developing brain, but the molecular basis of these deficits is largely unknown. Protocadherin 10 (Pcdh10) is a cadherin superfamily neural cell adhesion molecule that has been associated withASD in human genetic studies. Mouse Pcdh10 is expressed highly in olfactory, limbic, and striatal regions, and plays an important role in activity-dependent synaptic pruning. Male mice lacking a single allele of Pcdh10 display reduced social approach behavior and impaired amygdala-dependent conditioned fear. To determine whether abnormal neural connectivity may underlie the behavioral deficits we observed, we measured dendritic length and spine density in Golgi stained lateral and basolateral amygdala neurons from Pcdh10+/- males. We found that Pcdh10+/- neurons have increased dendritic spine density, specifically, increased thin elongated filopodia-type spines. These data suggest that abnormal regulation of synapse formation in the amygdala may underlie the behavioral deficits observed in Pcdh10+/- mice.

Title: Rapamycin, an inhibitor of mTORC1 signaling activity, improved measures of sociability in the BTBR T+ Itpr3tf/J mouse model of autism spectrum disorder

Authors: *J. A. BURKET[1], A. D. BENSON[1], A. H. TANG[2], S. I. DEUTSCH[1];
[1]Psychiatry and Behavioral Sci., [2]Microbiology and Mol. Cell Biol., Eastern Virginia Med. Sch., Norfolk, VA

Abstracts: mTOR signaling overactivity is a common pathological point of convergence for several syndromic forms of autism spectrum disorders (ASDs), such as Tuberous Sclerosis Complex and fragile X syndrome, stimulating interest in inhibiting mTORC1 activity as a therapeutic strategy for syndromic and nonsyndromic forms of ASDs. Administration of mTORC1 inhibitors (e.g. rapamycin) in syndromic mouse models of ASDs improved behavior, cognition, and neuropathology. However, since only a minority of ASDs are due to the effects of single genes (~10%), there is a need to explore inhibition of mTOR activity in mouse models that may be more relevant to the majority of nonsyndromic presentations, such as the genetically-inbred BTBR T+Itpr3tf/J (BTBR) mouse model of ASDs. BTBR mice have social impairment and exhibit increased stereotypic behavior. Thus, we wondered if inhibiting mTORC1 with rapamycin would improve the sociability of this strain. We reported previously that D-cycloserine, a partial glycineB site agonist of the NMDA receptor, had prosocial effects in the BTBR mouse. NMDA receptor activation is an important regulator of mTORC1 signaling activity. The current study investigated the ability of rapamycin to improve sociability and stereotypic behavior in BTBR mice. Using a standard paradigm to assess mouse social behavior, rapamycin improved several measures of sociability in the BTBR mouse. Whereas vehicle-treated Swiss Webster control mice showed a preference for exploring/sniffing the enclosed stimulus mouse ($p<0.01$), the vehicle-treated BTBR mice did not show this preference. However, rapamycin-treated BTBR mice spent more time engaged in exploring/sniffing the enclosed stimulus mouse ($p<0.01$). During free interaction between test and stimulus mice, vehicle-treated BTBR and Swiss Webster mice did not differ from each other in terms of discrete episodes of social approach and anogenital sniffing. However, treatment of the BTBR strain with rapamycin significantly increased their discrete episodes of social approach ($p<0.05$) and anogenital sniffing

($p<0.001$), relative to the vehicle-treated BTBR mice. Rapamycin treatment did not affect episodes of social approach and anogenital sniffing made by the Swiss Webster mice. In summary, treatment with a centrally-effective dose of rapamycin improved the sociability of the BTBR mouse strain on several reliably-obtained measures (i.e., exploring/sniffing of the enclosed stimulus mouse and measures of social approach and anogenital sniffing during free interaction of test and stimulus mice). These data support therapeutic targeting of upregulated mTORC1 signaling activity to improve sociability.

Title: Multiple Shank3 mutant mouse models of autism result in decreased synaptic homer1b/c in striatum

Authors: *C. F. OCHOA[1], J. M. REIMERS[1], Z. XUAN[1], T. C. JARAMILLO[1], M. KOUSER[1], H. E. SPEED[1], C. M. DEWEY[3], S. LUI[1], C. M. POWELL[1,2];
[1]Neurol. & Neurotherapeutics, [2]Psychiatry, UT Southwestern, Dallas, TX; [3]Buck Inst. for Res. on Aging, Novato, CA

Abstracts: Autism Spectrum Disorders (ASDs) are characterized by dysfunction in two major behavioral domains including impaired social communication/interactions and restrictive and repetitive behaviors (DSM-5, May 2013). Mutations and deletions in the SHANK3 gene have been independently implicated in both idiopathic autism spectrum disorders (ASD) and 22q13 Deletion Syndrome or Phelan-McDermid Syndrome (PMS). Approximately 75-80 % of patients with PMS meet diagnostic criteria for autism, with the rest exhibiting symptoms of ASD. In an

effort to better understand autism and PMS, we and others have created multiple autism-relevant genetic models in mice based on mutations in the Shank3 gene. These include Shank3 exon 4-9 deletion, exon 13 stop, exon 21 deletion, and exon 21 point mutation mouse models. Because each of these models has some level of constructive validity for autism and PMS, we are interested in identifying convergent molecular abnormalities among these models as potential treatment targets for this form of ASD. Because Shank3 is the major Shank isoform expressed in striatum and because each mouse model has behavioral abnormalities that may be modulated by dorsal striatum, our initial studies have focused on this brain region. By making synaptosomes from the dorsal striatum of these multiple Shank3 mutant models, we have identified alterations in synaptic levels of multiple postsynaptic density proteins in Shank3 mutants. The most striking and consistent alteration is a decrease in Homer1b/c levels in the dorsal striatum of all Shank3 mutants. This finding suggests that Shank3 is crucial for maintaining Homer1b/c levels at the synapse. Furthermore, these data suggest that mGluR/Homer interactions may be altered in these Shank3 mutants. This may have important consequences for synaptic function, a focus of our future studies.

Title: The role of CHD8, an autism spectrum disorder risk gene, in brain development

Authors: *O. DURAK[1], Y. KAESER-WOO[2], A. MORTELL[2], A. NOTT[2], L.-H. TSAI[1]; [1]Brain and Cognitive Sci., Picower Institute, MIT, Cambridge, MA; [2]Picower Inst. for Learning and Memory, Cambridge, MA

Abstracts: Autism spectrum disorder (ASD) is a complex developmental disability which is typically characterized by social deficits, communication difficulties, stereotyped behaviors and cognitive delays. It is well established that ASD has a strong genetic origin as supported by a number of genome-wide association and exome sequencing studies. Several studies identified de novo mutations in chromodomain helicase DNA-binding protein 8 (CHD8) in patients with ASD

and provide strong evidence in favor of CHD8 as a genuine autism risk factor. CHD8 is a member of the chromodomain helicase binding (CHD) family of proteins which are thought to regulate gene expression. CHD8 initially was isolated as a regulator of β-catenin-dependent transcription, and previous studies suggest that CHD8 directly interacts with β-catenin to inhibit its transcriptional activity. β-catenin-dependent transcriptional activity is implicated in the regulation of neural progenitor proliferation, dendritogenesis, axon establishment and guidance, and synaptogenesis. However, it remains unknown what role CHD8 plays in ASD etiology and neuronal development. In the current study, using the *in utero* electroporation technique we have shown that CHD8 knockdown affects neural progenitor proliferation in developing cortex, and dendritic arborization of pyramidal neurons in postnatal cortex. Consistent with the change in proliferation, Wnt-signaling activity was significantly altered following CHD8 knockdown. Additionally, we have identified a previously unknown role of CHD8 in regulation of β-catenin mRNA levels, which potentially could explain why proliferation and dendritogenesis is altered. Finally, *in utero* knockown of CHD8 in layer 2/3 pyramidal neurons results in deficits in social interaction behavior in adult mice. Currently, we are using transgenic mouse models and human induced pluripotent stem cells to further understand how CHD8 mutations could contribute to underlying causes of phenotypes associated with ASD.

Title: Role of A2BP1, a candidate gene for ASD, in establishing the architecture of the developing cerebral cortex

Authors: *K.-I. NAGATA, N. HAMADA, H. ITO, I. IWAMOTO, R. MORISHITA, H. TABATA;
Inst. For Developmental Research, Aichi Human Service Ctr., Kasugai, Japan

Abstracts: Ataxin-2-binding protein 1 (A2BP1 also known as Fox1 or Rbfox1) is an RNA-binding protein necessary for proper pre-mRNA splicing events in a variety of genes crucial for neuronal functions. Critical functions of A2BP1 in brain development have been approved by human mutations in A2BP1 gene that cause neurodevelopmental disorders including autism spectrum disorder (ASD). To elucidate the pathophysiological relevance of A2BP1, we here performed cell biological analyses of the neuron-specific isoforms (A016 and A030) during cerebral development *in vitro* and *ex vivo*. Knockdown of A2BP1 isoforms by the *in utero* electroporation method caused abnormal neuronal positioning during corticogenesis, which were most likely to be attributed to impaired cell migration. Knockdown of the A2BP1 isoforms induced distinct morphological defects in migrating cortical neurons, while the cell cycle of neuronal progenitor cells were not affected by silencing of the 2 isoforms. Aberrant morphology was confirmed in *in vitro* analyses; A2BP1-silencing in primary cultured hippocampal neurons resulted in the reduction of primary axon length and total length of dendrites. In addition, when A2BP1-A016 and -A030 were silenced in cortical neurons in one hemisphere, axonal growth to the contralateral hemisphere was severely and moderately suppressed, respectively. Taken together, impaired cortical neuron migration and disturbed interhemispheric axon development may induce structural and functional defects of the cerebral cortex, and consequently contribute to emergence of the clinical symptoms of neurodevelopmental disorders such as ASD.

Title: KRAS mediated enhancement of ERK signalling during brain development results in synaptic plasticity deficits and learning disabilities

Authors: *R. BRAMBILLA[1], A. PAPALE[1], N. SOLARI[1], R. D'ISA[1], M. CAMBIAGHI[1], M. CURSI[1], L. LETIZIA[1], M. CEROVIC[2], N. HARDINGHAM[2], E. MENNA[3], M. MATTEOLI[3]; [1]San Raffaele Scientific Inst., Milano, Italy; [2]Cardiff Univ., Cardiff, United Kingdom; [3]Univ. of Milan, Milan, Italy

Abstracts: Ras-ERK signalling activation in the adult mammalian brain is a necessary step to establish both long-term plasticity and long-term memories, as conclusively demonstrated by a number of electrophysiological and behavioural studies. Dysregulation of this cascade gives rise to a class of genetic syndromes that collectively goes under the name of "Rasopathies". Interestingly, patients affected by these pathologies may manifest a certain degree of mental retardation and some learning disabilities. In order to determine the exact role of Ras-ERK signalling in the postnatal forebrain we generated new mouse models in which a potent constitutive active form of KRAS, the G12V mutation, can be conditionally induced without overexpression, leading to a selective abnormal ERK activation in specific neuronal types. We found that a sustained activation of KRAS in excitatory cells of the forebrain has no effect on behaviour suggesting that Ras signalling in this subset of neurons does not significantly alter synaptic functions. On the contrary, a wider expression of the KRAS mutant leads to an increased activity of GABAergic interneurons, already occurring in the early phases of postnatal development. Importantly, this enhancement of ERK activity in interneurons leads to a permanent increase in the inhibitory tone throughout the brain, resulting in a reduced synaptic plasticity in the hippocampus and in a severe form of intellectual disability.

Title: The molecular basis of altered emotional learning in an environmentally induced animal model of Autism

Authors: *A. BANERJEE, J. A. LUONG, A. MORALES, A. HO, B. SAULS, J. E. PLOSKI; Univ. of Texas At Dallas, Richardson, TX

Abstracts: Autism Spectrum Disorders (ASD) are complex neurodevelopmental disorders characterized by core symptoms including repetitive behavior, impaired social interactions and deficits in social communication. Apart from these core symptoms, a significant number of ASD individuals display higher levels of anxiety and some studies indicate that a subset of ASD

individuals are impaired in their ability to be fear conditioned. Therefore we sought to further examine emotional learning in an environmentally induced animal model of ASD, where pregnant rats are exposed to the known teratogen, valproic acid (VPA) on day 12.5 of gestation. Specifically we exposed dams to either one of two different doses of VPA (500 and 600 mg/kg) or vehicle on day 12.5 of gestation. Resultant progeny at 60 days of age were auditory fear conditioned to a 5 kHz 75 dB tone. Animals exposed to 500 mg/kg VPA displayed normal acquisition of fear conditioning, but exhibited reduced extinction of fear memory. However we observed that rats exposed to 600 mg/kg of VPA exhibited a significant reduction in acquisition of fear conditioning. To examine the molecular basis of VPA induced impairment in fear learning in animals exposed to VPA (600 mg/kg), we performed whole genome gene expression analysis using DNA microarrays to examine differences in gene expression within the amygdala from rats exposed to VPA and vehicle. Homer1a was one of the genes which exhibited a significant upregulation within the amygdala. Homer1a is an activity induced immediate early gene (IEG) which is formed from a longer homer1 gene by alternative transcription termination. It acts as a dominant negative regulator and uncouples long forms of homer-ligand interaction resulting in molecular reorganization of the synapse. We chose to focus on Homer1a due to its critical role in the normal functioning of the glutamatergic system, its involvement in the process of fear learning and its previous implication in ASD. To validate the microarray data and to additionally examine how homer1a mRNA levels varied within the basolateral nucleus of the amygdala (BLA) in animals exposed to either 500mg/kg or 600 mg/kg we performed quantitative PCR (qRT-PCR) using homer1a specific primers. We observed a dose dependent increase in homer1a mRNA levels in VPA exposed animals indicating that the precise levels of homer1a within the BLA may be critical for proper fear learning. We have generated adeno-associated (AAV) viruses designed to express homer1a which we have bilaterally infused into the rat BLA to examine how over expression of homer1a can influence fear learning.

Title: Oxytocin counteracts inflammatory effects of bacterial endotoxin in gut cells

Authors: *H. TAMIR[1,6], B. Y. KLEIN[2], D. L. HIRSCHBERG[3], R. J. LUDWIG[2], M. M. MYERS[2,4,5], S. GLICKSTEIN[7], M. G. WELCH[1,5,2,4];
[1]Pathology & Cell Biol., [2]Developmental Neurosci., [3]Ctr. for Infection and Immunol., [4]Pediatrics, [5]Psychiatry, Columbia Univ. Col. of Physicians and Surgeons, New York, NY; [6]Mol. Imaging and Neuropathology, New York State Psychiatric Inst., New York, NY; [7]EB Sci., Oakland, CA

Abstracts: It is increasingly likely that the gut is impacted at a cellular level in a subset of individuals with autism spectrum disorders (ASD). This is supported by metanalyses showing that children with ASD experience significantly more nonspecific gastrointestinal (GI) symptoms and abnormal bacterial endotoxin lipopolysaccharide (LPS) responses, when compared to non-affected peers. We have previously reported that OT and its receptor (OTR) modulate the signaling of multiple molecules in the cellular stress pathway, including PI3K, Akt and importantly, the mammalian target of rapamycin complex1 (mTORC1) in gut cell culture; Akt and mTORC1, which modulate cellular stress signaling, and OT, known to modulate affiliative behaviors, have been associated with ASD etiology through genetic screens and functional analysis. Gut inflammation may be modulated by OT/OTR in a subset of individuals with ASD and gut symptoms: (1) OT/OTR reduces inflammation and restores normative function in an experimental model of colitis in rats and mice. (2) Mice lacking the OTR show altered gastrointestinal structure, motility, inflammation, macromolecular permeability, and mucosal maintenance. All of these findings suggest that understanding the pathophysiology of OT/OTR in the gut could lead to a better understanding of the pathophysiology of ASD phenotypes. In the current study, we stimulated the Caco2BB enterocyte gut cell line with bacterial 100- 400 ng/ml LPS for 90 min to induce an inflammatory response and treated the cells with 7.8 - 62.5 nM OT to test whether OT could modulate the response. LPS alone activated Akt, mTORC1 substrate S6K1 and induced the NF-KB inflammatory transcriptional program. Treatment with OT after LPS inhibited the activation of Akt and S6K1, and attenuated increases in pIKB. Conversely, LPS alone inhibited the activation of IRE1, a sensor of endoplasmic reticulum stress. OT treatment after LPS counteracted this inhibition. Further, LPS alone inhibited IRE1a substrate X-box binding protein 1, thus arresting transduction of the unfolded protein response. OT treatment after LPS counteracted the same inhibition and reactivated the response. We also demonstrated the OTR dependence of this response using the OTR-specific antagonist OTA. Results show that OT can reverse multiple LPS-induced inflammatory signals and suggest that OT may protect enterocytes from stress. These findings add to our understanding of abnormal intracellular stress

mechanisms in the gut during inflammation, and may lead to new treatments, particularly for a subset of autistic children with GI symptoms.

Title: A novel *in vivo* assay of Pten autism alleles reveals necessary roles for Pten in cortical GABAergic interneuron development

Authors: *D. VOGT, K. K. CHO, A. T. LEE, V. S. SOHAL, J. L. RUBENSTEIN;
Dept. of Psychiatry, Univ. of California San Francisco, San Francisco, CA

Abstracts: Pten is a strong autism candidate gene and is involved in signaling events that are a hub for many other autism candidate genes. Pten inhibits signaling downstream of PI3K and its loss of function is associated with neuronal overgrowth, including soma, axon and dendrite hypertrophy. While Pten's role in cancer and glutamatergic neurons has been studied, its role in GABAergic neuron development has not been extensively explored. Cortical GABAergic interneurons are highly diverse and have been implicated in neuropsychiatric disorders, including autism. Here, we examine the role of Pten in cortical GABAergic interneuron development and show its necessity for multiple events in cortical interneuron development. Moreover, we have developed an *in vivo* assay to test the functionality of human variants reported in autism populations. We transduced medial ganglionic eminence (MGE) cells with Pten alleles associated with autism, then transplanted these cells to assay the effects of these alleles in critical steps in cortical interneuron development. Specifically, we assessed the role of Pten in MGE-derived cortical interneuron development, including the evaluation of somatostatin and parvalbumin subgroups. We found that Pten is necessary for cortical GABAergic interneuron development and introduce novel assays to quickly assess autism alleles *in vivo*.

Title: Thimerosal induces autistic behaviors in mice: Possible involvement of metalloprotease activation, zinc dyshomeostasis, and BDNF upregulation

Authors: ***M. YOO**[1], J. LIM[1], T.-Y. KIM[1], H.-R. BYUN[1], B.-R. SEO[1], J. A. CHOI[1], J.-Y. KOH[1,2];
[1]Neural Injury Res. Ctr., Asan Life Sci. Res. Inst., Seoul, Korea, Republic of; [2]Dept. of Neurol., Asan Med. Ctr., Seoul, Korea, Republic of

Abstracts: Whereas a number of genetic factors for autism spectrum disorder (ASD) have been identified, still the majority of cases remain idiopathic. Of diverse candidate environmental factors, childhood vaccination, especially with those containing thimerosal (TM), was proposed as a risk factor for idiopathic ASD. Although the role of TM has long been controversial, a recent epidemiological study seems to support the possibility (Geier et al., Transl Neurodegeneration, 2013). Since some ASD cases have been associated with increased BDNF levels, in the present study, we examined the possible link between TM and BDNF levels *in vitro* and *in vivo*. In addition, we tested whether TM treatment induces typical autistic behaviors in mouse. To mimic human vaccination schedules, mice were inoculated intramuscularly at postnatal day (p) 7, p9, p11, and p15 with 14.2, 10.8, 9.2, or 5.6 μg/kg of TM respectively. Control mice of the same age received corresponding volumes of saline. To assess autistic behaviors, the three-chamber sociability/social novelty test and open field interaction test were performed when mice were 4 weeks old. Compared with control mice, TM administered mice showed autistic behaviors such as preference for exploring an empty chamber to an unfamiliar

mouse (stranger1), and preference for the stranger 1 to a novel stranger (stranger 2). Postmortem brain examinations revealed that BDNF levels were substantially increased in neurons and microglia of cortex and hippocampus. In addition, intracellular free zinc levels and MMP activity were found increased in the same cells. Considering organic mercurials such as APMA are often potent MMP activators, we then examined whether TM is also a direct MMP activator, using cortical cell culture. Exposure of cortical cultures to 10μM TM markedly induced MMP-2, 9 activation, assessed by *in situ* zymography. At the same time, intracellular zinc levels as well as BDNF levels were significantly increased. All these changes were completely blocked by GM6001, a pan-MMP inhibitor, indicating that TM effects were indeed mediated by MMP activation. Present results demonstrate that TM, an organic mercurial compound, activates MMP, which then increases free zinc levels and BDNF levels both *in vitro* and *in vivo*. Such molecular changes may contribute to autistic behaviors that TM-treated mice exhibit. MMPs may prove a potential drug target that can prevent early changes associated with idiopathic ASD.

Title: Comprehensive analysis of gene expression associated with the prefrontal circuit maturation

Authors: *S. UEDA[1], M. NIWA[2], A. SAWA[2], T. SAKURAI[1];
[1]MIC, Grad. Sch. of Med., Kyoto Univ., Kyoto, Japan; [2]Dept. of Psychiatry, Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstracts: The prefrontal cortex (PFC) is a pivotal brain region for cognitive functions, including working memory, planning, reasoning, and decision-making. Recent studies have

identified abnormalities (e.g. deficient myelination, aberrant neurotransmission, excitatory/inhibitory imbalance) in the PFC of developmental psychiatric disorders, namely autism and schizophrenia, supporting an idea that dysregulation of the circuitry development in PFC may be involved in these disorders. Knowledge on how these processes proceeds during normal brain development is crucial to understand involvement of developmental dysregulation in pathogenesis of these disorders. To this end, we performed comprehensive quantitative polymerase chain reaction (qPCR) analysis using mouse brains. Expression of oligodendrocyte/myelin related genes (e.g. *Cldn11*, *Plp1*) and fast-spiking interneuron marker gene, *Pvalb*, were dramatically increased between postnatal days 7 (P7) and P21, and peaked at P21 and P35, respectively. On the other hand, there were little changes in genes for neurotransmitter receptors (dopamine, AMPA, and NMDA receptors), postsynaptic molecules, and cell adhesion molecules. These patterns are unique to PFC compared to any other brain regions. In addition, we characterized responsiveness to NMDA antagonist by measuring extracellular glutamate level in the mouse PFC using *in vivo* microdialysis after a MK-801 administration. While basal extracellular glutamate level reached nearly equal adult level, MK-801 sensitivity was still high at P42, and then it was stabilized to adult level at P56. These results indicate that timing of prefrontal circuit maturation may be around P42 or later. These basic data on normal development should help us to have better ideas on the events in normal and pathological situations taking place in the PFC.

Title: The chromosome 20p12.1 autism genome-wide significant association signal implicates the long non-coding RNAs RPS10P2AS and MACROD2-AS1

Authors: *D. B. CAMPBELL, N. GREPO;
Psychiatry, USC, Los Angeles, CA

Abstracts: We recently reported that the long non-coding RNA *MSNP1AS* (moesin pseudogene 1 anti-sense) is a functional element revealed by an autism genome-wide association study (GWAS) signal on chromosome 5p14.1. *MSNP1AS* expression was increased in postmortem temporal cortex of individuals with autism and increased *MSNP1AS* expression was correlated with the autism-associated genotype. These data indicated that the non-coding RNA *MSNP1AS*, rather than the flanking protein-coding genes *CDH9* and *CDH10*, was the functional element implicated by the chromosome 5p14.1 autism GWAS signal. Shortly after the first autism GWAS report was published, another autism GWAS report indicated genome-wide significant association of the chromosome 20p12.1 marker rs4141463. Although rs4141463 lies within an intron of the protein-coding *MACROD2* (MACRO domain containing 2) gene, expression of *MACROD2* is neither altered in postmortem temporal cortex of individuals with autism nor correlated with rs4141463 genotype. Our bioinformatics approaches revealed two non-coding RNA transcripts near the autism susceptibility signal: *RPS10P2AS* (ribosomal protein S10 pseudogene 2 anti-sense) and *MACROD2-AS1* (MACROD2 anti-sense 1). In a panel of 15 human tissues, qPCR revealed that both *RPS10P2AS* and *MACROD2-AS1* were expressed at higher levels than the protein-coding *MACROD2* in fetal temporal cortex and adult peripheral blood. In postmortem temporal cortex, expression of *RPS10P2AS* was increased 7-fold in individuals with autism (P=0.02) and increased 8-fold in individuals with the autism-associated rs4141463 genotype (P=0.01). Similarly, *MACROD2-AS1* was increased 6-fold in individuals with autism (P=0.03) and increased 9-fold in individuals with the autism-associated rs4141463 genotype (P=0.02). Ongoing experiments will determine the impact of over-expression of the long non-coding RNAs *RPS10P2AS* and *MACROD2-AS1* on neuronal gene expression and morphology. These data indicate that multiple genome-wide significant associations with autism implicate long non-coding RNAs. Because long non-coding RNAs are more abundant in human brain than protein-coding RNAs, this class of molecules is likely to contribute to autism risk.

Title: Activity-dependent neuroprotective protein (ADNP) interacts with the eukaryotic translation initiation factor 4e (eIF4E): an autism upstream regulator

Authors: *I. GOZES, A. MALISHKEVICH, N. AMRAM, G. HACOHEN-KLEIMAN; Sackler Sch. Med/Tel Aviv Univ., Tel Aviv, Israel

Abstracts: Activity-dependent neuroprotective protein (ADNP) discovered in our laboratory, is essential for brain formation(1, 2). De novo mutations in ADNP in humans lead to autism(3), and partial deficiency in ADNP in mice is associated with microtubule (MT) deficiencies and brain dysfunction, which is translated into social and cognitive deficits. The deficits are exacerbated with aging and are coupled to tau hyperphosphorylation and neuronal cell death(4). A recent publication showed that knockout of the eukaryotic translation initiation factor 4E (eIF4E) - binding protein 2 (4E-BP2)-an eIF4E repressor or eIF4E overexpression led to increased translation of neuroligins, which are postsynaptic proteins that are causally linked to autism spectrum disorders (ASDs)(5). Here, bioinformatics identified binding sites on ADNP for eIF4E and co-immunoprecipitation revealed a direct association between ADNP and eIF4E. Further expression studies showed increased eIF4E expression in the ADNP-deficient male mice. These studies position ADNP as an upstream candidate regulator of autism, controlling the expression of translation initiation factor (s) influencing key output behaviors. We thank Prof. O. Elroy-Stein for the antibodies. 1.A. Pinhasov et al., Activity-dependent neuroprotective protein: a novel gene essential for brain formation. Brain Res Dev Brain Res 144, 83 (Aug 12, 2003). 2.S. Title: Reduced striatal 5-HT2A receptor but not serotonin transporter levels in the subchronic valproate model

Authors: *M. M. SKOVBORG[1], F. BERTELSEN[1,2], D. FOLLONI[1], P. WEIKOP[3], J. SCHEEL-KRÜGER[1], A. MØLLER[1,2], A. M. LANDAU[1,2];
[1]CFIN, [2]PET-centre, Aarhus Univ. Hosp., Aarhus C, Denmark; [3]Lab. of Neuropsychiatry, Psychiatric Ctr. Copenhagen, Copenhagen, Denmark

Abstracts: Introduction: Alterations in the serotonin (5-HT) system are often detected in patients with Autism Spectrum Disorders (ASD). ASD is characterised by impaired social interactions, impaired verbal and non-verbal communication, and by restricted, repetitive or stereotyped behaviour. In order to classify as ASD, the symptoms must be apparent before 3 years of age. Because prenatal exposure to Valproate (VPA) is associated with ASD, we have developed a novel animal model of autism in which pregnant rats were exposed to subchronic doses of VPA resulting in increased neuronal cell number, behavioural deficits and decreased striatal 5-HT levels in the VPA exposed rats compared to controls. In light of the latter finding, the aim of the current study is to further investigate the serotonin system with focus on the 5-HT_{2A} receptor and the serotonin transporter (SERT). **Methods:** Pregnant Wistar rats were treated with VPA (20 or 100 mg/kg) or saline from day 12 until the end of pregnancy. Brains from the male offspring (n=7/group) were removed and fresh frozen at postnatal day 50 and then sliced into 20 μm thick sections. We performed *in vitro* autoradiography of striatal $5HT_{2A}$ receptors using [^{3}H]Ketanserin as the radioligand and mianserin to assess non-specific binding. We assessed striatal SERT levels using [^{3}H]DASB as the tracer and citalopram to detect non-specific binding. Statistics were done on the specific binding values using a one-way analysis of variance (ANOVA) followed by a Bonferroni post hoc test. **Results:** The 5-HT_{2A} receptor binding was significantly decreased in dorsolateral and ventrolateral striatum in rats prenatally exposed to VPA compared to saline controls ($p<0.05$ and $p<0.01$ respectively). The post hoc test revealed that the decrease in dorsolateral striatum was only significant for the rats exposed to 20 mg/kg/day whereas the decrease in ventrolateral striatum was significant in both VPA-groups. However, VPA did not induce changes in striatal [^{3}H]DASB binding. **Conclusions:** The lower 5-HT_{2A} receptor binding combined with reduced levels of 5-HT in striatum indicate a down-regulation of the serotonin system in the VPA-exposed rats consistent with imaging studies in human in which 5-HT_{2A} receptor levels are altered. The lack of difference in SERT-binding is in

contrast to human imaging studies which detect reduced SERT availability, however methodological and species differences may account for the differences in data. The changes at the receptor and not the transporter level in our study may suggest changes in serotonin metabolism and release coupled to 5-HT_{2A} receptor regulations.

Title: Modulation of aberrant ERK signaling as a potential therapeutic strategy in the BTBR mouse model of autism

Authors: ***N. CHENG**[1], Y. AHN[1], R. MYCHASIUK[1], R. TOBIAS[1], D. RUSKIN[2], S. MASINO[2], J. M. RHO[1];
[1]Univ. of Calgary, Calgary, AB, Canada; [2]Trinity Col., Hartford, CT

Abstracts: Autism spectrum disorder (ASD) is a common life-long neurodevelopmental disorder defined by three core symptoms: impaired social interactions, communication deficits, and stereotyped repetitive behaviors. Unfortunately, there are no effective treatments that directly address these core deficits and the underlying mechanisms remain poorly understood. Notably, the most common genetic linkages to ASD include ones that involve the extracellular-signal-regulated kinase (ERK) pathway. This pathway is highly conserved in all eukaryotes and critically involved in neurodevelopmental processes such as cellular proliferation, differentiation, and apoptosis. It involves a cascade of kinase activation where phosphorylated MEK (pMEK) in turn phosphorylates and activates ERK (pERK). pERK subsequently activates downstream targets including cAMP response element binding protein (CREB), a transcription factor involved in a variety of cellular processes. Here, we hypothesize that there is aberrant ERK signaling in ASD, and interventions aimed at normalizing this pathway could alleviate ASD symptoms. We used the BTBR mouse model because it robustly exhibits all three core behavioral features of ASD. We found that protein expression levels of three key components of

the ERK pathway were slightly but significantly increased in P35 BTBR neocortex compared with control B6 mice (pMEK: 104% increase, $p<0.04$; pERK: 43% increase, $p<0.05$; and pCREB: 26% increase, $p<0.05$). Based on these findings, we asked if pharmacological inhibition of ERK signaling would mitigate ASD-like behaviors in BTBR mice. U0126 (a highly selective and potent MEK inhibitor) was injected i.p. daily (12.5 mg/kg/day) in BTBR and B6 mice from P24 to P35; control groups were sham-injected with vehicle. At P35, we assessed all groups of mice with two behavioral tests: inchworming (a novel motor stereotypy recently identified in BTBR mice by our lab) and the established 3-chamber test of sociability. U0126 treatment significantly reduced inchworming behavior in BTBR mice ($p<0.0002$), and led to more social interactions in the 3-chamber assay ($p=0.11$). Our preliminary results suggest that ERK signaling is aberrantly up-regulated in BTBR mice and its inhibition may have therapeutic potential in reversing some of the core symptomatology of ASD.

Title: sncRNA expression differs more with age and by region in typical brain development than in ASD

Authors: B. STAMOVA[1], B. P. ANDER[1], N. BARGER[2], F. R. SHARP[1], *C. SCHUMANN[2]; [1]Neurol., [2]Psychiatry and Behavioral Sci., UC Davis MIND Inst., Sacramento, CA

Abstracts: Small non-coding RNAs (sncRNA), including microRNA (miRNA) and snoRNA, play a fundamental role in brain development throughout lifespan. Yet, little is known about their function in typical or atypical human brain development. To provide a baseline for contextualizing aberrant patterns of development, we first assessed differential expression of sncRNAs in typically-developing (TD) postmortem human brains in two temporal cortical regions - superior temporal sulcus (STS) and adjacent primary auditory cortex (PAC). STS is association cortex involved in social perception and commonly implicated in neurodevelopmental and psychiatric disorders; PAC processes basic auditory sensory information. We then similarly assessed age-matched brains from individuals with autistic

spectrum disorder (ASD) for comparison. Using Affymetrix miRNA 3.0 arrays, we explored how sncRNA expression patterns vary within TD and within ASD brains: 1) between spatially proximate, but functionally distinct, regions and 2) within these regions from childhood to adulthood. We found distinct regional and age-related changes of differentially expressed sncRNAs in TD in STS and PAC, however these differences were attenuated in ASD. Spatially, between STS and PAC, 22 sncRNAs were differentially expressed in TD cases, versus only 11 in ASD. In STS, 18 mature miRNAs changed with age in TD, while only 4 in ASD. In PAC, 27 mature miRNAs changed with age in TD, while only 2 in ASD. Age-related miRNAs in TD brains, based on similarity of expression profiles, group into defined positive and negative co-expression clusters, suggesting co-regulation of downstream mRNA targets. In contrast, ASD brains display significant deviations from this coordinated miRNA expression, thus potentially dysregulating a large number of downstream mRNA targets. In TD, putative targets of differentially expressed miRNAs are enriched in processes such as neurotransmitter signaling pathways, mTOR signaling, and in transcriptional regulation. ASD brains share common pathways with TD, and have enrichment of pathways not observed in TD, such as PTEN, PI3K, Erb, CNTF, neurotrophin, dopamine and cholecystokinin signaling. Several differentially expressed miRNAs found in our regional and age-related analyses have been previously associated with ASD dysregulation, providing additional support for their relevance to aberrant brain development across distinct brain regions. Our TD findings provide a necessary baseline for identifying sncRNA deviations in several disorders, including ASD, where we found evident attenuation of spatial and age-related differentially expressed miRNAs within temporal cortex.

Title: Interneuronal subpopulations in prefrontal cortex (BA 46) in autism

Authors: *V. MARTINEZ-CERDENO, E. HASHEMI, J. ARIZA;
Pathology, UC Davis, Sacramento, CA

Abstracts: An alteration in the number of interneuron types in a specific region of the cortex would likely alter the pattern of connections between cortical areas and could produce disturbances in cognitive functioning similar to those seen in autism. An alteration in the balance of excitatory neurons and inhibitory neurons is already known to be related with diseases such as squizophrenia and epilepsy. Here, we investigate the contribution of distinct cortical interneuron populations within the area BA46 of human prefrontal cortex, to the pathogenesis of autism. Parvalbumin (PV), calbindin (CB), and calretinin (CR) are markers of separate populations of interneurons defined by their morphology, their laminar distribution, and their developmental pattern. Even there is a small amount of colocalization, CR+, CB+, and PV+ neurons represent morphologically non-overlapping populations of neurons (Hof, 99). We obtained 10 autism cases and 10 age-matched controls (from the Autism Tissue Program), and based on gross cortical neuroanatomy in each case we isolated a block containing area BA 46. We cut 14 µm sections, stained one with Nissl, and based on cytoarchitecture selected a 2 mm wide bin extending through the thickness of the cortical grey matter in BA 46. On the adjacent section we performed triple immunostaining using different color combinations, and counterstained with Nissl. Using Stereo-investigator, we quantified the number of single PV+, CB+, CR+, double and triple stained cells within supragranular and infragranular layers in the area of interest, and compared the number of cells using paired t-tests.

Title: Developmental trajectories of neuron numbers across amygdaloid nuclei in Autism Spectrum Disorder

Authors: *N. BARGER[1], M. V. VARGAS[2], C. M. SCHUMANN[3];
[1]Univ. of California, Davis - MIND Inst., Sacramento, CA; [3]Psychiatry and Behavioral Sci.,
[2]MIND Institute, Univ. of California, Davis, Sacramento, CA

Abstracts: Concordant with the core features of Autism Spectrum Disorder (ASD), we have previously found that neuron numbers in the amygdala, a brain region implicated in social and emotional behavior, are reduced in ASD adults. Given that a large subset of individuals with ASD exhibit atypical amygdala growth trajectories in MRI analyses, we sought to address whether neuronal developmental trajectories in the amygdala were additionally altered in children and across the lifespan. The amygdala is structurally and connectively heterogeneous and not all of its nuclei evidence reduced neuron numbers. Therefore, we assessed developmental patterns in four individual amygdaloid nuclei, the lateral, basal, accessory basal, and central nuclei, to understand how the process of cellular development may vary across nuclei to produce significant variation in the adult phenotype. We used the optical fractionator technique to estimate neuron number in Nissl-stained sections from postmortem samples of autistic and control cases 2-44 years of age. Neuron numbers in each diagnostic group were regressed against subjects' numeric age for each nucleus. In controls, age and neuron number evidenced no significant relationship in any nucleus analyzed ($p > 0.05$). In our preliminary analyses of ASD, lateral nucleus neuron numbers shared a significant, negative relationship with age ($p = 0.02$), while the neuron numbers in the basal nucleus showed a trend towards a negative linear relationship with age ($p = 0.11$). Regressions for the accessory basal and central nuclei were not significant. We are collecting data on additional cases in each diagnostic group to further test these findings. We have previously found significant reductions in neuron numbers in the lateral nucleus of the amygdala in adults with ASD. These preliminary findings suggest that autistic individuals are not born with a deficit of lateral nucleus neurons, but may experience increased rates of neuron loss through development compared with typically developing individuals. Additionally, our data indicate that neurons may be lost in the basal nucleus through development in ASD, but perhaps not at rates that yield significant average changes across groups in smaller samples of autistic adults. Increasing our sample population can provide even greater insight into developmental processes in the basal nucleus. Our findings highlight the importance of assessing autistic neuropathology across age groups to identify both potential mechanisms underlying significant variation in adult brains as well as aberrant developmental trends that may not be readily apparent in the adult phenotype due to changes across lifespan.

Title: NMDA receptor dysfunction contributes to impaired long-term depression in a valproate-induced rat autism model

Authors: *H.-F. WU[1,2], H.-J. YEN[2], P.-S. CHEN[3], H.-C. LIN[2];
[1]Physiol., [2]Physiol. and Brain research center, Natl. Yang-Ming Univ., Taipei, Taiwan;
[3]Psychiatry and Addiction Res. Ctr., Natl. Cheng Kung Univ., Tainan, Taiwan

Abstracts: Autism-like phenotypes in male valproate (VPA)-exposed offspring has been linked to high glutamatergic neurotransmission in the thalamic-amygdala pathway. Amygdala, in the brain area, is related to socio-emotional behavior. Additionally, the activation of NMDA receptor (NMDAR) is the major cellular components of long term potentiation (LTP) and long term depression (LTD). However, the regulation of synaptic NMDAR activity within amygdala in autism disorders remains poorly understood. In this study, we characterized the LTD of amygdala in the VPA exposed offspring. By using the behavioral tracking technique to observe the social interaction, anxiety and depression-like responses *in vivo* and electrophysiology technique of extracellular recording of the amygdala brain slices *in vitro*. We found that the VPA-exposed offspring showed the less social interaction whereas higher emotional-related behaviors. Furthermore, the input-output relationship was not changed but the NMDA receptor-dependent long term depression was impaired in cortico-amygdala circuit in the VPA exposed offspring. The results suggested that the NMDA receptor regulates the synaptic activity in the amygdala which involved in VPA- exposed autism mode.

Title: EU-AIMS - a boost for pre-clinical and clinical autism Research

Authors: *W. SPOOREN;
Hoffmann-La Roche, Basel CH 4070, Switzerland

Abstracts: Autism spectrum disorder (ASD) is a severe neurodevelopmental condition affecting 1% of the population. Recent identified genetic risk factors have given insight into the neurobiology. To move this field into evidence based medicines, fourteen leading academic centers across Europe have partnered with Autism Speaks, Autism Europe and six industry partners, i.e. Eli Lilly, J&J, Pfizer, Servier, Vifor and Roche. This consortium named EU-AIMS, was set-up in the context of the Innovative Medicines Initiative (EU) in 2012 and is led by Roche together with Kings College (UK) and has a budget of over 50 million $. The goal is to create a fully integrated pre-clinical and clinical research effort to advance this field significantly. We now report our first results: (1) EU-AIMS validated protocols to generate neurons from patient keratinocytes through reprogramming IPS cells. (2) Using a reversible KO model, EU-AIMS demonstrated that mice lacking NLGN3 share a convergent molecular signature with fragile-X syndrome, which could be rescued in adulthood. (3) By using MRI we have characterized endophenotypes of four animal models carrying mutations from ASD patients. 4) Two unprecedented naturalistic observational studies will be started in 2014 across Europe characterizing patients ageing from 6 months - 30 years: a) The Infant-at-Risk study prospectively studies 300 infants at high genetic risk and 100 low-risk infants from over 36 months. The aim is to identify factors that predict ASD. b) The Longitudinal European Autism Project (LEAP) is the largest autism project to date and includes 400 participants with ASD and 250 control participants from 6-30 years. Each participant will be seen at two time-points and all participants are comprehensively clinically characterized. Finally, EU-AIMS is setting-up an unprecedented European wide clinical network and has recruited more than 70 centers in 37 countries to share information, align and run clinical studies in a way that is unique in the world. Title: Synaptic characterization of Nlgn3 KO Rats

Authors: *R. NAIR[1], E. SYLWESTRAK[1], P. SCHEIFFELE[2], A. GHOSH[1];
[1]F.Hoffmann La Roche, Basel, Switzerland; [2]Biozentrum, Univ. of Basel, Basel, Switzerland

Abstracts: Autism spectrum disorders (ASDs) are neurodevelopmental disorders, diagnosed early in development during the time of circuit formation. ASDs are characterized by impairments in social interactions and communication, and can be accompanied by repetitive behaviors. Genetic factors contribute strongly to the etiology of autism. A large number of genes encoding synaptic proteins have been implicated in ASDs suggesting that synaptic dysfunctions contribute to the pathogenesis of ASDs. In particular, one class of monogenic heritable form of autism is associated with mutations in neuroligin (NLGN) genes that encode postsynaptic cell adhesion molecules, which are essential for normal synapse function. Mutations in neuroligin3 (NL3) consisting of a single amino acid substitution from the Arg451 to Cys451 (R451C) as well as complete loss of NL3 have been implicated in autism. In this study, we have made use of a knockout rat line of NL3, which has been generated using zinc finger nuclease (ZFNs) technology. The rat is a preferred model system for studying many neurological disorders such as autism, mainly for its social behavior, size and, physiology. The major goal of this study is to understand the fundamental defects in autism models and hopefully reverse the changes using pharmacological tool. In the layer 2/3 of the somatosensory cortex, we found an increase in inhibitory synaptic transmission. However in the CA1 region of the hippocampus, no obvious changes were detected.

Title: Decreased PI3K-Akt-mTOR signaling pathways in human autism and in rats exposed to valproic acid

Authors: *M. FAHNESTOCK[1], C. NICOLINI[2], Y. AHN[3], B. MICHALSKI[2], J. M. RHO[3]; [1]Dept Psychiatry & Behavioural Neurosciences, [2]Psychiatry & Behavioural Neurosciences, McMaster Univ., Hamilton, ON, Canada; [3]Depts. of Paediatrics & Clin. Neurosciences, Alberta Children's Hosp. Res. Inst., Univ. of Calgary, Calgary, AB, Canada

Abstracts: The molecular mechanisms underlying autistic behavior remain to be elucidated. Maternal exposure to the anticonvulsant valproic acid (VPA) during pregnancy induces autism-like phenotypes in both humans and rodents. Here, using both human and rat tissue, we provide two molecular pathways that contribute to autistic behaviour by adversely affecting spines: the Akt/mTOR pathway by disrupting spine protein translation and the TrkB/PI3K/Akt pathway by interfering with PSD-95 transport. Protein levels of the BDNF receptor TrkB, TrkB downstream signalling molecules in the PI3K-Akt-mTOR pathway, mTOR effectors such as p70S6K and 4E-BP1, as well as the excitatory post-synaptic marker PSD-95 were examined by Western blotting in post-mortem fusiform gyrus tissue from 11 subjects with idiopathic autism and 13 control subjects. A similar analysis was carried out on cortical tissue from rats exhibiting autism-like behaviour whose mothers were treated with VPA at embryonic day 12.5. Genetic studies on single-gene developmental disorders such as fragile X syndrome, tuberous sclerosis and Rett syndrome have shown that both up- and down-regulation of the Akt/mTOR pathway are associated with de-regulation of spine protein synthesis and changes in brain connectivity. Here we show that protein products of genes in the Akt/mTOR pathway are ***down***-regulated in subjects with idiopathic autism and in rats exposed to VPA. Our results demonstrate for the first time that disruptions of this pathway are not limited to genetic forms of autism, but are widespread in the autism population. Furthermore, we show that down-regulation of the mTOR pathway affects spine protein translation not via the expected 4E-BP pathway, but, similarly to Rett syndrome, specifically via the p70S6K/eIF4B pathway, which controls translation of mRNAs coding for translational machinery components. Also, full-length TrkB protein expression is decreased in idiopathic autism and is associated with reduced PI3K, Akt and PSD-95. TrkB is involved in transport of PSD-95 via PI3K-Akt, and thus, TrkB may disrupt brain connectivity by interfering with PSD-95 trafficking. Lastly, we propose an epigenetic mechanism, supported by our animal data showing that prenatal exposure of rats to VPA, an HDAC inhibitor, is also associated with down-regulation of the Akt-mTOR pathway. Our results implicate epigenetic down-regulation of PI3K-Akt-mTOR pathways in idiopathic autism.

Title: Role for the secreted amyloid-β precursor protein (sAPPα) in Autism as early neurodevelopmental disorder

Authors: *D. K. LAHIRI[1], D. K. SOKOL[2], B. RAY[1];
[1]Dept. of Psychiatry, [2]Dept. of Neurol., Indiana Univ. Sch. of Med., Indianapolis, IN

Abstracts: Autism is a neurodevelopmental disorder marked by deficits in social skills and communication and by repetitive behavior. Intellectual disability often accompanies autism. In addition to behavioral deficits, autism is characterized by aberrant neuronal connections and brain overgrowth. We previously reported that the Alzheimer's disease (AD) associated amyloid-β precursor protein (APP), especially its neuroprotective processing product, sAPPα, is elevated in persons with autism (Ray et al, 2011).This has led to the "anabolic hypothesis" of autism (and possibly fragile X) etiology, in which neuronal overgrowth in the brain results in interneuronal misconnections that may underlie multiple autism symptoms (Sokol et al, 2011). APP, a large membrane spanning glycoprotein, is produced in oligodendrocytes and neurons. A sequential cleavage of APP via specific secretase enzymes generates either to amyloid-beta (Aβ) peptides seen in AD amyloid plaques, or to the nonamyloidgenic sAPPα associated with neurotrophic properties. Our group first reported higher levels of sAPPα and lower Aβ peptides in plasma from children with severe autism later replicated independently. We further validated the proposed nonamyloidgenic "anabolic hypothesis" for autism (Lahiri et al, 2013) in autopsied brain tissue samples. Brain tissue specimens (from the Autism Tissue Program and University of Maryland Brain Bank) were homogenized, fractionated, and levels of sAPPα and sAPPtotal were assayed by sensitive sandwich ELISA and Western blotting. Data were analyzed statistically after normalization to the concentration of the total sample. Brain samples from 7 subjects with

autism were compared to 8 age matched controls. Children with autism appeared to be severely affected: incidence of seizures (42.9%), intellectual (mean 57.3, SD 21.01) and social (mean 47.7, SD 23.9) quotients available for 3/7 subjects. Brain extracts from frozen, left temporal lobe showed significant elevation in sAPPα levels for children with autism compared to controls ($p<0.02$). Levels of other APP pathway metabolites, including Aβ peptides, are being analyzed. This novel work warrants further work with a large number of subjects . Our work suggests the relationship of APP to other proteins and pathways that have already been directly associated with autism, such as fragile X mental retardation protein, Ras/ERK and PI3K/Akt/mTOR. Thus, elevated levels of sAPPα detected in autism brain tissue support the sAPPα-driven anabolic pathway for neurodevelopmental disorders, including autism, and open up new therapeutic drug targets.

Title: Prenatal exposure to histone deacetylase inhibitors delays neuronal maturation by regulating gene expression of morphogenesis-related molecules

Authors: *T. KAWANAI[1], R. WATANABE[1], A. INOUE[1], Y. AGO[1], K. TAKUMA[1], T. MTSUDA[1,2];
[1]Lab. of Medicinal Pharmacol., Grad. Sch. of Pharmaceut. Sci., Osaka Univ., Osaka, Japan;
[2]Unit-Grad. Sch. of Child Dev., Osaka Univ., Osaka, Japan

Abstracts: We have recently demonstrated that prenatal exposure to a histone deacetylase (HDAC) inhibitor valproic acid (VPA) at embryonic day 12.5 (E12.5) causes autism-like behavioral abnormalities, such as social interaction deficits, anxiety-like behavior and spatial learning disabilities, in male mouse offspring (Int. J. Neuropsychopharamacol., 2013). We have also found that the prenatal VPA exposure causes a transient increase in acetylated histone levels in the embryonic brain, followed by an increase in apoptotic cell death in the neocortex and a decrease in cell proliferation in the ganglionic eminence, and it decreases Nissl-positive cell numbers in the prefrontal and somatosensory cortices after birth. In this study, we examined the effect of prenatal exposure to HDAC inhibitors on neuronal maturation. VPA (500 mg/kg, i.p.),

trichostatin A (TSA; 500 μg/kg, i.p.) or vehicle was injected into pregnant mice on gestational days 12.5 or 14.5, and primary neurons were prepared from the cerebral cortex at E16. Cells were stained with MAP-2 antibody and quantitative morphological analysis was carried out using a Neurolucida software (MBF Bioscience). Prenatal exposure to VPA at E12.5, but not at E14.5, caused decreases in total numbers and length of neuronal dendrites at 14 days *in vitro* (14 DIV). The differences disappeared at 21 DIV. Similar delay of cellular maturation was observed in cortical neurons from embryos exposed to TSA at E12.5. Furthermore, the present study demonstrated that the prenatal exposure to HDAC inhibitors at E12.5 decreased neuroligin-1 mRNA level and increased CNTNAP2 and Shank3 mRNA levels. These findings suggested that prenatal exposure to HDAC inhibitors at E12.5 delays neuronal maturation by regulating gene expression of morphogenesis-related molecules.

Title: Blocking MEK-ERK1/2 activity in TSC rescues defects in neuronal dendritic trees

Authors: *C. M. BARTLEY[1], L. ZHANG[2], X. GONG[2], L. S. HSIEH[2], T. V. LIN[2], A. BORDEY[2];
[1]Neurobio. and MSTP Program, Yale Univ., New Haven, CT; [2]Neurosurgery, and Cell. & Mol. Physiol., Yale Univ. Sch. of Med., New Haven, CT

Abstracts: Tuberous sclerosis complex (TSC) is a monogenic disorder due to mutations in TSC1 or TSC2. Most patients display cortical malformations called tubers associated with seizure activity. One of the hallmarks of tubers is an abnormal morphology of cortical neurons. In particular, tuberous neurons display severe dysmorphogenesis of their dendritic trees. Because

the dendritic tree determines the synaptic connectivity and input integration that is necessary for proper network function, alterations in dendritic morphology affect neuronal network activity. Recent studies reported that ERK1/2 activity is increased in both human TSC patients and mouse models of TSC cortical malformations (i.e., tubers). Here we explored whether ERK1/2 activity was increased in Tsc1null neurons and contributed to their abnormal dendritic development. We found that ERK1/2 activity was indeed increased in Tsc1null neurons *in vivo*. Increasing MEK-ERK1/2 activity with expression of a constitutively active MEK1 vector in developing neurons led to increased dendritic complexity. Expressing a dominant negative MEK1 vector in Tsc1null neurons normalized their abnormal dendritic morphology. Finally, pharmacologically decreasing MEK-ERK1/2 activity in Tsc1null neurons significantly rescued dendritic defects. These data demonstrate that altered MEK-ERK1/2 activity increases dendritic complexity and contributes to pathologic dendritic patterning in TSC thus providing a potential additional therapeutic option.

Title: Dynamic autism-associated protein interaction networks engaged by glutamate activity at the synapse

Authors: *S. E. SMITH, S. C. NEIER, T. R. DAVIS, A. G. SCHRUM;
Mayo Clin., Rochester, MN

Abstracts: A key limitation in the field of autism research is that despite knowing the identity of tens or even hundreds of risk factors for autism, we do not understand how (or if) these diverse genetic and environmental insults converge on common cellular or molecular processes to cause the core symptoms of the disorder- impaired social interaction, reduced communicative behavior and increased repetitive, stereotyped behaviors. There is strong evidence that many different autism risk factors disrupt glutamatergic signaling, leading to the current “synaptic hypothesis of autism”, but the shared mechanisms, if any, remain unclear. To begin to address this problem, we

have developed a novel multiplex immunoassay to quantify dynamic protein-protein interaction networks at the glutamate synapse, Quantitative Multiplex Immunoprecipitation (QMI). The QMI platform currently measures the relative abundance of 16 autism-associated proteins expressed at the glutamate synapse, and the degree of interaction among them (240 interactions). To validate the assay, we observed several known interactions among synaptic proteins, for example Fyn-GRM5 and GRIA1-Homer1. We also observed several previously unreported protein complexes that we are working to confirm using traditional methods (e.g., IP-Western blot). Upon glutamate stimulation or pharmacological blockade of glutamate receptors, we observed dynamic changes in 15-30% of the observed protein co-associations. We are now beginning to analyze mouse models of autism on the QMI platform (e.g. Shank3 KO, Fragile X mouse, Ube3a mouse) to identify structural changes in the protein interactome at the synapse of these mice, both under baseline conditions and following neuronal activity modulation. Our goal is to better understand the network-scale alterations in protein associations during glutamatergic signaling, and to define how different autism-associated risk factors may play important, perhaps convergent, roles in these synaptic network processes.

Title: Role of FMRP in activity-dependent expression of synaptic proteins revealed by TimeSTAMP-tagging of PSD95

Authors: *Y. GENG[1], Y. YANG[1], M. Z. LIN[2];
[1]Pediatrics, [2]Pediatrics, Bioengineering, Stanford Univ., Stanford, CA

Abstracts: Protein synthesis is highly regulated throughout nervous system development, plasticity, and regeneration. Studies in Fragile X Fragile X mental retardation have indicated that protein synthesis, especially local protein regulation at synaptic level, has been significantly disturbed. However, tracking the distributions of specific new protein species has not been possible in living neurons or at the ultrastructural level. Previously we created TimeSTAMP epitope tags, drug-controlled tags for immunohistochemical detection of specific new proteins synthesized at defined times. We extend TimeSTAMP to label new protein copies by fluorescence. Using TimeSTAMP:YFP, we demonstrate that copies of the synaptic protein PSD95 are synthesized in response to local activation of growth factor and neurotransmitter receptors, and preferentially localize to stimulated synapses. Our preliminary data suggests that local PSD95 synthesis is significantly impaired in a mouse model of Fragile X mental retardation.

Abstracts: Although considerable evidence suggests that the chemical synapse is a lynchpin underlying neurodevelopmental disorders, how molecular insults differentially affect specific synaptic connections remains poorly understood. For instance, Neurexin 1a and 2 (NRXN1 and

2) and CNTNAP2 (aka. CASPR2), all members of the neurexin superfamily of transmembrane molecules, have been implicated in such brain disorders. However, their loss leads to deficits that have been best characterized with regard to their impact on excitatory cells. Notably, other disease-associated genes such as BDNF and ErBb4 implicate specific interneuron synapses in neurodevelopmental disorders. Consistent with this, cortical interneuron dysfunction has been linked to epilepsy, schizophrenia, and autism. Using a microarray screen that focused upon synapse-associated molecules, we identified Cntnap4 (contactin-associated protein 4, also known as Caspr4) as highly enriched in developing interneurons. In this study we show that Cntnap4 is localized presynaptically and its loss leads to a reduction in the output of cortical PV- positive GABAergic basket cells. Paradoxically, the loss of Cntnap4 augments dopamine release in the nucleus accumbens. Consistent with a small number of CNTNAP4 human gene deletions we identified in neuropsychiatric patients, Cntnap4 mutant mice exhibit sensory-motor gating and grooming endophenotypes. These behavioral abnormalities could be pharmacologically reversed in adult animals by functionally normalizing the observed synaptic defects in the two systems, providing some promise for possible therapeutic intervention in neurodevelopmental disorders.

Title: Neural mechanisms of circuit homeostasis failure in MeCP2 disorders

Authors: *H. LU[1,6], R. T. ASH[2], W. WANG[3], D. YU[3], B. R. ARENKIEL[3,2], S. M. SMIRNAKIS[4,2], H. Y. ZOGHBI[3,2,5,6];

Abstracts: Background: Loss-of-function mutations in methyl CpG binding protein 2 (MeCP2), as occurs in Rett syndrome, and duplication of the genomic region including *MECP2* (Xq28), as occurs in *MECP2* duplication syndrome, lead to overlapping clinical features including autism, epilepsy, and intellectual disability. Similarly, mouse models lacking versus overexpressing MeCP2 exhibit partially overlapping autism-associated behavioral phenotypes even though they demonstrate opposite patterns of global gene expression, LTP induction, synapse strength/number, and dendritic arborization. How opposite changes at the levels of transcription, synaptic function, and neuronal morphology lead to autism-like and other phenotypes remains unexplained. We hypothesize that similar impairment of circuit function contributes to the overlapping behavioral phenotypes of Rett and *MECP2* duplication mice. **Methods:** To study the state of neural circuit homeostasis in *MECP2* disorders, Rett (*Mecp2* null, 129 background) and *MECP2* duplication (Tg1, FVB background) mice were crossed to transgenic animals expressing the genetically encoded calcium indicator GCaMP3 in excitatory neurons (thy1-gcamp3, C57Bl6J background). Coronal slices were prepared from F1 experimental animals at 8 weeks of age, and calcium events in hippocampal CA1 neurons were imaged by ex-vivo 2-photon microscopy. **Results:** Change of MeCP2 expression in either direction led to circuit hypersynchrony both at baseline and in response to small perturbations in the balance of excitation and inhibition. Experiments in conditional *Mecp2* mutants revealed that MeCP2 function in excitatory neurons enables the desynchronized network state at baseline, while MeCP2 function in inhibitory neurons is critical for maintaining this desynchronized state in response to perturbation. Pathological hypersynchrony appeared to be driven by decreased recurrent inhibition in both mutants, in addition to a selective increase in local excitatory connectivity in Tg1 mice and abnormal cellular excitability in *Mecp2* null mice. **Conclusions:** Opposite deviations of MeCP2 expression from normal level lead to similar CA1 circuit functional phenotypes characterized by hypersynchrony and impairment in CA1 circuit homeostasis, suggesting that impaired neuronal circuit homeostasis may be a common theme underlying the similar behavioral abnormalities seen in *Mecp2* mutants.

Title: Fn14-TWEAK mediate an inflammatory response in Status Epilepticus

Authors: *Z. POTTANAT;
Neurol. (FOFF LAB), Foff Lab., CHARLOTTESVILLE, VA

Abstracts: Objective: Status Epilepticus (SE) is a life threatening disorder characterized by continuous seizure activity and neuronal death. There is current interest in neuroprotective agents that can be given to reduce disease complications. FN14, a member of the TNF-α receptor superfamily, and its ligand, TWEAK, have been shown to be upregulated in other models of neuronal injury. We tested the hypothesis that FN14 is similarly up regulated during SE and is detrimental to neuronal health. Methods: SE was induced via intraperitoneal injections of pilocarpine using published methods. Control mice were given saline injections (n=5) only. Hippocampal and cortical brain tissue was collected at 6 (n=5) or 24 (n=7) hours after SE onset and RNA/protein prepared. We used quantitative PCR and western blots to assess levels of FN14, TWEAK, and downstream effector RNA and protein, respectively. Results: Fn-14 was upregulated in SE in a time dependent manner. At 6 and 24 hours, there were a 38-fold and 188-fold increase in FN14 RNA respectively ($p = <0.001$).Western blots confirmed an upregulation in protein levels as well. In accordance with published records in other neuronal injury models, TWEAK ligand levels remained stable. Upregulation of FN14 corresponded with activation of the inflammatory NFκB pathway. Interpretation and future studies: Upregulation of the FN14/TWEAK pathway has been postulated to mediate neuronal damage in acute neurologic disease. Here we show that the pathway is highly upregulated in SE. Experiments are underway to determine if genetic loss of FN14 or antibody-mediated abrogation of the pathway reduces neuronal loss.

Title: Alterations of amino acids involved in threonine metabolism in a rat model of acute seizures induced by lithium-pilocarpine

Authors: *V. ARRIAGA-AVILA, J. LANDGRAVE-GÓMEZ, O. MERCADO-GÓMEZ, R. GUEVARA-GUZMÁN;
Univ. Nacional Autonoma de Mexico, Ciudad de Mexico, Mexico

Abstracts: To date, some reports suggest that changes in the amino acid metabolism are involved in a variety of neurological disorders such as epilepsy. In this sense, a nutritional challenge such as calorie restriction (CR) or ketogenic diet (KD) that modulates the amino acid metabolism, has been observed that has anticonvulsant activity. Environmental inputs, such as nutrition, can modulate cell metabolism, and the relationship between epigenetic modifications and metabolism regulation is beginning to emerge. Because CR and KD can induce changes in metabolism, the aims of the present work were to study whether acute seizures induce alterations involved on threonine metabolism and if the feeding restriction model(FR)would reverts those changes on amino acids, which may contribute to the anticonvulsant effect observed in other studies. The model of acute seizures consisted in a pre-treatment of lithium chloride (3 mEq/kg) followed by pilocarpine administration (60 mg/kg) with a previous injection of scopolamine nitrate (1 mg/Kg) 30 min before. The FR was to allow rats to fed for two hours daily for 21 days; control and pilocarpine animals consisted of feeding ad libitum. Animals were divided into four groups (i.e.ad libitum, ad libitum+pilocarpine, FR, and FR+pilocarpine) and sacrificed 24 hrs after drug administration; serum samples were collected afterwards. For amino acid analysis, high-performance liquid chromatography (HPLC) was performed. In order to remove proteins by precipitation, plasma sample was mixed 1:1 with acetonitrile. The mixture was centrifuged at 14,000 RPM for 8 min. The supernatant was filtered and diluted 1:20 with Krebs-Ringer solution (pH=3.0). Twenty μL were transferred into a Microtube insert and placed in vials with screw caps, and then stored in a refrigerated sampler of the HPLC system at 4o C. The analysis was done with an Agilent 1100 HPLC system (Agilent Technologies, Santa Clara, CA) equipped with a fluorescence detector, a binary pump, an automatic injector sampler and a column thermostat.Our results shown a significant decrease of threonine, methionine and glycine concentration on plasma in ad libitum + pilocarpine group compared with that of the ad libitum control group ($n=5$, $p<0.005$). Moreover, the FR + pilocarpine group showed an increase of threonine compared with that of the ad libitum + pilocarpine group ($n=5$, $p<0.005$). Conclusions:

Seizures per se decrease the concentration of amino acids involved in threonine metabolism (i.e. threonine, glycine, and methionine). However, this alteration was only partially reverted in some of them, but fully reverted in threonine concentration in animals that followed the FR model.

Title: Characterization of chloride homeostais alteration in a rodent model of temporal lobe epilepsy

Authors: *N. KOURDOUGLI, C. PELLEGRINO, G. CHAZAL, J.-L. GAIARSA, V. CRÉPEL, C. RIVERA;
BP13, INSERM UMR901, MARSEILLE, France

Abstracts: Epilepsy is one of the most common neurological disorders, with a 0.5% prevalence. The seizure focus can be the entire brain or a particular region; the most commonly affected is the temporal lobe. This pathology is characterized by an initial generalized seizure, followed by a clinical quiescent period. Within this period functional and morphological network reorganization presumably occur that leads to spontaneously recurring seizures at later stages of the disease. In this context, the working hypothesis for seizures genesis have been linked to altered GABAergic signaling and excitotoxicity-induced cell-death. Gamma-Amino Butyric Acid (GABA) is the main inhibitory neurotransmitter in the central nervous system, but under physio-pathological conditions it leads to hyperexcitabilty, through a dysregulation of chloride homeostasis in neurons. This phenomenon is controlled by Cation Chloride Co-transporters (CCCs), like the neuronal specfic K+-Cl- co-transporter KCC2 and the widely distributed Na+-K+-2Cl- co-ctransporter NKCC1. In many pathophysiological conditions, it has been shown that KCC2 is down-regulated and NKCC1 up-regulated, result in a depolarizing effect of chloride permeable GABAA receptors. Using a rodent model of Temporal Lobe Epilepsy (TLE) we aim at studying the network reorganization within the latent phase following the status epilepticus (SE) in the hippocampus. To assess those questions we analyzed by histological, molecular and biochemical techniques the expression of both KCC2 and NKCC1 transporters, as well as the

time course of cell death. Our results show an increase cell death right after the SE with concomitant changes in expression intensity and distribution of KCC2 that correlates with the post SE changes in GABAergic neurotransmission. These preliminary results support the idea of an altered GABAergic signaling during the latent phase due to compromised chloride regulation. Further investigate is required to assess if these changes lead to network reorganization and recurrent seizures in this model of TLE.

Title: Interleukin-1β and IL-1RI expression in the developing rat thalamus and amygdala following status epilepticus

Authors: *D.-M. ALVAREZ-CRODA[1,2], L. BELTRÁN-PARRAZAL[1], C. MORGADO-VALLE[1], C. A. PEREZ-ESTUDILLO[1], M. L. LÓPEZ-MERAZ[1];
[1]Ctr. de Investigaciones Cerebrales, [2]Posgrado en Neuroetología, Univ. Veracruzana, Xalapa, Veracruz, Mexico

Abstracts: Status epilepticus (SE) induces age-dependent neuronal injury in specific rat amygdaloid and thalamic nuclei; however, the cell death mechanisms involved in this process are not completely understood in the developing rat brain. SE induced in twenty-days-old rats (P20) causes neuronal cell death in ventral lateral, posteromedial and basomedial amygdala nuclei, whereas in P15 rats, SE induces injury mainly in the medial amygdaloid nucleus. Regarding the thalamus, SE induced in P12 rats produces neuronal cell death in the lateral and medial nuclei. It is known that inflammation can contribute to SE-induced neuronal injury in the immature brain. Interleukin-1β (IL-1β) gene and protein expression is up regulated following seizures and this cytokine has been associated with neuronal cell death following epileptic activity. The aim of

this study was to evaluate the temporal pattern of neuronal cell death in the amygdala and thalamus from P14 rats after SE and to determine whether IL-1β and its type I receptor (IL-1RI) are expressed in those brain areas. Rat pups were given 3 mEq/kg lithium chloride i.p. on the day before the induction of SE, which was carried out at P14 by subcutaneous injection of 100 mg/kg pilocarpine hydrochloride; control animals (n=7) were given an equal volume of saline subcutaneously. Six (n=7) and 24 h (n=9) following SE, rats were anesthetized and transcardially perfused with 4% phosphate-buffered paraformaldehyde. Subsequently, brains were dehydrated, embedded in paraffin and cut into 10-μm-thick coronal sections at the level of dorsal hippocampus. Fluoro-Jade B staining was carried out in order to detect neuronal cell death, whereas IL-1β and IL-1RI were detected by immunohistochemical procedures. Neither neuronal cell death nor IL-1β/IL-1RI expression was observed in control animals. Injured neurons were detected in the dorsomedial thalamus 6 and 24 h after SE; IL-1β was expressed only 6 h following SE, while no expression of IL-1RI was observed in this thalamic nucleus. No F-JB positive cells or IL-1RI expression was detected in the lateral thalamic nucleus, but IL-1β was expressed 6 h after SE. Respecting amygdala, neuronal injury was detected 24 h after SE in the medial nucleus, whereas IL-1β and IL-1RI were observed 6 but not 24 h after SE in this brain region. Results suggest that the IL-1β/IL-1RI system could be involved in region-specific neuronal cell death mechanisms following SE in the immature rat brain.

Title: Cellular and regional specific changes in multidrug efflux transporter expression during recovery of vasogenic edema in the rat hippocampus and piriform cortex

Authors: *T.-C. KANG, J.-Y. KIM, A.-R. KO, Y.-J. KIM, J.-E. KIM;
Col. Med, Hallym Univ., Chunchon, Korea, Republic of

Abstracts: Since ATP-cassette-binding protein (ABC) family plays a role as drug efflux transporters, ABC family expression is an important factor in the therapeutic failure of antiepileptic drugs (AEDs). We investigated the correlation between ABC family alterations and vasogenic edema formation following status epilepticus (SE) to understand the characteristics of seizure-induced over-expression of drug efflux transporters. Vasogenic edema was peaked 3 - 4 days after SE in the hippocampus and piriform cortex (PC). In the hippocampus, the expressions of breast cancer resistance protein (BCRP), multidrug resistance protein-4 (MRP4) and p-glycoprotein (p-GP) were decreased 4 days after SE, but subsequently increased at 4 weeks after SE. Multidrug resistance protein-1 (MRP1) expression gradually decreased in endothelial cells until 4 weeks after SE. Enhancements of BCRP, MRP4 and p-GP expressions were mainly detected in astrocytes, neuropils and reactive astrocytes, respectively. In the PC, BCRP, MRP4 and p-GP expressions were transiently decreased and subsequently increased after SE. MRP1 expression was gradually decreased in the PC following SE. Up-regulation of BCRP expression was detected in palisade astrocytes around the vasogenic edema lesion. MRP4 expression was increased in neuropils. p-GP expression was up-regulated in endothelial cells. Our findings indicate that SE-induced vasogenic edema formation transiently reduced drug efflux pump expressions in endothelial cells. Subsequently, during recovery of vasogenic edema drug efflux pump expressions were differentially up-regulated in astrocytes, neuropils and endothelial cells. Therefore, we suggest that vasogenic edema formation may be a risk factor in pharmacoresistent epilepsy.

Title: Balance in mitochondrial fission and fusion in neuronal injury in pilocarpine-induced epileptic rats

Authors: D. CARRERA-CALVO[1], J. SOLÍS-NAVARRETE[1], *L. CÓRDOVA-DÁVALOS[1], O. MERCADO-GÓMEZ[1], V. ARRIAGA-ÁVILA[1], E. MARTÍNEZ-ABUNDIS[2], R. GUEVARA-GUZMÁN[1];
[1]UNAM, DISTRITO FEDERAL, Mexico; [2]Univ. Juárez Autónoma de Tabasco, Comalcalco, Tabasco, Mexico

Abstracts: Epilepsy is a neurological disorder that is characterized by recurrent and spontaneous seizures this causes neuronal damage and loss in several regions from hippocampus. There are some reports showing that mitochondrial fission is involved in oxidative stress and apoptosis of several neurodegenerative diseases. Recently, it has been reported the role of mitochondrial fission in a pharmacological animal model; the results show that mitochondrial fission increased after seizures. However, the information about the balance of mitochondrial fission and fusion events for cell survival is scarce and was not fully appreciated until fairly recently. The aim of this study is to show that there is a balance between mitochondrial fission and fusion events in epileptic seizures development in Wistar male rats. Our data show that fission protein Drp1 expression increases at short time in cytoplasm, but in mitochondria there are no changes in level expression. Therefore, there is no increase translocation Drp1 protein to outer membrane mitochondria, and Fis1 did not change in level expression. Moreover, mitochondrial fusion, which is mediated by Mfn1, an outer membrane mitochondrial protein, and Opa1, an inner membrane mitochondrial protein, show an increase in level expression for a short time. In summary, this study demonstrated that mitochondrial fusion is up-regulated after seizures during three days and Drp1 fission protein is expressed but not translocated to outer membrane mitochondria during seizures.

Title: PARP1 activation/expression modulates regional specific neuronal and glial responses to seizure in a hemodynamic-independent manner

Authors: *J.-E. KIM, J.-Y. KIM, Y.-J. KIM, A.-R. KO, T.-C. KANG;
Anat. and Neurobio., Dept. of Anat. and Neurobiology, Hallym Univ., Chuncheon, Korea, Republic of

Abstracts: In the present study, we investigated the role of poly(ADP-ribose) polymerase-1 (PARP1) activity in the differential neuronal/glial responses to pilocarpine (PILO)-induced status epilepticus (SE) within the rat hippocampus and piriform cortex (PC). CA1- and CA3 pyramidal cells showed PARP1 hyperactivation-dependent neuronal death pathway following SE. PC neurons and hilar neurons exhibited PARP1 degradation-mediated neurodegeneration following SE. PARP1 degradation was also observed in astrocytes within the molecular layer of the dentate gyrus. PARP1 induction was detected in CA1-3 reactive astrocytes, as well as in reactive microglia within the PC. PARP1 inhibitors deteriorated the astroglial death in the molecular layer of the dentate gyrus, and induced astroglial death in the stratum lucidum of the CA3 region. *Ex vivo* study showed that these regional and cellular specific patterns of PARP1 activation/degradation were hemodynamic-independent responses. Taken together, our findings indicate that PARP1 hyperactivation, degradation and induction may distinctly involve neuronal damage, astroglial death and reactive gliosis in response to SE. Therefore, the present study suggests that the selective modulation of PARP1 activation/expression may be a considerable strategy for therapy in various neurological diseases.

Title: Clonal analysis of newborn hippocampal dentate granule cell proliferation and development in temporal lobe epilepsy

Authors: *S. P. SINGH, S. C. DANZER;
Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstracts: Hippocampal dentate granule cells (DGCs) are among the few neuronal cell types generated throughout adult life in mammals. In the normal brain, adult neurogenesis gives rise to DGCs neurons which integrate into the granule cell layer of the dentate gyrus in a stereotypical fashion. By contrast, in the epileptic brain, DGC neurogenesis is profoundly altered. Specifically, granule cell progenitors exposed to status epilepticus (SE) exhibit increased proliferation and integrate abnormally. The factors regulating these responses remain uncertain and could involve changes in systemic cues, regional cues or cell-intrinsic properties. Here, we used clonal analysis of DGC progenitors to determine whether increased proliferation and abnormal integration of newborn DGCs appears uniformly across DGC progenitors or whether progenitors respond heterogeneously to the insult, exhibiting progenitor-specific or region-specific differences. To this end, we used Gli1-CreERT2-Brainbow reporter mice to differentially label progenitor cells and their clonal progeny following pilocarpine-induced SE. Hippocampi were isolated and rendered translucent using Scale reagent. Confocal microscopy was used to generate 3-dimensional reconstructions of the entire dentate. Clonal DGC clusters from epileptic animals were compared to clusters from controls. This study is designed to determine whether there are differences among hippocampal progenitors following SE-induced DGC proliferation and integration. The results of this study will provide novel insights into the potential mechanisms regulating DGC dysmorphogenesis in epilepsy.

Title: Breaking the bottleneck of using kainate-resistant C57BL/6J mice in epilepsy research: Developing an advantageous early-onset mouse model of epilepsy

Authors: *S. PUTTACHARY[1], S. SHARMA[1], K. TSE[2], J. CRUTISON[1], A. SEXTON[1], T. THIPPESWAMY[1];
[1]Biomed. Sci., Iowa State Univ., Ames, IA; [2]Univ. of Liverpool, Liverpool, United Kingdom

Abstracts: Temporal lobe epilepsy (TLE) is the most common form of acquired human epilepsy. A robust preclinical model to boost new and effective antiepileptic drugs (AEDs) is crucial as, current drugs are not responsive in 1/3rd of epileptic patients. Hitherto, rat models of TLE have been used to mimic some aspects of human TLE. Currently, the epilepsy research has gained momentum by using of transgenic mouse models bred on C57BL/6J genetic background. Lack of reliable critical control in using C57BL/6J wild-type mouse model has let-down many researchers due to specific disadvantages such as, a well-documented kainate (KA) resistance to neurotoxicity, unreliable seizure response and high mortality (>20%). We have recently addressed these issues by administering KA in repeated low doses (RLD) intraperitoneally (i.p, 5mg/kg at 30min intervals) in C57BL/6J mice (7wk age), until they achieved first convulsive motor seizure (CMS) stage-5 (severe seizure group, SSG) and stage ≤3 (Mild seizure group, MSG) during 2h status epilepticus (SE) (PLoS ONE, 2014, 9(5): e96622). The SE was later terminated with diazepam (10mg/kg, i.p). Experiments were carried out in accordance with IACUC (ISU, USA) and at end of experiment animals were euthanized by an overdose of pentobarbital (100mg/kg, i.p). For the first time, with continuous video-EEG monitoring (EEG acquired through Dataquest® and analyzed with Neuroscore DSI®) for 18 weeks, we demonstrate that C57BL/6J mouse indeed become epileptic as early as 48-72h and show numerous classical spontaneous recurrent seizures (SRS) later (31±4.8 CMS episodes in SSG, 5±1.8 CMS episodes in MSG during 18wks, $p<0.05$, Mann-Whitney test, n=18). The key to SRS onset is the severity and duration of electrographic CMS episodes (>10min) during SE and RLD method of KA administration. We characterized all the patterns of SRS episodes. Five EEG patterns of spontaneous recurrent CMS consisted of stage-3 to -5 with a minimum duration of 30s for each episode. Three patterns of EEG non-convulsive seizure (NCS) episodes (>12s) consisting of stage 1 and 2 spikes were identified. Two patterns of inter-ictal spikes (0.2-4Hz) consisted of stage-1 or -2 spikes or a mixture of both were observed before the first onset of a CMS episode. All types of SRS episodes observed peaked in the first 2 months and subsequently declined. These findings provide evidence for a more robust and early onset C57BL6 mouse model of epileptogenesis that can be widely used for drug screening and as a wild-type control in experiments involving transgenic mice. Because of very early onset of SRS in our model, compared to rat models, it reduces time and amount of drugs required and overall cost-effective.

Title: Changes in the expression of histone deacetylases 1-11 mRNAs in the hippocampus in mouse models of temporal lobe epilepsy

Authors: *G. SPERK, R. JAGIRDAR, M. DREXEL, R. TASAN;
Dept Pharmacol, Med. Univ. Innsbruck, Innsbruck, Austria

Abstracts: Epigenetic histone modifications involve acetylation and deacetylation of histone proteins contributing to transcriptional silencing of gene expression. Deacetylation of histone proteins is catalyzed by histone deacetylases (HDAC) comprising four different classes with 11 isoforms. We investigated changes in the expression of HDAC mRNAs in an animal model of temporal lobe epilepsy. In this model local injection of kainic acid (KA; 0.350 nmol/70 nl) into the hippocampus of mice induced a status epilepticus (lasting for 3 d) and thereafter in average 2 spontaneous seizures per day. In the injected hippocampus, losses in pyramidal neurons and granule cell dispersion (after 14 d) were seen. Mice were killed after different intervals (4 to 28 d) and HDAC 1-11 mRNAs were determined by *in situ* hybridization. In the dentate gyrus, expression of HDAC 1, 2, 7 and 11 mRNAs was significantly decreased 4 h after KA ipsi- and contralaterally to the injection, recovering after 48 h. In contrast, HDAC5 mRNA levels were significantly increased 4 and 12 h after KA injection, remaining increased in the injected hippocampus at later intervals. There was also a pronounced increase in HDAC9 mRNA expression 14 and 28 d after KA in granule cells of the injected dentate gyrus. To investigate this further we determined HDAC mRNA expression also in pilocarpine injected mice (300 mg/kg, i.p.). Also these mice develop a status epilepticus with subsequent spontaneous seizures, but expose no granule cell dispersion. They showed decreased HDAC 1 to 3 mRNA levels but no increases in HDAC 5 and 9 mRNAs in the granule cells at the late intervals. Our data show distinct and specific expression patterns for the different HDAC mRNAs in both animal models for TLE indicating rather specific changes in the expression of numerous genes after seizure induction. The early bilateral decreases in HDAC 1, 2, 7 and 11 mRNAs may be caused by the

initial status epilepticus and may be related to the rapid expression of various genes. Subsequently increased expression of HDACs 2 and 3 may counteract this reaction. Overexpression of HDAC9 mRNA may be associated with the granule cell dispersion developing at later time points.

Title: Predicting and reversing depression and cognitive deficits in experimental temporal lobe epilepsy

Authors: *C. BERNARD[1], A. GHESTEM[1], F. BARTOLOMEI[1], S. SIYOUCEF[1], E. BOUVIER[2], C. BECKER[2], J.-J. BENOLIEL[2];
[1]Inst. de Neurosciences des Systemes, INSERM U1106, Marseille cedex 05, France; [2]UMRS 975, Paris, France

Abstracts: Depression and cognitive disorders are common and severe comorbidities in TLE, with a major negative impact on the quality of patients' life. Among TLE patients, 14-31% develop depression. Several hypotheses have been proposed to explain these comorbidities, including the deleterious consequences of the treatment, a direct consequence of the circuit reorganization associated with epilepsy, and factors predisposing certain individuals; epilepsy then acting as a revelator of depression and/or cognitive deficits. The latter hypothesis remains to be tested. Predisposition could be triggered by a first "hit", e.g. a non-epileptogenic brain insult, which would leave permanent imprints in neuronal circuits. A subsequent "hit", an epileptogenic insult, would then result in comorbidities. In this scheme, either hit would not be sufficient in isolation to trigger comorbidities, a double hit is necessary. The goal of this study is to provide the proof-of-concept that past events may prime individuals for comorbidities once they become epileptic, and to identify biomarkers predictive of such vulnerability. We used Social Defeat (SD) in rats as a first hit. Eleven days after SD, 40% of animals were characterized by low levels of serum BDNF. Status epilepticus was used as a second hit. Once animals were epileptic, only

the low BDNF group presented a depressive phenotype and severe cognitive deficits. Infusion of 7,8-DHF, a BDNF mimetic, before the second hit, abolished the vulnerability phenotype. Epilepsy still developed but none of the animals displayed a depressive phenotype and severe cognitive deficits. We conclude that a past history of stress can sensitize some individuals to depression, which is revealed after an epileptogenic insult. Serum BDNF is a biomarker identifying this vulnerable population. A treatment with a BDNF mimetic can reverse the phenotype.

Title: Diffusion tensor imaging detects progressive changes in hippocampal subfields during epileptogenesis

Authors: ***A. SIERRA LOPEZ**[1], T. MIETTINEN[1], R. SALO[1], T. LAITINEN[1], A. PITKÄNEN[1,2], O. GRÖHN[1];
[1]Neurobio., A.I.Virtanen Inst., Univ. of Eastern Finland, Kuopio, Finland; [2]Neurol., Kuopio Univ. Hosp., Kuopio, Finland

Abstracts: Lack of imaging biomarkers for monitoring disease progression, recovery and treatment efficacy is a major unmet need in many neurological diseases, including epilepsy. It has been recently shown that diffusion tensor imaging (DTI) provides a high microstructural contrast also outside major white matter tracts. We hypothesized that *in vivo* DTI detects progressive changes in the hippocampus as well as in other brain areas during early stages of epileptogenesis. To test the hypothesis, we induced status epilepticus (SE) with systemic kainic acid or pilocarpine in adult male Wistar rats. Animals were scanned using *in vivo* DTI in a 7T/30cm magnet before and at 10, 20, 34 and 79 days after SE. Data were acquired using a

diffusion-weighted segmented spin echo echo-planar imaging pulse sequence (TR = 2.5 s and TE = 30 ms, 4 segments), 21 diffusion weighting directions (= 4 ms, Δ = 11 ms, b-value = 1000 s/mm^2), FOV of 21.12 x 14.08 mm^2 and in-plane spatial resolution of 110 x 110 μm^2. Number of slices was 14, slice thickness 500 μm, and number of averages 32, resulting in 140 min scan time. Analysis of the dentate gyrus (DG) showed increased fractional anisotropy (FA) (day 34, $p<0.01$; day 79, $p<0.001$) along with increased axial diffusivity (day 34, $p<0.001$; day 79, $p<0.001$) during the 79-d follow-up. In the CA3bc, we also found increased FA (day 79, $p<0.001$), and a progressive change in the main diffusion orientation from rostral-caudal to more dorsal-ventral (day 34, $p<0.001$; day 79, $p<0.001$). In order to validate the DTI findings, Fourier analysis of images captured from myelin-stained histological preparations and from GFAP immunohistochemistry was performed. The analysis revealed that in the DG only myelinated axons showed increased anisotropy ($p<0.001$) and orientation changes ($p<0.001$), consistent with DTI findings. In the CA3bc, both axons and astrocytes showed increased anisotropy ($p<0.01$) and orientation changes ($p<0.001$). Additionally, we performed tract-based spatial statistics (TBSS) analysis on DTI data to find statistical differences throughout the brain. TBSS analysis showed increased FA ($p<0.05$, FWE corrected) in the thalamus, whereas in the fimbria, external capsule and optic tract FA was decreased in rats with SE as compared to that in controls at the latest time point. Increased FA correlated to axonal alterations or on-going inflammation. Our findings demonstrate that *in vivo* DTI is able to detect progressive microstructural alterations in the brain during epileptogenesis, which suggest that DTI provides a tool for identification of imaging biomarkers for epileptogenesis and the progression of epilepsy.

Medicine, section of Microbiology, Univ. of Ferrara, Ferrara, Italy; [4]Med. Res. Council (MRC) Clin. Sci. Ctr., Imperial Col. London, Hammersmith Hosp., London, United Kingdom; [5]Div. of Brain Sci., Imperial Col. London, Charing Cross Hosp., London, United Kingdom

Abstracts: Temporal lobe epilepsy (TLE) often occurs secondary to other pathologies like tumors, traumas or stroke after a latent period that can last from months to years. However, preventive treatments in at-risk individuals are not currently available. The identification of biomarkers of the transformation of a normal tissue in epileptic (epileptogenesis) would be very useful to identify and validate new treatment strategies. MicroRNAs (miRNAs) represent an attractive option. miRNAs play important roles in the nervous system and their expression is altered in many neurological disorders. To better understand miRNA expression changes associated with the development of epilepsy, miRNA arrays were performed on laser-microdissected dentate granule cells and on plasma in different stages of epilepsy development in a rat model. An epileptogenic insult (status epilepticus, SE) was induced by pilocarpine administration (370 mg/kg i.p.) and rats were sacrificed at different time points: 4 days after SE (early latency), 8 days after SE (late latency), within 12 hours from the 1st spontaneous seizure and 50 days after the 1st seizure (chronic phase). We identified a profile of miRNAs differentially expressed in the different phases of the pathology, both in dentate gyrus and in plasma samples. miRNAs whose expression is altered before the first seizure are the best candidates to become biomarkers of epileptogenesis and may also be therapeutic targets useful to prevent the development of the pathology. In contrast, miRNAs identified in the late phases might correlate with particular histologic subtypes and different prognoses. They may therefore be useful to stratify patients with different prognoses, in particular post-surgery patients from whom bioptic tissue is available.

Title: Loss of GluR1 and NeuN labeling within the dysgranular retrosplenial cortex after status epilepticus is not associated with cell death

Authors: *S. HU, A. M. SLOMKO, D. I. GREENTREE, J. WONGVGRAVIT, N. W. MACKLIN, L. K. FRIEDMAN;
Cell Biol. and Anat., New York Med. Col., Valhalla, NY

Abstracts: The hippocampus is highly sensitive to seizure-induced damage and is therefore a major region examined by numerous investigators whereas other limbic structures such as the retrosplenial and cingulate cortex; regions involved with seizure activity, memory, and other cognitive functions have received much less attention. One study showed that neuronal loss and volume reduction within the densely packed retrosplenial granular cortex (Rgb) occurred in response to pilocarpine-induced status epilepticus whereas the dysgranular adjacent retrosplenial region (Rdg) was spared. While examining the efficacy of retigabine on the seizure threshold and hippocampal injury in adult rats at times following kainate (KA) -induced status epilepticus, obvious depletions of the GluR1 subunit were observed in large patches within the Rgb and Rdg. Therefore, histological and NeuN staining were used to assess the morphology of the retrosplenial cortex to determine whether reduction in GluR1 was associated with cell loss. NeuN immunohistochemical labeling decreased markedly in Rgb and Rdg subregions in animals treated with KA relative to controls which corresponded to the same regions of GluR1 depletion at both acute (72 h) and delayed (28 d) time points. KA+retigabine treated rats exhibited the same pattern but with increased delay. Despite NeuN depletion, Nissl staining revealed loss of cortical neurons was either absent or restricted to the Rgb. Retrospective horseradish peroxidase transport (HRP) studies illustrated these neurons receive input from the cingulate cortex (Cg1 and Cg2) and project to adjacent Rdg neurons as well as basolateral amygdala and entorhinal cortex, significant circuitry of the limbic/ autonomic loop involved with emotion and memory. Reduced fast synaptic transmission mediated by GluR1 subunits with simultaneous depletion of NeuN staining of nuclear elements in populations of limbic cortical neurons in the absence of cell loss may indicate a “circuitry break” due to lack of neurotransmission and transcriptional regulation within critical regions responsible for memory deficits and other cognitive comorbidities associated with sustained seizures.

Title: Role of phosphatidylinositol 3-kinase in excitotoxicity induced by intrahippocampal microinjection of pilocarpine in C57BL/6 mice

Authors: *I. V. LIMA[1], A. C. CAMPOS[2], L. B. VIEIRA[3], M. F. D. MORAES[4], A. L. TEIXEIRA[2], A. C. P. DE OLIVEIRA[3];
[1]Pharmacol., Federal Univ. of Minas Gerais, Brazil, Brazil; [2]Clin. Med., [3]Pharmacol., [4]Physiol. and Biophysics, Federal Univ. of Minas Gerais, Belo Horizonte, Brazil

Abstracts: Introduction: Phosphatidylinositol 3-kinase (PI3K) is an enzyme involved in different pathophysiological processes, including neurological disorders. However, its role in seizures and epilepsy is still not fully understood. We investigated the role of PI3Kγ in seizures, glutamate release and neuronal death in mice subjected to intrahippocampal microinjection of pilocarpine (PILO). Methods: Adult male WT and PI3Kγ-/- were submitted to stereotaxic surgery for bilateral cannulae implantation guided to the hippocampus. After 5 days of recovery, the Status Epilepticus (SE) was induced by a bilateral intrahippocampal injection of PILO (20 µg per side/200 nL) or saline as control. Behavioral activity was recorded during 90 min after injections, followed by an injection of diazepam (10 mg/kg, i.p.) for seizures interruption. Seizures were classified according to the scale established by Racine (1972). Twenty-four hours later, the animals underwent thoracotomy and intracardiac perfusion and then were decapitated. Hippocampal brain slices were prepared and stained with Fluoro Jade C to evaluate hippocampal neuronal death. Another group of WT and PI3Kγ-/- mice were decapitated and had their hippocampi removed for synaptosomes preparation. Synaptosomes from WT mice were pre-incubated with a PI3Kγ inhibitor (AS605240 - 1, 10 or 100 nM) or vehicle to evaluate glutamate release induced by KCl. All experiments were approved by the Institutional Ethics Committee (CEUA-UFMG Protocol 068-2011). Data were analyzed by ANOVA and expressed as mean ± SEM ($P<0.05$). Results: PI3Kγ-/- mice exhibited more susceptibility to PILO-induced SE. Moreover, the latencies to trigger the seizures and the number of 4 and 5 seizures' scores of Racine Scale were higher in PI3Kγ-/- group than in WT group. Furthermore, glutamate release was enhanced in synaptosomes from PI3Kγ-/- and WT incubated with AS605240 (10-100nM) in comparison with non-treated WT. There was a neuronal death in CA1, dentate gyrus and CA3 hippocampal regions in both groups after PILO injection. However, neuronal death was more

pronounced in PI3Kγ-/- mice in CA1 region. Conclusions: We have observed that the absence of PI3Kγ enhances the susceptibility of the animals to seizures induced by PILO. There was an increase of glutamate release in PI3Kγ-/- and WT hippocampal synaptosomes pre-incubated with AS605240. Moreover, there was an increase of neuronal death in PI3Kγ-/- animals. Genetic ablation of PI3Kγ-/- enhanced the pathological pattern in an animal model of seizures induced by pilocarpine, suggesting that the enzyme PI3Kγ can play a neuroprotective role during the seizures.

Title: Memory and forgetting in epileptics and controls: Testing the free-recall of emotional and neutral stimuli across three trials

Authors: *V. M. SOLIS, SR;
Psychology Dept. Natl. Univ. of Mexico, Mexico City, Mexico

Abstracts: Numerous studies document various kinds of memory loss in epileptic patients. The present investigation addresses the following questions. First, is there any evidence of such losses for the free-recall of emotional and neutral verbal stimuli across trials? Second, would a control group with matched normal participants exhibit better retention than that of epileptic patients? Third, incremental memory (hypermnesia) usually emerges when free-recall is tested across successive trials; therefore, it is likely that our control group will display the phenomenon. More importantly still, can hypermnesia be observed in epileptic patients? To our knowledge, this questions has never been asked before, therefore, it is important to ask whether a generalised memory decrement in epileptic patients will also be accompanied by a lack of incremental retrieval across trials. We used a mixed factorial design; Group (epileptic and control, n=10 per group) varied between-participants. Stimuli (emotional and neutral) as well as Trials (R1, R2 and R3) varied within-participants. Our main results suggest: Firstly, net level of recall was indeed

better for controls than epileptics ($p < .008$). Secondly, recall was also significantly better for emotional than for neutral stimuli ($p < .0001$). More importantly, however, is the fact that we observed hypermnesia for epileptic patients. There was a significant Trials effect in both groups, ($p < .003$ for controls; $p < .02$ for epileptic patients). Thus, although somewhat attenuated relative to controls, epileptic patients still managed to recall significantly more items across three trials. We conclude that although the memory of epileptic patients shows several deficits compared to controls, the mechanisms responsible for incremental item sampling across trials are still operational in spite of their neurological condition.

Title: A virtual t-maze to assess oscillations during a working memory task in patients with temporal lobe epilepsy

Authors: *A. A. ROBBINS[1], A. S. TITIZ[1], G. L. HOLMES[2], B. C. JOBST[3];
[1]Geisel Sch. of Med., Hanover, NH; [2]Neurolog. sciences, Univ. of Vermont Col. of Med., Burlington, VT; [3]Neurol., Dartmouth Hitchcock Med. Ctr., Lebanon, NH

Abstracts: Spatial navigation tasks are often used in experimental neuroscience to investigate the mechanisms of learning and memory. These tasks also allow for insight into alterations in memory processes that occur in disease states. Working memory deficits have been shown previously in rodent models of early life seizures. In the present study, we investigate if patients with epilepsy demonstrate similar deficits in working memory by utilizing a using a virtual T-maze task (vTMT) that we developed using the "Source Engine" (Valve™). The vTMT is an alternation task where the subject is instructed to navigate hallways to find a reward at either end of a T-shaped arena. The vTMT task included three levels. The first level was a training level where directional markers indicate the location of a reward. The second and third levels had no directional markers, but the location of the reward alternated between sides as with the first level. The final two levels differed by the number of cues, where the second level had objects in the

destination rooms to differentiate the two sides. All of the rooms in the third level of the vTMT were visually identical. Patients with TLE showed marked impairments in this task where they had a lower average percentage of correct trials in levels 2 and 3 when compared to normal control subjects (66.71±8.94% vs 92.6±2.11% $p<0.05$). Local field potential (LFP) recordings were made from both hippocampal depth and cortical grid electrodes while the patients performed the task. In this study, we present results from the analyses of coherence of LFP in two regions of the environment: the central corridor and the junction of the central corridor and the arms.

Title: Real-time cortical language mapping during spontaneous conversation with children

Authors: ***J. A. WILSON**[1], R. ARYA[1], H. FUJIWARA[1], F. T. MANGANO[2], D. ROSE[1]; [2]Neurol., [1]Cincinnati Children's Hosp., Cincinnati, OH

Abstracts: Invasive pre-surgical evaluation with subdural electrodes in a subgroup of people with drug resistant epilepsy has 2 core objectives: localization of the seizure-onset zone and defining its anatomic relationship to functionally essential cortex. The conventional standard-of-care is based on direct current electrical cortical stimulation (ECS) and use of task-response paradigm to map language and motor cortical areas. ECS testing requires extensive patient cooperation, which is often difficult for young children. Here we present a method utilizing real-time signal processing and visualization during spontaneous conversation for rapid identification of receptive and productive cortical language areas in pediatric epilepsy patients with implanted subdural ECoG grids. Up to 128 ECoG channels were acquired during a 5 min. baseline and 5-10 min. conversation period. BCI2000 and SIGFRIED were used for signal processing, classification, and visualization. A baseline resting model was created from the baseline data using the SIGFRIED procedure (Brunner et al, Epilepsy Behav. 2009;15(3):278-286). A natural conversation was recorded from two cardioid microphones. During the procedure, the power from each microphone was calculated every 50ms, and signals that exceeded a threshold triggered either a speech production or reception state if detected on the patient's or researcher's

microphone, respectively. During these states, the high-gamma (70-115 Hz) ECoG power was compared to the baseline model on each channel, producing a composite score indicating whether the value was significantly different from baseline. Finally, a Bonferonni-corrected t-test was used to determine whether individual channels were significantly different during silent, talking, and listening periods. Results were compared with picture naming during ECS, where only sites tested with ECS were compared. In all patients, 100% of facial sensorimotor and 83% of all naming sites were correctly identified, with false-positive rates of 31% and 37%, respectively. All naming sites were in left-hemisphere implant patients. False-positive sites were generally concentrated in cortical areas related to language, including Broca's and Wernekie's areas, and auditory cortex. This procedure had excellent sensitivity and selectivity, and has the potential to address major shortcomings of existing functional mapping techniques, particularly in children. In the near future, this method may be used to inform the decision-making progress prior to resection surgery, and provide regions of interest for ECS testing.

Title: Effects of subclinical epileptiform discharges on driving performance in people with epilepsy

Authors: *Y. SI[1], E. GUDBRANSON[1], W. C. CHEN[1], M. MIDURA[1], R. WU[1], B. GENG[1], P. VITKOVSKIY[1], A. SIVARAJU[1], R. SAINJU[1], A. FERNANDEZ[1], A. ALAREDDY[1], I. QURAISHI[1], R. B. DUCKROW[2], L. J. HIRSCH[2], H. BLUMENFELD[3];
[1]Neurol., [2]Neurology, Neurosurg., [3]Neurology, Neurobiology, Neurosurg., Yale Univ. Sch. of Med., New Haven, CT

Abstracts: Public safety is one of the critical concerns among drivers with epilepsy. Although people with epilepsy are permitted to drive under certain legal restrictions if their overt seizures are controlled, it is still unclear whether interictal spikes and other subclinical epileptiform discharges (SEDs) might affect driving performance. Previous studies suggest that SEDs have an additional and independent mild effect on transient cognitive processes (alertness, mental speed

etc). To investigate this further the present study explores the effects of SEDs on driving safety. A computer-based video driving simulator was prospectively provided for inpatients with epilepsy who underwent continuous video-electroencephalography (VEEG) monitoring in our epilepsy center. EEG recordings of SEDs, video/behavioral recordings and synchronized driving data were extracted and collected. Clinical relevance with regard to driving behavior during SEDs was evaluated using crashing the car as a terminal impairment criterion. 641 SEDs during driving were found in 16 patients. 132 (20%) of SEDs were isolated spikes, 299 (47%) were isolated sharp waves, 195 (30%) were spike/sharp-slow wave complexes lasting up to 10 seconds, and 15 (2%) were longer-lasting subclinical epileptiform events (duration 10 to 30 seconds). By comparing the baseline of driving performance for each participant with SED epochs, no significant impairment of driving performance was found during isolated spikes or sharp waves. The longer-lasting subclinical epileptiform events were associated with collisions in a few cases, but we are unable to verify statistical significance of this finding so far due to low sample size. Analysis of SED characteristics such as morphology, and localization (temporal, extemporal, generalized) revealed no obvious relationship to impaired driving, however there seems to be a slight trend that longer lasting generalized SEDs were more likely associated with crash. In conclusion, SEDs might generally have a lower risk of traffic accident than overt clinical seizures. However, whether collisions were associated with some sustained subclinical epileptiform events is unclear, and considering the limited sample of different SED subgroups, additional work should be done to determine whether certain types of SEDs might produce transient cognitive impairment during driving. In addition, more subtle behavioral changes aside from collisions could be detected until using larger cohort in future investigations.

Title: A portable handheld device for prospective driving evaluation in the epilepsy monitoring unit

Authors: N. LI[1], J. THOMSON[1], W. CHEN[1], D. KLUGER[1], C. CUNNINGHAM[1], R. GEBRE[1], Y. SI[1], J. BLUMENFELD[1], E. CHEN[1], M. JOHNSON[1], P. VITKOVSKIY[1], Y. BAYKARA[1], E. GUDBRANSON[1], A. MORAWO[1], *H. BLUMENFELD[2];
[1]Neurol., [2]Neurology, Neurobiology, & Neurosurg., Yale Univ. Sch. of Med., New Haven, CT

Abstracts: Patients with epilepsy often have impaired consciousness during seizures and lose the ability to interact with their surroundings. How impaired consciousness in epilepsy affects driving abilities is particularly relevant because driving is an essential part of daily life. Prior work on this subject has been limited by both the transient nature of seizure occurrence and the lack of standardized easy-to-use behavioral testing instruments to evaluate patients during seizures. We partly overcame these obstacles in previous work with computer-based driving simulators. However desktop or laptop computers and external controllers such as steering wheel and gas/brake pedals are cumbersome in the inpatient video/EEG monitoring unit. With the recent development of handheld devices with high-definition graphics and powerful processing capabilities, we have introduced tablet computers as behavioral testing instruments that are lightweight, easy-to-pick-up, and absorbing. We customized a commercially available driving game that can be used on handheld tablets to prospectively evaluate ictal and interictal driving performance. We also developed specialized apps to acquire and save specific driving performance metrics including car position, car velocity, acceleration/braking, steering wheel movement, and collision events using the devices' built-in sensors. The driving data acquisition was synchronized with continuous EEG and video data obtained from the epilepsy patients during their hospital stay, although in principle the same approach could be used in the outpatient setting. Preliminary testing in 12 patients demonstrated the feasibility of examining driving performance prospectively in patients with epilepsy using a handheld device with good patient tolerability and convenience. Data analysis enabled complete reconstruction of all driving performance parameters, simultaneous with video/EEG results. With ongoing data collection and analyses, we hope to elucidate the relationship between specific seizure variables and driving risk in the ictal and interictal periods, with the objective of providing more informed advice regarding driving to legislators, physicians and patients with epilepsy.

Title: Examining white matter abnormalities in patients with Temporal Lobe Epilepsy using diffusion MRI

Authors: *A. J. BARNETT[1], M. P. MCANDREWS[2];
[1]Univ. of Toronto, Toronto, ON, Canada; [2]Neuropsychology, Univ. Hlth. Network, Toronto, ON, Canada

Abstracts: Temporal lobe epilepsy (TLE) is a neurological disorder that has been shown to cause widespread structural and functional changes in the brain. These changes are largely seen in the medial temporal lobes, specifically the hippocampus (HC), where seizures are thought to originate. Diffusion tensor imaging (DTI) studies have also shown white matter abnormalities within this population. The aim of the current study was to examine how white matter abnormalities in patients with TLE interact with cognitive performance and disease characteristics. We collected diffusion weighted MRI data for 15 patients with left TLE (LTLE), 9 patients with right TLE (RTLE), and 19 healthy controls. DTI data was analyzed in a voxel-wise fashion using tract-based spatial statistics to examine differences in fractional anisotropy (FA), mean diffusivity (MD) and radial diffusivity (RD) which are considered to be indirect measures of white matter integrity. We also ran an automated segmentation to calculate HC volume for patients and controls. Using these measures from DTI, we examined the relationship between white matter integrity with cognitive performance and disease characteristics (disease duration, age of onset). Results demonstrated that the LTLE group had reduced white matter integrity in the left temporal lobes, along with reduced left HC volume. The RTLE group showed bilateral white matter integrity reductions in the temporal lobes compared to healthy controls and reduced right HC volume. We found in our patient groups that smaller right HC volume was associated with reduced FA in the right temporal lobes. In patients with LTLE, performance on the Boston Naming Test was positively correlated with left temporal FA and negatively correlated with RD. Duration of disease was also associated with reduced FA in the left temporal lobes. These results suggest that there are local and distal white matter alterations in TLE and these alterations are associated with disease characteristics and, in LTLE, language ability.

Title: Improving seizure detection with single/multiunit information in the MTL requires the extraction of specific subpopulations

Authors: *X. LONG[1], A. MISRA[1], M. R. SPERLING[2], A. D. SHARAN[3], K. A. MOXON[1]; [1]Sch. of Biomed. Engin., Drexel Univ., Philadelphia, PA; [2]Neurol., [3]Neurolog. Surgery, Thomas Jefferson Univ., Philadelphia, PA

Abstracts: Over the past several decades, numerous studies have attempted to investigate the behavior of single neurons and multiunit during and immediately prior to seizure. The majority of these studies report a heterogeneity in firing behavior of neurons, complicating the use of single/multiunit information in automated detection or prediction algorithms. Here we present an approach to subdividing this heterogeneous population (specific to neurons of the mesial temporal lobe MTL) to obtain reliable information to aid in the detection of seizure events. Firing rate and unit-field coherence were extracted from A) multiunit recordings and B) putative interneuron recordings from 35 seizure recordings (and corresponding interictal recordings) in 7 patients with seizures that spread to the MTL. These variables were used in a parametric threshold based algorithm and their ability to detect seizures along with the latency to seizure detection were assessed in comparison to a more traditional LFP-amplitude based detection algorithm. While both multiunit and interneuron specific information appeared to improve the detection latency, multiunit information was associated with a loss in sensitivity and a greater than 20 fold increase in false detection rate. In contrast, interneuron specific information retained a high sensitivity while the relative increase in false detection rate was comparatively reduced (4x). Most importantly, when using interneuron specific information, the latency to detection was consistently negative (i.e.) the algorithm predicted electrographic seizure onset, despite recordings occurring outside of the clinically identified seizure focus. Thus the clinical utility of

single/multiunit information is highly dependent on which subpopulation is extracted for analysis, and this information may complement existing seizure detection efforts, as well as challenge our interpretation of the focal seizure onset zone.

Title: Single-unit activity evoked by electrical stimulation of human epileptogenic cortex

Authors: ***A. BARBORICA**[1,2], C. DONOS[1], I. MINDRUTA[3], J. CIUREA[4];
[1]Physics, Univ. of Bucharest, Bucharest, Romania; [2]FHC Europe, Bucharest, Romania; [3]Neurol., Univ. Emergency Hosp., Bucharest, Romania; [4]Neurosurg., Bagdasar-Arseni Emergency Hosp., Bucharest, Romania

Abstracts: Background: Intracranial direct electrical stimulation (DES) during presurgical stereoelectroencephalograpic (SEEG) evaluation of patients with drug-resistent epilepsy is a powerful method for mapping the epileptogenicity of various brain areas. In order to elucidate the basic neural mechanisms underlying electrographic responses to DES, we aim at investigating human single unit firing during intraoperative DES of epileptogenic areas for different stimulation amplitudes and frequencies. Methods: We performed SEEG presurgical evaluation of 8 patients with drug-resistant focal epilepsy to locate the seizure-onset zone (SOZ) and delineate the area to be resected. Prior to the resective surgery, we are stereotactically inserting three microelectrodes, spaced 2mm apart, in a linear configuration, following a trajectory targeting SOZ. We use standard clinical microelectrodes and equipment used in functional mapping for deep brain stimulation implantations. Bipolar electrical stimulation is applied between the two outer macro contacts of the electrodes while recording the unit activity on the center microelectrode. Constant current 0.5 to 1 mA biphasic pulses, 0.3 ms pulse width, frequency 1, 10, 30, 60 and 130 Hz were applied for 30 s using a clinical stimulator (Guideline LP+, FHC Inc, Bowdoin, ME). Results: We have recorded to date 14 neurons in SOZ and

adjacent areas. We were able to find typical patterns for inter-ictal spiking and single-pulse stimulation: burst only, burst-suppression, suppression-only, no-change. In addition, repetitive stimulation resulted in a buildup of the firing rate over the stimulation duration in about 28% of the neurons. Higher stimulation frequency had a suppressive effect on the neuronal firing. Conclusions: SOZ neurons exhibit heterogenous responses to repetitive stimulation. Evidence for increased plasticity of the epileptogenic cortex was supported by the activity of a subpopulation of neurons. Detailed analysis of the firing patterns may provide an insight on the network mechanisms underlying epileptogenicity.

Title: Glutamate-mediated up-regulation of the multidrug resistance protein 2 in porcine and human brain capillaries

Authors: *H. L. MUNGUÌA[1,2], J. D. SALVAMOSER[2], B. PASCHER[3], T. PIEPER[3], T. GETZINGER[3], M. KUDERNATSCH[4], H. POTSCHKA[2];

Abstracts: As a member of the multidrug-resistance associated protein family MRP2 (ABCC2) affects the brain entry of different endogenous and exogenous compounds including toxicants and drugs. Considering the functional role of this transporter at the blood-brain barrier the regulation of its expression and function is of particular interest. However, so far there is only limited knowledge regarding the factors that might regulate MRP2 in neurological disease states. Thus, we addressed the hypothesis that MRP2 might be affected by a glutamate-induced signaling pathway that we previously identified as one key mechanism in the regulation of the transporter P-glycoprotein. Studies in isolated porcine brain capillaries confirmed that glutamate and NMDA exposure up-regulates expression and function of MPR2. The involvement of the NMDA receptor was further confirmed by the fact that the NMDA receptor antagonist MK-801 abolished the impact of glutamate. In addition, co-incubation of porcine capillaries with the cyclooxygenase-2 inhibitor celecoxib efficaciously prevented a glutamate-induced up-regulation of MRP2. Translational studies in human capillaries from surgical specimen demonstrated a relevant MRP2 efflux function, and confirmed the effect of glutamate exposure as well as its prevention by cyclooxygenase-2 inhibition. Taken together the findings revealed a role of a glutamate-induced NMDA receptor/cyclooxygenase-2 signaling pathway in the regulation of MRP2 expression and function. The response to excessive glutamate concentrations might contribute to overexpression of MRP2, which has been reported in neurological diseases such as epilepsy. The resulting overexpression might have implications for brain access of endogenous and exogenous compounds including therapeutic drugs.

Title: Impaired cerebrovascular reactivity in patients with mesial temporal lobe epilepsy

Authors: *K. ALHADID[1,2], O. SOBCYK[2], J. POUBLANC[3], A. CRAWLEY[3], L. VENKATRAGHAVAN[4,5], J. A. FISHER[5,2,6], D. J. MIKULIS[7,1,4,2], T. A. VALIANTE[8,1,4,2]; [1]Toronto Western Res. Inst., Toronto, ON, Canada; [2]Inst. of Med. Science, Univ. of Toronto, Toronto, ON, Canada; [3]Joint Dept. of Med. Imaging, Univ. Hlth. Network, Toronto, ON,

Canada; [4]Univ. Hlth. Network, Toronto, ON, Canada; [5]Dept. of Anaesthesia and Pain Management, Univ. Hlth. Network, Toronto, ON, Canada; [6]Dept. of Physiology,University of Toronto, Toronto, ON, Canada; [7]Joint department of Med. Imaging, Univ. Hlth. Network, Toronto, ON, Canada; [8]Dept. of Surgery, Div. of Neurosurgery, Univ. of Toronto, Toronto, ON, Canada

Abstracts: Purpose: Epilepsy surgery can achieve excellent outcomes in mesial temporal lobe epilepsy (mTLE) patients when the epileptogenic zone is accurately localized. Ancillary tests such as FluoroDeoxyGlucose Positron Emission Tomography (FDG-PET) are used for this task when standard tests are inconclusive, or discordant. Although decreased inter-ictal metabolism and perfusion to the epileptogenic temporal lobe has been demonstrated, the underlying mechanism for these alterations remain poorly understood. Cerebrovascular reactivity (CVR) is the change in a measure of cerebral blood flow (CBF), such as the BOLD MRI signal, to a vasoactive stimulus, such as hypercapnia. We hypothesized that the reduced inter-ictal hypometabolism in mTLE patients is also associated with vascular dysfunction detectable on CVR studies, and thus would help delineate the epileptogenic zone. Methods: A homogenous group of unilateral mTLE patients who had undergone standard pre-operative investigations for seizure localization were included (n=5) in this study. We used BOLD MRI as the high-resolution surrogate for CBF and a standardized CO2 stimulus sequence targeting arterial partial pressure of CO2 (PaCO2) (RespirAct™). The experimental protocol consisted of a one step 10-mmHg increase in PaCO2 from baseline levels for 2 minutes, followed by a gradual increase in PaCO2 from 30 mmHg to 55 mmHg over 4 minutes. CVR was calculated as the best-fit regression for the BOLD signal vs. PaCO2. CVR was scored as both the amplitude and time constant of response, voxel-by-voxel, according to the mean and variance of the corresponding voxel from a previously generated reference cohort of healthy volunteers who had undergone the same protocol. Inter-hemispheric discrepancies in CVR values were also evaluated. Results: Preliminary findings demonstrate a marked increase in CVR in the epileptogenic temporal lobe compared to normal controls, and when compared to the contralateral non-epileptogenic temporal lobe in the same patient. Discussion: The observed increase in CVR in unilateral mTLE patients ipsilateral to the epileptogenic side might represent a pathophysiological increase in vascular capacity required to support the sustained increase in neuronal activity during a seizure. CVR imaging might represent a non-invasive test similar to FDG-PET for lateralization of the epileptogenic zone, without the requirement of radioactive tracers.

Title: Hippocampal newborn cells in infantile rasmussen encephalitis patients

Authors: *E. D. MAGNO[1], E. A. CAVALHEIRO[1], R. CORAS[2], I. BLÜMCKE[2]; [1]Neurology/Neuroscience, UNIFESP, São Paulo, Brazil; [2]Inst. of Neuropathology, Hosp. Univ. of Erlangen, Erlangen, Germany

Abstracts: Aim: Determine the neurogenesis rate in hippocampal tissue from Rasmussen Encephalitis patients and compare with tissue obtained from human autopsy. Methods and Results: Five hippocampal specimens were obtained from surgery to treatment of drug-resistant Rasmussen Encephalitis (RE) (age range from 3 to 15 years old). All patients included in this study were adequately informed and gave their written consent for the scientific project, which was approved by the local ethics committees of the University of Erlangen (Germany) and the Universidade Federal de São Paulo (Brazil). All procedures were conducted in accordance with the Declaration of Helsinki (1964). Hippocampal tissue obtained from three human autopsy cases (age range from 5 to 27 years old) were used as control, whose causes of death were unrelated to reports of neurological disease. All specimens were submitted to immunohistochemical and immunofluorescence techniques for neuronal counting (NeuN, H&E) and the verification of neurogenesis (Ki67, vimentin and Sox2) in the hippocampal dentate gyrus. After quantification in an optic microscope, comparisons were performed by analysis of variance followed by Bonferroni´s posthoc test (ANOVA-Bonferroni) and non-parametric t-test, with Mann-Withney posttest. The number of neurons in the dentate gyrus, but not in the CA1-4 hippocampal subfields, was significantly decreased in RE patients when compared to control specimens. In contrast to autopsy specimens, the dentate gyrus of RE patients showed an expressive increase in neurogenesis when the marker Ki-67 was used, but no significant changes could be detected with vimentin or SOX-2. Conclusion: These results suggest that Rasmussen Encephalitis is accompanied by increased neurogenic rates in the dentate gyrus when compared to specimens obtained from non-epilepsy cases. Besides, the neuronal cell loss observed in the dentate gyrus of these patients was not accompanied by similar changes in other hippocampal areas. Studies aiming at investigating the relation of these changes with the severe inflammatory process observed in RE are now in progress.

Title: Epileptogenic mechanisms in mesial temporal lobe epilepsy: an *in vitro* optical imaging study of resected human hippocampus specimens

Authors: ***H. KITAURA**[1], H. SHIROZU[2], M. SONODA[2], H. SHIMIZU[1], H. MASUDA[2], H. TAKAHASHI[1], S. KAMEYAMA[2], A. KAKITA[1];
[1]Pathology, Brain Res. Inst, Niigata Univ., Niigata, Japan; [2]Neurosurg., Nishi-Niigata Chuo Natl. Hosp., Niigata, Japan

Abstracts: Mesial temporal lobe epilepsy (MTLE) is the most frequent focal epilepsy syndrome, and the vast majority of seizures originate from the mesial structures of the temporal lobe. Tissues surgically resected from the hippocampus usually exhibit various degrees of neuronal loss, a condition that is referred to as hippocampal sclerosis. The epileptogenic mechanisms operating in the sclerotic hippocampi of patients with MTLE remain uncertain. To investigate this issue, we performed flavoprotein fluorescence imaging *in vitro* using surgically removed human hippocampus specimens. As a control, we retrieved hippocampus specimens showing no histopathologic abnormalities removed surgically from two patients with no MTLE symptoms, but harboring either cortical tubers or focal cortical dysplasia nearby. According to the severity of hippocampal sclerosis in the patients with MTLE, we defined cases with no apparent neuronal loss, restricted neuronal loss in the CA1 subfield, and severe loss in the CA1/3/4 subfields as having no, mild, and severe HS, respectively. Flavoprotein fluorescence responses in the subiculum and CA1 subfield in the no HS group were significantly more marked than in the controls. In the mild and severe HS groups, the responses in each subfield were markedly diminished where neuronal loss was evident; however, similar enhanced responses were observed in the subiculum. Interestingly, stimulation of the CA4 subfield elicited recurrent activity in the dentate gyrus (DG) only in the severe HS group, and the activity was abolished by

application of CNQX. These findings indicated mossy fiber sprouting in the DG, as supported by our histological observations of TIMM-positive fibers. In the subiculum in all HS groups, recording of local field potential demonstrated spontaneous discharges with a clear high-frequency oscillation component. In the DG in the severe HS group, distinct spontaneous rhythmic activities lasting 10 s or more were observed. Application of an adenosine blocker clearly attenuated these spontaneous activities in the subiculum, but not those in the DG. Thus, intrinsic spontaneous activity, i.e. ictogenesis, may develop initially in the subiculum of patients with MTLE before neuronal loss occurs in the CA subfields of the hippocampus. Such abnormal discharges may then induce neuronal loss in the CA subfields, resulting in loss of target neurons in the dentate granule cell projection pathway. Therefore, mossy fiber sprouting may be induced in the DG. We speculate that the mechanism of epileptogenesis in MTLE specifically involves individual subicular neurons, and subsequently the dentate granular circuits.

Title: Pyramidal cell morphology in human cortical dysplasia

Authors: ***W. G. JANSSEN**[1], F. HAMZEI-SICHANI[2,4], J. C. ZINN[3], J. EVANS[4], A. D. SHARAN[4], M. R. SPERLING[5], K. SIMONYAN[3], P. R. HOF[1], J. H. MORRISON[1]; [1]Neurosci., [2]Neurosurg., [3]Neurol., Icahn Sch. of Med. at Mount Sinai, NEW YORK, NY; [4]Neurosurg., [5]Neurol., Thomas Jefferson Univ., Philadelphia, PA

Abstracts: Malformations of cortical development underlie a significant portion of adult and pediatric forms of medically intractable epilepsy. Severe forms of focal cortical dysplasia are characterized by dysmorphic/cytomegalic neurons and balloon cells in the context of a pervasive laminar disorganization. To date, direct measures of the morphology of human dysplastic neurons have not been possible on a large scale. Here, we present detailed, high-resolution structure of dysplastic pyramidal neurons in the seizure onset zone (SOZ) of the inferior parietal

lobule of two adult patients with epilepsy. Pyramidal neurons of presumably normal cortical area around the seizure onset zone as determined by intracranial EEG and cortical mapping were used as control. The null hypothesis of no significant morphological changes in the synaptic connectivity of the SOZ and each spine type (mushroom and thin) were tested, as measured by spine length, spine volume, and spine head diameter. Detailed structural data for layer II/III and layer V dysplastic pyramidal neurons of the SOZ were obtained through morphometric analysis of Lucifer Yellow filled neurons in brain slices prepared from surgical resections (300 μm thick). High quality dye-loaded neurons were selected and imaged at high magnification (63X, 1.4 N.A. 100 nm cubic voxel) using confocal laser scanning microscopy. The neuronal morphology, dendritic arbor and dendritic spine morphology were extracted from stacks of scanned images using a custom-designed algorithm (NeuronStudio). Morphometric analysis provided unbiased measurements of both local and global structure of the pyramidal neurons. Basal thin spines were found to be significantly longer in the control than in the dysplastic cells ($p < 0.001$, corrected), with differences in mean lengths differing by as much as 0.2 micrometers at 95% confidence. The mean volume of basal mushroom spines, however, differd by as much as 0.04 cubic micrometers (95% confidence bound), nearly 30% of the mean volume of dysplastic basal mushroom spines ($p < 0.01$, corrected), with the control being larger. Thin spine head diameter also varied by a difference in means of 0.1 micrometers and 0.12 micrometers (apical, basal) between the dysplastic cells and control cell ($p < 0.001$, corrected), with control being larger. The null hypothesis was therefore rejected, alluding to significant changes in the dysplastic pyramidal neurons of the SOZ, such as significant loss of synaptic input to stable mushroom spines. These findings provide morphological evidence on how and why the dysplastic tissue is more prone to seizures in this common form of medically intractable epilepsy.

Title: The functional connectome of high frequency networks during epileptic seizures

Authors: *S. FUERTINGER[1], F. HAMZEI-SICHANI[2,3], J. C. ZINN[1], M. R. SPERLING[4], A. D. SHARAN[3], K. SIMONYAN[1];
[1]Neurol., [2]Neurosurg., Icahn Sch. of Med. At Mount Sinai, New York City, NY; [3]Neurosurg., [4]Neurol., Thomas Jefferson Univ., Philadelphia, PA

Abstracts: High frequency oscillations (HFO, 100-500 Hz) or ripples in cortical networks have been shown to underlie seizure generation in human intracranial electroencephalographic (iEEG) recordings as well as a in *in vitro* recordings from brain slices of rodents in various animal models of hippocampal and neocortical epilepsy. HFOs in contrast to other epileptiform discharges such as sharp waves or spikes are the most reliable marker of the epileptogenic area leading to the best surgical outcome when used to define the extent of surgical resections. However, a rigorous analysis of the interplay of different cortical generators of HFOs during ictal and interictal periods in a graph theoretical context has been lacking. Here, we have applied such scheme to iEEG recordings (1000-2000 Hz) of patients with epilepsy during two well-defined cortical states, namely the awake-resting (1 hour) and awake-seizure (peri-ictal 10 minutes) states. Normalized mutual information (NMI) coefficients were calculated for each pair of intracranial electrode time courses in each cortical state after band-pass filtering for ripple frequency. Graphs were constructed by interpreting electrodes as network nodes and associated NMI coefficients as weights of the graph's edges. The resulting weighted undirected networks were analyzed to assess topological changes between rest and seizure. Differences in network segregation were estimated by calculating the clustering coefficient. We used local efficiency to assess variations in network integration. Deviations in nodal influence were quantified by estimating nodal connectivity in terms of degree and strength. Variations in graph metrics of the rest and seizure networks were tested for statistical significance using a two-sample t-test at a corrected $p \leq 0.01$. The strength of network connectivity significantly increased in the seizure period compared to the resting state ($p < 0.001$) with highly interconnected nodes (hubs) moved from the area adjacent to the seizure onset zone (SOZ) into the SOZ. Local efficiency, which estimates a node's average communication performance, was significantly increased in the seizure period than during rest ($p < 0.001$). Nodal clustering coefficients showed a trend towards higher values during seizure ($p = 0.052$). Remarkably, changes in nodal strength revealed silent zones in the networks corresponding to HFO sources adjacent to the SOZ. The observed increase in efficiency during seizure was indicative of a sudden parallel activation of spatially distributed nodes. Simultaneously, decreased clustering during seizure implied a loss of functional organization characteristic of cortical networks.

[4]Neurosurg., [5]Neurol., Thomas Jefferson Univ., Philadelphia, PA

Abstracts: Genetic and acquired abnormalities of neuronal connectivity are thought to underlie many types of human epilepsy. However, direct measures of the morphology of cortical neurons in the disordered microcircuit in human epileptic tissue have not been possible on a large scale. Here, we present detailed, high-resolution structure of human neocortical pyramidal neurons in three salient cortical areas associated with seizures, namely the seizure onset zone (SOZ), the seizure spread zone (SSZ) and the silent area with no seizure propagation, all within the inferior parietal lobule of two patients with epilepsy. The type of seizure locus was determined based on intracranial EEG recording and mapping by stimulation of each subdural electrode. The null hypothesis of no significant morphological changes in the synaptic connectivity of each area and each spine type (mushroom and thin) was tested, as measured by three spine morphological features (spine length, spine volume, and spine head diameter). Detailed structural data for layer II/III and layer V pyramidal neurons of each area were obtained through morphometric analysis of Lucifer Yellow filled neurons in brain slices prepared from surgical resections (300 μm thick). High quality dye loaded neurons were selected and imaged at high magnification (63X, 1.4 N.A. 100 nm cubic voxel) using confocal laser scanning microscopy. The neuronal morphology, dendritic arbor and dendritic spine morphology were extracted from stacks of scanned images using a custom-designed algorithm (NeuronStudio). Morphometric analysis provided unbiased measurements of both local and global structure of the pyramidal neurons. We found the head diameter of thin and the length of mushroom dendritic spines to be significantly smaller in the SOZ and SSZ compared to the silent area. The head diameter of mushroom dendritic spines was significantly higher in the SOZ compared to SSZ and the silent area. The volume of mushroom dendritic spines was significantly higher in SOZ compared to SSZ and in SSZ compared to the

silent area. The length of thin dendritic spines was significantly lower in the SOZ compared to SSZ and the silent area. Corrected p-values were <0.05. The null hypothesis was therefore rejected, alluding to significant changes in SOZ, such as strengthened synaptic input to stable mushroom spines. These findings provide morphological evidence on how and why the SOZ is more prone to seizures which is a necessary step to understand the pathophysiology of this common disorder of the nervous system.

Institute., Barakaldo, Spain; [4]Inst. de Investigación Sanitaria Hosp. de la Princesa, Madrid, Spain; [5]Dept. of Data Analysis. Fac. of Psychology and Educational Sci., Ghent Univ., Ghent, Belgium

Abstracts: The use of information theory in neuroscience have allowed to evaluate the interaction between groups of correlated variables, revealing their functional role and underlying

circuits capable of processing information (Borst and Theunissen, 1999, Nat Neurosci; Panzeri et al., 1999, Proc Biol Sci; Quiroga and Panzeri, 2009, Nat Rev). In addition to information storage/coding/decoding, information theory can address whether the interactions between the correlated variables are mutually redundant or synergetic (Schneidman, Bialek and Berry, 2003, J Neurosci; Bettencourt et al., 2007, Phys Rev E). In general, synergy occurs if the knowledge of some variables contributes to predict another variable with more information than the sum of the information provided individually by the variables; redundancy corresponds to situations with the same information being shared by the variables. In particular, the well-known interaction information (McGill, 1954, Psychometrika) applied to triplets quantifies the amount of either redundant (positive interaction) or synergetic information (negative interaction) contained in the triplet; notice that unlike the mutual information, the interaction information can be either positive or negative. We calculated the interaction information in electricorticography data that have a clinical validation: after resection, no further seizures occurred. Using the pre-surgery data recorded from the epileptic patient and knowing the resection area, we addressed both the functional organization and dynamics of redundancy and synergy near the epileptogenic network (the circuit triggering epileptic seizures). Regarding functional organization, redundancy (corresponding to positive values of interaction information) matched with the resection area, while synergy (negative values) emerged in its surroundings. In relation with dynamics, redundancy had the biggest contribution at higher frequency bands (14-100Hz) whilst synergy was more expressed at very slow frequencies (1-7Hz). Thus, the application of the interaction information to this clinical data unveils new aspects of epileptogenic structure in terms of interaction nature (redundancy vs synergy) and dynamics (fast vs slow rhythms).

Title: Alterations of 5-HT1A receptor-induced G-protein functional activation and relationship to memory deficits in patients with pharmacoresistant temporal lobe epilepsy

Authors: *M. CUÉLLAR-HERRERA[1], L. ROCHA[3], F. VELASCO[2], D. TREJO-MARTINEZ[2], A. NUCHE-BRICAIRE[2], M. ALONSO-VENEGAS[4], A. L. VELASCO[2];

Abstracts: The 5-hydroxytryptamine-1A (5-HT1A) receptors are known to be involved in the inhibition of seizures in epilepsy. Moreover, studies propose a role for the 5-HT1A receptor in memory function; it is believed that the higher density of this receptor in the hippocampus plays an important role in its regulation. Positron emission tomography studies in patients with mesial temporal lobe epilepsy (mTLE) have demonstrated a decrease in 5-HT1A receptor binding in temporal regions may play a role in memory impairments of these patients. The evidences lead us to speculate whether this decrease in receptor binding is associated with a reduced receptor number or if the functionality of the 5-HT1A receptor-induced G-protein activation and/or the

second messenger cascade is modified. The purpose of the present study is to determine 5-HT1A receptor-induced G-protein functional activation by 8-OH- DPAT-stimulated [35S]GTPγS binding assay in hippocampal tissue of surgical patients with mTLE. We correlate functional activity with epilepsy history and neuropsychological assessment of memory. We found that maximum functional activation stimulation values (Emax) of [35S]GTPγS binding were significantly increased in mTLE group when compared to autopsy samples. Furthermore, significant correlations were found: 1) positive coefficients between the Emax with the age of patient and frequency of seizures; 2) negative coefficients between the Emax and working memory, immediate recall and delayed recall memory tasks. Our data suggest that the epileptic hippocampus of patients with mTLE presents an increase in 5-HT1A receptor-induced G-protein functional activation, and that this altered activity is related to age and seizure frequency, as well as to memory consolidation deficit.

Title: Changes in neuronal activity outside of the seizure focus in patients with temporal lobe epilepsy

Authors: *J. NAFTULIN, O. AHMED, S. CASH;
Massachusetts Gen. Hosp., Boston, MA

Abstracts: Epilepsy affects approximately one percent of the population and epileptic seizures can be divided into two broad categories: primarily generalized and focal seizures. Focal seizures start in a localized brain region and then can either remain focal or spread to other brain regions (secondary generalization). However, our concept of the focus, and even the existence of a true focus, is being increasingly questioned due to a variety of imaging and physiological data. Here,

we examined how activity outside the seizure focus changes at the time of seizure onset. Stereotactic depth electrodes were implanted in patients with longstanding pharmaco-resistant epilepsy for stage II lateralization. We compared focal temporal lobe seizures that remained focal and those that secondarily generalized. Spectral analyses were used to quantify changes in power over delta (1-4 Hz), theta (4-8 Hz), alpha (8-13 Hz), beta (13-30 Hz), gamma (30-70 Hz), and high gamma (70-120 Hz) frequency bands in regions inside, close to, and well outside the area of seizure onset. We examined a total of 70 seizures in 12 patients. In focal seizures that remained focal, we found only 20 out of 464 (4.3%) electrodes outside the seizure focus showed significant increases in any of the frequency bands at the time of seizure onset. However, 44 out of 272 (16.2%) electrodes outside the seizure focus showed significant increases at the moment of onset in focal seizures that would go on to secondarily generalize. Thus, we find that at the moment of seizure onset, changes outside the focus are rare during focal seizures that remain focal, but more frequent during focal seizures that will later go on to secondarily generalize. These observations may help to better understand the neuronal dynamics underlying the initiation of focal seizures, and to design better brain-machine-interface algorithms to distinguish between subtypes of focal seizures.

Title: The role of bdnf-trkb signaling in epileptogenesis in human hypothalamic hamartoma

Authors: Y. HUANG[1], S. SEMAAN[1], Q. LIU[2], *Y. CHANG[2], J. WU[2];
[1]St. Joseph's Hosp. and Med. Ctr., Phoenix, AZ; [2]Barrow Neurolog. Inst., St. Joseph's Hosp. & Med. Ctr., PHOENIX, AZ

Abstracts: Human hypothalamic hamartoma (HH) is a developmental malformation that occurs in the region of the tuber cinereum and inferior hypothalamus. This lesion is associated with a range of neurological and endocrine disorders including intractable seizures, cognitive impairment, behavioral disturbances, and central precocious puberty. HH is often characterized

by gelastic seizures, which are usually refractory to classical anti-epileptic drugs and alternative therapies. The most effective treatment of gelastic seizures associated with HH is surgical resection of the lesion. Evidence indicates that the source of gelastic seizures in patients with HH lies within the lesion itself. Our previous studies using surgically resected HH tissues have revealed that a proportion of HH neurons are non-GABAergic neurons with an immature phenotype (Wu et al., 2005, 2007, and 2008). This suggests that these neurons may have a relatively low expression level of the outwardly-directed K^+-Cl^- co-transporter (KCC2) and a relatively high intracellular Cl^- concentration. As a result, the inhibitory neurotransmitter GABA rather plays an excitatory role in these immature HH neurons, potentially leading to gelastic seizures. However, the signaling mechanisms underlying KCC2 downregulation and GABA-induced neuronal excitation and epileptogenesis in HH remain to be elucidated. In the present study, we examined the effects of pharmacological manipulations of BDNF-TrkB signaling in seizure-like discharges and neuronal firing of HH neurons using surgically resected HH tissues. We found that exposure of recorded HH neurons to BDNF increased neuronal firing rate. Pharmacological blockade of BDNF-TrkB signaling using a selective inhibitor for Trk kinase, K252a, reduced large-sized HH neuron firing, but minimally affected small-sized HH neuron firing rate. In fresh HH slices, although BDNF did not show clear effect on spontaneous inhibitory post synaptic potential (sIPSCs), it reduced GABA-induced inward current under patch-clamp whole-cell recording configuration in acutely dissociated single large HH neurons. Finally, we found that in HH tissue, the BDNF mRNA expression was significantly enhanced, whereas the anti-KCC2 immunostaining signal was weaker in HH tissue compared to normal human hypothalamic control tissue. In conclusion, our data suggests that the BDNF-TrkB signaling plays an important role in downregulation of KCC2 expression, which in turn alters $GABA_A$ receptor function and leads to epileptogenesis in HH lesion.

Title: Yield of linear pairwise granger causality in seizure onset identification versus visual EEG evaluation in pharmaco-resistant non-lesional partial epilepsy

Authors: *E. ANDRADE, Z. LIU;
Univ. Florida, GAINESVILLE, FL

Abstracts: Several studies have revealed the presence of at least three well defined ictal neuronal networks as the cause of partial complex seizures. Evidence includes *in vivo* animal and human electrophysiological recording. Several papers have postulated the role of autoregressive models such as linear pairwise granger causality (LPGC) as a noninvasive method to detect ictal onset. To test the effectiveness of LPGC, we hypothesize that the ictal onset (IO) in patients with partial epilepsy refractory to medical treatment (PERT) originate in a single network and propagates within the same hemisphere. The feasibility of this hypothesis was retrospectively analyzed on 90 clinical seizures from 23 subjects admitted to the epilepsy monitoring unit for phase I (pre surgical) evaluation. The visual assessment of the ictal electroencephalogram EEG was used as a control and compared to that of the validated LPGC. First, ictal EEG was defined by an experienced board certified pediatric epileptologist blind to the study. Second, the EEG raw data were analyzed using PGC. Boot-strapping methodologies were used to address the statistical significance of the network interactions defined with PGC. Time frequency distribution was plotted for each seizure and compared versus controls. PGC showed no statistically significant difference for intra-hemispheric directionality in subjects with partial complex seizures when the IO was over the left temporal (p=0.0548) and right frontal lobe (p=0.0558). Furthermore, there were no significant differences when looking at the inter-hemispheric PGC measures obtained in subjects with seizures with an IO over the left frontal (p=0.2882), left temporal (p=0.1572), right frontal (p=0.6772) and right temporal networks (p=0.7795) when compared against the parietal lobe (Figure 1). The findings of our pilot study indicate no actual ipsilateral ictal propagation. Alternatively, ipsilateral ictal propagation may not identifiable with PGC. To answer this last question, we now proposed further evaluation using segmentation and surrogate analysis.

Title: Differential neuronal loss in the hippocampus of patients with temporal lobe epilepsy and psychiatric comorbidities

Authors: ***J. B. DE ROSS**, L. KANDRATAVICIUS, R. C. SCANDIUZZI, C. G. CARLOTTI JR, J. A. ASSIRATI JR, J. E. C. HALLAK, J. P. LEITE, J. A. S. CRIPPA;
Neurosci. and Behavior Sci., Univ. of Sao Paulo, Ribeirao Preto, Brazil

Abstracts: Despite the high prevalence of psychiatric comorbidities in pharmacoresistant mesial temporal lobe epilepsy (MTLE) patients, the mechanisms underlying this association are poorly understood. Recent studies have shown distinct neuropathological features in patients with MTLE and psychiatric comorbidities, like differential neuronal loss among the hippocampal formation subfields. Examining a new series of patients, our goal was to evaluate neuronal density in these cases and correlate possible differences with clinical data. Retrospectively, 43 cases were selected from patients with pharmacoresistant MTLE who underwent surgery to epilepsy control. Specimens were divided into three groups according to psychiatric diagnosis: interictal psychosis (MTLE + P), major depression (MTLE + D) and without psychiatric symptoms (MTLE). Tissue from autopsies were used as controls (CTRL). Neuronal density was calculated in hippocampal formation subfields in sections immunostained with NeuN antibody. Compared to CTRL, MTLE specimens showed significant neuronal loss in all hippocampal subfields, with exception of parasubiculum and entorhinal cortex. Among patients with psychiatric comorbidities, MTLE + P group showed lower neuronal density in CA2 when compared to MTLE + D group ($p=0.024$). No effect of haloperidol in neuronal density was seen in MTLE + P group. However, MTLE + D patients taking selective serotonin reuptake inhibitors

(SSRI) showed increased neuronal density in granular layer of dentate gyrus (p=0.032) when compared to those not taking SSRI. Our results indicated that MTLE + P patients present decreased neuronal density in the CA2 subfield. Likewise, a postmortem study of schizophrenic individuals also demonstrated decreased neuronal density of non-pyramidal neurons in this same region. A recent study showed that CA2 subfield is essential for social memory processing in rodents, behavioral parameter usually altered in subjects with psychiatric disorders. In addition, our results indicated that MTLE + D patients taking SSRI have greater neuronal density in the granular layer of dentate gyrus. Several studies indicate hippocampal neurogenesis as a necessary mechanism for SSRI antidepressants action. However, since we performed mature neuron count, neurogenesis detection techniques are needed to confirm and expand this finding.

Title: Brain connectivity analysis can identify primary epileptogenic zone in pediatric epilepsy patients

Authors: *D. LEE[1,2], Y. HUR[3], R. YU[1], H. KIM[1];
[1]Dept. of Pediatrics, [2]Epilepsy Res. Inst., Yonsei Univ. Col. of Med., Seoul, Korea, Republic of;
[3]Dept. of Pediatrics, Inje Univ. Haeundae Paik Hosp., Busan, Korea, Republic of

Abstracts: Resective surgery can be an effective treatment in intractable epilepsy and patients can be freed of seizure by removing the epileptogenic zone. It is critical to accurately localize the epileptogenic zone for successful resective surgery. Many models of source localization analysis such as equivalent current dipole, sequential dipole fitting, and independent component analysis have been applied to the issue. More recently, functional brain connectivity analysis such as Granger causality methods has been proposed to better explain causality and directionality of epileptic network. This analysis method can identify the causality between different cortical areas and it can be used to identify the source of the abnormal electrical signals. However, sensitivity and specificity of this approach has not been fully evaluated yet. We propose to test

the validity of brain connective analysis as a mean to identify true epileptogenic zone. We used focal epilepsy patients who underwent resective surgery with good outcome as a reference. We compared surgical sites and the site that was identified by connectivity analysis to see how close they matched. We analyzed sharp and wave discharge in preoperative electroencephalography to identify the primary epileptogenic zones using direct directed transfer function (dDTF) based on a multivariate autoregressive model. We compared the areas identified by dDTF with the resection areas in the patients.

Abstracts: More than 30% of patients develop drug refractory epilepsy (DRE). The Temporal Lobe Epilepsy (TLE) with or without Hippocampal Sclerosis (HS) tends to be refractory. For many years DRE has been related with inherited or acquired alterations in multidrug transporters, but these haven't been adequate to explain the molecular and cellular mechanisms of drug-resistance. In recent years, it has been suggested that the influence of some microtubule-associated proteins (MAPs) and molecules of inflammation may contribute with recurring neuronal excitability episodes. Tau protein is a MAP that in increased levels or in the hyperphosphorylated state has been associated with the probability of seizure attacks. In the same way, Tumor Necrosis Factor-α (TNF-α) enhances neuronal excitability and the Cyclooxygenase-2 (COX-2) has been related with antiepileptic drug transport. Objective: Due to the impact of this molecules in seizures and because DRE could be a polygenic disorder, we analyzed the risk effect of 14 single nucleotide polymorphisms (SNPs) in Tau, GSK-3β, HSP-70, TNF-α, COX-2 and complement receptor 1 (CR1) genes Method: Genotyping was performed by

qPCR, in 35 clinically diagnosed patients with DRE (23 HS cases and 12 TLE without HS) and 47 controls of Mexican population. Allelic frequencies were analyzed with a Chi-square test. Results: The SNP located in CR1 gene could be linked with a risk increased of DRE (p=0.03). When we analyzed allele frequencies separating patients with or without HS, we found a possible association of CR1 and HSP-70 SNPs that would be exclusive in patients with HS (p=0.007, p=0.03). Also, in TLE group without HS, we found one SNP in Tau gene and another in GSK-3β gene that may be associated as differential markers between patients with HS and without.

Title: Empirical mode decomposition as a seizure detection tool

Authors: *K. R. ASHMONT[1], R. WAHNOUN[2,1], P. ADELSON[2,1], S. HELMS TILLERY[1], B. GREGER[1];
[1]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ; [2]Barrow Neurolog. Inst. at Phoenix Children's Hosp., Phoenix, AZ

Abstracts: Focal resection surgery can offer long term control of seizures for people with drug resistant epilepsy. Successful surgery relies on the accurate identification of where and when the patient's seizures start. The current identification "gold standard" involves the implantation of electrocorticography (ECoG) grids below the skull, followed by continual monitoring of cortical activity for up to two weeks. During this time, all of the information collected is visually reviewed by highly trained epileptologists. This process requires extensive time and is highly subjective. Here, we propose the use of empirical mode decomposition (EMD) as a seizure detection tool to supplement the visual review process. EMD is an adaptive sifting algorithm that breaks complex waveform data into intrinsic mode functions (IMF). Sifting begins by connecting local maxima and local minima with two cubic spline interpolations, generating maxima and minima envelopes of the data x_i (t). The mean of these envelopes m_j is then calculated and subtracted from the data h_j=x_i (t)-m_j. h_j is considered an IMF if: (1) the number of extrema

and zero crossings are equal or differ at most by one, and (2) m_j is zero at any point. If h_j does not meet the IMF criteria, h_j is re-sifted h_j=h_((j-1))-m_j with j = j+1 until it does, then ⟦IMF⟧_k=h_j. If h_j does meet the IMF criteria, then ⟦IMF⟧_k is subtracted from the data, leaving residual data x_(i+1) (t)=x_i (t)-⟦IMF⟧_k. The residual data is then reintroduced to the sifting process. The sifting process continued until the peak to peak amplitude of x_(i+1) (t) is less than 20 μV and its frequency is below 2 Hz. We applied EMD to recordings performed using clinical ECoG grids and sampled at 500 Hz. EMD was applied to 5 s windows of the ECoG data, and this window was moved through the data with a step size of 3 s. We marked a seizure as detected when an increase in the number of IMFs lasted for at least four consecutive windows, with the seizure onset time taken as the median of the first of these windows. EMD seizure detection within 1 min of the seizure onset time as noted by the epileptologist was considered a true-positive. We were able to successfully detect six of six seizures from one patient with the EMD seizure onset time an average of 8.67 s from the epileptologist noted onset time. Three of the EMD detections occurred prior to, while three occurred after the seizure onset time noted by the epileptologist. Further, the post-ictal state was indicated by a decrease in the number of IMFs and was useful in excluding to false-positive EMD seizure detections. In future work we will optimize the EMD parameters and expand testing to all electrodes in the grid and to additional patients.

Title: Changes in extracellular metabolites during cooling of the epileptogenic cortex in human epilepsy; an intraoperative microdialysis study

Authors: *T. INOUE[1], S. NOMURA[1], M. FUJII[1], Y. HE[1], Y. MARUTA[1], H. KOIZUMI[1], E. SUEHIRO[1], H. IMOTO[1], T. YAMAKAWA[2], M. SUZUKI[1];
[1]Dept. of Neurosurg., Yamaguchi Univ., Ube, Japan; [2]Fuzzy Logic Syst. Inst., Kitakyushu, Japan

Abstracts: Introduction: Although focal brain cooling has been a candidate for epilepsy treatment, the therapeutic feasibility remains to be elucidated. Of particular importance in this regard is to clarify cooling-induced neurovascular and metabolic changes. To address this issue, cerebral blood flow (CBF) and microdialysis measurements were performed during focal brain cooling of epileptogenic zone in epileptic patients. Methods: A PID-controlled, thermoelectrically-driven cooling device (cooling area: 40×40 mm for cortex, 10x10mm for hippocampus) was intraoperatively applied on the cortical or hippocampal epileptogenic foci in intractably epileptic patients, and CBF measurement (n=6) and microdialysis (n=9) were performed. Findings: Although CBF in the epileptic foci was transiently reduced during 15°C cooling, it was reversible and immediately recovered following rewarming. Cooling-induced metabolic changes were qualitatively similar across patients. Of glycolytic metabolism, lactate levels were significantly reduced ($p<0.01$) during cooling and rewarming period, while glucose and pyruvate levels remained relatively unaffected. Extracellular levels of glutamate, gamma-aminobtyric acid (GABA) and grycerol were significantly decreased during cooling ($p<0.05$) with the effect remained even after rewarming ($p<0.05$). Interpretation: It has been reported that autoregulation and metabolic coupling in epilepsy are impaired. This study showed, for the first time, coupling of CBF and metabolism with cooling of the epileptogenic zone to 15°C. Decreased lactate, grycerol and glutamate levels suggested neuroprotective effects of cooling. Together with the previous our investigations in animals, the results suggested a feasibility of hypothermal device-based therapy.

Ctr., Tel-Aviv, Israel; [6]Dept. of Psychology, Bar-Ilan Univ., Ramat Gan, Israel

Abstracts: Epilepsy is associated with dynamic changes in the excitation-inhibition balance (EIB). Characterizing and monitoring these changes is of high importance for diagnosis and treatment of the disease. Recently, several studies demonstrated that a healthy cortex displays critical dynamics, namely, it maintains a continuous balance of excitatory and inhibitory forces, preventing premature termination or explosive growth of neuronal activity. This critical state is characterized by scale-free cascades of activity, termed neuronal avalanches. Here we quantitatively assessed deviations from critical dynamics by applying the neuronal avalanche metrics to resting-state electroencephalography (EEG) and magnetoencephalography (MEG) recordings from epilepsy patients and healthy control subjects. We found that periods of inter-ictal epileptiform activity (IEA) display super-critical dynamics. This was manifested in the shape of the cascade size distribution, which deviated from the expected power law and displayed a prominent 'bump' over large avalanches, as well as by an increase in the 'branching parameter', which represents the gain of the system. In some patients, deviation from critical dynamics was evident from the full recording. In others, it was evident only after separating the data into periods containing IEA, as compared with quiet periods, which displayed normal critical dynamics. Furthermore, in some patients the avalanche metrics were predictive of the level of IEA, as measured by the number of inter-ictal spikes in a given time window. In such cases, periods with high incidence of IEA can be detected without resorting to spike detection. In addition to looking for differences in time, we also looked for difference in space. Applying source analysis allowed us to compare the known epileptic foci (identified by other methods) to other cortical regions. This comparison revealed clear differences in terms of the avalanches metrics, again indicating super-critical dynamics in the epileptic foci. These findings demonstrate a novel approach for assessing deviations from EIB in both space and time based on non-invasive recordings in epilepsy patients.

Title: Brain metals: Methods of analysis and their role in epilepsy

Authors: *L. K. FRUTOS[1], ***L. K. FRUTOS**[1], E. L. OHAYON[1], A. LAM[1,2];
[1]Green Neurosci. Laboratory, Neurolinx Res. Inst., San Diego, CA; [2]Toronto Western Res. Institute, Univ. of Toronto, Toronto, ON, Canada

Abstracts: The human brain is abundant in metals which are an essential part of brain biochemistry, structure and, by extension, cognitive functions. Changes to the level of metals in the brain occur in typical brain development and aging, but may also result in, or be the consequence of, neurological conditions. Some conditions are well known to involve etiologies of large shifts in brain metal distribution and concentrations (both increases and deficiencies). Examples include: Menkes disease (Cu deficiency), Wilson's disease (Cu accumulation) and neuroferritinopathy (Fe accumulation). However, it is not always recognized that many common conditions may have forms that are linked to changes in brain metals and metal-metabolism. In this presentation we focus on the possible roles of metals in epilepsy. These include idiopathic and pharmacoresistant epilepsies. We survey historical and recent evidence of "deficiencies" and "surplus" in various metals, as (i) possible causal mechanisms and (ii) the results of seizures. We further describe the historical advancements in methodologies used to examine brain metals, from histology to neuroimaging and novel optical and x-ray techniques. These include recent examples of synchrotron x-ray fluorescence imaging from our laboratory. Finally, we suggest that multi-scale, spatial and temporal characterizations of metal distributions in the brain may be critical for developing treatments for certain forms of epilepsy as well as for a deeper understanding of cognitive function in the healthy brain.conditions.

Title: Mild traumatic brain injury in adult mice induces marked neurogenesis in the dentate gyrus

Authors: *T. L. NIEDZIELKO[1], P. C. PUGH[2], J. H. CHANCEY[2], L. OVERSTREET-WADICHE[2], C. L. FLOYD[1];
[1]Physical Med. & Rehab, [2]Neurobio., Univ. Alabama, Birmingham, BIRMINGHAM, AL

Abstracts: The United States Centers for Disease Control and Prevention estimate that 1.7 million persons per year sustain a traumatic brain injury (TBI) and approximately 75% of these TBIs are forms of mild TBI (mTBI). In moderate/severe models of TBI, neurons throughout the hippocampal formation are particularly vulnerable to injury. The dentate gyrus (DG) of the hippocampus undergoes granule cell (GCs) neurogenesis throughout adulthood; however, the contribution of neurogenesis to DG function is poorly understood. As pathophysiological stimuli such as seizures and brain lesions can alter GC neurogenesis, we hypothesize that mTBI alters neurogenesis and these alterations in the hippocampus may have significant consequences for acute and long-term hippocampal network activity. Thus, this study utilized adult male transgenic mice with enhanced green florescent protein expressed under transcriptional control of the mouse proopimelanocortin gene promoter (POMC-GFP) to identified newborn GCs. Age matched adult male mice were randomly assigned to mTBI or sham control groups. Animals received mTBI via a 100g weight dropped from 60cm onto a 1.25cm metal disk attached to the skull. Sham animals received all surgical procedures except the weight drop. Animals were euthanized on post-TBI day 2, 6, or 10 and brains were removed for serial sectioning and histological analysis including cresyl violet (nissel substance), expression of GFP, Ki-67 and doublecortin expression. Expression of histological markers was quantified using unbiased stereology. Acute hippocampal slices were taken from separate animals for electrophysiological assessment of intrinsic properties of mature GCs in whole-cell patch clamp. We found no differences between mTBI and sham groups in neuronal number as indicated by cresyl violet histology in the dentate gyrus. However, the number of GFP-positive cells was significantly increased in the mTBI groups versus sham at all post-TBI time points, with corresponding increases in the proliferative markers Ki-67 and doublecortin. There was also an increase in the total dendrite length of newborn GCs in the mTBI group at the 2 day time point. Whole-cell patch clamp recording revealed that mTBI alters the intrinsic properties of mature GCs. Our results demonstrate that mild TBI induces negligible DG cell loss yet profoundly enhances neurogenesis and alters the physiology of mature DG neurons. These alterations could represent a novel mechanism that could contribute to the persistent behavioral impairments seen after mTBI. Supported by R01NS075162.

Title: T cell infiltration into the brain after traumatic brain injury is associated with injury severity

Authors: *X. E. NDODE-EKANE, L. MATTHIESEN, A. PITKÄNEN;
Neurobio., A.I. Virtanen Institute, Univ. of Eastern Fin, KUOPIO, Finland

Abstracts: Traumatic brain injury (TBI) is the most common cause of permanent disability and death in people under the age of 40. About 11% of TBI patients develop posttraumatic epilepsy (PTE). However, the mechanisms that underlie the development of PTE remain unclear. T cell infiltration into the brain parenchyma is a prominent inflammatory response following TBI. Reports suggest that T cells may contribute to the progression of epileptogenesis and the development of post-traumatic epilepsy (PTE). Our objective here is to understand the dynamics of T cell infiltration into the brain after TBI, and the functional significance of T cell invasion to post-traumatic epileptogenesis and progression of neurological deficits. To achieve this, TBI was induced in adult rats using lateral fluid-percussion injury. A composite neuroscore test was performed to assess the severity of somato-motor deficits, at 24 h, 2 d, 4 d, and 7 d after injury. Thereafter, animals were sacrificed by transcardiac perfusion with 4% paraformaldehyde. T cells were identified in brain sections by immunohistochemical staining with an antibody against the T cell antigen CD3. The number of T cells was stereollogically assessed in the ipsilateral cortex, hippocampus and thalamus. Analysis of sham-operated animals revealed very low T cells counts in all areas. However, the number of T cells in all regions increased dramatically at 24 h post-injury. At 2 d the number was even higher, being 154% of that at 24 h post-TBI. At 4 d and 7 d, their number dropped to 77% and 10%, respectively, of that at 24 h. The highest number of T cells was observed in the cortex when compared with other areas ($p<0.05$). Visual analysis of brain sections at the chronic phase (3 months post-TBI) showed a resurgence of T cells particularly in the ipsilateral thalamus and cortex. There was a strong inverse correlation between the total number of T cells at the acute phase (24 h, 2 d, 4 d and 7 d time-points) and the neuroscore at 24 h or 2 d post-injury reflecting the severity of injury ($p<0.05$). This data suggest

that the severity of post-traumatic neurological deficits can predict the level of post-traumatic T cell response. The increase in T cell number in the early days following TBI and in the chronic phase suggest a time window during which T cells can influence epileptogenesis.

Title: Neuronal death and glial activation in rat organotypic hippocampal slice cultures exposed to a blast injury

Authors: *A. P. MILLER[1,2], A. SHAH[1], B. V. APERI[1], M. D. BUDDE[1], F. A. PINTAR[1,2], S. KURPAD[1,2], B. D. STEMPER[1], A. GLAVASKI-JOKSIMOVIC[1,2];
[1]Dept. of Neurosurg., [2]Cell Biology, Neurobiology, and Anat., Med. Col. of Wisconsin, Milwaukee, WI

Abstracts: Blast induced traumatic brain injury (bTBI) is a substantial and significant injury that has escalated amongst military personnel. Understanding the molecular events and cascades underlying cell death and glial response are essential to elucidate potential future therapeutic strategies. The aims of this investigation are to characterize the blast response in organotypic hippocampal cultures (OHCs) and to illuminate the microglia and astrocyte activation in response to shock wave damage. The hippocampi were isolated from 7-10 day old rats, dissected into 400 μm sections, and grown using the standard interface method. At 8 days *in vitro* OHCs were exposed to a shock wave overpressure of 150 kPa (low) or 270 kPa (high) using a vertical open-ended helium driven shock tube. Cell death was analyzed at various time points post injury via propidium iodide (PI) uptake. PI staining was quantified by measuring the mean pixel intensity (MPI) of cornu Ammonis 1 (CA1) and dentate gyrus (DG) hippocampal regions using MATLAB software (Mathworks, Inc., Natick, Massachusetts). At 3 or 7 days post injury OHCs were fixed with 4% paraformaldehyde and processed for immunohistochemistry against neuronal (beta III Tubulin; Tuj1), microglia (ionized-calcium-binding adapter molecule 1; IBA-1), and

astrocyte (glial fibrillary acidic protein; GFAP) markers. Following immunostaining, microglia activation was assessed based on changes from resident ramified to rounded amoeboid-like appearance, while astrocyte activation was analyzed by intensity of GFAP fluorescence. Compared to control sections the shock wave-exposed OHCs exhibited significant increase in PI uptake both in high and low groups at all time points post injury. Cell death gradually increased in the low blast group over 7 days. OHCs exposed to high blast exhibited an initial dramatic increase in cell death until it plateaued at approximately 24 hours post-injury. MPI was significantly different between high and low groups only at earlier time points. Tuj1 immunostaining indicated that the majority of blast-evoked cell death was restricted to neurons which co-expressed PI and Tuj1. Preliminary data suggest that at 3 days post injury the percentage of activated microglia was significantly higher in the high blast group compared to control OHCs. Our preliminary data also imply significant astrocyte activation in OHCs exposed to a high blast at 7 days post injury. Together our data suggest that our novel *in vitro* bTBI model is useful tool to study cellular and molecular changes in neuronal tissue following blast exposure.

Title: Effect of aging on cognitive outcome and neuroinflammatory response after traumatic brain injury

Authors: *A. CHOU, J. M. MORGANTI, S. ROSI;
Univ. of California, San Francisco, San Francisco, CA

Abstracts: Traumatic Brain Injury (TBI) can alter neuronal function and inflammatory responses even beyond the site of injury. TBI outcomes are worse in elderly patients including higher fatality rates and greater severity of TBI-related disabilities. In various animal models

recapitulating TBI, aging predisposes exacerbated neuronal loss, inflammation, and motor function acutely. However, no mechanism for age-related exacerbation of TBI has been identified. In the current study we investigated the effect of aging on TBI-induced cognitive deficits and neuroinflammatory response. TBI was induced by controlled cortical impact over the right parietal cortex in 3 and 18 month old male mice. Thirty days after injury, hippocampal-dependent learning and memory functions were measured using the radial arm water maze (RAWM) which consists of eight arms with an escape platform located at the end of one arm. Our data demonstrates that both age and TBI increases the number of errors that the animal commits to locate the escape platform when compared to their respective young and sham controls. We further characterized changes in synaptic plasticity markers in the ipsilateral hippocampus. Many studies have shown that reducing the pro-inflammatory response can alleviate TBI-induced outcomes. While acute pro- and anti-inflammatory responses are exacerbated by age, it is unclear if the pro-inflammatory response is prolonged or if there is diminished anti-inflammatory response over time in old animals as compared to young animals. We characterized the inflammatory response of the injured brain in both young and old animals by flow cytometry and quantitative PCR on isolated microglia/macrophages from the injured hemisphere at a sub-acute time point 7 days after injury. Our results demonstrate that 7 days after injury there was a significant decrease in anti-inflammatory cytokine and M2 macrophage expression in old animals compared to the young. These data suggest an imbalance in the regulation of inflammation in the aging brain which may sustain a proinflammatory environment after injury.

Title: Effects of PTEN inhibition on neuronal morphological changes and survival after traumatic brain injury

Authors: ***C. LIANG**[1], K. ELMORSHEDY[1], P. SWIATKOWSKI[1], T. M. KAZDOBA[1], I. NIKOLAEVA[1], M. BEAMER[2], D. F. MEANEY[2], G. D'ARCANGELO[1], B. L. FIRESTEIN[1];

[1]Cell Biol. and Neurosci., Rutgers Univ., Piscataway, NJ; [2]Dept. of Bioengineering, Univ. of Pennsylvania, Philadelphia, PA

Abstracts: In response to traumatic brain injury (TBI), neuronal tissues are damaged by rapid and transient mechanical deformation, followed by secondary injury due to excess glutamate release, which causes morphological changes in neurons. These changes include focal swellings in dendrites, or varicosity formation, and spine retraction and re-emergence. Previous studies in the Firestein laboratory showed that a large number of small varicosities are neuroprotective, while large varicosities are detrimental to neuronal survival. In this study, we aim to test how alteration of the mTOR pathway, by deleting or inhibiting PTEN, contributes to changes in neuronal morphology, neuronal survival, and neural circuitry after TBI. We mimic the primary mechanical injury and secondary excitotoxicity by utilizing an *in vitro* stretch injury model or NMDA treatment. We first examined varicosity formation in hippocampal neuronal cultures from NEX-PTEN mice after NMDA treatment, and we observed a decrease in the percentage of neurons with varicosities in PTEN knockout mice compared to littermate controls. In contrast, we did not see a significant difference in varicosity size between each genotype. In parallel, we used an *in vitro* stretch injury model to induce mechanical injury to rat hippocampal neurons. We compared the percentage of neurons that formed varicosities at different time points after stretch and varicosity size in cultures pre-treated with bpV(phen), a PTEN inhibitor, and control cultures. We found that PTEN inhibition causes a time-dependent two-phase change in varicosity formation: during the initial phase after stretch injury, neurons with PTEN inhibited had a larger number of smaller varicosities than observed in control neurons, while in the latter phase during our observation, PTEN inhibition caused a higher percentage of neurons with varicosities, which were larger in size than observed in control cultures. Together, our studies provide new evidence for a role of PTEN and the mTOR pathway in neuronal recovery from TBI.

Title: Expression and effects of c-Ski in mice brain after traumatic brain injury

Authors: *Y. ZHOU, P. LI, X. CHEN, Y. PENG, Z.-A. ZHAO, Y.-L. NING, N. YANG, Y. ZHAO, X.-Y. CHEN, R.-P. XIONG;
Mol. Bio Ctr., Res. Inst. Surg and Daping Hosp. ,TMMU, Chongqing, China

Abstracts: Traumatic brain injury (TBI) causes neuronal apoptosis, inflammation, and reactive astrogliosis, which contribute to secondary tissue loss, impaired regeneration, and the leading cause of death and disability. c-Ski, the cellular homologue of v-Ski, was a multifunctional modulator that involved in proliferation, apoptosis, inflammation, fibrosis, and cell differentiation. However its distribution and function in the central nervous system (CNS) during TBI are not well understood. In this study, using immunohistochemistry in a moderate controlled cortical impact model of mice, we found that the expression of c-Ski was observed mainly in the cortex surrounding the injury site and reached its peak on day 3 and then significantly decreased. And c-Ski was also expressed at relatively low levels in the ipsilateral hippocampus, thalamus and contralateral cerebral cortex. Immunofluorescence double-labeling showed that c-Ski was localized almost exclusively in neuronal cells. To further investigate the function of c-Ski, we found that increasing local Ski expression by gene transfer in the above model reduced lesion volume by increasing quantity of neurons and decreasing inflammation by histological assessments. In addition, Consistent with the histological changes, the neurological deficit scores in the gene-transfer mice were significantly lower than that of control on day 3. Together with our data, we speculate that c-Ski play an important role in CNS pathophysiology after TBI and is a prospective new target for therapeutic approaches to TBI.

Title: Phosphorylation of Tau after blast exposure: A potential predisposition to Alzheimer's-like pathology

Authors: *P. ARUN, D. M. WILDER, A. A. EDWARDS, Y. WANG, I. D. GIST, J. B. LONG; Ctr. for Military Psychiatry and Neurosci., Walter Reed Army Inst. of Res., Silver Spring, MD

Abstracts: Blast-induced traumatic brain injury (TBI) is one of the major disabilities in service members returning from recent military operations. Blast-induced TBI is associated with acute and chronic neuropathological and neurobehavioral deficits. Epidemiological studies indicate that brains of 30% of victims who die acutely following TBI have Aβ plaques, a pathological feature of Alzheimer's disease (AD), which suggests that TBI may predispose to AD, although to date this notion remains somewhat speculative. *Tau* protein, phosphorylated at serine396 (S396), is rich in paired helical filaments which form neurofibrillary tangles (NFTs) observed in the brains of patients with AD. The number of NFTs is tightly linked to the degree of dementia, indicating that the formation of NFTs may underlie and contribute to neuronal dysfunction. In this study, rats were exposed to single or double blasts using a shock tube. Brain regions were collected at different intervals for Western blotting. Preliminary results indicate that phosphorylation of *Tau* protein occurs preferentially at S396. S396 phosphorylation of *Tau* varied in different regions of the brain and the degree of phosphorylation increased with number of blast exposures. Increased S396 phosphorylation occurred acutely after blast exposures and subsequently returned towards normal levels by day 28, which at this stage did not positively correlate with the accumulation of amyloid precursor protein (APP). These results indicate that acute *Tau* protein phosphorylation at S396 and chronic accumulation of APP in the brain after blast exposure may predispose to Alzheimer's-like disease.

Title: Quantitative microscopic analysis of morphology of individual neuronal mitochondria in the cortex of anesthetized mice under injury

Authors: *M. KISLIN[1], E. PRYAZHNIKOV[1], E. LIHAVAINEN[2], R. AFZALOV[1], D. TOPTUNOV[1], A. S. RIBEIRO[2], L. KHIROUG[1];

Abstracts: Functions of mitochondria are directly related to their morphology, and morphological abnormalities such as fragmentation have been frequently reported in disease models *in vitro*. Using intravital two-photon microscopy, we imaged the dynamics of neuronal mitochondrial morphology under traumatic conditions in the brain of anesthetized Thy1-mitoCFP mice and quantified these dynamics utilizing an automated analysis method based on supervised learning. To test the sensitivity of mitochondrial morphology within cortical layer 1 to injury, we measured the degree of mitochondrial fragmentation in three models: i) mild photodamage (MPD); ii) focal laser-lesion (FLL); and iii) Rose Bengal photosensitization (RBPS). To access the time course, changes in mitochondrial morphology were analyzed during acute (3 hours), subchronic (2, 4, 7 days) and chronic (3 weeks) phases. MPD was induced in a small volume by exposing the tissue to approximately 50-fold higher light energy than during imaging; FLL was produced by targeted laser light eliminating individual branches of the apical dendrites in a controlled volume of somatosensory cortex; RBPS was achieved by i.v. injection of Rose Bengal followed by exposure to green light. We found that MPD resulted in a rapid mitochondrial fragmentation in the high-exposure region. Surprisingly, the damage did not extend to the surrounding tissue and recovery of mitochondria morphology occurred only 4 days after MPD. FLL resulted in a complete loss of the CFP fluorescence at the lesion site and induced mitochondria fragmentation at the perilesion site that recovered during one week. Spontaneous dendritic regrowth into the lesion site occurred during 7-14 days and was accompanied by recovery in mitochondrial morphology. RBPS rapidly produced a core with severe mitochondrial fragmentation that did not show any recovery over 3 weeks. We observed some recovery of mitochondrial morphology after 3 weeks but only in relatively small parts of the remote area. Finally, we used dual TG mouse line to evaluate the temporal relationship between mitochondrial morphology and the dendritic structure during the first 3h after RBPS. Interestingly, structural changes in neurons, such as blebbing, were always observed with some delay after the mitochondrial fragmentation occurred first in response to RBPS. We propose that microscopic imaging with supervised learning-based analysis of neuronal mitochondrial morphology *in vivo* reveals a pivotal role of mitochondria in neuronal survival or death, and can therefore be used as a sensitive readout suitable for assessing the effectiveness of neuroprotective therapies in preclinical studies.

Title: Progression of myelin pathology in TBI with traumatic axonal injury of the corpus callosum

Authors: *A. J. MIERZWA[1,2], C. M. MARION[1,2], G. M. SULLIVAN[1,2], D. MCDANIEL[1,2], R. C. ARMSTRONG[1,2];
[1]Uniformed Services Univ. of the Hlth. Sci., Bethesda, MD; [2]Ctr. for Neurosci. and Regenerative Med., Bethesda, MD

Abstracts: Traumatic brain injury (TBI) from impact-acceleration forces often results in post-concussive symptoms that persist into a chronic disease phase, even in patients diagnosed initially as mild TBI. To better understand the progression to chronic disease, we examined acute through chronic white matter pathology in mice using a concussive TBI model of traumatic axonal injury. TBI was produced in adult male C57BL/6J mice by controlled impact onto the skull at bregma. Animals were perfused at multiple time points between 3d-6wks post-TBI and tissues were processed for either electron microscopy or immunohistochemistry. At all times post-TBI, degenerating axons were evident mainly in the corpus callosum, particularly over the lateral ventricles. Degenerating axons were distributed among intact fibers-- modeling the diffuse pattern of traumatic axonal injury in TBI. Axon diameters were reduced among the overall population of remaining axons. Demyelination may contribute to functional deficits and potentially leave denuded axons vulnerable to further damage. After TBI, demyelination of intact axons significantly increased at 3d followed by remyelination evident at 1 wk. In addition, abnormal myelin figures were prevalent at all post-TBI time points, yet extremely rare after sham surgery. Redundant myelin sheaths formed from myelin that collapsed back onto itself as the axon degenerated or from excessively long outfoldings of myelin,which may be indicative of myelin synthesis. For comparison with an example of demyelination and remyelination, we examined the number of redundant myelin figures in the cuprizone model of widespread corpus

callosum demyelination. Surprisingly, TBI mice had 10-fold more redundant myelin figures than observed during either the demyelination or remyelination phase of the cuprizone disease course. Due to the dispersed nature of demyelination and axon degeneration in TBI, oligodendrocytes may increase myelin synthesis to remyelinate intact axons or the excessive myelin formed by reflect dysregulation in maintaining multiple sheaths among a cohort including intact and degenerating axons. Excessive myelin outfoldings may increase myelin debris, which can stimulate microglial activation. Immunohistochemistry demonstrated microglial activation and reactive astrogliosis that persisted 6 wks post-TBI. Further studies will be important to determine the contribution of this myelin pathology to persistent white matter neurodegeneration and neuroinflammation after TBI.

Title: Early M1 and M2 response in hippocampus following traumatic brain injury

Authors: *M. A. ANSARI[1], K. N. ROBBERTS[2], T. L. SUDDUTH[3], D. M. WILCOCK[3], S. W. SCHEFF[2];
[1]Sanders-Brown Ctr. on Aging, Univ. Kentucky, Lexington, KY; [2]Sanders-Brown Ctr. on Aging, Univ. of Kentucky, Lexington, KY; [3]Sanders-Brown Ctr. on Aging, Uneversity of Kentucky, Lexington, KY

Abstracts: Traumatic brain injury (TBI) triggers a complex series of inflammatory responses that are categorized into two phases, M1 (pro-inflammatory) and M2 (anti-inflammatory). M1 participates in multiple secondary injury cascades (SIC), while M2 maintains cell/tissue homeostasis and contributes to repair/regenerative assets. The terms M1 and M2 are derived from subsequent classical and alternative activation of macrophages, including microglia, astrocytes, and neutrophils. Following TBI, the blood brain barrier is breached allowing blood born immune cells to infiltrate the brain. Modulating the neuroinflammatory response may be

part of a rational therapy to enhance recovery following TBI. The present study was undertaken to investigate the very early neuroinflammatory response in the hippocampus, a brain area that is involved in a variety of cognitive functions and is affected after TBI. Young adult rats were killed at 2, 4, 6, 10, & 24h following a moderate unilateral cortical impact injury. The hippocampus was analyzed for both the phenotype (gene expression) and protein level of cytokines of M1 (IFNγ, TNFα, IL-1β, & IL-6) and M2 (IL-4, IL-10, & IL-13). Phenotypic expression of M1 cytokines (IFNγ, IL-6, IL-1β, & TNFα) was significantly elevated as early as 2h. Maximum expression of IFNγ, TNFα, & IL-1β genes occurred at 2-6h, while in IL-6, it was between 4-10h. Although values of M1 phenotype began to decline at 24h, they were elevated compared to sham operated animals. The level of IFNγ protein was not significantly altered while other M1 cytokines were significantly elevated within 2h post injury. The maximum surge of various M1 cytokines was between 2 and 6h, although not identical [TNFα (2h), IL-1β (6h), & IL-6 (4-6h)]. Levels of M1 proteins remained significantly higher than sham animals during the initial 24h post trauma. The M2 response was unlike the M1 response, with maximum levels of M2 observed at 24h post injury. Level of IL-10 was the only one that initially elevated at 6h. Like the protein levels, maximum gene expression in all the M2 cytokines was at 24h. The M1 response arises rapidly after TBI and it might overwhelm the early, relatively smaller, and transient M2 response. Our data suggests that a treatment which is able to enhance the M2 response, should be initiated early (before 10h), which would not only minimize inflammation mediated SIC, but also improve recovery after TBI.

Title: MTORC1 signal activation in the mouse hippocampus after traumatic brain injury

Authors: *I. K. NIKOLAEVA[1], B. CROWELL[2], J. VALENZIANO[4], D. MEANEY[4], G. D'ARCANGELO[3];

[1]Grad. Program for Mol. Biosci., [3]Cell Biol. & Neurosci., [2]Rutgers, the State Univ. of New Jersey, Piscataway, NJ; [4]Univ. of Pennsylvania, Philadelphia, PA

Abstracts: The mTORC1 signaling pathway mediates many aspects of cell growth and regeneration, and is upregulated after moderate to severe traumatic brain injury (TBI). The significance of this increased signaling event for recovery of brain function is presently unclear. We hypothesized that different cell types experience increased mTORC1 signaling after TBI, and that cell type determines whether this event is beneficial or detrimental to recovery. To test this hypothesis, in this study we established the time course and the cell specificity of mTORC1 signaling activation in the mouse hippocampus after moderate controlled cortical impact (CCI). We then blocked the peak of mTORC1 signaling by injecting rapamycin 1 hour after CCI. Behavioral studies indicated that this treatment improves performance in cognitive tests several weeks after injury. Our work suggests that the early peak of mTORC1 signaling after TBI occurs predominantly in neurons and it is deleterious to brain function. Suppression of this biochemical event, achieved shortly after injury has occurred, may represent an effective form of intervention to improve recovery in human patients. Title: TBI influences systemic inflammation by mediating differentiation of myeloid cells

Authors: *S. LEE, N. SINGHAL, J. SACRAMENTO, A. LIN, J. C. BRESNAHAN, M. S. BEATTIE;
Neurolog. Surgery, Brain and Spinal Injury Ctr., UCSF, SF, CA

Abstracts: Traumatic brain injury (TBI) leads to pro-inflammatory responses in both CNS and peripheral organs. The inflammatory responses may be involved in the subsequent development of clinical systemic inflammatory response syndrome, which eventually causes immune dysfunction and increases susceptibility to infection in chronic TBI patients. We examined the influence of TBI on systemic and CNS inflammation. Using a CCI-TBI model in C57BL/6 WT mice, we first examined the effects of TBI on the activation of peripheral immune cells. Flow cytometric analysis showed that 7 days after TBI, $CD11b^{high}$ cells were significantly increased in the circulation compared to $CD11b^{low}$ cells. Most of these cells were $Ly6C^{high}$, inflammatory monocytes, suggesting TBI stimulates the differentiation of myeloid cells.TBI also significantly induced mature myeloid cell populations ($CD11b^{+}F4/80^{+}$ macrophages and $CD11b^{+}CD11c^{+}$ dendritic cells) in the circulation at 7 days post injury. We also investigated the effects of TBI on trafficking of inflammatory myeloid cells in CNS. Consistently, we found that $CD45^{+}F4/80^{+}$ and $CD45^{+}CD11c^{+}$ cells were significantly increased in the injured brain at 7 days by immunostaining analysis. We also demonstrated significantly increased gene expression of proinflammatory mediators by real time quantitative RT-PCR in the spleen. Finally, *in vitro* studies using myeloid cells isolated from blood from WT mice demonstrated potent effects of LPS on differentiation of immature myeloid cells to mature myeloid inflammatory cells ($CD11b^{+}F4/80^{+}Ly6C^{high}$ cells). In addition, LPS also increased $Ly6C^{+}$ cells in splenocytes. Interestingly, LPS down-regulated CD3ζ in CD3 lymphocytes, suggesting proinflammatory response impedes T cell function. Together, our new findings suggest that TBI systemically induces pro-inflammatory responses by modulating myeloid cell differentiation in the circulation and subsequently affects leukocyte trafficking into the CNS. In addition, proinflammatory responses may contribute to T-cell dysfunction in spleen, and subsequent susceptibility to infections. Therefore, modulating immune responses may serve as an important therapeutic target for TBI patients.

Title: Decreased axonal transport following pediatric traumatic brain injury

Authors: *L. A. HANLON[1], J. W. HUH[2], D. P. FOX[1], R. RAGHUPATHI[1];
[1]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Dept. of Anesthesiol. and Critical Care, Children's Hosp. of Philadelphia, Philadelphia, PA

Abstracts: Axonal injury is a common occurrence in pediatric TBI and has been associated with long-term cognitive and behavioral deficits. In the acute post-traumatic period (hours to days), injured axons may have transport and/or conduction deficits, while in the chronic phase degeneration of axons has been observed. We have reported accumulation of amyloid precursor protein (APP) indicative of impaired axonal transport in the acute phase after closed head injury in an 11-day-old rat; immunoreactivity for APP is typically absent by 7 days after injury, thereby rendering it useless as a marker of transport deficits in the chronic phase (weeks to months). To determine the presence of axonal transport deficits in this post-traumatic period, 11-day-old rat pups were subjected to a moderate brain injury over the left parietal cortex, and received intracerebral injections of the retrograde tracer, fluorogold (FG, 2% in ddH2O) into either the left cortex (ipsilateral to the injury) or the right cortex (contralateral to impact site) at 2 weeks after injury; 5 days later, brains were analyzed for the presence of FG-labeled cells in the homotypic region of cortex contralateral to the site of injection. Compared to sham-injured animals, brain-injured animals had 79 % fewer labeled cells (when FG was injected into the un-injured cortex) and 64% fewer labeled cells when FG was injected into the injured cortex. Nissl staining did not reveal a loss of cells in the cortex in either hemisphere, suggesting that the decreased FG labeling was not due to a lack of cells available to take up the tracer. In previous studies, we have reported that the anti-inflammatory compound minocycline decreased the extent of traumatic axonal injury at 3 days after injury. To determine whether minocycline could also reverse axonal transport deficits in the chronic phase, a group of animals was treated with minocycline immediately following injury (90 mg/kg) and then every 12 hours for 3 days (45 mg/kg). The extent of FG-labeled cells in the cortex contralateral to the site of injection at 2 weeks post injury in minocycline-treated rats was similar to that in the vehicle-treated cohort (64 vs. 63 % compared to sham-injured animals), suggesting that acute attenuation of axonal injury may not affect transport deficits in the chronic post-traumatic period.

Title: Decreased expression of wild-type alpha-synuclein in rat ipsilateral hippocampus after traumatic brain injury

Authors: H. Q. YAN[1,2], Y. LI[1,2], J. J. HENCHIR[1,2], X. MA[1,2], S. CARLSON[1,2], *C. DIXON[1,2]; [1]Neurosurg., Univ. of Pittsburgh, PITTSBURGH, PA; [2]VA Pittsburgh Healthcare Syst., Pittsburgh, PA

Abstracts: Traumatic brain injury (TBI) is the leading cause of death and injury-related disability among young adults. TBI can result in the disturbance of cognitive, behavioral, emotional, and physical functioning. Synucleins (Syn), a family of synaptic proteins, includes alpha-synuclein (α-Syn), which plays a pivotal role in Parkinson's disease and related neurodegenerative diseases. The native function of α-synuclein is not completely understood, but is thought to involve regulation of synaptic vesicle trafficking. While the pathological forms of α-syn are considered to be the primary targets of TBI-associated neurodegeneration, disruption of the native function of α-Syn may contribute to pathology by diminishing synaptic function. Thus, the goal of the project was to examine the effects of TBI produced on wild-type α-Syn expression at 6 hours to 8 weeks post injury. Male Sprague-Dawley rats were anesthetized and surgically prepared for controlled cortical impact (CCI) injury (4 m/sec, 2.6 mm) or sham surgery. Rats were randomly assigned TBI or sham surgery and sacrificed for Western blot analysis and immunofluorescence double labeling assay by using commercial available antibodies. Semiquantitative measurements of the hippocampal tissues from rats sacrificed at 6 hour, 1 day, 1 week, 2 weeks 4 weeks and 8 weeks after injury or sham operation (N= 6 per group per time point) that were assessed using Western blot analysis show that expression of α-Syn are decreased ipsilaterally from 6 h to 8weeks in the hippocampus ($P < 0.05$). Double-label immunofluorescent staining sacrificed at 1 week after TBI or sham for α-Syn, neuron marker NeuN and astrocytes marker glial fibrillary acidic protein (GFAP) confirmed the Western blot findings. There is no overt change of NeuN immunostaining after TBI in regions of α-Syn loss. The increased expression of GFAP represents concomitant astrogliosis. This study suggests that wild-type α-Syn protein in the ipsilateral hippocampus is decreased after TBI compared to the sham controls. Additional work is required to determine if this represents a shift toward more cytotoxic forms of α-Syn or a reorganization of synaptic vesicle trafficking after TBI.

Title: Structural differences between granule cells and semilunar granule cells

Authors: F. ELGAMMAL[1], A. GUPTA[2], A. PRODDUTUR[2], B. SWIETEK[2], *V. SANTHAKUMAR[3];
[1]Dept Neurol. & Neurosci, Fatima Elgammal, Newark, NJ; [2]Dept. Neurol. & Neurosci., [3]Dept Neurol. & Neurosci, New Jersey Med. School, Rutgers, Newark, NJ

Abstracts: In earlier studies, we identified that semilunar granule cells (SGCs), glutamatergic neurons in the inner molecular layer with axonal projections to CA3 (Williams et al., 2007), show enhanced excitability after brain injury. SGCs receive significantly greater inhibitory inputs than granule cells and demonstrate a post-traumatic decrease in the frequency of inhibitory synaptic inputs rather than an increase observed in granule cells (Gupta et al., 2012). Here, we examined whether differences in dendritic morphology contribute to the divergent intrinsic pattern and post-traumatic plasticity of synaptic inputs between the two cell types. Whole-cell recordings from dentate neurons were obtained from acute hippocampal slices prepared 1 week after lateral fluid percussion injury (FPI) or sham-injury in young adult rats. Recorded neurons were filled with biocytin and processed for post-hoc cell identification. Neuronal reconstructions and morphometric analysis were performed on Neurolucida. Simulations were performed using NEURON. Both granule cells and SGCs showed an increase in the frequency spontaneous EPSCs one week after FPI. Frequency of sEPSCs in SGCs from sham-injured rats was significantly greater than in granule cells. Molecular layer interneurons demonstrated fewer spontaneous inhibitory inputs and a post-FPI increase in sIPSC frequency, indicating that location may not account for the differences in synaptic inputs between SGCs and granule cells. Morphometric analysis revealed a greater dendritic contraction angle in SGCs.

Although the total dendritic length was not different between the two cell types, SGCs had more numerous first and second order branches and greater dendritic length in low order branches than granule cells. However, granule cells had greater dendritic length than SGCs at locations distal to the somata. Furthermore, hilar axonal length was greater in SGCs than in GCs, as were branching order of SGCs, suggesting SGCs target more hilar neurons than do GCs. Detailed morphological simulations of granule cells and SGCs incorporating identical active and passive properties suggest that the morphological differences contribute to greater attenuation of proximal EPSCs in SGCs. These data reveal unique dendritic morphological characteristics of granule cells and SGCs that could contribute to the differences in their synaptic inputs and post-traumatic plasticity.

Title: Temporal changes in brain lipids after traumatic brain injury - A global lipidomics study

Authors: T. ANTHONYMUTHU[1,2,3], Y. Y. TYURINA[4,3], J. LEWIS[1,2], V. A. TYURIN[4,3], A. A. AMOSCATO[4,3], P. KOCHANEK[1,2], V. E. KAGAN[4,3], *H. BAYIR[1,2,3];
[1]Critical Care Med/Sch Med., Univ. Pittsburgh, PITTSBURGH, PA; [2]Safar Ctr. for Resuscitation Res., [3]Ctr. for Free Radical and Antioxidant Hlth., Univ. Pittsburgh, Pittsburgh, PA; [4]Envrn. and Occup. Hlth., Univ. Pittsburgh, PITTSBURGH, PA

Abstracts: Studies of the brain lipidome after traumatic brain injury (TBI) are one of the emerging research areas, essential for understanding the cellular responses and identification of

new drug targets. While lipid peroxidation has been associated with TBI induced neurological dysfunction, its role in the production of lipid mediators remains poorly understood. To experimentally address these issues, here, we used a global lipidomics approach to monitor the temporal changes in glycerophospho lipidome and fatty acyl lipidome of rat brain after controlled cortical impact. The left parietal cortex in 17 day old rat was impacted by a 6mm pneumatically driven metal impactor tip with 4±0.2 m/sec velocity. The depth of the penetration was 2.5 mm and the duration was 50 milliseconds. LC-MS/MS analysis of pericontusional lipid contents revealed time dependent changes in three glycerophospholipid classes and in all monolyso-glycerophospholipids at 1h, 4h, and 24h after injury vs naïve controls. The content of cardiolipin, a mitochondrial specific phospholipid, decreased by 30% at 1 and 24 hr time points and by 50% at 4hr time point compared to naive. The other two lipid classes, phosphatidylserine (PS) and phosphatidic acid (PA) were changed in the selected species containing docasahexaenoic acid (DHA). Stearyl-docasahexaenoyl and stearyl-docasapentaenoyl PS species were reduced to 83±4 % whereas both species in PA were increased to about 149±5%. A 3-5 fold increase in the levels of monolyso-phospholipid species was observed after TBI in all the phospholipid classes except lysophosphatidylglycereol and lysophosphatidic acid. Among fatty acid oxidation products, all octadecanoids, eicosanoids and docosanoids were increased more than 10-fold, whereby the changes in docosanoids correlated with the reduction in PS and increase in monolyso-PS species stoichiometrically (in all experiments and groups $n=4$, $p<0.05$). These results are consistent with a reduction in mitochondrial content after TBI, likely through mitophagy. Moreover, permanent activation of phospholipase A_2-driven mechanisms up to 24hr post injury may have mediated the phosphatidylserine specific production of DHA-derived mediators contributing to maintenance of cellular homeostasis after TBI.

Title: HB-GAM overcomes the CSPG-dependent inhibition of neurite growth and cell attachment

Authors: *M. N. PAVELIEV, H. RAUVALA;
Neurosci. Ctr., Univ. of Helsinki, Helsinki, Finland

Abstracts: Chondroitin sulfate proteoglycans (CSPG) are the glial scar components that inhibit posttraumatic nerve regeneration in the mammalian central nervous system. Here we demonstrate that the extracellular matrix-associated protein HB-GAM (also known as pleiotrophin) overcomes the CSPG-dependent inhibition of neurite growth and cell attachment in cortical and hippocampal neurons from neonatal mice and from rat embryos and in the PC12 cell line. Both substrate-precoated and soluble forms of HBGAM exhibit this effect. Moreover HB-GAM rescues neurite growth in neuronal cultures primed on CSPG for 1.5 days before the addition of HB-GAM. The HB-GAM receptor N-Syndecan is not required for the neurite growth-promoting effect of HBGAM in the presence of CSPG as the effect is preserved in N-Syndecan KO mice. Our results indicate that HBGAM may have therapeutic potential for the treatment of the regeneration failure in the injured human CNS. We are currently working on the *in vivo* proof of concept in the mouse traumatic brain injury model.

Title: MicroRNAs regulate mitophagy induced by experimental traumatic brain injury

Authors: H. CHAO[1], X. XU[1], N. LIU[1], *J. JI[2];
[1]Nanjing Med. Univ., Nanjing, China; [2]Dept. of Envrn. and Occup. Hlth., Univ. of Pittsburgh, PITTSBURGH, PA

Abstracts: Mitophagy is a kind of reaction of eukaryotic cells when under pressure . In previous research , interaction of cadiolipin and LC3 (microtubule-associated-protein-1 light chain 3) is important for mitophagy induced . But the mechanism for the regulation of these remains unknown . And MicroRNA have key roles in normal CNS development and function, as well as

in disease condition . Based on previous study, mitophagy can be detected after stretch in the primary cortical neurons . In the current report, we found that one hour after mechanical stretch in primary cortical neurons MiR-137, MiR-21, and MiR-10 significantly decreased compared with sham controls . And the mechanical stretch induced mitophagy can be suppressed by overexpression of MiR-137, MiR-21, and MiR-10 . When the neurons were transfected with cadiolipin synthase (CLS), mechanical stretch only caused significant decrease of MiR-137 but not MiR-21 and MiR-10 . Our results suggested that MiR-137 might regulate neuronal mitophagy via CLS-LC3 pathway. Further detailed mechanism about the miRNA and mitophagy after stretch needs to be clarified .

Title: Cold environment exacerbates brain pathology and oxidative stress following traumatic brain injuries. Potential therapeutic effects of nanowired antioxidant H-290/51

Authors: *A. SHARMA[1], D. F. MURESANU[2], P.-O. SJÖQUIST[3], Z. TIAN[4], H. S. SHARMA[5];
[1]Uppsala Univ., Uppsala, Sweden; [2]Clin. Neurosciences, Univ. of Med. & Pharm., Cluj-Napoca, Romania; [3]Div. of Cardiology, Dept. of Med., Karolinska Institute, Karolinska Univ. Hosp., Stockholm, Sweden; [4]Chem. & Biochem., Univ. of Arkansas, Fayetteville, AR; [5]Surgical Sciences, Anesthesiol. & Intensive Care Med., Uppsala Univ. Hosp., Uppsala, Sweden

Abstracts: Traumatic brain injuries (TBI) are one of the most devastating causes of death and disability across the World. Our soldiers are the most vulnerable to TBI either during peacekeeping or combat operations even at extreme hot and cold environments. Some reports suggest that hyperthermia following TBI is harmful but so far no studies are conducted on the effects of cold environment on the pathophysiological outcomes of TBI. In present investigations we examined the effects of cold environment on TBI in our rat model with regard to generation of oxidative stress and brain pathophysiology. In addition, we also evaluated the effects of a potent antioxidant compound H-290/51 with or without TiO2 nanowired drug delivery on the pathophysiology of TBI in cold environment as compared to room temperature. TBI was inflicted under Equithesin anesthesia in Wistar Male rats over the right parietal cortex by making an incision of 2 mm deep and 4 mm long after opening of the skull bone (ca. 4 mm diameter, area 12.56 mm2). The animals were allowed to survive 48 h after TBI. To understand the effects of cold environment animals were exposed at 5°C for 3 h daily for 5 weeks before injury. The control groups were maintained at normal room temperature (21±1°C). In these animals oxidative stress parameters e.g., Leucigenin (LCG), Luminol (LUM), Malondialdehyde (MDA) and Glutathione (GTH) were measured in the brain along with blood-brain barrier (BBB) breakdown, brain edema formation and neuronal injuries using standard procedures. Our observations show that TBI in animals subjected to cold environments resulted in about 80 to 190 % increase in LCG, LUM and MDA and 220 % decrease in GTH in the brain as compared to rats subjected to TBI at room temperature. The magnitude and intensity of BBB breakdown to radioiodine and Evans blue albumin, edema formation and neuronal injuries were also exacerbated in TBI group in cold by 120 to 280 % from the injured group placed at room temperature. Nanowired delivery of H-290/51 (50 mg/kg) 6 to 8 h after TBI in cold group was able to significantly thwart brain pathology and oxidative stress whereas normal delivery of H-290/51 failed to achieve any reduction in oxidative stress or brain pathology following TBI in this cold exposed group. However, normal delivery of H-290/51 at identical periods significantly reduced the oxidative stress and brain pathology following TBI at room temperature. These observations are the first to demonstrate that cold aggravates the pathophysiology of TBI and this could be partially due to an enhanced production of oxidative stress in cold environment, not reported earlier.

Title: Tio2 nanowired dl-3-n-butylphthalide (dl-nbp) delivery, a chinese traditional medicine profoundly attenuates blood-brain barrier disruption, brain edema formation and neuronal injuries following concussive head injury

Authors: *L. FENG[1], A. SHARMA[2], H. YIN[3], J. V. LAFUENTE[4], H. S. SHARMA[2];
[1]Neurol., Bethune Intl. Peace Hosp., Hebi Province, China; [2]Surgical Sciences, Anesthesiol. & Intensive Care Med., Uppsala Univ. Hosp., Uppsala, Sweden; [3]CSPC NBP Pharmaceut. Med., Shijiazhuang, China; [4]Neurosciences, Univ. of Basque Country, Bilbao, Spain

Abstracts: The DL-NBP is an extract from Chinese celery and is used in stroke patients showing marked improvement in their cognitive and mental health. Since concussive head injury (CHI) is often fatal in more than 90% of cases involving our soldiers in the battlefield and the remaining 10 % of cases show lifetime disability there is an urgent need to find out better therapeutic use of novel medicine or use of available medicine in a more effective way. Keeping these views in mind we wanted to explore the role of DL-NBP in CHI using nanodrug delivery employing TiO2 nanowires in our rat model of CHI that induced profound brain pathology similar to that of clinical cases. The CHI was induced by dropping a weight of 114.6 g on the right parietal skull bone over a distance of 20 cm in anesthetized rats resulting an impact of 0.224 N on the skull surface. This impact induces severe brain pathology over 4 h to 24 h. In our model CHI inflicted arts were allowed to survive either 8 h or 24 h after trauma. In these CHI inflicted rats blood-brain barrier (BBB) disruption to Evans blue and radioiodine and brain edema formation was measured after 4 h, 8 h, 12 h and 24 h survival. The neuronal damages were also examined at each time point using histological techniques. We observed a progressive increase in the BBB breakdown from 4 h after CHI that continued to enhance by 200 % at 8 h, 400 & after 12 h and 600 & at 24 h after injury. The neuronal damages were also showed massive increase by 8 h after CHI (+4 to 6 fold) followed by 7 to 8 fold at 12 h and 9 to 10 fold at 24 h in the cortical and subcortical areas. There was a voluminous increase in brain swelling by 1 % at 4 h, 2 % at 8 h, 4% at 12 h and 6 % at 24 h as compared to intact controls. In separate group of rats with CHI, we administered NBP (40 or 60 mg/kg, i.p.) 2h and 4 h after injury in 8 h survival group and 8 h and 12 h after trauma in 24 h survival group. We found that NBP in 40 mg was able to reduce BBB

breakdown, brain edema formation and brain pathology after 8 h CHI, whereas, 60 mg dose of NBP was needed for identical neuroprotection in 24 h CHI group. Interestingly, TiO2 Nanowired NBP requires only 20 mg/kg in 8 h group and 40 mg/kg NBP in 24 h group for effective neuroprotection indicating a potential enhanced effectiveness of DL-NBP following TiO2 nanowired delivery in CHI. These observations are the first to point out a new role of DL-NBP in treating CHI with regard to pathophysiology of brain injury. Furthermore, the nanowired delivery of NBP is far superior to NBP alone, not reported earlier.

Title: Nanowired delivery of histamine receptor antagonists attenuate nitric oxide synthase upregulation and spinal cord pathology following trauma

Authors: *R. PATNAIK[1], A. SHARMA[2], J. V. LAFUENTE[3], D. F. MURESANU[4], A. NOZARI[5], H. S. SHARMA[2];
[1]Indian Inst. of Technology,Banaras Hindu Univ., Varanasi, India; [2]Surgical Sciences, Anesthesiol. & Intensive Care Med., Uppsala Univ. Hosp., Uppsala, Sweden; [3]Neurosciences, Univ. of Basque Country, Bilbao, Spain; [4]Clin. Neurosciences, Univ. of Med. & Pharm., Cluj-

Napoca, Romania; [5]Anesthesiol. & Critical Care Ctr., Massachusetts Gen. Hospital, Harvard Med. Sch., Boston, MA

Abstracts: The possibility that histamine receptors could modulate cell damage in spinal cord injury (SCI) is investigated in this study using nanowired delivery of selected Histamine H1, H2 and H3 receptor modulating drugs. There are reasons to believe that histamine receptors could influence SCI pathology either through direct mechanisms or via upregulation of nitric oxide synthase (NOS). In present investigation we explored whether drugs influencing histamine H1, H2 and H3 receptors could modify SCI induced cord pathology through modification of neuronal NOS expression in our rat model. A focal trauma to the rat spinal cord was made by making an incision into the right dorsal horn of the T10-11 segments and the animals were allowed to survive 5 h after injury. This SCI significantly increased the spinal cord edema formation, BSCB breakdown to protein tracers and induced a marked reduction in the SCBF in the T9 and T12 segments. Pronounced upregulation of nNOS is seen in these segments at 5 h together with cell death and cord pathology. TiO2-Nanowired delivery of histamine H1 receptor antagonist mepyramine (1 mg, 5 mg and 10 mg/kg, i.p,) did not attenuate spinal cord pathology or nNOS expression following SCI. On the other hand, blockade of histamine H2 receptors with nanowired cimetidine or ranitidine (5 mg) 30 min after trauma significantly reduced these early pathophysiological events and nNOS expression. However, normal drug require 10 mg/kg doses for similar neuroprotection. The effects of normal or nanowired ranitidine were far superior in attenuating SCI pathology and nNOS upregulation. Nanowired delivery of histamine H3 receptor agonist α-methylhistamine (1 mg/kg/i.p.), that inhibits histamine synthesis and release in the CNS is able to thwart SCI pathology and nNOS expression significantly in the non-injured T9 and T12 segments. Whereas normal dose of histamine H3 agonist (2 mg) is needed for the same effects. On the other hand, blockade of Histamine H3 receptors with nanowired Thioperamide (1 mg) or normal drug (at 1 or 5 mg/kg, i.p.) exacerbated the spinal cord pathology and NOS expression. These observations are the first to suggest that stimulation of H3 receptors and blockade of H2 receptors attenuates nNOS expression and thereby induce neuroprotection in SCI. Nanowired delivery of right drug in low doses are able to thwart SCI pathology whereas, higher dose of the normal drug is needed to have similar effects. Taken together, our results indicate that histamine induced pathophysiology of CNS injury is mediated via nNOS expression, not reported earlier.

Title: Superior neuroprotective effects of nanowired delivery of AP-713 as compared to AP-173 and AP-364 compounds on functional recovery and cellular injuries following spinal cord trauma

Authors: *A. K. PANDEY[1], A. SHARMA[2], J. V. LAFUENTE[3], Z. TIAN[4], D. F. MURESANU[5], R. PATNAIK[6], T. LUNDSTEDT[7], E. SEIFERT[8], H. S. SHARMA[2]; [1]Senior Res. Neurosciences, Univ. of Med. & Pharm., Cluj-Napoca, Romania; [6]Biomaterials, Biomed. Engin., Indian Inst. of Technology, Banaras Hindu Univ., Varanasi, India; [7]Medicinal Chem., Uppsala Univ., Uppsala, Sweden; [8]Acure Pharma, Uppsala, Sweden

Abstracts: In our laboratory drugs attached to TiO2 nanowires causes enhanced delivery of compounds resulting in increased therapeutic efficacy. This investigation was undertaken to know whether any drug attached to nanowires might have better therapeutic efficiency in a model of rat spinal cord injury (SCI). We used 3 different compounds AP-173, AP-713 and AP-364 (Acure Pharma, Sweden) with different neuroprotective efficacy. These compounds were TiÖ2-nanowired and delivered following SCI in rats and compared with normal compounds. The SCI was produced by making a longitudinal incision into the right dorsal horn of the T10-11 segments under Equithesin anesthesia. In separate group of rats these compounds either alone or tagged with nanowires were applied topically within 5 to 10 min after SCI and allowed to survive 12 h. In these animals, behavioral outcome, blood-spinal cord barrier (BSCB) permeability, edema formation and cell injury were examined. The SCI resulted in severe motor paralysis, widespread disruption of the BSCB to Evans blue albumin (EBA), [131] Iodine tracers and exhibited profound edema formation. Cell or tissue destruction was present around the lesion

site extending up to T4 and L2 levels. Topical application of normal compounds in high quantity (10 µg in 20 µl) markedly attenuated behavioral dysfunction that are prominent around 2-3 h after SCI. BSCB disruption, edema formation and nerve cell, glial cell and axonal injuries are less pronounced in drug treated injured animals at 12 h. These beneficial effects are most marked in animals that received AP-713. Interestingly, when these compounds were administered with nanowires, their beneficial effects on functional recovery and spinal cord pathology were further enhanced. Thus, nanowired AP-713 attenuated functional disturbances up to 5 h after SCI. Spinal cord cell and tissue destruction was minimal in this group at 12 h. The other nanowired compounds were not that effective. Topical administration of nanowires alone did not influence spinal cord pathology or motor function after SCI. Taken together, our results are the first to demonstrate that the drug-delivery and their therapeutic efficacy is enhanced when the compounds are administered with nanowires depending on their inherent property and not due to nanowiring alone.

Title: Perivascular basement membrane proteins changes long-term after a juvenile traumatic brain injury: Possible link with amyloid-beta accumulation

Authors: *A. JULLIENNE[1,2], J. BADAUT[2,3,4], J. ROBERTS[5], V. POP[2], M. P. MURPHY[5], E. HEAD[5], W. J. PEARCE[1], G. J. BIX[5];

Abstracts: Traumatic brain injury (TBI) is a leading cause of death and disabilities and it induces several neurovascular unit (NVU) dysfunctions including BBB disruption. We previously showed that, even when the BBB is no longer disrupted, a juvenile TBI leads to long-term transformations of endothelial cells with a decrease of P-glycoprotein (P-gp), associated with amyloid-β (Aβ) accumulation 2 months after injury in a rat model of cortical impact. These results led us to the hypothesis that a juvenile TBI causes long-term transformations of the NVU, leading to neurodegeneration-like processes. Here, we studied P-gp expression and Aβ accumulation up to 6 months after injury but we also focused on post-TBI (2 and 6 months) changes of 2 basement membrane proteins, perlecan and fibronectin, known to be implicated in perivascular drainage of Aβ. We used a model of controlled cortical impact in P17 rat and immunohistochemistry led us to the observation that, even after 6 months, when cognitive dysfunctions are emerging, Aβ accumulation and P-gp decreased expression are still present. Meanwhile, perlecan and fibronectin immunostaining are increased around cerebral blood vessels in injured animals after 2 and 6 months, suggesting their possible implication in Aβ accumulation. Interestingly, perlecan and fibronectin have also been shown to have neuroprotective and pro-angiogenic properties. So this increase could be a compensatory mechanism aiming at protecting the NVU. We investigated whether there is angiogenesis but the number of vessels was not different between naïve and TBI animals at both time points. However, we observed a decrease in the diameter of cerebral blood vessels at 2 and 6 months after the impact. These results support the hypothesis that a juvenile TBI induces long-term modifications of the cerebrovasculature that could compromise cerebral blood flow and cerebral integrity in the case of a future injury.

Title: Serum Amyloid A1 is induced in the liver following traumatic brain injury

Authors: S. VILLAPOL[1], D. KRYNDUSHKIN[1], M. BALAREZO[1], A. CAMPBELL[1], J. SAAVEDRA[2], F. P. SHEWMAKER[1], *A. J. SYMES[1];
[1]Pharmacol., USUHS, BETHESDA, MD; [2]Pharmacol., Georgetown Univ., Washington, DC

Abstracts: Pathological events associated with traumatic brain injury (TBI) affect many peripheral tissues, with the potential that the peripheral response could influence recovery of the brain. The liver mounts an acute phase response to many different forms of trauma, infections and inflammation including in response to TBI. We have previously shown that angiotensin II AT1 receptor (AT1R) blockers (ARBs) ameliorate detrimental morphological and functional outcomes from TBI. As AT1Rs are highly expressed in hepatic parenchyma we hypothesized that angiotensin II, acting through the AT1R in hepatic tissue may influence the hepatic response to TBI. To test our hypothesis, we performed controlled cortical impact (CCI) injury on 9-week-old male mice and treated with the ARB, telmisartan (1 mg/kg/day, starting 1 hour after injury) or saline. Mice were sacrificed at 6 hours (hpi), 1, 3, 7, and 30 days post injury (dpi). We focused on the hepatic synthesis of Serum Amyloid A1 (SAA1), a protein that is strongly induced in the acute phase response, is released into the circulation and is a powerful proinflammatory mediator. Hepatic expression of SAA1, AT1R, and pro-inflammatory cytokines were analyzed by QPCR, western-blot or immunohistochemistry. Hepatic expression of AT1AR mRNA was increased at 3dpi, but not at earlier time points. SAA1 was rapidly induced after TBI, with SAA1 mRNA increasing over 50 fold by 6 hpi, reaching a maximum of 145 fold by 1dpi, and decreasing to 14 fold induction by 3dpi. Telmisartan treatment reduced hepatic SAA1 mRNA and protein in the liver only at 3dpi, but not at earlier time points. Increased SAA1 expression was also detected in the serum. Immunohistochemical analysis indicated that SAA1 was colocalized with a marker for cholangiocytes at 3 dpi. We also detected increased hepatic expression of mRNA encoding the pro-inflammatory cytokines CXCL1 and CXCL10 at 6 hpi, but not CCL2, IL-6 or IFN-gamma. Interestingly, there was increased neutrophil infiltration into the liver after TBI, detected by staining for myeloperoxidase. We also found increased numbers of apoptotic cells by TUNEL staining at 3 dpi. These effects were not altered by telmisartan treatment. Thus we have shown that there is a strong hepatic response to TBI that includes induction of specific cytokines and the acute phase protein SAA1. Telmisartan can modulate SAA1 expression at 3dpi, which coincides with the induction of AT1R mRNA suggesting that any modulation by angiotensin may occur at later time points. Hepatic induction of SAA1 after TBI may contribute to the neuroinflammation that is an important component of the response to TBI.

Title: The cerebral cortex proteome in rodent models of fear conditioning and repetitive blast

Authors: *A. M. BOUTTE[1], J. GUINGAB-CAGMAT[3], E. MAUDLIN-JERONIMO[4], Y. CHEN[4], L. SIMMONS[5], S. AHLERS[4], R. GENOVESE[5], F. TORTELLA[2], K. SCHMID[2], J. DAVE[2];
[1]Neurosci. and Psychiatry, [2]Brain Trauma Neuroprotection and Neurorestoration Branch, Ctr. for Military Psychiatry and Neuroscience, Walter Reed Army Inst. of Res., Silver Spring, MD; [3]Banyan Biomarkers, Inc., Alachua, FL; [4]Dept. of Neurotrauma, Operational and Undersea Med. Directorate, Naval Med. Res. Ctr., Silver Spring, MD; [5]Behavioral Biol. Branch, Ctr. for Military Psychiatry and Neuroscience, Walter Reed Army Inst. of Res., Silver Spring, MD

Abstracts: Objective. Mild traumatic brain injury (mTBI) and post-traumatic stress disorder (PTSD) remain serious medical issues for active duty service members and veterans. However, little is known about their underlying mechanisms. This study characterizes changes in the rodent cerebral cortex proteome in a model of conditioned fear and/or blast over-pressure (BOP). Methods. Using male Sprague-Dawley rats, inescapable electric shock (IES) and repetitive blast over-pressure (75kPa BOP/day X 3 days) were used as models of stress or mTBI, respectively (Genovese et. al, 2013). Experimental groups: (1) sham IES + sham BOP (SS), (2) IES + sham BOP (IS), (3) sham IES + BOP (SB), and (4) IES + BOP (IB). Cerebral cortex peptides were generated by in-gel tryptic digest and analyzed by nLC-MS/MS on a Thermo LTQ Velos. Searches and peptide assembly were performed using Sequest/Scaffold (SQ-SCF) or Myrimatch/IDPicker (MM-IDP), FDR<0.05%. Spectral count was determined using Prism (t-Test, $p \leq 0.05$). Ontology was conducted with WebGestalt and is expressed as the ratio of enrichment (R-value,$p \leq 0.05$). Pathways were derived from Pathway Studios analysis. Results. We defined the cerebral cortex proteome using two platforms in order to increase protein identification fidelity and determine which proteins and ontological groups were affected in experimental groups compared to sham controls. Venn diagram analysis of proteins identified with MM-IDP and SQ-SCF database searching identified 1101 unique proteins that were common to all experimental groups. Gene ontology analysis revealed that, overall, these proteins mapped to platelet-activating factor acetyl-transferase activity, and glutamate decarboxylase

activity (R=22.52). Other categories were lactate dehydrogenase activity (R=15.02) and peroxiredoxin activity (R=12.51). The number of differentially abundant proteins varied with condition. IES alone or BOP alone led to abundance changes in 50 and 32 proteins, respectfully. IES followed by BOP led to abundance changes of 14 proteins. Interestingly, each condition influenced specific biological processes pathways. Small molecule metabolism (16%) dominated IES. Transport (7%) and small molecule metabolic process (6%) were affected by BOP. In IES with BOP, most proteins sorted to platelet activation and blood coagulation as well as axon guidance (3%, each). Studies are in progress to determine which disease pathways are identified by IES, BOP, and IES followed by BOP. Conclusions. A greater understanding of unique changes in the brain proteome as a consequence of stress and blast will pave the way for novel biomarker discovery and therapeutics relevant to PTSD and mTBI.

Title: MALDI analysis of lysophosphatidic acid levels after experimental traumatic brain injury in the rat

Authors: *W. S. MCDONALD[1], R. R. DRAKE[2], J. WOJCIAK[3], A. J. MORRIS[4], E. E. JONES[2], R. A. SABBADINI[3], N. G. HARRIS[1];
[1]Neurosurg., Univ. of California, Los Angeless, Los Angeles, CA; [2]Dept. of Pharmacol., Med. Univ. of South Carolina, Charleston, SC; [3]Lpath Inc., San Diego, CA; [4]Univ. of Kentucky Col. of Med., Lexington, KY

Abstracts: Many traumatic brain injured (TBI) patients sustain permanent physical, cognitive and emotional disabilities that persist throughout their lives. The natural response of the brain to TBI suggests a specific molecular system may be involved in injury pathogenesis as well as limit functional recovery. Lysophosphatidic acid (LPA) is a bioactive phospholipid that increases in the CSF after injury and alone, can activate initial injury responses like cell death and inflammation. In the brain, there are several LPA species involved in physiological processes but

after injury the specific LPA species that's modulated and the brain regions affected by these molecular changes have not been identified. Determining the specific molecular changes that underlie secondary injuries of trauma is essential to developing targeted therapeutics for TBI that can promote cognitive and physical recovery. To bridge this gap in knowledge we've utilized Matrix-Assisted Laser Desorption Ionization imaging mass spectrometry (MALDI -IMS) to identify the regional- and species-specific changes of LPA in the brain after TBI. Brains were obtained from adult, CD1 male rats at 3 hours after controlled cortical impact (CCI), aged-matched naive rats were used as controls. The brains were harvested, sectioned and MALDI spectra collected for each 50 micron tissue location using a Bruker Daltonic Solarix 7T mass spectrometer. The identities of the analyte molecules were confirmed by on-tissue collision induced fragmentation, and each was co-localized to adjacent H&E stained coronal sections. The results revealed an approximate 1.5-fold increase in LPA 18:1 species in the contralateral white matter and contralateral CA1 and CA3 as compared to control. Significant increases in LPA precursors Lysophosphatidylcholine (LPC) and Lysophosphatidylethanolamine (LPE) within the hippocampus and white matters regions were also identified in the injured brains. This data suggests that within 3 hours after injury molecular changes in LPA production within the hippocampus and white matter tracts may contribute to the long terms cognitive and motor disabilities associated with TBI. This study has provided much needed insight into the early molecular changes that may underlie the longer-term effects of TBI.

Title: Glucose-dependent insulinotropic polypeptide (GIP) ameliorates traumatic brain injury-induced memory deficits in rats

Authors: *Y. YU[1], T.-H. HSIEH[2,3], J.-H. LAI[4,3], K.-Y. CHEN[2,3], J.-W. LIN[4], Y.-H. CHIANG[2,3,4];
[2]Grad. Inst. of Neural Regenerative Medicine, Col. of Med. Sci. and Technol., [3]Ctr. for Neurotrauma and Neuroregeneration, [4]Dept. of Surgery, [1]Taipei Med. Univ., Taipei, Taiwan

Abstracts: Mild traumatic brain injury (mTBI) becomes a major public health issue that represents 75-90 % of all treated TBI cases. mTBI leads to various cognitive, emotional and physical and sleep-related symptoms for a period of time. To date, no clear pharmaceutical-based therapies are used to manage the development of pathological deficits associated with mTBI. Glucose-dependent insulinotropic polypeptide (GIP), an incretin similar to glucagon-like peptide-1(GLP-1), showing potential for providing neurotrophic and neuroprotective effects. In this study, we aim to investigate the impact of GIP on cognitive deficits induced by mTBI *in vivo* animal model. An mTBI rat model generated by mild controlled cortical impact (mCCI) were used to evaluate the therapeutic potential of GIP. Time-course analysis of learning and memory ability following mTBI were tested by Morris water maze (MWM) and novel object recognition (NOR) for identifying the therapeutic effects of GIP in cognitive function. In results, mTBI animals showed that the impaired long-term memory were observed following mTBI lesion under the tests of MWM and NOR. When compared to the saline-treated group, administration of GIP were significantly ameliorated mCCI-induced memory deficits. We thus conclude GIP produces significant beneficial effects in memory recovery after mTBI. With the identities of neuromodulatory role of GIP in the future preclinical studies, our results may provide mechanistic insights on the development of novel strategy of GIP for mTBI treatment in the near future.

Title: TBI-induced memory deficits are fully rescued by cannabinoid receptor agonist administration

Authors: M. B. ARAIN[1], L. A. CRAIG[2], *S. T. NAKANISHI[3];
[1]Alberta Children's Hosp. Res. Inst., Calgary, AB, Canada; [2]Regeneration Unit in Neurobio., Calgary, AB, Canada; [3]Dept. of Physiol. and Pharmacol., Univ. Calgary, Calgary, AB, Canada

Abstracts: A traumatic brain injury (TBI) is caused by a force applied to the head, resulting in damage to neural tissue. TBIs are among the most common sources of disability in young adults and are often associated with sport-related impacts or motor vehicle accidents. A moderate or severe TBI often leads to long-term cognitive challenges including learning and memory deficits, for which there are no known effective treatments. The endocannabinoid system has diverse physiological functions and is involved in reward pathways, appetite, anxiety, synaptic plasticity, and bioenergetics. In the context of a TBI, cannabinoid 1 receptors (CB1Rs) are a potentially interesting target because the activation of CB1Rs could counteract several of the known pathological processes initiated by a TBI including excitotoxicity, neuroinflammation, and changes in bioenergetics. We tested the hypothesis that administration of a CB1R agonist would prevent TBI-induced deficits in learning and memory in young adult male Sprague-Dawley rats. Using the controlled cortical impact TBI model (5mm diameter impact head, 4.0 m/s velocity, 2.5mm depth, 100ms duration), we replicated previously reported results showing that rats with a TBI (n=8) show deficits in short-term memory (Novel Object Discrimination Test) and spatial learning and memory (Morris Water Task). We administered a CB1R agonist (ACEA, 2mg/kg) daily for one week after the injury in a second group of animals with TBI (n=8), and conducted the same behavioral tests 2 weeks post-surgery. We found that the TBI + CB1R agonist-treated animals spent significantly more time exploring a new object in their environment than the TBI-only animals in the Novel Object Discrimination Test (One-way ANOVA, $p<0.01$, with Tukey post hoc tests) and that the performance of TBI + CB1R agonist-treated animals was indistinguishable from the sham surgery-drug (n=6) or sham surgery-vehicle (n=7) groups, and naïve animals (n=4). Similarly, in the Morris Water Task, TBI + CB1R agonist treated animals were significantly better at finding the hidden escape platform after five days of training than TBI-only animals (One-way ANOVA, $p<0.0001$, with Tukey post hoc tests). Once again, the performance of TBI + CB1R agonist-treated animals was indistinguishable from sham surgery-drug (n=6), or sham surgery-vehicle, and naïve animals (n=4). These results demonstrate that CB1R activation rescues learning and memory functions after a moderate-to-severe TBI in young adult rats.

Title: Enriched environment can prevent most behavioral alterations induced by different schedules of noise exposure

Authors: S. J. MOLINA[1], M. SAINT-MARTIN[1], F. CAPANI[2], *L. R. GUELMAN[1]; [1]Dept. Farmacologia, Fac Med, UBA-CEFYBO-CONICET, Buenos Aires, Argentina; [2]Lab. de plasticidad y citoaerquitectura neuronal, ININCA-CONICET, Buenos Aires, Argentina

Abstracts: It is known that acute noise exposure can induce transient or permanent hearing loss. However, few data are available regarding its effects on extra-auditory structures, in particular within developing Central Nervous System (CNS). Previous studies of our laboratory showed that exposure of 15-days-old rats to moderate noise during 2 hours can induce hippocampus (HC)-related behavioral, biochemical and histological alterations, including changes in anxiety-like behaviors. Nevertheless, no data on the behavioral effects induced by noise in other exposure schedules have been obtained yet. Moreover, since the use of potential strategies of neuroprotection has not been explored in our model, rearing noise-exposed animals in an enriched environment (EE) was used as a non-pharmacological tool. Therefore, the aim of the present work was to test if EE can prevent behavioral changes induced by exposure to noise using different exposure schedules. Rats of 15 days were exposed during 2 hours to white noise (95-97 dBA), for one or five consecutive days, using an “ad-hoc” sound camera. After weaning, groups of 3-4 rats were transferred to an enriched cage, consisting of toys, a wheel, tunnels and ramps, while other groups were placed in standard cages. One week later, different behavioral tests were performed, including open field (OF), elevated plus maze (EPM) and inhibitory avoidance (IA) tasks. Results show that whereas no changes in associative or habituation memory were found in rats exposed to noise for 2 h, significant changes were observed when rats were exposed for 5 consecutive days. In addition, a decrease in anxiety-like behaviors was observed in both groups, which could be interpreted as a maladaptive behavior. Rearing rats in EE almost fully prevented these noise-induced behavioral changes. These findings suggest that visual, social and/or physical stimulation during the peri-adolescence period, after exposure to a physical agent such as noise, might contribute to stabilization of normal emotional and behavioral parameters.

Title: Novel allosteric inhibitors of TNF-R1 modulate post-traumatic sleep resulting from experimental diffuse TBI in the mouse

Authors: R. K. ROWE[1], J. L. HARRISON[2,1], H. ZHANG[3], D. P. HESSON[3], M. GREENE[3], *J. LIFSHITZ[1,2];
[1]Barrow Neurolog. Inst., Phoenix Children's Hosp., Phoenix, AZ; [2]Neurosci., Arizona State Univ., Tempe, AZ; [3]Pathology and Lab. Med., Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA

Abstracts: Clinical studies indicate as many as 70% of traumatic brain injury (TBI) survivors suffer from sleep-wake disturbances. We have previously shown diffuse TBI acutely (1-6 hours post-injury) increases sleep in the mouse_a phenomenon we termed post-traumatic sleep. During this acute window of post-traumatic sleep, cortical levels of inflammatory cytokine tumor necrosis factor-α (TNF-α) were significantly increased, suggesting a relationship between inflammation, sleep regulatory cytokines and sleep. In this study, we administer three novel allosteric inhibitors of TNF receptor 1 (TNF-R1) to test their effect on post-traumatic sleep in the mouse following diffuse TBI. We hypothesize that the administration of TNF-R1 inhibitors immediately following TBI will modulate post-traumatic sleep in the mouse through suppression of neuroinflammatory signaling. In these experiments, adult male C57Bl/6 mice were subjected to moderate midline fluid percussion injury (n=26; 1.3 atm; 6-10 min righting reflex) or sham injury (n=7). Cohorts were divided into groups receiving either high (20 mg/kg) or low (2 mg/kg) doses of novel TNF-R1 inhibitors (Compound 7, SGT11, F002) or vehicle (10% DMSO in PBS). Immediately following TBI or sham injury, mice were given intraperitoneal injections of a TNF-R1 inhibitor or vehicle. Post-traumatic sleep was recorded via non-invasive piezoelectric sleep cages. After 6 hours, mice were euthanatized and cortical biopsies were collected for analysis of cytokine levels by ELISA. From 3 to 6 hours post-injury, vehicle-treated brain-injured mice exhibited increased post-traumatic sleep compared to vehicle-treated uninjured shams ($F(1,11)=11.56$, $p=0.0059$). Brain-injured mice treated with high dose

Compound 7 (F(1,9)=2.115, p=0.1798) low dose Compound 7 (F(1,7)=4.525=0.0710), or low dose F002 (F(1,9)=1.656, p=0.2303) showed no significant difference in post-traumatic sleep compared to vehicle-treated uninjured shams, suggesting a positive drug effect. However, brain-injured mice treated with SGT11 and high dose F002 slept similarly to vehicle-treated brain-injured mice. These data indicate that injury-induced post-traumatic sleep can be decreased by allosteric inhibition of TNF-R1. Compound 7 and low dose F002 decreased post-traumatic sleep to vehicle-treated uninjured sham levels. Further analysis of cortical cytokine levels will confirm TNF inhibition. These preliminary studies will guide future investigation of these novel compounds on functional and pathological outcomes following diffuse TBI in the mouse, potentially identifying a therapeutic intervention for sleep-wake disturbances following TBI.

Title: Effects of tamoxifen in hindlimb kinematics after a penetrating injury in CA1 hippocampal region

Authors: *J. R. LOPEZ RUIZ[1], L. P. OSUNA CARRASCO[1], B. DE LA TORRE VALDOVINOS[1], N. E. FRANCO RODRIGUEZ[1], C. R. MOYA GARCÍA[2], I. JIMÉNEZ[4], J. M. DUEÑAS[1], S. DUEÑAS[3];
[1]Fisiología, [2]Ciencias computacionales, [3]Neurociencias, Univ. De Guadalajara, Guadalajara, Mexico; [4]Fisiología, Biofísica y Neurociencias, CINVESTAV, México DF, Mexico

Abstracts: Tamoxifen recovers many hindlimb kinemtic parameters after a hippocampal penetrating injury, these effects were clearly observed 30 days after injury1. The present experiments were made in rats to study both, hindlimb kinematic changes and morphologic alterations produced by a penetrating injury in hippocampal CA1 region, and to study tamoxifen effects (1 mg/kg applied for three days) in kinematic changes and neuron survival 30 days after injury. Angular changes in kneee and ankle ocurred in non treated animals 30 days after injury. In trated animal, similar angular changes were observed. Tamoxifen produced an statistical significant recovery in the ipsilateral maximal knee angle. The number of pyramidal neurons in CA1 region is greater in treated vs untreated rats. The better outcome in kinemetics recovery produced by tamoxifen in hippocampal injury seems to be related to a larger number of pyramidal neurons compared to non treated animals. The injured CA1 produced more restricted kinematic changes than when the dentate gyrus was damaged. Experiments are under analysis to value the tamoxifen effects in forelimb kinematics after CA1 hippopcampus penetrating injury.

Title: A strategy to restore brain circuitry using micro-tissue engineered neural networks

Authors: *J. P. HARRIS[1,2], L. A. STRUZYNA[1], P. L. MURPHY[1], D. K. CULLEN[1,2]; [1]Neurosurg., Univ. of Pennsylvania, Philadelphia, PA; [2]Philadelphia Veterans Affairs Med. Ctr., Philadelphia, PA

Abstracts: Disruption of the connectome plays a prominent role in neurotrauma and many neurological diseases; however, there is currently no strategy to repair long-distance axonal connections in the brain. Therefore, we have developed micro tissue-engineering techniques to

create miniature tubular constructs containing discrete neuronal populations spanned by long integrated axonal tracts. Our previous work demonstrated that these preformed micro-tissue engineered neural networks (TENNs) stereotaxically delivered via a needle can reconstruct corticothalamic pathways in a rodent. Here, our objective was to minimize insertion trauma by creating an advanced biomaterial encasement strategy for needle-less delivery of micro-TENNs. The micro-TENNs were composed of a small hollow agarose hydrogel shell (≤700μm OD) filled with a laminin-collagen (350μm ID) extracellular matrix. Micro-TENNs were seeded with primary cortical neurons at the tube extremities to form defined populations connected by long bi-directional axonal tracts. Immunocytochemistry revealed that this neuronal and axonal architecture was maintained up to 21 days *in vitro*. Micro-TENNs were coated with low viscosity carboxymethyl cellulose (CMC) to enable needle-less delivery. The CMC becomes rigid with mild dehydration but softens upon brain insertion. Qualitatively, coated and uncoated micro-TENNs show similar architecture while coating had no effect on viability with nearly 100% live cells in both cases. We also assessed the insertion and buckling force of coated micro-TENNs to determine if the coating stiffness was sufficient for brain insertion. Penetration force was measured via an Instron mechanical tester and, based on previous work, 0.6% agarose was used to mimic the brain. We found that coated micro-TENNs were sufficiently strong to be implanted, withstanding ~900 mN before buckling while the insertion force needed was only ~21 mN. Uncoated micro-TENNs required a needle 60% bigger than coated micro-TENNs; therefore, we anticipate that this coated method will minimize insertion damage due to a reduced form factor. We are currently evaluating the host response and micro-TENN survival and integration following needle-less micro-TENN delivery. Micro-TENNs represent the first strategy capable of simultaneously providing neuronal replacement and re-establishing long-distance axon pathways, potentially facilitating nervous system repair following connectome disruption in TBI, Parkinson's disease, stroke, and brain tumor excision.

Title: Traumatic brain injury and posttraumatic epilepsy: *In vivo* neuroprotective role of M-type K+ channel

Authors: *S. M. BIERBOWER, M. S. SHAPIRO;
Physiol., Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstracts: Traumatic head injury (TBI) is a leading cause of death and disability among all age groups, occurring from a variety of causes, including car accidents, falls and battlefield events. Among the most common consequences of a TBI are seizures and development of epilepsy. Currently, there are few-to-none preventative treatments to prevent epilepsy after a TBI; a gap that this project seeks to address. In neurons throughout the brain, "M-type" K+ currents, underlied by the KCNQ family of ion channels, play dominant roles in control over excitability, and are thus implicated in myriad neurological and psychiatric disorders. Recently, the use of M-channel "openers" has emerged as novel anti-convulsive and anti-nociceptive compounds, and the FDA-approved drug, retigabine (RTG), is now in the clinic. However, beyond its anti-convulsive efficacy, we have shown in rodent models that RTG is neuroprotective against cell death, deleterious inflammation and motor impairment after a stroke, and we here show such a benefit after a TBI as well. Importantly, cytotoxic and vasogenic edema, neuronal death and morphological changes are all associated with acquired epilepsy after a TBI. Our data indicate that M-channel openers represent a novel and powerful anti-epileptogenic therapy that can prevent acquired seizures and epilepsy after a TBI, not solely by reducing electrical excitability, but by reducing the inflammatory and cell edema consequences of a TBI that are linked to irreversible brain damage. We are testing this hypothesis in mice with a controlled cortical impact "blunt force" TBI that best simulates trauma after vehicular accidents or falls. The effects of RTG on brain damage and pro-epileptic changes were assessed by video monitoring of seizure behavior and EEG recordings, and brain slice staining for fiber "sprouting" and loss of neuronal cell bodies in the hippocampus. Our data so far show strong effects of RTG administered within 30 min of a TBI, with a reduction in vasogenic edema and cell death by nearly half, compared to vehicle-only controls.

Title: A "NEET" mitochondrial target: The importance of mitoNEET in pioglitazone mediated neuroprotection following TBI

Authors: *H. M. YONUTAS[1], J. D. PANDYA[2], A. H. SEBASTIAN[2], W. J. GELDENHUYS[3], R. T. CARROLL[3], P. G. SULLIVAN[1];
[1]Spinal Cord and Brain Injury Res. Center/Anatomy and Neurobio. Dept., [2]Spinal Cord and Brain Injury Res. Ctr., Univ. of Kentucky, Lexington, KY; [3]Northeast Ohio Med. Univ., Rootstown, OH

Abstracts: A major focus has developed to discover neuroprotective therapeutic agents to help the estimated 1.7 million Americans who receive traumatic brain injury (TBI) annually. Due to the complicated nature of TBI, the most promising compounds target multiple mechanisms such as neuroinflammation, ROS production and mitochondrial dysfunction. Previous reports have shown that pioglitazone, a known PPAR agonist, can alter neuroinflammation and decrease ROS production. Additionally, pioglitazone has been found to increase mitochondrial bioenergetics, cortical sparing and functional recovery following TBI, which aligns well with our theory that mitochondrial dysfunction is a pivotal link in the neuropathological sequelae of brain injury. The positive effects seen with pioglitazone seem to be independent of interactions with PPAR and may be attributed to its ability to bind with a novel mitochondrial protein called mitoNEET. Therefore, we hypothesize that pioglitazone's neuroprotective mechanism is dependent on interactions with mitoNEET. To test this hypothesis we have used mitoNEET null mice and a novel mitoNEET ligand called NL-1. *Ex vivo* dose response studies show that pioglitazone can increase mitochondrial bioenergetics in isolated mitochondria with and without Ca2+ insult, which is an effect lost in the mitoNEET null mice. Next, wild-type and mitoNEET null mice (pioglitazone and NL-1 study) and Sprague Dawley rats (NL-1 study) who were subjected to sham or severe controlled cortical impact (CCI) TBI surgery. Preliminary results demonstrate that pioglitazone loses its ability to increase mitochondrial respiration and provide neuroprotection in mitoNEET null mice and that treatment with a specific mitoNEET ligand (NL-1) increases cortical sparing and motor recovery following TBI. Therefore, we believe pioglitazone to be a novel mitochondrial targeting drug which is able to alter mitochondria bioenergetics following TBI through interactions with mitoNEET. Results from these studies will help to shed light on the fundamental processes involved in TBI neuropathology and may pinpoint potential novel interventions and targets for the treatment of TBI.

Title: The membrane-resealing agent, Poloxamer 188, provides protection from blood brain barrier disruption and neuronal damage following traumatic brain injury

Authors: ***L. L. KRAFJACK**, D. P. FOX, R. RAGHUPATHI;
Drexel Univ. Col. of Med., Philadelphia, PA

Abstracts: Mechanically-induced pore formation (mechanoporation) within cell bodies and axons has been implicated as one of the early events of traumatic brain injury (TBI) that contributes to neurodegeneration and traumatic axonal injury. Previous studies demonstrated that intracerebroventricular (ICV) injection of the membrane-resealing agent, Poloxamer 188 (0.6mg in 5μL), prior to TBI decreased the extent of traumatic axonal injury in white matter tracts below the site of impact and in the thalamus at 4hr post-injury. The present study sought to determine the effect of Poloxamer 188 on neuronal damage, blood brain barrier (BBB) disruption, and membrane permeability immediately (10min) following lateral fluid-percussion brain injury. Neuronal damage was determined using microtubule-associated protein 2 (MAP2) and neuronal nucleus (NeuN) protein immunoreactivities; BBB damage was evaluated using IgG extravasation; and membrane permeability was assessed by uptake of membrane-impermeable dextrans (average mol. wt. = 10kDa). Brain injury resulted in a loss of MAP2 immunoreactivity in the cortex of the injured hemisphere following injury (8% of total area of the cortex), which was not attenuated by pre-injury ICV administration of Poloxamer 188 at any dose (0.6, 1.2, or 1.8mg). Injury also resulted in a decrease in NeuN immunoreactive cells in the cortex and the thalamus of the injured hemisphere by 67% and 27%, respectively, compared to sham-injured animals, which was not affected by pre-injury administration of Poloxamer 188. Approximately 50% of the remaining NeuN(+) cells in the cortex, exhibited intense NeuN immunoreactivity, whereas the rest were weakly immunoreactive. Pre-injury administration of Poloxamer 188 increased the proportion that was intensely immunoreactive for NeuN in a dose-dependent

manner, with the 1.2mg dose being the most effective dose (75% intensely immunoreactive). In addition, diffuse extracellular IgG immunoreactivity was observed within the cortex, white matter and hippocampus covering 23% of total area of the injured hemisphere; pre-injury administration of any of the 3 doses of Poloxamer 188 reduced the area of IgG immunoreactivity by approximately 50% ($p<0.05$ compared to saline-treated animals). Although dextran-flooded profiles were observed in both the cortex and thalamus of the injured hemisphere, indicative of mechanoporation, Poloxamer 188 did not reduce the number of these profiles. Taken together, these data suggest that Poloxamer 188 may provide partial neuroprotection early after injury that may be independent of its ability to reseal cell membranes.

Title: Targeting the p53 pathway to protect against traumatic brain injury

Authors: *L.-Y. YANG[1], K.-H. CHANG[1], Y.-H. CHU[1], N.-H. GREIG[2], J.-Y. WANG[1]; [1]Grad. Inst. of Med. Sci., Taipei Med. Univ., Taipei City, Taiwan; [2]Inst. on Aging, NIH, Baltimore, MD

Abstracts: Traumatic brain injury (TBI) is a major cause of death and disability worldwide. Programmed death of neuronal cells plays a crucial role in acute and chronic neurodegeneration following TBI. p53 tumor suppressor protein, a transcription factor, has been recognized as an important regulator of apoptotic neuronal death. Pifithrin-α (PFT-α) was shown to specifically prevent cell death by inhibiting p53 transcriptional activity.PFT-α has been shown to be neuroprotective against stroke and trauma injury. Previous study indicates that PFT-α oxygen analogue is more stable and active *in vivo* than PFT-α. The aim of our study is to investigate whether inhibition of p53 using pifithrin-α (PFT-α) or PFT-α oxygen analogue (PFT-α(O)) would be a potential neuroprotective strategy for TBI. To investigate whether these drugs protect excitotoxicity *in vitro*, primary rat cortical cultures were treated with glutamate (50mM) in the presence or absence of various concentration of p53 inhibitor PFT-α or PFT-α(O). Cell survival or death was estimated by LDH assays. *In vivo*, adult SD rats were subjected to controlled cortical impact (CCI, with 4m/s velocity, 2mm deformation). Five hours after injury, PFT-α or

PFT-α(O) (2 mg/kg, i.v.) was administered to rats. Sensorimotor and cognitive functions were evaluated by behavioural tests. Apoptotic cells and p53-positive neurons were identified by doubled staining with cell -specific markers. Levels of mRNA encoding for proinflammatory related proteins (IL-6 and IL-1β) and p53-regulated genes (BAX, PUMA, Bcl-2 and p21) were measured by reverse transcription followed by real time-PCR from TBI without or with PFT- α (O) treatment. We found that PFT-α(O) (10uM) enhanced neuronal survival against glutamate-induced cytotoxicity more effectively than PFT-α (10uM). PFT-α (O) treatment enhanced functional recovery and decreased contusion volume at 24 hours post-injury. Neuroprotection by PFT-α (O) treatment also reduced p53-positive neurons in the cortical contusion region and the area CA1 of the rat hippocampus. In addition, Pro-inflammatory cytokines (IL-1β, IL-6) andp53-regulatedPUMA mRNA levels at 8h significantly reduced by PFT-α(O) administration after TBI. Our data suggest that post-trauma administration of PFT-α (O) improves histological and functional outcomes after experimental TBI and reduces inflammatory responses and apoptosis. The inhibition of p53-induced apoptosis by PFT-α (O) may develop into a novel neuroprotective strategy for TBI.

Title: A new treatment method for severe TBI

Authors: *S. LU;
411th Navy Hosp, Shanghai, China

Abstracts: Research Program on the Application of Open Cerebral Decompression in Severe Cerebral Injury **Background** The mortality and disability rate in TBI, especially in severe TBI (Glasgow 3-8), now still remains high. Of the 150,000 patients in the United States who died of trauma each past year one-third (about 50,000) had developed secondary cerebral injury. In China, the death rate in severe craniocerebral injury (GSC 3-5) is as high as 90%. Therefore it can be seen that the current method used for the treatment of severe TBI and its curative effect are unsatisfactory. In this paper, the author suggests a method of open cerebral

decompression for patients of severe craniocerebral injury according to his years of experience, practice and study in neurosurgery so as to make a fundamental change in the treatment of severe craniocerebral injury. **Object** To make a substantial increase in the survival rate and a decrease in the death rate in the treatment of severe TBI patients through a series of systematic study of open cerebral decompression and therefore make a major breakthrough in the treatment of severe TBI patient **Matters Relating to Collaboration** The author is seeking a collaborator who is interested in the application of open decompression in severe craniocerebral injury to make a joint research. It is proposed that: A. The two sides should sign a cooperative research project contract (on the experiment and clinical study of the application of open decompression in severe craniocerebral injury). B. All the funds for research should be offered by the collaborator side or acquired through the brain trauma foundation or other channels. C. The sites for experimental studies and the necessary experimental researchers should be offered by the collaborator side. The author should participate in the joint research. D. The author is intended to apply for the registration of three invention patents in the collaborator's country. If the side of collaborator succeeds in assisting the medium to transfer the possession of the patents, the two sides should share the benefits (with the costs in paying patent application fee, annual fee, taxes, etc. deducted) in the ratio of 5:5. **A Brief Description of the Three Patents** A. Non-bleeding scalp incision nail B. Skull protective device C. Tentorium cerebelli incision knife

Title: Ischemic lesion in the white matter produces enduring spasticity in a rodent model

Authors: *P. K. BOSE[1,2,3], G. MUSTAFA[2], J. HOU[2], R. NELSON[1], J. DALY[1,3], S. E. NADEAU[1,3], S. DORE[4], F. J. THOMPSON[1,2,5];

Abstracts: The human periventricular white matter (PVWM), a vascular endzone, is particularly vulnerable to injury in middle cerebral artery strokes and ischemic damage and this site is the primary cause of enduring paresis and spasticity. Rehabilitation approaches leveraging use-dependent neuroplasticity have improved recovery but the ultimate potential for recovery is limited by loss of WM substrate. There is a critical lack of knowledge regarding the full neurobiological spectrum of the injury. Little is known, for example, about the functional potential of damaged neurons in overlying motor cortices. A preclinical model is needed that fully recapitulates injury to PVWM in humans, thereby providing a means to fully study the neurobiological consequences of this ischemic lesion and a test platform for the development and refinement of effective rehabilitation therapies. In this study, we used simultaneous stereotaxic microinjection of two potent vasoconstrictors, endothelin-1 (ET-1) and L-NIO, into the internal capsule (IC) of adult anesthetized rats (2.04 mm posterior and 3.6 mm lateral to bregma) to produce the WM injury. During post-operative follow-up, the velocity-dependent ankle torques and time-locked triceps surae EMGs were recorded as a quantitative measure of spasticity across a wide range of velocities (612 - 49 deg/sec) to permit analyses of tonic (low velocity) and dynamic (high velocity) contributions to lower limb spasticity. The ET-1+L-NIO injected animals developed both dynamic and tonic spasticity accompanied by time-locked elevation of triceps surae EMGs. This spasticity persisted at post-injection week 12. Moreover, injected animals exhibited hemiparesis and placing deficits contralateral to the injection side. The 3-D angular Kinematics (Vicon) and the Catwalk gait analyses (Noldus) also revealed significant and detectable deficits in gait kinematics, step sequence, phase dispersion, and impairment of other gait parameters in the limbs contralateral to injection site. However, these deficits in gait parameters were not enduring, and significant spontaneous recovery occurred within 2 weeks following the injections. Fluoro-Jade staining of the post-fixed brain samples revealed significant demyelination in the IC. Our data to date suggest that ET-1+L-NIO injection in the IC can produce an ischemic lesion in the WM sufficient to produce enduring spasticity and detectable deficits in the gait that are relevant to human stroke. This preclinical injury model may enable better understanding of the neurobiology of WM injury and the development and refinement of effective therapies.

Title: Mild traumatic brain injury (mTBI) produces alteration in orofacial and peripheral pain in a rodent model

Authors: *G. MUSTAFA[1,2], J. HOU[1,2], S. TSUDA[1,2], R. NELSON[1], A. SINHAROY[1], R. M. CAUDLE[3], J. K. NEUBERT[4], F. J. THOMPSON[1,2], P. BOSE[1,2,5];
[1]Brain Rehabil. Res. Ctr. (BRRC), North Florida/South Georgia Veterans Hlth. Syst., Gainesville, FL; [2]Dept. of Physiological Sci., [3]Dept. of Oral and Maxillofacial Surgery, [4]Dept. of Orthodontics, [5]Dept. of Neurol., Univ. of Florida, Gainesville, FL

Abstracts: TBI-induced diffuse axonal injury results chronic pain syndromes in patients including neuropathic, central and thalamic pains which are often difficult to manage. TBI-induced pain has not been well studied, although the prevalence of chronic pain is common among TBI patients, and is higher (72%) in mild TBI than severe TBI (32%). It is proposed that TBI-induced neuroplasticity is likely to affect both central and peripheral mechanism of pain processing and may include a wide array of changes in the expression of pain signaling molecules including serotonin (5-HT), norepinephrine (NE), GABA and substance P. Accordingly, a detailed study of the distribution of these molecules in both spinothalamic and spinal trigeminal pathway, could build upon the strengths of this line of inquiry. In particular, new insights could provide a better understanding of chronic pain secondary to TBI such as post-TBI headache pain, neck and shoulder pain, back pain, orofacial pain, and neuropathic pain. Therefore, the primary purpose of this study is to provide a comprehensive and quantitative evaluation of TBI-induced thermal sensitivity and to identify changes in several key signaling molecules that are known to relate to pain modality. We used a rodent model of closed head mTBI (modified Marmarau's model, 450 g X 1.25 m, anesthetized helmeted adult Sprague Dawley rats) and measured thermal sensitivity in hind-paws and orofacial regions using a conventional hot plate assay and an orofacial pain assessment device respectively before and after mTBI. Our data to date indicate that animals with mild TBI exhibit significant increases in thermal sensitivity starting at 4 weeks post-TBI; this increased sensitivity was enduring and was prominent when testing was repeated at post-TBI week 8. A separate cohort of animals showed significant increases in their facial thermal sensitivity compare to that of the pre-TBI state. Immunohistochemical studies of 5-HT, GABA, NE and substance P receptors (NKR1) in post-fixed dorsal root ganglia, and brain samples indicate significant increases in serotonin immunoreactivity in the ventral posteromedial thalamic nucleus, and also in the facial nucleus

after mTBI. Both GABA and DβH expressions are increased in the spinal trigeminal nuclei, Cuneate and Gracile nuclei, while up-regulation of NK1R was found in trigeminal nuclei in the mTBI tissues compared to levels tested in normal tissues. These data indicate a wide array of changes in the pain signaling molecules following mTBI. Accordingly, we propose a working hypothesis that includes an interconnected neuromodulatory role of these key molecules in the development chronic pain over time after mTBI.

Title: Acute intrathecal baclofen (ITB) reduces TBI-Induced spasticity in a dose-dependent manner without adversely affecting cognitive performance

Authors: *F. J. THOMPSON[1,3,4], J. HOU[3], R. NELSON[2], G. MUSTAFA[3], A. SINHAROY[2], R. PANDEY[5], Z. WILKIE[2], S. TSUDA[3], L. PAGE[7], P. BOSE[2,3,6];
[1]Brain Rehabil. Res. Ctr., North Florida/South Georgia Veterans Hlth. Syst., Gainesville, FL; [2]Brain Rehabil. Res. Ctr., North Florida/South Georgia Veterans Hlth. Syst., GAINESVILLE, FL; [3]Physiological Sci., [4]Neurosci., [5]Pediatrics, [6]Neurol., Univ. of Florida, Gainesville, FL; [7]Medtronic Neuromodulation,Targeted Drug Delivery R & D, Medtronic, Minneapolis, MN

Abstracts: Spasticity is a major health problem for patients with moderate to severe traumatic brain injury (TBI). Although the use of anti-spastic medications, particularly ITB, can decrease the severity of TBI-spasticity, the current federal guidelines preclude the use of ITB therapy during the first year following TBI due to insufficient data to determine potential risk associated with early therapies on cognitive function, balance, and motor recovery. Therefore, an aim of the present study was to provide a comprehensive evaluation of the safety, feasibility, and efficacy

of early intervention treatments (initiated at one week after TBI and continued for 4 weeks) on the long-term outcome of spasticity, cognition function, and balance recovery. These studies tested three different doses: low (0.4μg/hr), medium (0.8μg/hr), and high (1.6μg/hr) of ITB (Lioresal®) treatments using Alzet osmotic mini-pumps in a TBI-induced spastic rodent laboratory model that we recently reported. These studies utilized tests of lower limb spasticity, balance, and serial learning to compare data obtained from normal, TBI-untreated, and TBI-ITB treated animals. Velocity dependent ankle torque & ankle extensor muscle EMGs (as measures of spasticity), rotorod balance performance, and the Morris water maze for spatial learning were used to investigate the dose-response effects of these early ITB treatment doses. Our data to date indicate that compared with time-matched data obtained from untreated TBI animals, ITB treatment significantly reduced spasticity in a dose-dependent manner. The higher dose (6.4 μg/μl) blocked the early (post-ITB treatment week 1) and late onset (post-ITB treatment week 3) spasticity with no negative impact on cognitive performances. However, animals receiving this dose, exhibited balance test deficiencies. In contrast, the medium dose blocked the early onset spasticity, significantly attenuated the late onset spasticity, and produced no negative impact on balance and cognitive performances. The lowest dose only attenuated the spasticity level (i.e. did not block) in both early and late stages of spasticity development with no adverse impact on balance and cognitive performances. These observations indicated that initiating ITB at one week post-TBI and continuing for one month of treatment using a medium dose (0.8μg/hr) was safe, feasible, and effective without detectable impact on cognitive, balance, and motor recovery. These studies also indicate that progressively, the data will reinforce confidence in the safety, feasibility, and efficacy of early intervention treatments for TBI-spasticity.

Title: Transcranial magnetic stimulation (TMS) improves TBI-induced spasticity, balance and anxiety disorders

Authors: *J. HOU[1,2], R. NELSON[1], Z. WILKIE[1], J. JOHN[1], G. MUSTAFA[2], S. TSUDA[2], A. SINHAROY[1], R. PANDEY[3], P. BOSE[1,2,4], F. J. THOMPSON[1,2,5];
[1]North Florida/South Georgia Veterans Hlth. Syst., Gainesville, FL; [2]Physiological Sci., [3]Pediatrics, [4]Neurol., [5]Neurosci., Univ. of Florida, Gainesville, FL

Abstracts: Mild traumatic brain injury (mTBI) is a common cause of military combat, sports and car accidents which can produce life-long disabilities including motor, anxiety and cognitive deficits. Currently, no clear understanding exists regarding the neurobiology of these long-term disabilities and thus the effective therapy still remained limited. Therefore, development of a safe and effective therapy for these long-term disabilities is urgently needed. Accordingly, the present study was conducted to test the therapeutic effects of TMS on our recently developed rodent model of mTBI which produce enduring spasticity, balance, anxiety and cognitive deficits. Mild TBI was produced by dropping a 450 g impactor onto the helmeted skull from 1.25 m height (modified Marmarou model) in anesthetized adult Sprague Dawley rats. The TMS was delivered three times per week for one month. The TMS treatments consisted of 75 single pulses TMS delivered to the surface of the cranium through a 25mm figure 8 coil (Magstim Rapid, UK) using an intensity ladder protocol that we recently reported (Hou et al., 2014). The velocity-dependent ankle torques (AT) and time-locked triceps surae EMGs were recorded as a measure of spasticity at pre-injury and PO week 5. At the completion of treatment (PO week 5), the untreated TBI animals showed significant increases in AT and EMGs (44.4% and 84.9%, respectively, compared to pre-injury level) at the highest test velocity. In contrast, the TMS treated animals revealed a significant reduction in spasticity (86.8% reduction AT). Balance performance was also measured using Rotorod. The TMS treated group showed 14% improvement in rotorod balance performance compared to TBI-untreated group. Anxiety behavior was measured using an elevated plus maze (EPM) and automated tracking software (EthoVision XT, Noldus Information Technology). The TBI animals spent significantly less time in the open arms compared to intact animals (1% vs. 36%). The TMS treatment group spent significantly longer time in the open arms, 10% more than the TBI untreated group. The Morris water maze (MWM) was used to assess cognitive function. Both TBI untreated and TMS treated groups showed significant increases in the latency and total distances to locate the platform compared to intact animals. However, no changes in serial learning were detected between TBI TMS treated and TBI-untreated animals. Our data to date indicate that TMS treatment significantly reduced the tested TBI-induced spasticity, balance, and anxiety disorders. Studies are on progress to further investigate the long-term residual therapeutic effects of TMS treatment on these disabilities utilizing chronic time points.

Title: Closed-head traumatic brain injury (cTBI) disrupts the integrity of central noradrenergic system in rat

Authors: *S. TSUDA[1,4], J. HOU[2,4], R. NELSON[2], G. MUSTAFA[2,4], Z. WILKIE[2], R. PANDEY[2], A. SINHAROY[2], F. THOMPSON[2,4,5], P. BOSE[3,4,6];
[2]Brain Rehabil. Res. Ctr. of Excellence, [3]Dept. of Physiological Sci., [1]Malcom Randal VA Med. Ctr., Gainesville, FL; [4]Dept. of Physiological Sci., [5]Dept. of Neurosci., [6]Dept. of Neurol., Univ. of Florida, Gainesville, FL

Abstracts: cTBI has been a major component of combat, sport, and other accident-related injuries which lead to life-long multiple morbidities in survived individuals, including cognitive, anxiety, and pain disorders. However, currently, no clear understanding exists regarding the eurobiology of long-term disabilities induced by cTBI, and no established herapeutic treatment has been available for these morbidities. We have eported that TBI dsrupts noradrenergic (NA) cells in locus coeruleus (LC, the principal site for norepinephrine [NE] biosynthesis) and their projections to spinal cord. However, it is not known to what extent NA cells in LC and NA fiber projections to specific neuronal substrate centers known to be involved in these morbidities are affected by cTBI. Considering the wide distribution of NE-releasing axons throughout the central nervous system (CNS) and well-known physiological roles of NE in related behavioral functions, NE potentially plays a prominent role in the pathophysiology of these morbidities. Accordingly, the purpose of this study is to provide a more comprehensive and quantitative evaluation of cTBI-induced alterations in LC cells and NA fiber projections to the neuronal substrate centers related to these morbidities. In the present study, we used post-fixed brain tissue samples taken from animals 4 months after cTBI (Marmarou TBI Model, 450g x 1.25 m) in which these multiple morbidities (cognitive, anxiety and pain disorders) were detected. Coronal sections of the brain (40μm) were stained for dopamine β-hydroxylase (DβH, a surrogate marker for NA-cells/fibers) and NE using standard fluorescent immunohistochemical techniques**.** Stained sections were then quantitatively analyzed by counting the total number of DβH-positive LC

cells and the DβH-positive fibers. Our results to date revealed that cTBI resulted in significant loss of DβH-positive neuronal cells in both dorsal and ventral aspects of the LC. However, the exact topographic positions of LC cell loss varied among individual cTBIs. There was significant reduction of DβH-positive fibers in the central nucleus of amygdala. Double immunohistochemistry revealed colocalization of DβH-positive neuronal fibers with NE. These results suggest that cTBI disrupts the neurobiological integrity of central noradrenergic system which provides significant inputs to the substrate centers related to anxiety, cognitive and pain disorders. These decreases in the central NA cells and fibers may coherently tie to many seemingly disparate CNS disabilities induced by cTBI.

Title: Moderate docosahexaenoic acid deficiency impairs recovery from traumatic brain injury

Authors: *J. BARNES, A. DESAI, K. KEVALA, M. RASHID, H.-Y. KIM;
Natl. Inst. On Alcohol Abuse and Alcoholism, Rockville, MD

Abstracts: Recent studies have shown that omega-3 (n-3) fatty acids, particularly docosahexaenoic acid (DHA 22:6 n-3), are important for brain development and function and improves outcome of traumatic brain injury (TBI). In the current study, we have examined the effects of DHA on the behavioral and histological outcome of brain injury in a mouse model of TBI inflicted by controlled cortical impact (CCI). Brain DHA status was manipulated by dietary means from pregnancy, and the offspring animals were tested at around 5 months age for motor function using rotarod/beam walk tests and cognitive behavior such as learning and memory using fear conditioning. Protein expression changes were evaluated by western blotting and immunohistochemistry. The mice with higher brain DHA status (by approximately 30%) exhibited significantly faster motor deficit recovery as assessed by beam walk and rotarod tests. Also, the group with higher brain DHA status showed significantly more freezing behavior

during contextual fear conditioning tests indicating greater fear memory. Preliminary results indicated that DHA modulated the expression of proteins implicated in inflammation, such as IkBa, as well as proinflammatory metabolites such as PGE2 in TBI mice. The phosphoTau level after TBI was also modulated according to the brain DHA status, indicating that DHA has a role in axonal pathology after brain injury. Moreover, the TBI-induced cleavage of the cytoskeletal protein alpha-spectrin was also less in mice that had more brain DHA, indicating lesser activation of calpain. These data suggest that DHA status in the brain is relevant to the outcome of TBI. Higher brain DHA ameliorates pathophysiology associated with TBI and improves functional recovery.

Title: Preservation of whisker sensation due to Wnt administration following traumatic brain injury in the barrel cortex of mice

Authors: *J. Y. ZHANG[1,2], J. LEE[2], X. GU[2], S. P. YU[2], L. WEI[2];
[1]Emory Univ., Decatur, GA; [2]Anesthesiol., Emory Univ., Atlanta, GA

Abstracts: Traumatic brain injury (TBI) is the leading cause of morbidity and mortality in children and young adults in the US. However, there are currently no effective pharmacological therapies. We previously reported on the effectiveness of Wnt therapy for promoting functional

recovery via the augmentation of endogenous neurogenesis. Since then, we have discovered that Wnt may play a neuroprotective role as well, and that this secondary benefit contributes to the functional preservation during the acute stages following TBI. We delivered the injury using the well-established controlled cortical impact (CCI) model of TBI in C57BL/6 mice (male, 11 week old). The injury was directed to the barrel cortex, which is the domain involved in whisker sensation. Three experimental groups included 1) sham surgery, 2) TBI plus intranasal administration of a recombinant Wnt ligand, and 3) TBI plus saline control. After the surgery, two behavior assays, the corner test and a home cage monitoring system, were used to assess behavioral recovery from TBI. The corner test is sensitive for whisker sensation and was performed on post-surgical days 3, 7, and 14, while the home cage monitor measures a variety of native behavior over the course of 24 hours and was performed on post-surgical days 2, 7, and 14. Mice received training and baseline establishment for these two tests before the TBI. Furthermore, mice were sacrificed at either 2 days or 14 days after TBI for terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) staining and Nissl analysis. To assess the extent of cell death, the brains were sectioned (10 μm thickness) and stained for TUNEL and NeuN, which are markers of cell death and mature neurons, respectively. Stereological counting showed that Wnt administration resulted in neuroprotection, with a significant reduction in TUNEL+ cells and TUNEL+/NeuN+ colabeled cells in Wnt-treated animals vs. the saline treated TBI controls. In functional tests, we found that the Wnt-treated mice were more resilient against the whisker sensory deficits following the barrel cortex injury, with significant reductions in aberrant turning behavior for Wnt-treated animals, as scored by the corner test. Furthermore, the home cage test showed that On day 14, saline-treated TBI animals displayed significantly attenuated total sleep times as compared to both sham animals and to Wnt-treated animals. Wnt therapy preserved sleep habits following TBI, which is associated with insomnia and sleep disturbances. In summary, the Wnt pathway is suggested to be an efficacious therapeutic target that can provide both neuronal and functional protection following TBI.

Title: Magnetic retention of human neuroprogenitor cells transplanted into a traumatic brain injury model

Authors: W.-B. SHEN[1], C. PLACHEZ[1], D. YARNELL[7], O. TSYMBALYUK[2], S. XU[3], A. C. PUCHE[4], J. SIMARD[2,7], P. S. FISHMAN[5,7], *P. J. YAROWSKY[6,7];

Abstracts: Stem cell therapy has been suggested as a treatment for traumatic brain injury (TBI). But a non-invasive delivery method and retaining stem cells at the site of TBI has not been addressed. We have devised a method of loading human neuroprogenitor cells (hNPCs) with superparamagnetic iron-oxide nanoparticles (SPION, Molday ION Rhodamine B™; MIRB; BioPAL, Worcester, MA) and assessed the ability of external magnets to retain MIRB-labeled hNPCs at the site of injury following transplantation. MIRB labeling does not affect hNPCs viability or proliferation or differentiation *in vitro* [Shen et al., 2013]. We tested 1) the viability of MIRB-hNPCs *in vitro* in a magnetic field; and 2) the survival, of MIRB-hNPCs in host rat brains after graft. First, we optimized the MIRB labeling conditions for dissociated hNPCs and hNPC neurospheres, including the concentration of MIRB, time for effective labeling hNPCs, and the time of labeled hNPCs hold the SPION. We found that hNPC lysosomes (Lamp1+) contained SPION. It remained stable inside the hNPCs over 3 weeks in cell culture (longest time tested). By fixing a magnet on the scalp on the same side as the injury prior to transplantation, hNPCs were retained at the site of injury in the cortex more than two-fold greater as compared to hNPC-injected TBI animals without a magnet. Detection of magnet-enhanced hNPC-MIRB retention was also found using T2-weighted MRI (Magnetic Resonance Imaging) and confirmed by Perl's staining. Post-transplantation, the cortex under the magnet had a greater percentage of live hNPC-MIRB cells than the comparable cortex in the non-magnet animal. Thus the delivery pathway and the method of retaining the cells are appropriate for this preclinical model in order to evaluate the effectiveness of this stem cell therapy.

Title: Behavioral changes in docosahexaenoic acid deficient female mice after traumatic brain injury

Authors: *A. DESAI, J. BARNES, K. KEVALA, H.-Y. KIM;
Natl. Inst. On Alcohol Abuse and Alcoholism, Bethesda, MD

Abstracts: Traumatic brain injury (TBI) may not only lead deficits in cognitive and vestibulomotor functions, it may also cause emotional problems. Deficiency of n-3 polyunsaturated fatty acids (PUFA), especially docosahexaenoic acid (DHA) has been linked to cognitive abnormalities as well as anxiety and depression. Most published studies that link DHA levels to recovery from TBI have used male mice, considering the influences of hormonal fluctuation in female mice. The objective of this study is to evaluate whether the recovery from TBI in female mice is similarly affected by DHA deficiency. Pregnant C57BL/6N mice (E14) were placed on n-3 deficient or n-3 adequate control diet. Female pups were weaned on the same diet and controlled cortical impact was performed on these mice at 5-6 months of age. The mice were then subjected to a battery of tests that consisted of beam walk test, open field test, light dark transition test, tail suspension test, forced swim test and fear conditioning to compare motor recovery, anxiety-like and depression-like behaviors and fear learning. The n-3 deficient diet significantly lowered DHA level in the brain, which was compensated by higher docosapentenoic acid (DPA) levels. The DHA deficient mice had impaired motor recovery and relatively poor memory as compared to the controls, implicating DHA deficiency as an important factor that may predict spontaneous recovery after TBI. However, significant differences were not found in anxiety-like and depression-like behavior. This study indicates that despite hormonal differences, DHA depletion can impair recovery in female mice.

Title: Classifying pediatric traumatic brain injury using an automated digital measurement algorithm to detect cerebral edema

Authors: *E. TA[1], S. LAUGHLIN[4], C. S. PARSHURAM[2], J. HUTCHISON[3], A. M. GUERGUERIAN[3], Y. INVESTIGATORS[5];
[2]Child Hlth. Evaluative Sci., [3]Neurosci. and Mental Hlth. Program, [1]The Hosp. For Sick Children - Res. Inst., Toronto, ON, Canada; [4]Radiology, The Hosp. For Sick Children, Toronto, ON, Canada; [5]Canadian Critical Care Trials Group, Toronto, ON, Canada

Abstracts: Introduction/Rationale: Traumatic brain injury is the leading cause for long-term disability and death in North American children. In the absence of a reliable and objective method of classifying injury severity, there is a growing need for early identification and classification tools. Computed tomography (CT) is the most accessible imaging modality for front-line clinical care in children with TBI and new software applications may be used to detect cerebral edema, a risk factor for poor outcome. While magnetic resonance imaging is more sensitive, it is far less accessible than CTs immediately after injury. This project will assess the ability of an automated digital measurement algorithm (ADMA) that can predict the need for medical interventions and outcome at hospital discharge by quantifying cerebral edema detectable on initial CT scan. The diagnostic accuracy of ADMA is hypothesized to be better than usual radiological interpretation and is expected to be associated with outcomes as measured by the Pediatric Cerebral Performance Category score. Experimental Approach: We propose to apply ADMA to CT scans of two epidemiological cohorts of children hospitalized with TBI (120 children; age: 0 -18 years) using MIPAV (Medical Image Processing, Analysis, and Visualization) software, using an algorithm developed with special considerations to the developmental brain maturity of the subjects. The first step of this project was to measure the capacity of ADMA to predict overall functional outcome. Results: Preliminary results in 77 subjects suggest the capacity to classify children with and without new cerebral dysfunction on hospital discharge using the Pediatric Cerebral Performance Categorical scale has an area under the receiver operating characteristic curve of 0.8083 (95% CI: 0.6756 - 0.8976). Impact of Research: We report promising findings for quantifying visible cerebral edema on standard clinical CT scans in a selected sample of children following TBI. Our future goal is to cross validate our findings in a separate sample, to evaluate the relationship to late brain MRI findings, all with a vision of producing a rapid objective method for to classify TBI in children early after injury.

Title: Neurotherapeutic effect in mice after traumatic brain injury by CD45+ hematopoietic cells from human cord blood

Authors: *P. LAZAROVICI[1], H. ARIEN-ZAKAY[1], G. GINCBERG[1], A. NAGLER[2], G. COHEN[1], S. LIRAZ-ZALTSMAN[1], V. TREMBOVLER[1], A. G. ALEXANDROVICH[1], I. MATOK[1], H. GALSKI[2], U. ELCHALAL[3], P. LELKES[4], E. SHOHAMI[1];
[1]Hebrew Univ. Jerusalem, Jerusalem, Israel; [2]Chaim Sheba Med. Ctr., Tel-Hashomer, Israel; [3]Hadassah Univ. Hosp., Jerusalem, Israel; [4]Temple Univ., Philadelphia, PA

Abstracts: Treatment of traumatic brain injury (TBI) is still an unmet need. Cell therapy by human umbilical cord blood (HUCB) has shown promising results in animal models of TBI and is under evaluation in clinical trials. HUCB contains different cell populations, but to date only mesenchymal stem cells have been evaluated for therapy of TBI. Here we present the neurotherapeutic effect, as evaluated by neurological score, using a single dose of HUCB-derived mononuclear cells (MNCs) upon intravenous (iv) administration one day post-trauma in a mouse model of closed head injury (CHI). Delayed (8 days post-trauma) intracerebroventricular administration of MNCs showed improved neurobehavioral deficits thereby extending the therapeutic window for treating TBI. Furthermore, we demonstrated for the first time, that HUCB-derived pan-hematopoietic CD45 positive (CD45+) cells, isolated by magnetic sorting and characterized by expression of CD45 and CD11b markers (96-99%), improved the neurobehavioral deficits upon iv administration, which persisted for 35 days. The therapeutic effect was in a direct correlation to a reduction in the lesion volume and decreased by pre-treatment of the cells with anti-human-CD45 antibody. At the site of brain injury, 1.5-2 h after transplantation, HUCB-derived cells were identified by near infrared scanning and immunohistochemistry using anti-human-CD45 and anti-human-nuclei antibodies. NGF and VEGF levels were differentially expressed in both ipsilateral and contralateral brain hemispheres, thirty-five days after CHI, measured by ELISA. These findings indicate the

neurotherapeutic potential of HUCB-derived CD45+ cell population in a mouse model of TBI and propose their use in the clinical setting of human TBI.

Title: Flavanol (-)-epicatechin is neuroprotective after intracerebral hemorrhage

Authors: ***J. WANG**, C.-F. CHANG, S. CHO;
Anesthesiology/Critical Care Med., Johns Hopkins Univ., Sch. of Med., BALTIMORE, MD

Abstracts: In the wake of intracerebral hemorrhage (ICH), a devastating stroke with no effective treatment, hemoglobin/iron-induced oxidative injury leads to neuronal loss and poor neurologic outcomes. (-)-Epicatechin (EC), a brain-permeable flavanol that modulates redox/oxidative stress via the NF-E2-related factor (Nrf) 2 pathway, has been shown to be beneficial for vascular and cognitive function in humans. Here, we examined whether EC can reduce early brain injury in ICH mouse models and investigated the underlying mechanisms. ICH was induced by injecting collagenase, autologous blood, or thrombin into mouse striatum. EC was administered orally at 3 h after ICH and then every 24 h for 3 days. Lesion volume, neurologic deficits, brain edema, reactive oxygen species, and protein expression and activity were evaluated. EC significantly reduced lesion volume and ameliorated neurologic deficits in both male and female ICH mice. Cell death and neuronal degeneration were decreased in the perihematomal area and were

associated with reductions in caspase-3 activity and HMGB-1 level. These changes were accompanied by attenuation of oxidative insults, increased phase II enzyme expression, and increased Nrf2 nuclear accumulation. Interestingly, in addition to providing neuroprotection via Nrf2 signaling, EC diminished heme oxygenase-1 induction and brain iron deposition via an Nrf2-independent pathway that downregulated ICH-induced activating protein-1 activation and decreased matrix metalloproteinase 9 activity, lipocalin-2 levels, iron-dependent cell death, and ferroptosis-related gene expression. Collectively, our data show that EC protects against ICH by activation of Nrf2-dependent and Nrf2-independent pathways and may serve as a potential intervention for patients with ICH.

Title: Digitally controlling the biomechanics of fluid percussion injury to better understand the range of mild tbi

Authors: *M. LONG[1,2], S. P. SINHA[3,2], N. NADPARA[4], K. PANG[5,2], B. PFISTER[1]; [1]Dept. of Biomed. Engin., New Jersey Inst. of Technol., Newark, NJ; [2]Grad. Sch. of Biomed. Sci., Rutgers Biomed. and Hlth. Sci., Newark, NJ; [3]Dept. of Neurol. and Neurosci., New Jersey Med. Sch., Newark, NJ; [4]Dept. of Biol., The Col. of New Jersey, Ewing Township, NJ; [5]Veterans Affairs Med. Ctr., East Orange, NJ

Abstracts: Awareness, diagnosis and management of mild traumatic brain injury (mTBI) are often difficult and not well defined. Furthermore, understanding the neural mechanisms involved in mTBI in the clinical setting remains elusive. However animal models of mTBI provide the ability to investigate pathologies - not otherwise available in humans. Many studies involving animal models of mTBI use magnitude levels of 1.0 - 1.5 atm and average 20 ms duration of impact. However, the classification of mild TBI is a wide range that should encompass, not only the high end, but also include magnitudes that are lower than 1.0 atm or have shorter temporal duration then previously reported. Here, we introduce a novel voice-coil fluid percussion injury

(vFPI) device that digitally delivers a reproducible and well-controlled percussion with control over the magnitude, rise time and duration of the pressure wave that can target the wide range of mTBI. First, We aim to compare our vFPI to the traditional pendulum fluid percussion injury (pFPI) device. We will assess the capabilities of the vFPI to that of the pFPI to produce injury duration comparable to current head impact studies. Adolescent male Sprague-Dawley rats (approx. 1 month) will be randomly assigned to SHAM or injury group. We will manipulate duration parameters available by each device to mimic head impact studies. The vFPI device efficiently produced ≤ 10 ms injury durations. We assessed acoustic sensory reactivity utilizing the acoustic startle reflex (ASR) test. The neural mechanisms of ASR are well documented and conserved between rodent and humans, thus providing a translational study on functional outcome. Sprague-Dawley rats were matched and randomly assigned into either SHAM or mTBI groups based on pre-injury baseline of ASR (acoustic stimuli: 100 ms white noise bursts at 82, 92 and 102 db). At 24 hrs post-injury, ASR showed persistent attenuation in mTBI subjects compared to SHAMS lasting up to 4 weeks post injury. Finally we targeted a wide-range of mTBI injury magnitude levels of 0.37 - 2.19 atm and observed the apnea levels of 0.0 - 56.5 s, latency of righting reflex levels of 23 - 1147 s. We aimed to create a device that aids in exploring the lower range of mTBI, and have demonstrated that the vFPI device facilitates this. We demonstrated that acute deficits are still present when the levels of pressure fall below the range suggested in the literature, which supports that mild TBI encompasses a range of parameters that should be studied.

Title: Enhanced fear learning and increased cortical GABA following mild traumatic brain injury in mice

Authors: *B. SCHNEIDER[1,2], F. GHODDOUSSI[3], J. CHARLTON[1], R. KOHLER[2], S. A. PERRINE[2], A. C. CONTI[1,4,2];
[1]John D. Dingell VA Med. Ctr., Detroit, MI; [2]Psychiatry and Behavioral Neurosci., [3]Anesthesiol., [4]Neurosurg., Wayne State Univ., Detroit, MI

Abstracts: Background Individuals with mild traumatic brain injury (mTBI) often develop symptoms that resemble anxiety, depression, and posttraumatic stress disorder (PTSD). It is unclear how mTBI results in PTSD-like symptoms, although studies suggest decreased prefrontal cortex (PFC) activation alters responses in downstream regions associated with fear learning, such as the amygdala and hippocampus. To investigate this, we used a mouse model of mTBI and examined the effects of mild injury on conditioned fear behavior and neurochemical alterations in the PFC. Methods Anesthetized male C57BL/6 mice (10-12 wks) were impacted over the sagittal suture of the intact skull or exposed to surgery alone (sham controls). PFC was harvested for proton magnetic resonance spectroscopy analysis *ex vivo* at 11.7 T at 8 d post-injury to assess neurochemical levels, including glutamate and gamma-amino-butyric acid (GABA). A second cohort was used to assess fear response (freezing) to contextual fear conditioning at 14 d post-injury. Fear conditioning consisted of 5 phases: habituation, acquisition, extinction, reinstatement, and extinction recall. Results Mice with mTBI demonstrated significantly increased freezing during acquisition and extinction compared to controls. There were no differences in baseline freezing or freezing during reinstatement or extinction recall. GABA levels were significantly increased in the PFC of mTBI mice compared to controls, but levels of glutamate were not different. Discussion The increased acquisition and slower extinction of conditioned fear observed in mTBI mice resemble features of fear conditioning reported in PTSD and mTBI cases. Increased GABA in the PFC may reflect an increase in inhibitory activity and support the hypothesis that mTBI-induced PFC hypoactivity limits top-down control over subcortical areas involved in FC; thereby increasing susceptibility to affective disorders. Therefore, this model of mTBI-induced changes in PFC may give an

improved understanding of mechanisms involved in developing affective alterations following mTBI.

Title: The emergence of a depressive phenotype after mild concussions in the adult mouse

Authors: *N. MISTRY[1], S. HALAVI[1], M. HAMER[2], A. OBENAUS[2,3,4], R. E. HARTMAN[1]; [1]Dept. of Psychology, [2]Dept. of Pediatrics, [3]Div. of Interdisciplinary Studies, Loma Linda Univ., Loma Linda, CA; [4]Cell, Mol. and Developmental Biol. Program, Univ. of California Riverside, Riverside, CA

Abstracts: Mild traumatic brain injuries (mTBI), including concussions, can lead to long-lasting cognitive and motor deficits, increasing the risk of behavioral problems and the development of future neurological disorders. Few studies have comprehensively examined both acute and long-term neurological and behavioral effects from mTBI. Our study focused on long-term behavioral deficits after single or repeated mild closed head injuries (mCHI). Mice received either a single mCHI, a repeated mCHI consisting of a single concussion to each hemisphere separated by 3 days. A moderate controlled cortical impact injury (CCI) along with sham-only anesthesia served as controls. We hypothesized that mice with repeated mCHI would have persistent long-term neurological and behavioral deficits. Neurological and behavioral tests were administered at 1, 3, 5, 7, and 90 days post-injury (dpi). Balance beam impairments began to emerge at 7 dpi in CCI mice and remained at 90 dpi. Impaired performance on the balance beam was only observed at 90 dpi in repeated mCHI mice. Perhaps most interestingly, depression-like behaviors and social passiveness were observed in repeated mCHI animals at 90 dpi. These data suggest that mCHI leads to delayed motor deficits and the emergence of affective disorders that are not observed after CCI.

Title: The effects of closed-head injury on scent marking behaviors in mice

Authors: ***S. HALAVI**[1], N. MISTRY[1], M. HAMER[2], M. EVANS[2], B. SEMPLE[4], A. OBENAUS[2,3,5], R. HARTMAN[1];
[1]Dept. of Psychology, [2]Dept. of Pediatrics, [3]Div. of Interdisciplinary Studies, Loma Linda Univ., Loma Linda, CA; [4]Neurolog. Surgery, Univ. of California, San Francisco, San Francisco, CA; [5]Cell, Mol. and Developmental Biol. Program, Univ. of California Riverside, Riverside, CA

Abstracts: Depression has been reported as the most common neuropsychiatric consequence of TBI. We have shown that closed head injury (CHI) in mice leads to social passiveness and learned-helplessness/depression-like behaviors on the tail suspension test (TST; see Mistry, et al. poster). In the current study, we assessed the acute and long-term effects of CHI on scent marking behavior in male mice exposed to novel females. Urine and fecal boli were collected on a piece of paper during exploration of an open field (30.5 cm x 30.5 cm) for 20 min. Baseline measurements were collected in an empty open field, and a novel female was placed in a small cage (6.3 cm wide x 10.3 cm tall) in the center of the open field for stimulus trials. Fecal boli were counted and the paper was sprayed with ninhydrin to visualize and quantify urine markings. In the acute experiment, 12 mice underwent baseline scent marking testing (SMT) followed by the presentation of a novel female stimulus 7 days later. Two days later, the mice were randomly assigned to control (n=6) and anesthesia/CHI (n=6) groups. Animals in the anesthesia/CHI group underwent 20 minutes of 3% isoflurane anesthesia. Five days later, both the groups underwent a second novel female stimulus trial. One day after the second stimulus, animals in the anesthesia/CHI group were anesthetized again and given a CHI over the right temporal-parietal cortex. Two more novel female stimuli were presented 3 and 7 days after injury, followed by the

TST 8 days after injury. In the long-term experiment, the mice in the control group (n=6) were anesthetized, and the mice in the treatment group (n=6) were anesthetized and received a CHI over the right temporal-parietal cortex. SMT (baseline and 1 novel female) and the TST were administered 3 months after injury. All mice, at both time points, engaged in significantly more scent-marking behaviors when exposed to a novel stimulus compared to the baseline. In general, CHI mice scent-marked slightly more than controls 7 days after injury, but CHI mice marked less than controls 3 months after injury. Additionally, the groups' TST performance did not differ after 8 days, but CHI mice gave up significantly more quickly on the TST after 3 months, suggesting that a depression-like phenotype may take some time to emerge after CHI. *Funding came from Loma Linda University School of Behavioral Health Seed grants to AO and RH.*

Title: Impairments in social familiarity-induced anxiolysis (SoFiA) after mild blast-induced traumatic brain injury (mbTBI)

Authors: *S. M. VEGA ALVAREZ[1,2], E. LUNGWITZ[4,5], N. RACE[3], T. R. WARNER[4,5], W. TRUITT[6,5,7], R. SHI[1,3];

Grad. Program, [5]Stark Neurosciences Res. Inst., [6]Dept. of Anat. and Cell. Biol., [7]Dept. of Psychiatry, Inst. of Psychiatric Res., Indiana Univ. Sch. of Med., Indianapolis, IN

Abstracts: Traumatic brain injury (TBI) recently took center stage as the signature wound of recent war conflicts. As the most common form of TBI, blast-induced traumatic brain injuries (bTBI) occur when the blast waves produce inertial forces leading to strain, shearing and compression of the brain. Due to the multifocal nature of TBI, a complex cascade of distinct but interconnected cellular events is initiated and leads to the development of secondary injuries.

Furthermore, bTBIs have been linked to a variety of pathologies and neurobehavioral deficits, including increased susceptibility to psychiatric, somatic and cognitive symptoms, which have the potential to become permanent. Consequently, the prevalence of mental health disorders observed in injured veterans continues to rapidly increase, which only adds to both direct and indirect economic burden on US economy from TBI. Therefore, understanding, preventing and treating TBIs must be a national priority. While extreme cases of bTBI result in early diagnosis, immediate treatment and monitoring of injury progression, symptoms of mild bTBI (mbTBI) can go unnoticed for quite some time and result in delayed therapeutic intervention. mbTBI are considered primary injuries caused by the overpressure component of the explosive wave and are characterized by absence in visible wounds, loss of consciousness or acute symptoms. Emotional and social deficits have been widely reported in TBI patients and these transient or permanent deficits have also been shown to significantly affect normal daily function. Consequently, by employing a model of mbTBI that closely resembles the human condition, we expect to elucidate subclinical cognitive deficits and behavioral abnormalities involved in altering coping mechanisms during social stress. Thus far, the mbTBI-causing pressure intensity wave has been correlated with a lack of motor deficits, evident by a lack of statistical significance between mbTBI and sham rats in terms of the length of time on a rotarod test. After mbTBI, the animal subjects do not perform different than uninjured rats when tested for cognitive impairment or basal anxiety. Interestingly, an assessment of Social Familiarity-induced Anxiolysis (SoFiA) revealed that, when subjected to a mbTBI, rats present social processing impairments. Hence, our model replicates subclinical cognitive and behavioral effects observed in humans after mbTBI. Currently, we are evaluating the role of oxidative agents, the oxidative stress-triggered inflammatory response and the benefits of multiple therapeutics in mbTBI cognitive and behavioral deficits.

Title: Neuroinflammation and cognitive deficits in a rabbit pediatric traumatic brain injury model

Authors: *Z. ZHANG[1,2], M. SARASWATI[2,1], R. C. KOEHLER[2,1], C. ROBERTSON[1,2,3], S. KANNAN[2,1,3];
[2]Dept. of Anesthesiol. and Critical Care Med., [3]Dept. of Pediatrics, [1]Johns Hopkins Sch. of Med., Baltimore, MD

Abstracts: Traumatic brain injury (TBI) is a common cause of disability in childhood, yet the mechanisms responsible for its complex spectrum of pathologies remain largely unknown. Pediatric rodent models of TBI often do not demonstrate the spectrum of motor and cognitive deficits as seen in pediatric TBI patients. To address these, we developed a model of pediatric TBI in New Zealand rabbits that mimics pediatric brain development better in the case of white matter maturation, microglial presence and response to injury. On postnatal day 5-7 (P5-7), the rabbits were injured with a standardized controlled cortical impact at a velocity of 5.5 m/s and a depth of 2 mm. Rabbits from the same litter were served as control (no intervention) and sham (craniotomy alone). Functional abilities (cranial nerve, motor and sensory functions) and activity levels (open field) were measured before TBI, 1-d and 5-day after TBI. Maturation level was monitored daily. The cognition was tested with spontaneous alternation in T-maze (spatial learning and memory) and novel object recognition at P14-24. Animals were sacrificed 1, 3, 7 and 21 days after TBI surgery for the evaluation of lesion volume (crystal violet staining) and microglia activation [ionized calcium-binding adapter molecule 1 (IBA1) and translocator protein (TSPO) staining]. Significant decrease in the overall motor functions, such as suck and swallow, head and hind leg movements, and a significant increase of muscle tone of the limbs, was noted 1d after TBI (13-23 kits/group, $p<0.05$), which well represent the acute phase of the TBI injury in patients; while these functional changes returned to normal 5 days after injury. In addition, TBI kits showed delayed achievement of normal developmental milestones, and 5/19 kits lost cliff-avoidance. Moreover, TBI kits showed significant cognitive deficits, including less percentage of correct alternation rates in T-maze (9-16 kits/group, $p<0.001$) and less discrimination between novel and old objects (8-12 kits/group, $p<0.001$). Lesion volume increased from 15% at 3-d to 30% at 7-d after injury, indicating ongoing secondary injury. In addition, intense microglial activation and TSPO expression were seen not only at the injury site but also in white matter regions of both the ipsilateral and contralateral hemispheres, representing diffused injury seen in patients. In conclusion, this pediatric TBI model produces short-term and long-term impairments comparable to those reported clinically, providing key insights into human pediatric TBI that may ultimately provide unique opportunities for therapeutic interventions.

Title: α-Synuclein increases in the injured spinal cord and is linked to axon loss

Authors: *A. D. SAUERBECK, D. M. MCTIGUE;
Ohio State Univ., Columbus, OH

Abstracts: Accumulation of the protein α-synuclein is linked to development of neurodegenerative diseases including Parkinson's disease, Alzheimer's disease, and multiple system atrophy. Recent work suggests that α-synuclein also plays a role after spinal cord injury (SCI). Even though its function in the normal CNS is still under investigation, numerous studies have shown that α-synuclein is linked to neuropathology. Because of chronic inflammation and the presence of toxic molecules like iron in the injured spinal cord, both of which increase the expression of α-synuclein, we hypothesize that SCI induces accumulation of α-synuclein and this contributes to post-injury processes. To test this hypothesis, adult rats received a mid-thoracic spinal contusion. Animals survived for up to 42 days post-injury and expression of α-synuclein was examined by western blot and immunohistochemistry to determine its spatial and temporal distribution. Following moderate SCI, α-synuclein accumulation was present in a subset of axons as early as 12 hours post-injury. Expression of α-synuclein continued to rise over time, reaching significant levels by 1 day post-injury (dpi) and remaining elevated for at least 42 days after SCI. During the first 3 dpi, the number of axons expressing excess α-synuclein rose. The axons with the highest level of α-synuclein expression were eventually lost, linking accumulation of α-synuclein to tissue loss after SCI. Concomitant with axonal α-synuclein accumulation, neighboring astrocytes also upregulated α-synuclein. Subsequent to loss of α-synuclein+ axons, astrocytes maintained robust expression of α-synuclein chronically. Beyond one week post-injury, most of the α-synuclein in the injured spinal cord was present in astrocytes in the spared white matter, with the majority bordering the lesion cavity. Our study shows for the first time that α-synuclein increases after traumatic SCI, localizes in damaged axons and astrocytes, and correlates with progressive tissue loss. α-synuclein accumulation begins by 12 hours post-injury suggesting it is an early pathological event after spinal trauma. These results position α-synuclein

as a possible contributor to acute and progressive cell death and degeneration after SCI. Given the well-established link between excess α-synuclein accumulation and cell death, and that α-synuclein is known to induce a toxic inflammatory response in astrocytes, these studies indicate the targeting α-synuclein may be a novel and exciting therapeutic target for attenuating deficits after SCI.

Title: Chronic oligodendrogenesis and remyelination after spinal cord injury in mice and rats

Authors: *Z. C. HESP[1], E. Z. GOLDSTEIN[1], C. J. MIRANDA[3], B. K. KASPAR[3], D. M. MCTIGUE[2];
[2]Neurosci., [1]The Ohio State Univ., Columbus, OH; [3]Nationwide Children's Hosp., Columbus, OH

Abstracts: Spinal cord injury (SCI) induces extensive cell death as well as significant cell proliferation. For example, while oligodendrocyte (OL) apoptosis continues for 2-3 weeks post-SCI, oligodendrocyte precursor cells (OPCs) concurrently proliferate around the lesion area. It is known that a least a portion of these proliferating OPCs differentiate into new OLs in the first two weeks post-injury (wpi). However, for how long OPCs proliferate or differentiate into OLs after SCI is unknown. Our work and that of others show that oligogenic factors are expressed in the spinal cord beyond 2wpi. Therefore, we hypothesized that OPCs continue to proliferate and differentiate beyond 2wpi. To test this hypothesis, mouse and rat SCI models were used. Sprague-Dawley rats and two OPC reporter mouse lines (PDGFαRCreER:ROSA and PDGFαR-CreER:mT/mG) received a moderate spinal contusion. At various times after injury, rats received a 1μl intraspinal injection of a GFP-expressing retrovirus to label proliferating cells, and mice received a 4-day oral regimen of tamoxifen (200-300mg/kg) to induce GFP expression in OPCs. GFP+ OPCs in both rat and mouse models retain GFP expression upon differentiation into OLs. To allow time for differentiation and myelination, animals were perfused 3-4 weeks after

virus/tamoxifen administration. OPC fate was assessed between 0-7wpi in rats and 0-12wpi in mice. Overall, we found evidence that oligodendrogenesis occurred at every time examined. New OLs were generated as late as 8-12wpi in mice and 4-7wpi in rats (the latest time available). New OLs expressed mature myelin proteins and wrapped axons in spared and lesioned tissue. The new OL-derived myelin segments displayed shortened internodes - a sign of remyelination. Functional remyelination was further verified by detecting the paranodal protein Caspr adjacent to new myelin segments. In addition, the expression of the pro-OL survival proteins CNTF and FGF-2 were increased chronically in both models. We conclude that oligodendrogenesis and remyelination are ongoing for 2-3 months after SCI in mice and rats. Additionally, the chronic injury environment is dynamic and amenable to OPC differentiation and functional remyelination. Understanding this endogenous response and chronic tissue milieu will be crucial for planning remyelination-based studies and may also provide insight into environments in which spontaneous OL differentiation occurs in the injured adult nervous system.

Title: Toll-like receptor 4 (TLR4) deficiency impairs oligodendrocyte lineage cell responses after spinal cord injury

Authors: *J. S. CHURCH, P. G. POPOVICH, D. M. MCTIGUE;
Neurosci., The Ohio State Univ., Columbus, OH

Abstracts: Prominent oligodendrocyte (OL) loss occurs after spinal cord injury (SCI), however the numbers rebound in the first 7-14 days post-injury (dpi) due to proliferation and differentiation of surviving OL progenitor cells (OPCs) into mature OLs. The mechanisms controlling this endogenous response, however, are not understood. Previous work from our group showed activation of toll-like receptor 4 (TLR4) on microglia induced OPC proliferation and oligodendrogenesis in the intact spinal cord. Thus, the current work tested the hypothesis

that TLR4 signaling contributes to oligodendrogenesis after SCI. Wild-type (WT, HeOuJ) and TLR4-deficient (TLR4d, HeJ) mice were given a midthoracic moderate contusion SCI and sacrificed for spinal cord histology and polymerase chain reaction (PCR) at 1, 7, 14, or 21dpi. Adjacent tissue sections were stained with antibodies recognizing nerve/glial antigen 2 (NG2) expressed by OPCs and glutathione S-transferase pi (GSTpi), a marker of mature OLs. NG2 expression increased over the first week post-injury in epicenter sections of WT and TLR4d mice. NG2 levels were reduced, however, in TLR4d mice rostral to epicenter at 21dpi and caudal to the epicenter from 7 - 21 dpi. The greatest accumulation of NG2 both rostral and caudal was seen in regions of motor tract dieback or degeneration. In both genotypes, significant OL loss occurred by 1dpi but returned to baseline numbers by 14dpi. OL numbers continued to rise above baseline values in WT mice distal to the epicenter between 14 - 21dpi. In contrast, OLs did not increase in TLR4d mice during this time and were significantly lower than in WT caudal to the epicenter. This indicates that intraspinal TLR4 signaling is essential for the delayed rise in OLs after SCI. Surprisingly, the oligogenic factors ciliary neurotrophic factor (CNTF) and insulin-like growth factor (IGF) were significantly elevated in TLR4 deficient spinal cords, revealing that their absence was not the cause of reduced OL numbers. TLR4d and WT spinal cords had similar levels of integrin alpha M (CD11b) and macrosialin (CD68) expression, but TLR4d cords had elevated Fc gamma RII (CD32) and reduced hemoglobin scavenger receptor (CD163) mRNA. Thus, an altered inflammatory environment may have changed the response of OL lineage cells after SCI. Collectively, this work shows that post-SCI OL replacement is influenced by the inflammatory environment, and highlights the importance of TLR4 signaling for normal post-SCI cellular repair mechanisms, growth factor expression, and inflammatory gene expression.

Title: Disruption of the gut microbiome enhances inflammation and impairs recovery after spinal cord injury

Authors: *K. A. KIGERL, J. C. HALL, P. G. POPOVICH;
Dept. of Neurosci., The Ohio State Univ., Columbus, OH

Abstracts: The intestinal microbiome contains approximately 10-fold more genes than the human genome. This vast genome can regulate numerous functions in the host, including metabolism, digestion and absorption of nutrients, and the development of the adaptive immune system. The gut microbiome also can influence disease development and CNS function. Intestinal "dysbiosis" is a condition in which an imbalance between beneficial, non-pathogenic and pathogenic or inflammatory bacteria develops in the gut. Common causes of gut dysbiosis include antibiotics, stress, and altered or impaired gastrointestinal tract peristalsis; all are associated with or caused by traumatic spinal cord injury (SCI). Although gut dysbiosis has been implicated in autoimmune diseases (e.g. multiple sclerosis, type I diabetes, rheumatoid arthritis), allergy and metabolic disorders, the consequences of dysbiosis have not been explored after SCI. Here, data are presented that show time-dependent changes in immune cell number and phenotype in gut-associated lymphoid tissues (GALT), i.e., the Peyer's patches and mesenteric lymph nodes (MLNs), after SCI. Specifically, the number of B- & T-cells in the GALT increases after injury and is associated with enhanced expression of inflammatory cytokines (i.e. TNFα, IL-1β). Changes in immune cell subsets and cytokine profiles occur coincident with SCI-induced changes in the composition of the intestinal microbiota. To determine whether changes in the intestinal microbiome affect intraspinal pathology and recovery of function after SCI, we intentionally induced dysbiosis in gut microbiota prior to injury. New data will show that disrupting the gut microbiome exacerbates intraspinal inflammation and lesion pathology, alters the composition of leukocyte subsets in GALT and impairs spontaneous locomotor recovery. Specifically, in mice receiving a combination regimen of broad-spectrum antibiotics prior to SCI to induce gut dysbiosis, axon and myelin pathology is exacerbated and recovery of locomotor function is impaired. These novel data illustrate the fundamental importance of the gut microbiome in regulating immune cell function and recovery after SCI.

Title: TLR4 signaling promotes iron storage but enhances iron-mediated oligodendrocyte death in the CNS

Authors: *E. GOLDSTEIN, J. S. CHURCH, P. G. POPOVICH, D. M. MCTIGUE;
The Ohio State Univ., Columbus, OH

Abstracts: Traumatic spinal cord injury (SCI) induces concomitant secondary cascades that exacerbate tissue loss. One prominent feature of secondary injury is elevated intraspinal iron from intraparenchymal hemorrhage that accumulates and persists in the lesion, leading to oxidative damage and cell loss. Neurons and oligodendrocytes (OLs) are especially vulnerable to iron-induced death. A potential strategy to combat iron-mediated damage is to stimulate iron sequestration by macrophages through toll-like receptor 4 (TLR4) activation. TLR4 stimulation promotes iron uptake and storage by macrophages and prior work from our group showed intraspinal TLR4 activation in uninjured spinal cords also promotes OL progenitor proliferation and new OL formation. Therefore, TLR4 is an attractive target for promoting tissue repair after SCI. To test the hypothesis that intraspinal TLR4 activation would be protective from iron-induced injury in the spinal cord, we microinjected a TLR4 agonist (lipopolysaccharide; LPS), iron or LPS + iron into the intact spinal cord and examined the tissue 24 hours later to determine if iron sequestration was enhanced and tissue damage reduced by concomitant TLR4 activation. LPS treatment concomitant with iron did promote iron storage as detected by a significant increase in ferritin expression and increased ferritin+ macrophages in the injection site. However, the combined treatment exacerbated OL loss. LPS or iron microinjected alone each caused ~50% loss of OLs, while co-injection of LPS + iron caused almost complete loss of OLs (95% reduction). Surprisingly, the combination did not enhance neuron loss, with all groups exhibiting a 25-30% reduction in neurons. Thus, concomitant TLR4 activation in the presence of excess iron does promote iron uptake and storage by microglia, however it also increases oligodendrocyte loss. These data demonstrate a deleterious role for microglia attempting to regulate excess iron in an injury environment. Ongoing studies are investigating mechanisms of enhanced microglial toxicity when exposed to concomitant TLR4 activation and excess iron.

Title: Activation of dectin-1, an anti-fungal immune receptor, by endogenous CNS proteins causes destructive inflammation after traumatic spinal cord injury

Authors: *Y. WANG[1], J. HALL[2], Z. GUAN[2], P. POPOVICH[2];
[1]Wexner Med. Ctr. At Ohio State Univ., Columbus, OH; [2]Ctr. fro Brain and Spinal Cord Repair, Waxner Med. Ctr. at the Ohio State Univ., Columbus, OH

Abstracts: Dectin-1 is a pattern recognition receptor (PRR) found on the surface of myeloid cells including neutrophils, dendritic cells, monocytes and macrophages. Pathogen-associated molecular patterns (PAMPs) are small pathogen-specific molecular motifs that are recognized by PRRs. Dectin-1 recognizes beta glucans on fungi. Many PRRs can also be activated by endogenous proteins that are released by necrotic cells at sites of injury. These so-called “danger associated molecular patterns” (DAMPs) may activate myeloid cells via dectin-1. Here, using co-immunoprecipitation techniques followed by mass spectrometry, we identified several proteins, many of which are derived from resident glia, that bind dectin-1 and may function as DAMPs after traumatic spinal cord injury (SCI). Moreover, SCI increases expression of dectin-1 mRNA and protein, predominantly in monocyte-derived macrophages, which migrate to the injury site and initiate an inflammatory response with adverse effects on neural repair. Indeed, dectin-1 knock out mice exhibit improved locomotor recovery and reduced lesion volume after SCI. Ongoing experiments will seek to further characterize endogenous non-pathogenic dectin-1 ligands and block their effects on activating intraspinal macrophages.

Title: Is placental growth factor involved in spinal cord repair?

Authors: *R. /. FRANZEN, L. CHABALLE, P. ROWART, F. SCHOLTES, J. SCHOENEN; GIGA Neurosciences, Univ. of Leige, Leige, Belgium

Abstracts: Following axon injury, regeneration outcome depends on the central or peripheral localization of the lesion, thus on the environment through which the axon regrows. In the peripheral nervous system (PNS), the post-injury Wallerian degeneration (WD) inflammatory process occurs rapidly and involves mainly Schwann cells and monocyte-derived macrophages, leading to successful regeneration. In the central nervous system (CNS), WD that involves resident microglia and monocyte-derived macrophages is much slower, leading to a poor clearance of myelin debris and a hostile environment for the axon, whose regeneration is aborted. In this context, the cellular and molecular mechanisms regulating WD in the PNS and the CNS have been extensively studied. In particular, infiltration of monocyte-derived macrophages has been shown to be essential for recovery after spinal cord injury (SCI), but this recruitment needs to be well orchestrated. Among the molecules likely involved in this control, the Placental Growth Factor (PlGF) possesses various properties that could make it an interesting actor in the repair process. Indeed, PlGF is an angiogenic factor with neuroprotective and neurotrophic properties. Moreover, PlGF is able to attract and activate monocytes, and has recently been shown to be involved in macrophage M1/M2 polarization process. We thus decided to assess PlGF role in the molecular and cellular mechanisms that follow SCI. Using Pgf null mice (Pgf -/-), we compared their behavioural recovery to the one of their wild-type (WT) littermates after a thoracic spinal cord contusion injury. Quantification of lesion extension and immunohistological studies were performed on their respective spinal cord tissues. Surprisingly, behavioural data show that Pgf -/- mice recover their motor (BMS and BMS subscores) and sensory (Von Frey test) functions significantly better than wt mice. This is correlated to a significant decrease of the lesion volume in Pgf -/- mice (Luxol Fast Blue/Eosin staining), 28 days after SCI. However, no difference in axon regrowth was observed when assessed with Neurofilaments and Gap-43 immunostainings. We then examined the injured tissues 5 days after SCI, to compare the inflammatory response, and more particularly the M1/M2 macrophage polarity. We found that in the lesioned site of Pgf -/- mice, there is a significantly higher number of M2 - polarized macrophages than in wt mice. These original data, which will be further confirmed by RT-qPCR assays for pro- and anti-inflammatory cytokines, strongly suggest that in absence of PlGF, the lesion environment is an anti-inflammatory milieu, allowing tissue preservation and supporting recovery.

Title: Transforming growth factor beta-induced expression of chondroitin sulphate proteoglycans in reactive astrocytes: roles of non-Smad signaling pathways and autophagy

Authors: *S. S. HANNILA, N. JAHAN, S. GHAVAMI;
Human Anat. and Cell Sci., Univ. of Manitoba, Winnipeg, MB, Canada

Abstracts: Following spinal cord injury, reactive astrocytes express high levels of chondroitin sulphate proteoglycans (CSPGs), which have been shown to inhibit axonal regeneration both *in vitro* and *in vivo*. The factors responsible for inducing CSPG expression have not been fully defined, but there is strong evidence that transforming growth factor β (TGFβ) plays an important role in this process. Administration of anti-TGFβ antibodies reduces glial scarring following spinal cord injury, and expression of CSPGs is significantly increased when astrocytes are treated with TGFβ. Inhibiting TGFβ signaling may therefore be an effective way to reduce CSPG levels in the injured spinal cord. Canonical TGFβ signaling is initiated by binding to the TGFβ receptor, which in turn leads to activation of the Smad2/3 signaling pathway. We have recently shown that levels of Smad2 are significantly reduced in neurons in response to elevation of intracellular cyclic AMP (cAMP), and so, we initially hypothesized that expression of the CSPG neurocan would be reduced following treatment with dibutyryl cAMP (dbcAMP). Surprisingly, while Smad2 levels were significantly reduced in astrocytes treated with dbcAMP and TGFβ, neurocan expression remained elevated, suggesting that Smad signaling is not required for CSPG expression. Subsequent experiments confirmed that activation of the TGFβ receptor is necessary for expression of neurocan, brevican, and aggrecan, but when astrocytes were incubated with either Smad2 or Smad4 siRNA prior to TGFβ treatment, CSPG levels were still significantly increased, which further suggests that TGFβ-induced CSPG expression is Smad-independent. In addition to the Smad signaling pathway, TGFβ also activates several non-Smad signaling pathways, and to identify which of these pathways is involved in CSPG expression, astrocytes were treated with inhibitors of the PI3K-Akt-mTOR or Ras-Erk pathways. No significant reductions in CSPG levels were observed when astrocytes were treated with the Erk inhibitor U0126, but levels of neurocan, brevican, and aggrecan were all significantly

reduced following treatment with two inhibitors of the PI3K-Akt-mTOR pathway: LY294002 and rapamycin, which suggests that CSPG expression is mediated primarily through this pathway. In addition, TGFβ induces several markers of autophagy, and CSPG expression was reduced in response to treatment with choloroquine, which indicates that autophagy may also play a role in this process. Targeting these pathways could potentially prevent CSPG deposition within the spinal cord and thereby create a more favorable environment for axonal regeneration.

Title: Epigenetic regulation of axonal regeneration

Authors: ***M. I. SHIFMAN**, J. CHEN, C. LARAMORE, A. CORNICK, J. SHAHOUD;
Ctr. for Neural Repair and Rehabil., Temple Univ. Sch. of Med., PHILADELPHIA, PA

Abstracts: Spinal cord injury (SCI) causes permanent disability because interrupted axons fail to regenerate. Even with regeneration-inducing interventions, some neurons are much worse than others at regenerating their axons. The reasons for this are not known, and the complexity of the mammalian spinal cord makes it difficult to distinguish true regeneration of injured axons from collateral sprouting of spared axons. By contrast, in lampreys, identified reticulospinal neurons (RS) have large axons whose regeneration can be followed in the living animal or verified unequivocally in histological preparations. Moreover, it is possible to correlate molecular expression patterns with regenerative abilities in individual neurons. Only about 50% of all injured axons regenerate through the scar. Therefore, factors intrinsic to the neurons could be involved in determining their regenerative abilities. Previous work has shown that successful axon regeneration dependent upon the transcription of a large number of regeneration-associated genes (RAGs). CNS axons fail to regenerate because they do not initiate intrinsic regenerative gene programs and they remain sensitive to multiple extrinsic inhibitory influences present within the adult CNS. However, the mechanisms underlying inability of CNS neurons to reactivate transcription of RAGs remain poorly understood. In eukaryotes, genomic DNA is

organized into chromatin and it structure regulated gene expression by preventing the transcriptional machinery from interacting directly with promoters and other DNA regulatory elements. Epigenetic mechanisms - DNA methylation and histone modifications - result in changes in the chromatin structure, which in turn influence gene transcription. We hypothesize that epigenetic modifications function as "master switches" that activate or suppress gene expression of RAGs after SCI. The existence of such a "master switch" could explain the major differences in regenerative potential between the good-regenerating and bad-regenerating neurons. Using unique ability of lamprey CNS to retrograde labeled regenerated and non-regenerated RS neurons we showed that histones H3 and H4 acetylation (indicator of transcriptional activation) is detected only in regenerating RS neurons and not in non-regenerating ones. Using *in situ* hybridization we are testing ***in vivo*** that bad-regenerating neurons have higher levels of histone deacetylases (HDACs) expression and as result, have lower level of histone acetylation that contribute to regeneration failure after SCI.

Title: Nogo, MAG, OMgp and CSPGs are not critical barriers preventing intraspinal regeneration of dorsal root axons

Authors: J. ZHAI[1], H. KIM[1], S. HAN[1], J. K. LEE[2], B. ZHENG[3], G. M. SMITH[1], *Y.-J. SON[1]; [1]Shriners Hosp. Pediatric Res. Ctr., Temple Univ. Sch. of Med., Philadelphia, PA; [2]The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL; [3]Dept. of Neurosciences, Univ. of California, San Diego, CA

Abstracts: Dorsal root (DR) axons fail to regenerate through the dorsal root entry zone (DREZ), the CNS/PNS border. This regeneration failure has been attributed largely to a number of

extrinsic factors abundantly present at the DREZ and within the spinal cord, which include myelin-associated inhibitors such as Nogo, oligodendrocyte-myelin glycoprotein (OMgp), myelin-associated glycoprotein (MAG) and various chondroitin sulfate proteoglycans (CSPGs). To test whether these factors indeed play a critical role in preventing axonal regeneration at the DREZ, we are evaluating regeneration of dorsal root axons in triple knockout mice lacking Nogo, OMgp and MAG. Two weeks after cervical or lumbar root crush, regenerating axons selectively labeled with AAV-eGFP are analyzed in sections or wholemounts. We have found that AAV-GFP extensively labels all subclasses of DRG axons and more importantly, helps us to easily distinguish regenerating from spared axons, which has been a major challenge in many analyses of dorsal root injury and regeneration. We have found that most axons fail to penetrate the DREZ in the tKO mice. Moreover, regeneration of dorsal root axons in the tKO was not improved even after additional removal of CSPGs with lentiviruses expressing chondroitinase. We are currently examining additional mice and extending our analysis to later time points. We also plan to test whether enhancing intrinsic growth ability by a conditioning lesion will promote intraspinal regeneration of axons in the tKO mice. Our results thus far suggest that myelin inhibitors and CSPGs are unlikely to play a critical role in preventing regeneration across the DREZ.

Consortium, Semel Inst. for Neurosci. and Human Behavior, Univ. of California, Los Angeles, CA

Abstracts: We screened nine genetically diverse inbred mouse strains for differences in axonal growth of adult dorsal root ganglion (DRG) neurons on CNS myelin. Naïve DRG neurite outgrowth on myelin was very limited, but preconditioning the neurons by a prior sciatic nerve crush increased axonal growth substantially across all strains, with by far the greatest change in neurons from CAST/Ei mice, which was 5.5 fold greater than the average of the eight other strains. Three independent *in vivo* CNS injury models consisting of dorsal column injury, optic nerve injury and stroke model revealed greater capacity for CNS axonal regeneration in CAST/Ei than C57BL/6 mice. Full-genome expression profiling of naïve and preconditioned DRGs across all strains revealed Activin-βA (Inhba) as the transcript whose expression most closely correlated with axonal growth on myelin. *In vitro* and *in vivo* gain- and loss-of-function experiments confirmed that Activin promotes axonal growth in the CNS. Substantial regeneration is possible, therefore, in the injured mammalian CNS when Activin signaling is intrinsically high, as in CAST/Ei, or when extrinsically modulated in other strains.

Title: The role of epigenetics in axonal regeneration and functional recovery following spinal cord injury

Authors: A. HERVERA[1], L. ZHOU[3], I. PALMISANO[1], G. KONG[3], R. PUTTAGUNTA[3], R. LINDNER[3], *S. DI GIOVANNI[2];
[1]Imperial Col. London, London, United Kingdom; [2]Imperial Col. London, London,, United Kingdom; [3]HIH, Tuebingen, Germany

Abstracts: Lack of a regenerative glial environment and of a neuronal intrinsic regenerative gene expression program compromise axonal regeneration after injury in the central nervous system. However, regenerative gene expression, mainly characterized by the induction of regeneration-associated genes (RAGs), is activated after regenerative PNS injury, including in dorsal root ganglia (DRG) neurons. Pseudounipolar sensory DRG neurons have a central and a peripheral axonal branch belonging to the same cell body, with opposite regenerative capacity. Lack of regeneration of the injured DRG central axon in the spinal cord can be reversed by an injury to the corresponding peripheral branch (conditioning lesion) of those DRG neurons. Interestingly, this conditioning lesion induces the expression of regeneration associated genes (RAGs) and axonal regeneration in DRG central axons. In search for molecular mechanisms that may rule this shift in injury induced-expression programs, we hypothesized that epigenetic modifications may play a role as master regulators. In fact, we recently found that the neuronal regenerative programme is supported by selected epigenetic modifications, including histone acetylation mediated by p300 and PCAF on regeneration-associated genes in DRG neurons and retinal ganglia cells. Additionally, p300 and PCAF, which induce gene expression via acetylation of histones and key transcription factors, can promote axonal regeneration in the injured optic nerve and in the injured spinal cord respectively. Recently, we systematically investigated the expression of histone modifying enzymes and of DNA methylation contributing to epigenetic regulation of the axonal regeneration programme. DNA methylation seemed to play a role in mechanisms other than axonal regeneration. However, we found that specific histone modifying enzymes are selectively down regulated in DRG neurons following injury in the peripheral (regenerative) but not central axonal branch. We also found that axonal retrograde signalling pathways are responsible to modulate their expression. Indeed, we determined that inhibition of specific enzymes results in increased outgrowth of DRG neurons in culture and *ex vivo* after the spinal delivery of specific inhibitors. Last, but not least, mice treated with novel specific inhibitors displayed improved locomotion as compared to vehicle treated littermates following SCI. This supports histone modifying enzymes as novel epigenetic modulators of the axonal regeneration programme, whose inhibition may lead to regeneration and locomotor recovery after spinal injury.

Title: Blocking cPLA2 ameliorated motor deficits and reduced tissue damage after spinal cord injury

Authors: *N.-K. LIU[1], L.-X. DENG[1], Y.-P. ZHANG[2], Q.-B. LU[1], X.-F. WANG[1], J.-G. HU[1], C. L. WALKER[1], J. V. BONVENTRE[3], C. B. SHIELDS[2], X.-M. XU[1];
[1]Indiana Univ., INDIANAPOLIS, IN; [2]Norton Healthcare, Louisville, KY; [3]Harvard Med. Sch., Boston, MA

Abstracts: Several lines of evidence suggest that phospholipase A2 (PLA2) may play a key role in mediating secondary spinal cord injury (SCI). PLA2 are a diverse family of lipolytic enzymes which hydrolyze phospholipids to produce free fatty acids and lysophospholipids. Cytosolic PLA2 (cPLA2) is one of the most important PLA2 isoforms. However, the role of cPLA2 in the pathogenesis of SCI is not fully understood, and is even controversial. In this study, we investigated whether cPLA2 plays a role in the pathogenesis of SCI using multiple approaches including molecular, pharmacological, genetic, and behavior assessments. Our results showed that SCI significantly induced cPLA2 expression and activation. Treatment with AACOCF3, a cPLA2 inhibitor, significantly reduced cPLA2 activity and PGE2 production in C57BL/6 mice after SCI as well as restored Na+-K+-ATPase activity (a marker for membrane integrity or damage) and reduced SCI-induced MPO activity (a marker for neutrophil infiltration). Remarkably, blocking cPLA2 with AACOCF3 reduced tissue damage accompanied by a

corresponding increase in white matter sparing in C57BL/6 mice after SCI. In addition, Luxol fast blue staining showed that the AACOCF3 treatment resulted in a corresponding increase in myelin sparing. Behavioral recovery was also improved after AACOCF3 treatment as shown in BMS, beam walking and foot print analyses. An important finding of the present study was that genetic deletion of cPLA2 resulted in neuroprotection and behavioral recovery following SCI. Genetic deletion of cPLA2 also inhibited the expression of active caspase-3 after SCI, suggesting that cPLA2 activation mediates neural apoptosis. These findings collectively suggest that cPLA2 may play a key role in the pathogenesis of SCI, and this molecule could be an attractive therapeutic target for ameliorating secondary tissue damage and promoting recovery of function after SCI.

Title: Targeting sci induced dendritic spine dysgenesis to attenuate neuropathic pain

Authors: *A. M. TAN[1], S. LIU[2], B. VOHRA[2], S. G. WAXMAN[2];
[1]Neurol., Yale University/VA Connecticut Healthcare Syst., West Haven, CT; [2]Yale University/VA Connecticut, West Haven, CT

Abstracts: Over fifty percent of patients with spinal cord injury (SCI) live a severely diminished quality of life due to neuropathic pain and spasticity that are refractory to current medical

treatment. A variety of factors contribute to these chronic complications after SCI. The primary goal of our research is to extend our mechanistic understanding of dendritic spine behavior in the spinal cord after injury and identify a clinically applicable strategy for addressing intractable pain and spasticity. Dendritic spines, micron-sized postsynaptic structures, have been of great interest within the learning and memory field. Because dendritic spines directly contribute to circuit function and represent modifiable sites of synaptic contact, dendritic spine morphology provides crucial insight into how neural networks form and retain function. Knowledge of dendritic spine behavior in the spinal cord would therefore elucidate mechanisms of spinal sensory-motor circuit dysfunction after SCI. We have previously shown that acute pharmacological inhibition of Rac1-mediated dendritic spine remodeling on nociceptive sensory neurons in the dorsal horn one-month after SCI significantly reduces the presence of neuropathic pain. These findings demonstrate that dendritic spine remodeling contribute to the maintenance of hyperexcitability in the spinal nociceptive system. Given this information, we address the following questions: 1) is acute Rac1-inhibitor treatment efficacious in the long-term? 2) If not, will a gene therapy approach be more effective and durable in SCI induced circuit remodeling and neuropathic pain? 3) Are there alternative molecular targets, downstream of Rac1-GTPase signaling, that are involved in regulating dendritic spine remodeling and neuropathic pain after SCI? Our recent preliminary studies demonstrate that acute pharmacological Rac1 inhibition after SCI reduces evidence of neuropathic pain. However, follow-up assessment demonstrates a partial loss of analgesic effect upon drug cessation, suggesting the return of abnormal dendritic spines and the need for a more durable therapeutic strategy. We are currently utilizing pharmacological and gene therapy approaches to investigate the mechanistic role of the Rac1 signaling pathway in dendritic spine remodeling in pain and other complications after SCI.

Title: Disrupted autophagy after spinal cord injury is associated with neuronal cell death

Authors: *S. S. LIU[1], C. SARKAR[2], E. Y. KOH[1], J. WU[2], M. LIPINSKI[2];
[1]Orthopaedics, [2]Anesthesia, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstracts: Autophagy is a lysosome-dependent intracellular degradation pathway, which plays a neuroprotective function in several neurodegenerative diseases. Although elevated autophagic markers have been reported after SCI, its mechanism, cell type specificity, and relationship with cell death remain unknown. In a rat model of moderate contusive SCI, we found increased levels of autophagy marker, LC3-II, by western blot, and increased numbers of cells accumulating LC3-positive autophagosomes by immunohistochemistry (IHC), starting at 1 day after injury and continuing for up to 5 weeks (Fig. 1). Initial accumulation of LC3 was accompanied by pronounced elevation in the levels of the autophagy substrate, p62 (Fig. 1). This indicates that the initial increase in markers of autophagy was due to defective lysosomal clearance of autophagosomes and their cargo. Accumulation of p62 was resolved by day 7 after SCI (Fig. 1), and was associated with elevated levels of the lysosomal enzyme cathepsin D. Therefore, increase in the size and activity of the lysosomal compartment may help restore autophagy flux at that time. Furthermore, we used IHC to study cell type specificity of autophagy after SCI. LC3 preferentially accumulated in oligodendrocytes and microglia in the white matter, and co-localized with the neuronal cell marker NeuN in the gray matter. LC3 was especially pronounced at day 1 after SCI in motor neurons in the ventral horn. Since our data indicate that at that time autophagic clearance is blocked, we hypothesize that it may contribute to neuronal cell death. Consistently, we found that p62 labeled cells were also positive for apoptotic cell death markers, cleaved caspase 3 and caspase 12, indicating association between disrupted autophagy and cell death. Together, our data indicate that autophagic degradation is temporarily blocked and may contribute to neuronal cell death after SCI.

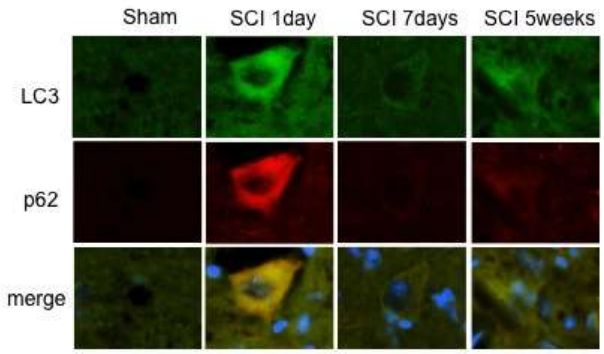

Figure 1: Immunohistochemistry of spinal cord cross-sections from ventral horn of gray matter: expression of LC3 (top row) and p62 (middle row) increased after SCI, and peaked at day 1, with a strong co-localization.

Title: Factors influencing macrophage polarization in spinal cord injury

Authors: *A. KRONER-MILSCH, A. D. GREENHALGH, J. G. ZARRUK, S. DAVID; Neurol., Ctr. For Res. In Neuroscience, Res. Inst. of the McGill Univ., Montreal, QC, Canada

Abstracts: Macrophages/microglia are rapidly activated after CNS injury and appear to have both detrimental and beneficial effects. Recent work suggests that the tissue environment influences macrophage polarization towards different phenotypes, referred to as M1 and M2. M1 polarization includes the production of nitric oxide and pro-inflammatory cytokines, while M2 macrophages are viewed as anti-inflammatory which contribute to wound healing and tissue repair. We and others have previously reported that M1 markers dominate the macrophage/microglial response after spinal cord injury (SCI). Phagocytosis *in vitro* by macrophages was also shown to reduce secretion of pro-inflammatory cytokines and we demonstrated that myelin phagocytosis skews M1 activated bone marrow derived macrophages (BMDMs) and microglia towards an M2 phenotype. We now show that TNF, which is rapidly upregulated after SCI in various cell types, is a crucial factor in preventing the myelin induced switch from M1 to M2. *In vitro*, rTNF completely abrogates the switch. TNF null mice show a better functional recovery after SCI and have more M2 macrophages at the injury site. Interestingly, BMDMs from TNF null mice show a strong reduction in the expression of M1 markers after LPS stimulation, which can be further reduced by myelin phagocytosis, suggesting a TNF dependent and a TNF independent mechanism. Furthermore, the reduction in neurite growth from DRG neurons treated with conditioned medium from LPS treated BMDMs is completely prevented when BMDMs from TNF null mice are used. We have also previously shown that the presence of iron in macrophages, mainly derived from phagocytosis of red blood cells (RBCs), is correlated with the expression of TNF. We now provide evidence that systemic iron loading in mice with SCI exacerbates TNF expression, increases production of reactive oxygen species and cell death in the injured cord, and also reduces locomotor recovery. We also show *in vitro* that BMDMs from TNF null mice loaded with RBCs show a significant reduction of M1 markers and increase in M2 markers as compared to BMDMs from wildtype control mice. These finding suggest that iron and iron induced TNF production play a crucial role in

maintaining the pro-inflammatory M1 phenotype of macrophages after SCI. Funded by a grant from the Canadian Institutes of Health Research (CIHR).

Title: Genetic modifications of Crmp enhance axonal regrowth after spinal cord injury by reducing cytoskeletal destabilization and inflammatory responses

Authors: *J. NAGAI[1], Y. KITAMURA[1], K. OWADA[1], Y. GOSHIMA[2], T. OHSHIMA[1]; [1]Wakamatsu-cho, Waseda Univ., Tokyo, Japan; [2]Dept. Mol. Pharmacol. Neurobiol., Grad. Sch. Med., Yokohama City Univ., Yokohama, Japan

Abstracts: The recovery after central nervous system (CNS) injury in the adult mammal by targeting suggested molecules were substantially limited perhaps because they contribute to either axonal elongation or glial scar formation. One prevailing theory is the presence of inhibitory molecules that prevent injured axons from regenerating beyond the injury site. Myelin-associated inhibitors (MAIs), which are expressed in myelin and mature oligodendrocytes and bind to Nogo-66 receptor on axonal membranes, are non-permissive substrates for neurite outgrowth. Extracellular matrix molecules, such as Semaphorin3A (Sema3A), secreted from astroglial scar tissue at the CNS injury site are likely to be important for the inhibition of axonal regrowth by acting on the axonal cytoskeleton. However, loss-of-function studies of MAIs still produce conflicting results on their role in axon regeneration after CNS trauma such as spinal cord injury (SCI) and the high lethality of Sema3AKO mice raises concerns over possible strong side effects of targeting Sema3A. To develop more effective therapies for CNS injuries, the focus should be on common downstream molecules of these signals that control axonal growth. Cytoskeletal dynamics is a key factor limiting regenerative capacity in terms of axonal formation, glial inflammation and scarring. Collapsin response mediator protein (CRMP) has been demonstrated to regulate the cytoskeletal responses to the

axonal outgrowth inhibitory signals *in vitro*, but the role of CRMP axonal regrowth and inflammatory responses *in vivo* after CNS trauma remains to be elucidated. Here, we found that inhibitory and toxic forms of CRMP were significantly increased in injured wild-type spinal cords. We generated mutant mice of CRMP genes and found remarkable locomotor recovery with robust axonal regrowth through microtubule polymerization and cell survival in CRMP4KO mice. Moreover, we also observed CRMP4 upregulation in inflammatory cells; activated microglia/macrophages and reactive astrocytes. Mice lacking CRMP4 exhibited suppression of non-traumatic and post-traumatic inflammation and dramatic reduction of scarring after SCI, providing permissive environment for the regenerative growth of injured spinal cord axons. These results provide us with new insights into CRMP as a novel factor that bridges two major inhibitory factors after SCI.

Title: Virally delivered ADAMTS-5 as a strategy to promote axon growth in inhibitory CSPG environments

Authors: *K. WINSOR, Z. WANG, D. COLEY, C. NIENHAUS, M. BLACKMORE; Marquette Univ., Milwaukee, WI

Abstracts: Chondroitin Sulfate Proteoglycans (CSPGs), a diverse family of proteins adorned by glycosaminoglycan side chains, are deposited at sites of injury to the central nervous system (CNS) and present a major barrier to axon growth. Thus to improve axon growth and recovery from CNS injury it will likely be necessary to enzymatically degrade CSPGs, or to render injured axons insensitive to CSPG-mediated inhibition. ADAMTS enzymes are expressed in nervous system tissue and can act to cleave the protein core of CSPGs. In particular, infusion of

ADAMTS-4 enzyme to sites of spinal injury has been reported to degrade the CSPG aggrecan and to improve functional outcomes. Here we test whether ADAMTS-5, which is structurally related and reportedly more enzymatically active than ADAMTS-4, can also improve axon growth in CSPG-rich environments. We tested full length ADAMTS-5 as well as two truncated forms that mimic endogenous degradation products with enhanced activity. Lentiviral constructs encoding ADAMTS-5 or its derivatives were applied to cell lines or to primary astrocytes in order drive production of ADAMTS enzymes, and conditioned media from transduced cells was applied to neurons cultured on CSPG substrates. Western blotting confirmed expression of exogenous ADAMTS-5 in transduced cells, but showed minimal secretion. Consistent with this, media from virally-transduced cells produced neither significant degradation of CSPGs, nor enhanced axon growth. Unexpectedly, however, media from early postnatal astrocytes dramatically enhanced axon growth on CSPG substrates, regardless of viral treatment. The astrocyte media improved axon growth only when neurons were exposed to the media, and not when the CSPG substrates were pre-exposed, suggesting that rather than degrading CSPGs the astrocytes produce a signal that acts directly on neurons. Moreover, although a secreted protein called periostin has recently been proposed to explain astrocyte-mediated improvements in axon growth on CSPG substrates, we detected no periostin expression in the astrocyte cultures, suggesting an alternative mechanism. Combined, these data illustrate challenges in the use of virally-expressed ADAMTS-5 enzyme as a potential therapeutic approach to CNS injury, but also illustrate an intriguing ability of early postnatal astrocytes to provide an unknown signal to neurons that renders them insensitive to CSPG-mediated inhibition.

Title: Cannabinoid CB2 receptor (CB2R) stimulation delays rubrospinal mitochondrial-dependent degeneration and improves functional recovery after spinal cord hemisection

Authors: *M. VISCOMI, L. LATINI, E. BISICCHIA, V. SASSO, V. CAVALLUCCI, M. MOLINARI;
Fondazione Santa Lucia, Rome, Italy

Abstracts: Spinal cord injury (SCI) is a devastating neurological disease that results in severe functional impairments for which there are no restorative therapies. In addition to the primary injury, functional impairments following a SCI are attributed to degenerative events in regions that are remote but functionally connected to the primary lesion site_i.e., supraspinal structures. These events include cell death and structural changes and are important predictors of outcome. However, few studies have examined the molecular and biochemical changes in remote neurons after SCIs as targets for therapeutic interventions. This study examines the effects of pharmacological modulation of type-2 cannabinoid receptor (CB2R) on the fate of axotomized rubrospinal neurons and functional recovery in a model of spinal cord dorsal hemisection (SCH) at the cervical level in rats. Beginning 7 days after damage, cross-sectional area and stereological analyses demonstrate that SCH induces severe atrophy and cell loss of contralateral rubrospinal neurons. At the same time, morphological and biochemical analyses demonstrate that SCH causes a significant de novo synthesis of CB2R in the axotomized rubrospinal neurons. Notably, in rubrospinal neurons morphological changes proceed concomitantly with molecular changes in the apoptotic cascade resulting in cytochrome c (cyt-c) release from damaged mitochondria, apoptosome formation, and caspase-3 activity. Pharmacological stimulation of CB2R, by its selective agonist JWH-015, by increasing the bcl-2/bax ratio and decreasing cytochrome c release, delays SCH-induced atrophy and cell loss in rubrospinal neurons as demonstrated by both morphological and biochemical approaches. Furthermore, JWH-015 treatment significantly improves the locomotor performance and the forelimb-hindlimb coordination as demonstrated by beam walking and CatWalk behavioral tests. These findings implicate the Endocannabinoid system (ECS), particularly CB2R, as part of the endogenous neuroprotective response that is triggered after an SCI. Thus, CB2R modulation might represent a promising therapeutic target that lacks psychotropic effects and can be used to exploit ECS-based approaches to counteract the remote degeneration of supraspinal regions after SCI.

Title: FasL modulates disruption of the blood-spinal cord barrier, glial scarring and inflammation after spinal cord injury: Evidence from human tissue and mouse model

Authors: *W.-R. YU, M. G. FEHLINGS;
Genet and Develop, U of Toronto, Divisions of Genet. & Develop. and Neurosurgery, Toronto Western Res., Toronto, ON, Canada

Abstracts: Accumulating evidence indicates that the death receptor Fas and its specific ligand (FasL) have a wide range of physiological non-apoptotic functions. We sought to study the role of Fas ligand-mediated blood spinal cord barrier (BSCB) disruption, glial scarring and inflammation following spinal cord injury (SCI). We examined FasL-mediated BSCB disruption, glial scar formation and inflammatory response in human SCI and in an *in vivo* Fejota™ clip compression model of SCI in FasL-deficient B6Smn.C3-*Tnfsf6*^{gld}/J and wild-type mice using immunohistochemistry, Western blotting, and ELISA with Mouse 32-plex cytokine/chemokine panel bead immunoassay. We report novel evidence that shows leakage of plasma protein (Fibronectin, Fibrinogen and Homeglobin) into the extravascular space and parenchyma of the spinal cord, increased expression of CX3CR1, IL-1β and reduction of anti-inflammatory cytokine IL-10 expression in the injury epicenter after acute and sub-acute human SCI. We also found significantly reduced expression of Fibronectin and Evans blue leakage at 3 days, and reduced glial scarring and inflammatory response (Iba1 and galectin-3 expression). Increased levels of MAP2 and CNPase, expression and improved neurological functional recovery were observed in FasL-deficient mice relative to wild-type mice after SCI. In conclusion, we report multiple lines of evidence that indicate that FasL activation plays a pivotal role in mediating BSCB disruption, glial scarring formation, the inflammatory response and neurological functional recovery after SCI. These data provided a compelling rationale for therapeutically targeting Fas/FasL in human SCI.

Title: Role of toll-like receptor 9 activation in the intact spinal cord: Effects on neurons and glia

Authors: *A. PALLOTTIE[1,2], L. NI[2], W. DONG[2], R. F. HEARY[1,2], S. ELKABES[1,2]; [1]Neurolog. Surgery, Grad. Sch. of Biomed. Sci., Rutgers Univ., Newark, NJ; [2]Neurolog. Surgery, Reynolds Family Spine Laboratory, New Jersey Med. School, Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstracts: Toll like receptor 9 (TLR9), best known for its role in the induction of innate immune responses, is expressed in the spinal cord and modulates sterile inflammation following spinal cord injury. To better define the effects of TLR9 activation in the spinal cord, naïve mice received a single intrathecal injection of a TLR9 agonist, CpG ODN 1826. Subsequently, the time course of the inflammatory reaction and the effects on neurons, astrocytes and myelin proteins were delineated in the lumbar region. As early as 6 hours post-injection (p.i.), there was a significant increase in CD45 (1.7-fold), CD11b (1.7-fold), and GR1 (4.1-fold)-positive cells in the spinal cord of CpG ODN 1826-treated mice as compared to vehicle-treated controls. At 24 hours p.i. the inflammatory response reached a peak with a 4.2-fold increase in CD45, 4.3-fold in CD11b, and 6.4-fold in GR-1-positive cells in the CpG ODN 1826-treated mice. This was followed by a marked reduction in inflammatory cell counts at 48 hours p.i. and a return to baseline levels by 96 hours. Despite the decline in inflammatory cells, a delayed decrease in myelin basic protein levels was observed at 96 hrs p.i. In contrast, the levels of the astroglial marker glial fibrillary acidic protein and neuronal marker NeuN remained unchanged. These results suggest that activation of TLR9 in the spinal cord can affect expression of myelin proteins or myelin integrity. Ongoing studies are determining the underlying mechanisms and whether this is a direct or indirect effect on oligodendrocytes.

Title: Depression-like behaviors and altered serotonergic signaling resulting from spinal cord injury in rats

Authors: *D. STEWART, C. FLOYD;
Physical Med. & Rehabil., Univ. of Alabama At Birmingham, Birmingham, AL

Abstracts: Spinal cord injury (SCI) is a devastating condition that affects approximately 12,000 persons annually in the U.S. The initial injury is followed by secondary pathophysiological sequelae, including reduced modulation of serotonin (5-HT) circuits controlling locomotion in the spinal cord. Additionally, psychological conditions such as clinical depression manifest in up to 60% of persons with SCI. Selective serotonin reuptake inhibitors (SSRIs) have been proposed as a therapy to enhance locomotor ability by restoring 5-HT signaling in the spinal cord. However, studies of SSRIs have not evaluated a reduction in depression symptoms in SCI models, a relevant topic due to the potential for globally altered 5-HT signaling in supraspinal circuits. The current study seeks to evaluate the effect of SCI on depression-associated behaviors and changes in 5-HT signaling after SCI in a rodent model. Our overarching hypothesis is that SCI will lead to changes in serotonin transporter (SERT) and 5-HT1a receptor (5HT1aR) expression in brain and spinal cord. In addition, an increase in depression-associated behavior will be evident in SCI animals. Adult male Sprague-Dawley rats were randomly assigned to receive either a moderate contusion SCI at thoracic level 10 or sham surgery (uninjured), recovering for either 14 or 28 days. Depression-associated behavior (sucrose preference test) and corticosterone (CORT) levels were measured before injury and at 14 or 28 days after SCI. Animals were euthanized and brain and spinal cord samples collected for Western blot analysis of 5-HT1aR and SERT levels. We found that sucrose preference decreased at 28, but not 14, days after surgery in SCI animals. In contrast, CORT levels were significantly increased at 28 days post-SCI in the injured group versus the uninjured group. Similarly, SERT expression increased in the raphe nuclei at both 14 and 28 days after SCI and decreased in the spinal cord rostral to the lesion epicenter, comparing SCI to uninjured group. Levels of 5-HT1aR were increased in the spinal cord rostral and caudal to the lesion and in the raphe nuclei at 28 days post-SCI in the injured group versus uninjured controls. These results indicate that SCI induces physiological and psychological changes in male Sprague-Dawley rats that are accompanied by region-specific 5-HT signaling changes. Animals receiving SCI exhibited signs of depression, including anhedonia and increased CORT. Future studies evaluating the effects of SSRIs will further elucidate the mechanism of 5-HT changes after SCI. Supported by the UAB TJ Atchison SCI Research Program.

Title: The severity-dependent negative effects of isolated thoracic spinal cord contusion in mice on cognitive and affective behaviors

Authors: ***Z. ZHAO**[1], B. A. STOICA[2], A. I. FADEN[2], J. WU[2];
[1]Univ. of Maryland At Baltimore, Baltimore, MD; [2]Anesthesiol. and the Ctr. for Shock, Trauma and Anesthesiol. Res. (STAR),, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstracts: Clinical studies have reported cognitive and affective deficits after spinal cord injury (SCI). Roth et al. demonstrated that 40-60% of SCI patients show impairment in attention, concentration, memory, learning, and/or problem-solving ability. The cause of the cognitive deficits in SCI patients has been debated, because of potentially confounding factors such as concurrent traumatic brain injury (TBI). Some have tried to address this issue by focusing on SCI patients without signs of TBI, and confirmed that these patients also show impairments in cognitive function. Yet few clinicians or experimentalists in SCI recognize that such injuries can cause chronic neurodegeneration in the brain, or that such progressive changes can negatively impact long-term cognitive outcomes or affective state. It is known that cognitive/affective impairments are detrimental to SCI patients not only in their own right but because they can compromise rehabilitation. Here we examined effects of isolated thoracic SCI in mice on cognition, depression, and brain neurodegeneration. To determine whether cognitive and affective impairments increase as a function of injury severity we exposed mice to sham, mild, moderate, or severe SCI using the Infinite Horizon Spinal Cord Impactor and evaluated performance on a variety of neurobehavioral tests that are less dependent on locomotion. We showed that locomotor function measured by BMS scores was reduced in an injury severity

manner. Cognitive impairments in the tests of Y-maze, novel objective recognition, and step-down fear conditioning increased with injury severity at two months post-injury. SCI also caused deficits in affective behavior as quantified in the sucrose preference, tail suspension, and forced swim test, dependently on injury severity. Stereological analysis demonstrated SCI severity-dependent neuronal loss chronically in the cerebral cortex, thalamus, and hippocampus. Our data suggest that spinal cord contusion in mice induces a chronic neurodegeneration in important brain regions associated with cognitive decline and physiological depression. Thus, these findings provide the experimental confirmation of clinical evidence suggesting SCI-related cognitive/affective deficits considerably revising concepts about the nature of SCI as a focal acute neurodegenerative disorder.

Title: Neuroprotective effect of sodium nitroprusside depends of cellular differentiation stage and damage conditions in different cell lineages

Authors: *R. MACIAS-VÉLEZ[1], L. SAUCEDO ARELLANO[1], M. RIVERA CERVANTES[1], R. SCHLIEBS[2];
[1]Univ. De Guadalajara, Guadalajara, Mexico; [2]Neurochemistry, Paul Flechsig Inst. for Brain Res., Leipzig, Germany

Abstracts: Under hypoxic conditions the formation of free radicals exceeds the antioxidant mechanisms, triggering multiple alterations to cellular components.Oxidative stress has been defined as a disturbance in pro-oxidant and antioxidant balance. If pro-oxidant stress goes beyond, it can cause cell damage and death.Sodium nitroprusside (SNP) is a nitric oxide (NO) donor, which has been used for testing the oxidative stress, particularly in in-vitro experimental models; as well to value the neuroprotective properties of NO, by the modulation of specific intracellular signaling pathways.The aim of this study was to value differentially incubation of two different cell lines and primary-neurons culture with addition SNP in culture media, favoring cell viability and determining differential susceptibility to hypoxia and oxidative stress caused by H2O2. And let to propose a potential explanation about how cell susceptibility depends of damage nature. Also this study valued the dual effect of NO released from SNP in culture media. This study used two cellular lines (5151, GT1-7) and primary culture neurons. Both were incubated for 2 and 6 hours in culture media containing different concentrations of SNP (1,10,100 y 1000µM) in order to obtain a dose-response curve, by a cellular viability test. Later, the cultures was submitted to an oxidative stress model with H2O2 (using two concentrations, 250 and 500µM) and a hypoxia model (by perfusion of 95% N2 and 5% CO2 in culture media). Subsequently under these damage conditions, we valued the SNP neuroprotective effect (1 and 10µM) which was added to culture media and tested by MTT analysis.Our results shown that SNP protect non-differentiated GT1-7 cells from damage cause by H2O2. But not in the other cell line and primary culture neurons.Also SNP plays a protective roll in differentiated GT1-7 cells damaged by hypoxia. By the same way SNP exert a protective effect in primary culture

neurons under hypoxic damage. So, the neuroprotective roll of SNP over cells subjected to pro-oxidant stress depends of stage of differentiation and nature of damage.

Title: The neurotherapeutic effects of the calcium binding protein apoaequorin

Authors: *V. L. EHLERS[1], E. L. ADAMS[1], N. B. FETTINGER[1], S. C. MICHELS[1], J. R. MOYER, Jr.[1,2];
[1]Psychology, [2]Biol. Sci., Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstracts: Stroke is a devastating condition that accounts for 1 out of every 19 deaths in the United States alone (Go et al., 2013). During ischemic stroke, deprivation of oxygen and glucose leads to intracellular calcium accumulation, triggering molecular cascades and activation of proteases, caspases, and calpains that lead to cell death (Choi, 1992). Several studies demonstrate that buffering excess intracellular calcium using endogenous calcium binding proteins (CaBPs) provides neuroprotection from ischemia (e.g., Fan et al., 2007). Apoaequorin (AQ), a CaBP isolated from the jellyfish Aequorea victoria, previously demonstrated neuroprotection using an *in vitro* model of ischemia. Specifically, an intrahippocampal infusion of AQ administered prior to ischemia resulted in reduced cell death, in addition to elevation of cytokine and chemokine mRNA (Detert et al., 2013). The anti-inflammatory cytokine IL-10 was significantly increased 1 h following AQ infusion, and remained elevated for up to two days post-infusion, suggesting the potential involvement of a neuroimmunomodulatory response in neuroprotection. Oral administration of AQ for 7 days prior to an ischemic insult also resulted in significantly reduced cell death (Hochstetter et al., SfN 2013). In the present studies, we investigated the neuroprotective effects of AQ oral administration using additional doses (0, 3.6, 48, 240, 480 mg/kg AQ mixed with peanut butter for 7 d) and lengths of administration (48 mg/kg AQ for 0, 1, 2, or 7 d). Using an *in vitro* model of ischemia, the present study found that oral administration

of AQ is neuroprotective in a dose- and time-dependent manner. Specifically, a dose of 48 mg/kg resulted in significantly reduced cell death when administered for 7 days prior to ischemia ($p < .05$). The results of these studies support our previous findings indicating hippocampal infusion of AQ is neuroprotective, and demonstrate that oral administration of AQ may serve as an additional route for neuroprotection. Ongoing studies are investigating whether oral administration of AQ leads to measurable levels of the protein in the brain, and if not, how AQ oral administration is providing its neuroprotective effects.

Title: GABA treatment induces significant differences in the unfolded protein response (UPR) in cerebral cortex and hippocampus in an oxygen and glucose deprivation (OGD) model

Authors: *M. SANTOS GALDIANO[1], D. PEREZ-RODRIGUEZ[2], B. ANUNCIBAY-SOTO[2], E. FONT[2], I. FERNANDEZ-UGIDOS[2], P. GONZALEZ-RODRIGUEZ[2], C. C. PEREZ-GARCIA[3], A. FERNANDEZ-LOPEZ[2];

Abstracts: GRP78/BIP is a molecular chaperone located in the RE that regulates the protein folding and elicits the unfolded protein response (UPR) following ER stress. GRP78/BIP is widely used as a measurement of the UPR a condition elicited by stroke. We here report the UPR response to oxygen and glucose deprivation (OGD) and glutamate excitotoxicity in the external and internal pyramidal cells of the cerebral cortex and CA1 and CA3 hippocampal pyramidal cells. The study has been performed in a *in vitro* slice model. While the presence of glutamate

elicited a strong UPR in both cerebral cortex and hippocampus, the OGD-dependent UPR was only detected in the hippocampus. The presence of GABA in the incubation media increased significantly the URP in the cerebral cortex to levels similar to those observed in the presence of glutamate. GABA did not modified the UPR elicited by glutamate. Thus, UPR seems to play a crucial neuroprotective role in the excitotoxic stress in both cerebral cortex and hippocampus. In contrast the neuroprotective role of UPR following OGD appears in the hippocampus but not in the cerebral cortex. Our results support that UPR in the cerebral cortex would be related with GABA receptors and would fit with previous studies indicating a relevant role of chloride channels.

Title: Distinct roles of polycomb group proteins and their associated proteins in neuronal cells and endocrinal cells

Authors: *F. BIAN[1], J. RICE[3,2], L. CAO[1], Y. LI[1], A. ZHOU[1];
[1]Neurosci. Inst., [2]Morehouse Sch. of Med., Atlanta, GA; [3]Spelman college, Atlanta, GA

Abstracts: Background: Polycomb group (PcG) proteins are transcriptional repressors expressed in various cell types. A protective role against ischemic injury has been shown for a few PcG proteins in neuronal cells. Differential changes in PcG proteins and some of their target proteins have been reported for different neuronal ischemic conditions. Little is known for the roles of PcG in different cell types. The objective of this study was to determine (1) whether PcG proteins may have different interacting partners in different cell types, and (2) how cellular proteomes may be regulated differently by changes in PcG protein levels. **Methods:** Mouse

brain-derived neuroblastoma NS20Y cells or pituitary adenoma AtT20 cells were transfected with cDNAs encoding Myc-tagged PcG protein Bmi1 or Ezh2, respectively. PcG-interacting proteins (direct or indirect) were isolated by immunoprecipitation (IP) using an anti-Myc antibody and determined by quantitative mass spectrometry (MS). Cellular proteomes were analyzed with a quantitative MS-based proteomic approach and characterized with the assistance of bioinformatic tools (MetaCore and Proxeon). **Results:** IP-MS analysis showed 12 Bmi1-interacting proteins in both NS20Y and AtT20 cells (common), 59 only in NS20Y cells and 44 only in AtT20 cells. Examples of common proteins include Csnk2a1, Hdac2, and Ywhab, which are the known Bmi1-interacting proteins. Bmi1-interacting proteins that were identified only in NS20Y cells or AtT20 cells also included those previously known and those reported here for the first time. Examples of the latter include Chd4, Ybx3, Ebna1bp2, Ubtf, Uchl1, and Upf1 in NS20Y cells, and Ercc6l2, HMX3, and Tardbp in AtT20 cells. Results of proteomic analysis of total cellular proteins showed enriched presences of different biological processes in WT NS20Y cells and AtT20 cells. Interestingly, overexpression of Ezh2 also induced differential proteomic changes in NS20Y cells and AtT20 cells. Notable examples are decreased levels of proteins associated with DNA damage/Role of SUMO in p53 regulation in NS20Y cells, and glycolysis, gluconeogenesis and glucocorticoid receptor signaling in AtT20 cells. Taken together, these results suggest that individual PcG proteins may play different regulatory roles in different cell types, and they do so by interacting with different partner proteins.

Title: Inhibition of 20-hydroxyeicosatetraenoic acid (20-HETE) synthesis decreases apoptotic and necrotic neurodegeneration produced by oxygen-glucose deprivation

Authors: L. DU[1], S. M. POLOYAC[1], T. C. JACKSON[1], H. BAYIR[1], P. M. KOCHANEK[1], R. S. B. CLARK[1], *M. D. MANOLE[2];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Univ. Pittsburgh, PITTSBURGH, PA

Abstracts: Neuronal hypoxia-ischemia induces membrane depolarization, phospholipase activation, and arachidonic acid (AA) release. Metabolism of AA by CYP 4A ω- hydrolase generates 20-HETE, a potent vasoconstrictor. 20-HETE increases in brain homogenates after resuscitation from cardiac arrest. Blocking CYP4A with the irreversible inhibitor HET0016 improves cortical perfusion and neurological outcome. The beneficial effect of CYP4A/20-HETE inhibition could be due to improved perfusion, direct neuroprotective effects, or both. The detrimental effect of 20-HETE in neurons is not completely understood. We hypothesize that inhibition of 20-HETE production after hypoxia in primary cortical neuronal rat cultures improves neuronal survival by preserving antioxidant reserves and decreasing apoptosis. Cortical neurons were exposed to the following conditions: oxidative stress using H_2O_2, excitotoxic stress using glutamate and glycine, and oxygen glucose deprivation (OGD) using 95% argon, 5% CO_2 and 0.5 mM Glucose. Cell death was assessed using the MTT assay, lactate dehydrogenate release, and flow cytometry. Incubation with 20-HETE produced a dose-dependent decrease in neuronal survival (73.5±6, 55±7, and 41±4% of control for 1, 10, and 100μM 20-HETE, respectively, $p<0.05$). Inhibition of 20-HETE formation using the CYP4A inhibitor HET0016 increased survival in neurons subjected to oxidative stress induced by H_2O_2 (65±7% vs. 89±15%, $p<0.05$, vehicle vs. HET0016). It also increased neuronal survival after excitotoxic injury induced by glutamate/glycine (69±7% vs. 81±10%, $p<0.05$, vehicle vs. HET0016). OGD impaired the cellular respiration as assessed by the MTT assay. Inhibiting 20-HETE formation with HET0016 increased neuronal survival after OGD (74.3±7.7 vs. 87.4±4.5%, $p<0.05$, OGD vs. HET0016 treated OGD at 2h, and 57.3±2.5 vs. 71.6±6.1%, OGD vs. HET0016/OGD at 24h, $p<0.05$). Treatment with HET0016 reduced pro-apoptotic caspase 3/7 activity (225±6 vs. 147±6, OGD vs. HET0016/OGD, $p<0.05$) and restored intracellular GSH levels (47±0.6 vs. 58±0.1, OGD vs. HET0016/OGD, $p<0.05$). These data suggest that the vasoconstrictor eicosanoid 20-HETE has direct neurotoxic effects, and contributes to excitotoxic and oxidative neuronal death. After neuronal hypoxia induced by OGD, 20-HETE inhibition increased neuronal survival, restored intracellular GSH levels, and reduced caspase 3/7 activation. In conclusion, inhibiting 20-HETE synthesis reduces neuronal death and apoptosis in a model of *in vitro* OGD. Preventing 20-HETE formation is a neurotherapeutic strategy that merits further exploration in models of ischemia-reperfusion.

Title: The tri-block co-polymer F-68 (Poloxamer 188) blocks oxygen-glucose deprivation-induced increases in reactive oxygen species and prevents lipid peroxidation

Authors: P. B. SHELAT, J. C. WANG, *J. D. MARKS;
Pediatrics, Univ. of Chicago, Chicago, IL

Abstracts: Inhibition of reactive oxygen species (ROS) production reduces neuronal death following oxygen-glucose deprivation (OGD) *in vitro* and hypoxia-ischemia (HI) *in vivo*, showing that ROS contribute to this death. We have shown that F-68 (also called Poloxamer 188), a tri-block co-polymer of poly[ethylene oxides] and poly[propylene oxides], profoundly rescues hippocampal neurons from severe OGD, preventing mitochondrial apoptosis. F-68 interacts with cell membranes, and blocks exogenous lipid peroxidation in neurons. We hypothesized that F-68 alters lipid peroxidation following OGD in embryonic rat hippocampal neurons. C11-BODIPY$^{581/591}$-labeled hippocampal neurons were exposed for 45 min to either OGD (1% O_2, 0 glucose, 37° C; an insult that kills about 60% of neurons), or saline containing glucose in ambient O_2 (control). Different coverslips were imaged (490 nm) every 15 min over the subsequent 2 hr in control saline, and fluorescence intensity quantified on a cell-by-cell basis. Compared with control cells, C11-BODIPY$^{581/591}$ fluorescence intensity progressively increased, beginning at 30 minutes after OGD and reaching a plateau 90 min after OGD. In contrast, neurons continuously incubated in F-68 (30 μM) following OGD failed to exhibit significant fluorescence intensity increases over time, suggesting that F-68 blocks OGD-induced membrane lipid peroxidation. Lipid peroxidation following OGD is mediated by peroxynitrite, produced by the diffusion-limited reaction of superoxide and nitric oxide. Therefore, we used CellRox Orange to determine F-68 effects on OGD-induced changes in ROS. Compared with control neurons, CellRox fluorescence was increased 1 hr after OGD ($P<.01$) and further increased at 2 hr after OGD ($P<.0001$). Neurons continuously incubated in F-68 following OGD did not exhibit significant mean intensity increases over the 2 hr period compared with F-68 incubated control neurons, indicating that F-68 blocked OGD-induced increases in ROS. We next used linear regression of the raw intensities over 30 min epochs to determine ROS production rates at each time point. Following OGD, mean CellRox slopes markedly and progressively increased from control slopes over 2 hrs after OGD. In contrast, mean CellRox slopes in F-68 treated neurons

following OGD did not significantly increase over time compared with the mean baseline slope. These data indicate that F-68 treatment blocks OGD-induced membrane lipid peroxidation and inhibits ROS increases following OGD. This F-68-induced block of ROS increases after OGD may occur as a result of the previously demonstrated inhibition by F-68 of OGD-induced mitochondrial dysfunction.

Title: 2-(4-Methoxyphenyl)ethyl-2-acetamido-2-deoxy-β-D-pyranoside confers neuroprotection in cell and animal models of ischemic stroke through calpain1/PKA/CREB-mediated induction of neuronal glucose transporter 3

Authors: S. YU, Q. HE, L. WEI, *F. DING;
Jiangsu Key Lab. of Neuroregeneration, Nantong University, China, Jiangsu, China

Abstracts: Objectives: Salidroside is proven to be a neuroprotective agent of natural origin, and its analogue, 2-(4-Methoxyphenyl)ethyl-2-acetamido-2-deoxy-β-D-pyranoside (named SalA-4g), has been synthesized in our lab. The aim of this study was to investigate whether SalA-4g could be developed into a promising neuroprotective drug for treating neuronal insult during cerebral ischemic stroke. Very importantly, the regulation mechanisms underlying the neuroactivity of SalA-4g were further explored. Methods: The *in vitro* and *in vivo* protective effects of SalA-4g were evaluated in primary hippocampal neurons exposed to oxygen and glucose deprivation (OGD) and the male Sprague-Dawley (SD) rat model of ischemic stroke induced by transient middle cerebral artery occlusion (MCAO), respectively. The cell survival and cell apoptosis were evaluated by MTT, Hoechst, TTC staining and TUNEL assays. To explore the mechanism of SalA-4g neuroprotection, glucose uptake and glucose transporter 3 (GLUT3) expression and recruitment were measured with a fluorescent dye (2-NBDG), immunocytochemistry and Western blot analysis. The calpain1/PKA/CREB signaling analysis was determined by Western blot analysis, immunocytochemistry, MTT, Hoechst and intracellular Ca2+ measurement using

the fluorescent indicator (Fluo-3/AM). Results: SalA-4g promoted neuronal survival and inhibited neuronal apoptosis in primary hippocampal neurons exposed to OGD and in rats subjected to ischemia by MCAO, respectively, and that SalA-4g was more neuroprotective than salidroside. SalA-4g elevated glucose uptake in OGD-injured primary hippocampal neurons and increased the expression and recruitment of GLUT3 in ischemic brain. Signaling analysis revealed that SalA-4g triggered the phosphorylation of CREB, and increased the expression of PKA RII in primary hippocampal neurons exposed to OGD injury, while inhibition of PKA/CREB by H-89 alleviated the elevation in glucose uptake and GLUT3 expression, and blocked the protective effects of SalA-4g. Moreover, SalA-4g was noted to inhibit intracellular Ca2+ influx and calpain1 activation in OGD-injured primary hippocampal neurons. Conclusion: SalA-4g neuroprotection might be mediated by increased glucose uptake and elevated GLUT3 expression through calpain1/PKA/CREB pathway.

Topic: C.02. Alzheimer's Disease and Other Dementias

Title: The ability of a pomegranate husk extract to modify alzheimer's disease pathology in aged transgenic mice

Authors: ***G. M. SUBAIEA**[1,2], A. H. AHMED[3], N. P. SEERAM[2], A. E. EID[3], N. H. ZAWIA[3]; [1]Col. of Pharm., Univ. of Hail, Hail, Saudi Arabia; [2]Biomed. and Pharmaceut. Sci., [3]Interdisciplinary Neurosci. Program, Univ. of Rhode Island, Kingston, RI

Abstracts: Accumulating research has demonstrated that polyphenolic compounds from natural products may have antioxidant and neuroprotective abilities in different models of Alzheimer's disease (AD). Pomegranate in particular has been shown to have promising effects. The present study explores whether the administration of a pomegranate peel extract could have a rescuing effect on AD pathology in aged transgenic mice. Daily doses of the extract or a control solution were fed to groups of aged transgenic mice (R1.40), ranging in age from 24-30 months. These mice already have abundant AD pathology since amyloid Beta (Aβ) deposition continues with age. The mice were treated for thirty-seven days total with assessment starting the last week of treatment. Mice were tested for improvements in spatial and long term memory function, and for

working memory using behavioral tasks including Morris water maze and the Y-maze. This was followed by measurements of cortical APP and total amyloid Beta levels by Western blot and ELISA, respectively. The resulting data demonstrated a specific, but significant decrease in AD pathology manifested by the lowering of Aβ42/40 ratio. Further experiments revealed that this reversal could be the product of the modification of the gamma-secretase enzyme responsible for generating the more amyloidogenic form. In conclusion, pomegranate peel extract appears to contain ingredients that act as gamma-secretase modulators, which may be identified and developed as compounds for use in future drug therapy.

Title: Activated Protein C exert its neuroprotective activity via FAIM2 against oxygen-glucose deprivation in cultured SH-SY5Y Cells

Authors: *M. K. SRIWASTVA[1], R. KUNJUNNI[1], K. PRASAD[2], R. SAXENA[3], V. SUBBIAH[1];
[1]Neurobiochemistry, [2]Neurol., [3]Hematology, All India Instiute of Med. Sci., New Delhi, India

Abstracts: Introduction: With the recent interest of Activated Protein C (APC) as possible targets for the cerebrovascular injury, we tested whether Activated Protein C protected via FAIM2 against oxygen-glucose-deprivation (OGD) induced ischemic injury in cultured SH-SY5Y cells. It is proposed that FAIM2 have protective role in cerebrovascular ischemic injury by phosphatidylinositol 3-kinase -Akt/protein kinase B pathway. Methods: Oxygen-glucose deprivation of SH-SY5Y cells were prepared in media deprived of glucose and fetal bovine serum and kept in a air-tight chamber containing 95%N2 and 5% CO2 for 3 hours with 24 hours reoxygenation. The ischemic injury was checked by measuring the release of lactate dehydrogenase (LDH) in to the medium and the cell viability was assessed by WST-8 assay. The expression of EPCR, PAR-1 & PAR-3 was quantified by flow cytometry. The expression of

FAIM2 and Fas was measured by real time PCR after 24 hours of reoxygenation. Results: APC pre-treatment at a dose of 100 nM reduce the cell toxicity upto 35% ($P<0.05$); the expression of all three receptors EPCR, PAR-1 and PAR-3 was up-regulated significantly ($p<005$) in both hypoxia treatment and hypoxia and APC both compared to control normoxic condition. The Quantitative Faim2 and Fas mRNA real-time PCR expression analyses at 24 h of reoxygenation revealed the expressions of FAIM2 upregulated while the expression of Fas downregulated upon APC treatment. Conclusion: We concluded that the effects of neuroprotection of APC in ischemic injury also occur through phosphatidylinositol 3-kinase -Akt/protein kinase B pathway via FAIM2. Title: Activation of the delta opioid receptor attenuates ASIC1a-mediated neuronal death

Authors: *J. VICK, T. SHERWOOD, E. SCHIMMOELLER, C. ASKWITH;
Neurosci., The Ohio State Univ., Columbus, OH

Abstracts: A decrease in extracellular pH accompanies multiple pathologies within the nervous system including stroke/ischemia, traumatic injury, seizure, and multiple sclerosis. Prolonged extracellular acidosis induces neuronal death through the acid sensing ion channels (ASICs) and is enhanced by several endogenous factors. However, whether any endogenous factors can prevent ASIC-mediated death is unknown. We find that enkephalins can dramatically attenuate acidosis-induced neuronal death in cultured cortical and hippocampal neurons. This action is dependent on activation of the delta opioid receptor (DOR) and is mimicked by non-peptide DOR agonists. Activation of DOR has previously been found to prevent ischemic neuronal death in rodent models of stroke. DOR-mediated protection from acidotoxicity was dependent on G-protein activity and occurred through manipulation of signal transduction cascades. Interestingly, while DOR agonists did not reduce ASIC current density or activation, ion selectivity was

altered. These results indicate that ASIC-mediated neuronal death can be attenuated by DOR activation and suggests that DOR agonists, which have shown neuroprotective properties in animal models, may prevent neuronal death in ischemic conditions. Finally, the connection between ASICs and the opioid system is further strengthened by this work. In the spinal cord, ASIC inhibition limits pain through an enkephalin-dependent mechanism. Our work suggests that enkephalins can affect ASIC-induced signaling as well. This observation could impact our understanding of ASICs role in behavior and pain in addition to neuronal death.

Title: Glucose-deprivation attenuates sortilin expression via AMP kinase cascade in PC12 cells

Authors: *K.-I. KAWASHIMA, K. FUJINO, Y. OGURA, N. MIYANISHI, T. NEDACHI; Toyo Univ., Gunma, Japan

Abstracts: PGRN (Progranulin) gene mutations are associated with several dementia, such as frontotemporal lobar degeneration (FTLD) and amyotrophic lateral sclerosis (ALS). PGRN is a secreted growth factor that promotes neuroprotection and cell proliferation. However, it remains largely unknown how these physiological actions of PGRN are regulated. Recently, sortilin, a member of a Vps10p domain receptor family, has been well documented as a receptor for PGRN. The expression levels of sortilin in neuronal cells, therefore, could be a factor to determine PGRN action; however, the regulatory mechanisms of sortilin are not fully understood. We have explored the stimuli that controls the expression of sortilin, and finally found the expression levels of sortilin is regulated by extracellular glucose concentration. We further investigated underlying mechanisms how the changes in glucose availability controlled sortilin expression and impact of this changes on PGRN-dependent bio-action. Initialy, we used PC12 cells exposed to two different DMEM medium (High Glucose-DMEM; 4.5 g/l, Glucose

Free-DMEM; 0.0 g/l glucose) to examine sortilin expression. After 24 hours of glucose deprivation, the gene and protein expression of sortilin was significantly reduced. Next, we focused on the molecular mechanisms how glucose deprivation reduced sortilin expression. AMP kinase (AMPK) is a well known kinase that activity was increased upon glucose deprivation. After confirming AMP kinase activation was observed by glucose deprivation, we tested the effects of AMPK activator (AICAR) on sortilin expression. Sortilin expression was reduced by AICAR treatment even in the presence of high concentration of glucose, suggesting that the reduced sortilin expression by glucose deprivation is mainly mediated by AMPK activation. In conclusion, we found that sortilin expression was significantly reduced by glucose deprivation via AMPK activation in PC12 cells. This mechanism may be important for regulating the bioactivity of PGRN in central nervous system.

Title: PPAR-γ by suppressing NADPH oxidase subunit p22-phox transcription attenuates ischemic brain damage

Authors: ***J.-S. WU**, H.-D. TSAI, W.-M. CHEUNG, T.-N. LIN;
IBMS Academia sinica, Taipei, Taiwan

Abstracts: Our previously data showed that Peroxisome proliferator-activated receptor-γ (PPAR-γ) protects neurons against hypoxic/ischemic injury by attenuating reactive oxygen species (ROS) production. Nonetheless, the detailed molecular mechanism is not fully understood. Resent studies indicate that NADPH oxidase is one of the major sources for ROS production in brain. In the present studies, we aim to investigate whether and how PPAR-γ interacts with NADPH oxidase, thereby downregulating ROS generation, to ameliorate ischemic

brain injury. (1) *In vitro* studies: we demonstrate PPAR-γ agonist (15-deoxy-Δ12,14-Prostaglandin J2) increased primary cortical neurons (PN) viability after oxygen glucose deprivation and reoxygenation (H/R). With pharmacological (PPAR-γ antagonist GW9662), loss-of-function (PPAR-γ siRNA), and gain-of-function (Ad-PPAR-γ) approaches, we demonstrated that PPAR-γ by inhibiting NADPH oxidase activity attenuated ROS formation and neuronal apoptosis. Western blot analysis further showed that PPAR-γ specifically decreased the p22-phox subunit level of NADPH oxidase. Results of reporter, ChIP, and confocol assays revealed that PPAR-γ blocked H/R-induced NF-κB nuclear translocation, which led to inhibited transcription of p22-phox. (2) *In vivo* studies: Western blot analysis revealed that 15d-PGJ2 reduced the level of protein oxidation and p22-phox in brain subjected to 30-min ischemia and 1-day reperfusion. By contrast protein oxidation and p22-phox level were higher in ischemic brain of heterozygous PPAR-γ (L/+) mice than wild type control. Furthermore, p22-phox siRNA significantly reduces cerebral infarct volume, improves functional recovery, and protects blood-brain barrier (BBB) integrity. In summary, we report a novel transrepression mechanism whereby PPAR-γ downregulates ischemia-induced p22-phox transcription and the subsequent NADPH oxidase activation, ROS formation and neuronal apoptosis. Title: Demonstration of ischemic preconditioning in white matter: Critical role for toll-like receptor-4

Authors: *M. A. HAMNER, R. V. LEE, Z. YE, D. C. HANSSEN, B. R. RANSOM, J. R. WEINSTEIN;
Neurol., Univ. Washington, SEATTLE, WA

Abstracts: Ischemic preconditioning (IPC) is a robust protective phenomenon in which a brief ischemic exposure confers tolerance to a subsequent ischemic challenge. Most experimental paradigms for IPC are carried out in rodents that have very little white matter (~10-15%) compared to man (~55%). Consequently, IPC has been studied predominantly, if not exclusively, in gray matter. In humans, most strokes injure both white matter (WM) and gray matter (GM), and clinical outcome depends on damage to both of these areas. We sought to determine if IPC exists in WM, and if present, did it depend on Toll-like receptor-4 (TLR4), a key receptor in innate immune response, as is the case in GM IPC. We used a standard protocol for inducing IPC in mice *in vivo* consisting of 15 minutes of common carotid artery ligation, producing a pattern of diminished blood flow which included the optic nerve. Seventy-two hours later, the mouse optic nerve (MON), a typical CNS WM tract, was removed and exposed *ex vivo* to oxygen-glucose deprivation (OGD) for 45 minutes followed by 5 hours of normoxia/normoglycemia. MON excitability was monitored quantitatively by measuring the area under the supramaximal compound action potential (CAP) before, during and after the acute insult. CAP data was normalized and recovery is shown as a percentage of the baseline level. MON histopathology was assessed by quantitative immunofluorescent microscopy. In wild type (*WT)* animals, preconditioned (ipsilateral) MON showed improved functional recovery (CAP area = 31±3% of baseline CAP area) compared with either sham-operated (21±4%, *$p<0.05$) or contralateral (14±2%, *$p<0.0001$) control MONs. IPC in GM depends on TLR4 and this also appeared to be the case in WM. *TLR4*$^{-/-}$ preconditioned MONs did not differ from either sham or contralateral controls in terms of CAP recovery after OGD. Compared to control nerves, MONs subjected to IPC lost fewer oligodendrocytes; damage to astrocytes and microglia was unchanged. Ischemic WM injury is mediated in part by excitoxicity. Glutamate levels in MON perfusate and AMPA glutamate receptor mRNA subtypes/isoforms were quantified by high performance liquid chromatography and qRT-PCR, respectively. IPC, however, had no effect on OGD-induced glutamate release or AMPA receptor expression. These findings demonstrate that: (i) IPC induces a robust protective effect in WM and (ii) this effect is dependent on functional TLR4.

Title: Alpha(α)-synuclein increases injury vulnerability due to oxidative stress or ischemia

Authors: *X. YANG[1], H. ZHOU[3], M. A. HAMNER[2], Z. YE[2], B. R. RANSOM[2];
[1]Neurobio., [2]Neurol., Univ. of Washington, Seattle, WA; [3]Neurol., Ruijin Hospital, affiliated with Shanghai Jiaotong Univ. Sch. of Med., Shanghai, China

Abstracts: The protein α-Synuclein (α-Syn) is implicated in the pathophysiology of Parkinson's disease. It is expressed in both neurons and glial cells, but its physiological functions in glia remain unclear. It is also unknown if α-Syn expression might condition susceptibility to brain injury, a question suggested by its association with CNS degeneration. To investigate these questions, normal astrocytes expressing α-Syn (wild type, α-Syn$^{+/+}$) were compared to astrocytes from α-Syn knockout (α-Syn$^{-/-}$) animals with regard to oxidative stress sensitivity. Cultured midbrain astrocytes were subjected to oxidative stress by exposure to various concentrations of hydrogen peroxide (H_2O_2). Astrocytes showed time- and dose-dependent H_2O_2 cytotoxicity. Unexpectedly, wild type (WT) astrocytes showed significantly greater injury compared to astrocytes from α-Syn$^{-/-}$ animals. Cytotoxicity was accompanied by progressive accumulation of intracellular Ca^{2+} ($[Ca^{2+}]_i$) and intracellular $[Na^+]$ ($[Na^+]_i$) in a H_2O_2 concentration-dependent manner. The WT astrocytes showed earlier and greater increases in both ions. Increase in $[Na^+]_i$ preceded change in $[Ca^{2+}]_i$, suggesting that the increase in $[Na^+]_i$ mediated the $[Ca^{2+}]_i$ increase, possibly via reversed Na^+/Ca^{2+} exchange. Enhanced vulnerability to oxidative injury was restored in α-Syn$^{-/-}$ astrocytes by transfecting with human α-Syn, confirming that α-Syn was responsible for the WT phenotype. We then tested if α-Syn$^{-/-}$ animals might be less vulnerable to ischemic brain injury than WT animals, using a validated model of CNS white matter injury, the acutely isolated mouse optic nerve (MON). Indeed, α-Syn$^{-/-}$ MONs suffered significantly less injury compared to WT controls after 60 min of ischemia (recovery = 42 ± 3% vs. 20 ± 2%, $p<0.001$). Finally, we used another injury paradigm, anoxia, which has an entirely different injury mechanism, to further test the impact of α-Syn expression on injury severity. As with ischemia, anoxia caused less damage in the α-Syn$^{-/-}$ animal. In summary, α-Syn expression confers markedly increased injury vulnerability to astrocytes and to intact CNS white matter. These findings suggest that for all the adaptive value of α-Syn, its expression has a dark side manifest by both cellular and tissue enhanced injury vulnerability.

Abstracts: Functionalized magnetic iron oxide nanoparticles (FMIONPs) are used for cancer therapy together with whole body hyperthermia (WBH) or for drug delivery to the target tumor tissues using external magnetic guidance. Our laboratory has previously shown that FMIONPs are innocuous in normal healthy rats up to 24 h, however, when administered following WBH an exacerbation of brain pathology occurs. Interestingly, when TiO2 nanowired Cerebrolsyin is delivered together with FMIONPs in WBH significant neuroprotection is seen. However, the detailed mechanisms of cerebrolysin-induced neuroprotection are still unclear. The present investigation was undertaken to explore the possible mechanisms of cerebrolysin-induced neuroprotection in FMIONPs induced brain pathology in WBH. Cerebrolsyin is a balance composition of several neurotrophic factors and active peptide fragments. Thus, a possibility

exists that TiO2 nanowired Cerebrolsyin could attenuate cellular stress responses following WBH together with FMIONPs administration. We used ubiquitin and heats shock protein (HSP) 72 kD to evaluate stress responses in WBH and FMIONPs combination. Young adult Male Sprague Dawley rats (age 25 to 27 weeks) were administered FMIONPs in a dose of 0.50 mg/mL in100 µl intravenously and then subjected to 4 h WBH at 38°C in a Biological Oxygen Demand (BOD) Incubator (relative humidity 45-47 % and wind velocity 20-22 cm/sec). Twenty-four h after WBH immunohistochemistry of Ubiquitin and HSP 72 kD were examined on paraffin sections from the brain passing thorough parietal cerebral cortex and hippocampus. In a separate group rats, TiO2 nanowired Cerebrolsyin (2.5 ml/kg) was also co-administered and the brains were processed under identical conditions for ubiquitin and HSP-72 kD immunoreactivity. In addition, albumin immunoreactivity was also assessed to test any breakdown of the blood-brain barrier (BBB) to the endogenous serum proteins. Our observation show that FMIONPs following WBH resulted in pronounced albumin leakage and upregulation of ubiquitin and HSP immunoreactivity in the cerebral cortex, hippocampus, hypothalamus and thalamus. Interestingly TiO2 nanowired Cerebrolsyin (2.5 ml) exhibited significant reduction (> 90%) in albumin, ubiquitin and HSP immunoreaction in the brain after FMIONPs treatment following WBH. Taken together our results for the first time show that FMIONPs induces enhanced stress reaction in the brain following WBH and TiO2 cerebrolysin treatment reduces these stress signals significantly indicating a potential role of Cerebrolysin in reducing brain pathology in cancer patients where FMIONPs are used as an adjunct therapy.

Title: Superior antioxidant effects of nanowired cerebrolysin in heat stroke following intoxication of engineered Ag and Cu nanoparticles

Authors: *D. F. MURESANU[1], A. SHARMA[2], R. PATNAIK[3], A. BUZOIANU[4], H. MOESSLER[5], H. S. SHARMA[2];
[1]Romanian Society for the Study of Neuroprotection and Neuroplasticity, Cluj Napoca, Romania; [2]Surgical Sciences, Anesthesiol. & Intensive Care Med., Uppsala Univ. Abstracts: Heat stroke is prevalent in our armed forces especially during summer seasons in desert environment. Heat stroke results in instant death or permanent disability in victims with profound manifestation of neurological disorders. Since our soldiers are also exposed to a variety of nanoparticles e.g., Ag, Cu, Silica dust during their day-to-day work it appears that nanoparticles exposure may aggravate their mental dysfunction in heat stress. Since brain damage following heat stroke is exacerbated by Ag or Cu nanoparticles there is an urgent need to find out suitable drugs to reduce the pathophysiology of brain injury in heat stroke. In this investigation we examined the effects of nanowired cerebrolysin with regard to its antioxidative effects in heat stroke management as compared to the other contemporary stroke therapies employed in clinics. Thus, the possibility that neuroprotective effects of cerebrolysin, a mixture of several neurotrophic factors and active peptides fragments could exert powerful antioxidant properties as compared other stroke therapies, e.g., levertiracetam (44 mg/kg), pregabalin (200 mg/kg), topiramat (40 mg/kg) and valproate (400 mg/kg) was evaluated in a rat model of heat stroke in normal and in Cu or Ag nanoparticles (50 to 60 nm, 50 mg/kg, i.p. /day for 7 days) treated group. Rats subjected to 4 h heat stress in a biological oxygen demand incubator at 38°C (Rel Humid 45-47 %; Wind vel 22.4 to 25.6 cm/sec) resulted in profound increase in brain Luminol, Malondialdehyde and Myeloperoxidase, and a marked decrease in Glutathione. These changes correlated well with the reduction in the cerebral blood flow (CBF) and development of brain edema formation. These pathophysiological responses were exacerbated in nanoparticles treated heat-stressed rats. Pretreatment with cerebrolysin (2.5 ml/kg) daily for 3 days significantly attenuated the oxidative stress parameters and brain edema formation as well as improved CBF in heat stressed group. The other drugs were not effective in reducing these parameters after heat stroke. Interestingly, in nanoparticles treated animals cerebrolysin 5 ml/kg was required to achieve similar reduction in oxidative stress parameters, brain edema formation and improvement in cerebral circulation. However, the other drugs even in higher doses were not able to alter these parameters in nanoparticles treated heat stressed animals. These observations

are the first to demonstrate that antioxidant capacity of cerebrolysin is far more superior in heat stroke than other therapeutic agents currently used to treat stroke related brain damages.

Title: Autophagic containment of mitochondria: Role in preconditioning protection

Authors: *B. N. LIZAMA-MANIBUSAN[1], A. M. PALUBINSKY[1], I. S. KHAN[3], R. J. SINGER[3], B. MCLAUGHLIN[2];

Abstracts: Chronic and acute CNS injuries share similar pathology including increased reactive oxygen species (ROS), oxidized protein accumulation and activation of cell death pathways. Identifying conserved mechanisms that determine cell survival under stress will allow us to develop more effective, well-tolerated therapies for stroke. In order to identify endogenous neuroprotective pathways, we use a model of ischemic preconditioning (PC), in which mild ischemic stress confers protection from subsequent stroke-like episodes. We have shown that the sub-toxic PC stress evokes protection in part by temporally and spatially limiting caspase activation and ROS production. Significant gaps remain however, in our understanding of proteins that play a role in the temporal and spatial constraint of caspases as well as other pro-death signals. Using a transient middle cerebral artery occlusion (tMCAO) model of PC in rats, we observed significant differences in the expression of mitochondrial containment and protein

detoxification machinery at 48h. In order to determine if formation of mitophagic containment of organelles is an adaptive event in PC, we developed a neuron-enriched PC model in which cultures are exposed to 15min of oxygen and glucose deprivation (OGD) followed by 24h of recovery. Preconditioned cultures exhibited 50% less cell death when subsequently challenged with an otherwise lethal OGD stress. Preconditioned cells had high levels of stabilized PTEN-inducible kinase 1 (PINK1), a known regulator of mitophagy, 3h-24h following PC. The autophagy protein LC3, as well as the neuroprotective chaperone heat shock protein 70 (HSP70) and its co-chaperone C-terminus of HSC70-interacting protein (CHIP), are also increased in response to PC. To directly test the role of autophagy in neuroadaptation, we exposed neurons to the small molecule autophagy inhibitor, bafilomycin A1, during sub-lethal OGD and assessed viability 24h later. Neurons in which autophagy was halted exhibited increased cell death when subsequently exposed to OGD. This suggests that PC protection requires removal of damaged organelles as part of neuroadaptation to stressful stimuli. Ongoing experiments are aimed at identifying additional molecules that promote autophagy in preconditioned cells. This work is supported in part by the Neuroscience Scholars Program Award (provided by the NIMH and SfN) and the Suzanne and Walter Scott Foundation.

Title: The possible role of PINK1 in cardiolipin mediated mitophagy

Authors: *M. K. DAIL[1], C. T. CHU[2];
[2]Neuropathology, [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstracts: Mitochondrial dysfunction has been implicated in a central role in the pathogenesis of Parkinson Disease, despite ambiguity of the cause of the dysfunction. Maintaining

mitochondrial quality is important to neurons, and a decline in quality of mitochondria has also been observed in PD. Mitophagy is a major mechanism of regulating mitochondrial quality. Dysregulation of mitophagy has been implicated in multiple neurodegenerative disorders including PD. Our group previously reported a novel mechanism of mitophagy in response to mitochondrial injury by PD-related toxins. Mitophagy occurs via the externalization of cardiolipin (CL) from the inner mitochondrial membrane to the outer by phospholipid scramblase (PLSCR3). There CL interacts with microtubule-associated-protein-1-lightchain-3 (LC3), which mediates autophagosome formation and mitochondrial cargo recognition. CL is synthesized by cardiolipin synthase (CLS1). RNAi knockdown of CLS1 and PLSCR3 decreased CL exposure and mitophagy in SH-SY5Y cells treated with rotenone or 6-OHDA, PD related toxins. The role of this pathway in genetic models of PD remains unknown. PINK1, a mitochondrial kinase, is known to regulate mitophagy. Thus we investigated whether PINK1 regulates mitophagy through effects on cardiolipin. We found that PINK1 may play a role in modulating CL availability.

Title: Haplo-insufficiency of autophagy proteins beclin 1 and VPS34 is linked to age-dependent neuroprotection

Authors: *N. C. MCKNIGHT[1], M. S. WOLD[2], Z. YUE[3];
[1]Neurol., Mount Sinai Sch. of Med., New York, NY; [2]Neurol., [3]Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstracts: Beclin 1 is an essential autophagy protein and its cellular functions intersect with the pathological pathways of AD and PD but we do not know the specific neuroprotective mechanisms of beclin 1 or how it may promote neural repair. Altered expression of beclin 1 is linked to several major diseases such as cancer, infectious diseases and neurodegenerative disorders and evidence demonstrates beclin 1 mediates removal of disease-related proteins

including APP metabolites, α-synuclein and mutant ataxin. In turn, beclin 1 may be a potential drug target but the physiological function of beclin 1 in neurons is poorly understood and whether the neuroprotective function of beclin 1 is mediated through strictly autophagy-dependent or independent pathways is unclear. Beclin 1 was the first described mammalian autophagy protein and a core component of the class III phosphatidylinositol 3-kinase (PI3K-III) complex, which plays an important role in membrane trafficking in autophagy, endocytosis, cytokinesis and phagocytosis. To date beclin 1 has largely been characterized in the context of autophagy. It modulates the lipid kinase activity of PI3K-III catalytic unit VPS34, which generates phosphatidylinositol 3-phosphate (PI(3)P), recruiting other autophagy proteins for the nucleation of autophagosome. Little is known, however, about how beclin 1 regulates specific functions of VPS34. Our lab has recently shown that beclin 1's autophagy-independent functions contribute to its function in neurons and neuronal viability is greatly reduced in the absence of beclin 1. We also illustrate reduced VPS34-associated PI(3)P levels in beclin 1 deficient MEF cells. It is important to understand the precise molecular mechanism whereby beclin 1 regulates VPS34 functions in autophagy, other membrane trafficking pathways, organelle homeostasis and cellular signaling pathways, the disruption of which may underlie the pathogenesis of multiple diseases. Here we show that haploinsufficiency of beclin 1 in the brain leads to alteration in VPS34 lipid kinase activity. Interestingly, we observe differences in behavior in beclin 1 heterozygous mice. We performed a microarray on beclin 1 heterozygous mice and observed significant differences in genes associated with learning and memory as well as mitochondria dynamics and protein kinase signaling. In addition we find that reduced beclin 1 levels and VPS34 activity is associated with enhanced disease related protein levels and we are currently investigating the mechanism. Together our data show the importance of the autophagy independent functions of beclin 1, which contribute to beclin 1's function in the nervous system.

Title: Characterization of inflammation in acute and non-acute ischemic infarcts in human brain tissue

Authors: K. P. DOYLE[1,2], J. BEISCHEL FRYE[1,2], *T.-V. V. NGUYEN[1,2];
[1]Departments of Immunobiology and Neurol., Univ. of Arizona, Tucson, AZ; [2]Arizona Ctr. on Aging, Tucson, AZ

Abstracts: Inflammation in the human brain after stroke is relatively uncharacterized. Therefore, it is unknown whether there is a canonical inflammatory response to stroke in the human brain, or if inflammation in the brain after stroke follows a different trajectory in different individuals. In support of the latter, there is evidence to indicate that some humans develop an adaptive immune response to brain antigens after stroke. For instance, brain antigens have been detected in lymphoid tissue after acute stroke, myelin reactive T lymphocytes have been found in some patients after stroke, and the presence of myelin reactive mononuclear cells in the circulation 90 days after stroke is associated with worse outcome. There are also several reports of oligoclonal bands in the cerebrospinal fluid of stroke patients, which suggests that in some people a B lymphocyte response to stroke may occur. Therefore, the goals of this study were to advance our understanding of inflammation in the human brain after stroke, investigate the extent of variability between individuals, and determine if some individuals develop an autoimmune response to stroke. Using both immunohistochemistry and multiplex immunoassay techniques, we characterized immune cell infiltration and measured cytokine levels in acute and non-acute ischemic infarcts in post-mortem human brain tissue.

Title: Effects of LPS pretreatment on body temperature and lesion volume after stroke

Authors: *S. LEWIS, D. N. DOLL, X. REN, H. HU, J. W. SIMPKINS;
Physiol. and Pharmacol., West Virginia Univ., Morgantown, WV

Abstracts: Stroke is a complex condition with many risk factors such as hypertension, diabetes mellitus, and obesity. Many of these risk factors are known to cause systemic inflammation and studies have shown that an increase in systemic inflammation plays a role in both the pathology and etiology of stroke. Additionally, one third of strokes occur during an active infection, which is also associated with a state of heightened systemic inflammation. To better understand the role of inflammation and stroke, we used lipopolysaccharide (LPS) to mimic a bacterial infection in C57Bl/6 mice prior to a transient middle cerebral artery occlusion (tMCAO). Mice were injected i.p. with 100 ug/ kg - 2 mg LPS/kg, thirty minutes or 6 hours prior to the tMCAO and body temperatures were monitored for 48 hours. LPS when combined with tMCAO produced a significant dose-dependent reduction in body temperature as compared to vehicle treated tMCAO animals. We observed that low dose LPS (100 ug/ kg), which only modestly reduced core body temperature exacerbated stroke volume, while high doses of LPS (200 ug/ kg - 2 mg/ kg), which severely reduced core body temperature, reduced stroke volume. This severe hypothermic response to high-dose LPS may contribute to the observation of preconditioning following LPS administration. Collectively, these data indicate that bacterial mimics have a dose-dependent effect on body temperature and a differential effect on lesion volume.

Title: Interleukin-1 receptor antagonist attenuates neonatal LPS exposure-enhanced neurotoxicity of dopaminergic system by rotenone challenge in adult rats

Authors: *L.-W. FAN[1], L.-T. TIEN[2], J. SHEN[1], H. ZHU[1], A. J. BHATT[1], Y. PANG[1]; [1]Pediatrics/Newborn Med., Univ. Mississippi Med. Ctr., Jackson, MS; [2]Sch. of Med., Fu Jen Catholic Univ., New Taipei City, Taiwan

Abstracts: We have previously reported that neonatal lipopolysaccharide (LPS) exposure induced a chronic neuroinflammation, which was linked to an enhanced susceptibility of substantia nigra dopaminergic neurons to rotenone in adult rats. The objective of this study was to examine whether co-administration of interleukin-1 receptor antagonist (IL-1ra) with LPS attenuates LPS-induced motor behavioral dysfunction and LPS-enhanced susceptibility to rotenone toxicity in later life of these rats. Intracerebral injection of either LPS (1 mg/kg) alone, or LPS (1 mg/kg) with IL-1ra (0.1 mg/kg), or saline was administered in postnatal day 5 (P5) Sprague-Dawley male rat pups. At P70, rats were exposed to rotenone through subcutaneous mini-pump infusion at a dose of 1.25 mg/kg per day for 14 days. Motor behavioral tests were carried out from P70 to P98. Rats were sacrificed and LPS-induced injury to the dopaminergic system was assessed by losses of tyrosine hydroxylase immunoreactive neurons in the substantia nigra. Our results show that co-administration of IL-1ra significantly protected against rotenone-induced neurobehavioral impairments, including bradykinesia, akinesia, and rigidity in rats with neonatal LPS exposure. IL-1ra treatment also provided protection against LPS-enhanced rotenone-induced brain injury in adult rats, including loss of tyrosine hydroxylase positive neurons, decrease in mitochondrial complex I activity, and increase in the number of activated microglia in the substantia nigra. Our data demonstrate that treatment with IL-1ra has long-lasting neuroprotection against perinatal brain inflammation-enhanced adult susceptibility to environmental toxin, suggesting that IL-1ra is critically involved in this double-hit model of dopaminergic neuronal injury.

Title: The acute inflammatory response following a cortical microhemorrhage is dominated by brain-resident microglia and not blood-borne macrophages

Authors: *S. AHN[1], J. C. CRUZ HERNANDEZ[1], J. ANRATHER[2], N. NISHIMURA[1], C. B. SCHAFFER[1];
[1]Biomed. Engin., Cornell Univ., Ithaca, NY; [2]Feil Family Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY

Abstracts: The presence of brain microhemorrhages has been linked to accelerated cognitive decline and to increased risk of dementia in patients. Progress on understanding the mechanisms by which these small brain bleeds lead to dysfunction in nearby neurons and other brain cells, however, has been hampered by a lack of good animal models of these lesions. To address this issue, our lab used tightly-focused femtosecond laser pulses to rupture targeted brain arterioles and produced a reliable and reproducible model of microhemorrhage that enables the study of mechanisms of brain injury. In previous experiments with this model, we showed that microhemorrhages do not cause neuronal death nor large-scale degeneration of axons and dendrites near the lesion. We also observed that inflammatory cells are recruited within minutes of the microhemorrhage and that this inflammation persisted near the lesion for weeks. This long-term inflammation could play a role in the cognitive dysfunction linked to microhemorrhages. In these previous experiments, however, we were unable to distinguish between brain-resident microglia and blood-derived macrophages in this inflammatory process. Here, we used bone marrow transplantation to create chimeric animals where we can distinguish between hematogenous and brain-resident inflammatory cells. Lethally irradiated C57Bl/6 mice were retro-orbitally injected with cells isolated from the bone marrow of donor animals. Animals recovered at least 6 weeks before experiments. We used mice that express GFP under the control of the promoter for the CX3CR1 fractalkine receptor, which show labeling in microglia and circulating monocytes. These animals were used as donors into wildtype mice (only monocytes labeled) and, in separate experiments, as recipients of wildtype bone marrow (only microglia labeled). A glass covered cranial window was implanted and animals were allowed to recover for 10 days. We then used two-photon excited fluorescence imaging to visualize brain vasculature (intravenous injection of Texas Red-dextran) and inflammatory cells (GFP+). Femtosecond laser pulses of ~ 0.5-μJ energy were tightly focused on the wall of the descending segment of penetrating arterioles, causing a rupture of the vessel wall and the formation of a small hemorrhage. We repeated imaging of these mice immediately, a few hours, 1 day, 3 days, and 1 week after the lesion. We found that microglia are responsible for nearly all of the inflammatory cells that surround the hematoma up to one week after the lesion.

Title: TNF-alpha inhibition modulates chronic inflammation following cervical spinal cord injury in rats

Authors: *J. R. HUIE[1], R. SAIGAL[1], A. LIN[1], J. SACRAMENTO[1], D. SZYMKOWSKI[2], A. FERGUSON[1], J. BRESNAHAN[1], M. BEATTIE[1];
[1]Brain and Spinal Injury Ctr., UCSF, San Francisco, CA; [2]Xencor, Inc, Monrovia, CA

Abstracts: Spinal cord injury (SCI) is a complex syndrome characterized by an initial mechanical disruption of tissue, followed by a secondary wave of cell death and inflammation. While a number of inflammatory processes are believed to peak and resolve acutely after injury, a growing body of evidence has indicated that inflammation is sustained in the chronic spinal cord, and may contribute to undermining recovery of function. Here we have used a unilateral cervical contusion model of spinal cord injury in the rat to detail the inflammatory profile of injury both acutely (3 hours post-injury) and chronically (100 days post-injury), and to test whether treatment with a dominant negative soluble TNF inhibitor (XPro1595, Xencor, Inc.) can mitigate the expression of inflammatory biomarkers at these timepoints. Inflammation was assessed using commercially-available gene microarrays (Qiagen/SABiosciences) that test the mRNA expression of 84 chemokines and cytokines associated with the inflammatory immune response. As expected, we found that SCI produced a marked upregulation of a broad range of inflammatory markers at the spinal lesion site at 3 hours post injury. This inflammatory response was reduced by a single intraperitoneal (i.p.) injection of XPro1595 (5 mg/kg), given 90 minutes after injury. Interestingly, at 100 days after injury, SCI subjects continued to exhibit robust expression of inflammatory markers when compared to age-matched sham controls. To test whether TNF inhibitor treatment in these animals could reduce chronic inflammation, rats were given i.p. injections of XPro1595 every three days for 10 days. We found that Xpro1595 treatment was able to modulate the inflammatory response compared to vehicle-treated SCI controls. XPro1595 reduced the expression of many inflammatory markers, with the strongest effect on interleukins, toll-like receptors, and C reactive protein, as well as chemokines that are

chemoattractant for neutrophils and monocytes. These findings suggest that in the injured cervical spinal cord, inflammation is a persistent phenomenon that can be observed during the chronic phase of injury. These findings also suggest that anti-inflammatory treatment with a TNF inhibitor may alleviate this inflammation, even if given at chronic timepoints.

Title: Role of orexin A signaling in dietary saturated fatty acid activated microglial cells

Authors: ***C. M. DUFFY**[1,2], J. P. NIXON[1,2], C. J. BILLINGTON[1,3,4], C. M. KOTZ[1,2,4], T. A. BUTTERICK[1,2];
[1]Veterans Admin. Hlth. Care Syst., Minneapolis, MN; [2]Dept. of Food Sci. and Nutr., Univ. of Minnesota, St Paul, MN; [3]Dept. of Med., Univ. of Minnesota, Minneapolis, MN; [4]Minnesota Obesity Ctr., St Paul, MN

Abstracts: Excess dietary saturated fatty acids such as palmitic acid (PA) induce inflammation in peripheral and central nervous system tissues, including the hypothalamus. Hypothalamic inflammation, thought to contribute to metabolic dysregulation, is mediated in part by microglial activation. In rodents, high fat diet-induced obesity activates microglia, resulting in nuclear translocation of nuclear factor-κB (NFκB) and increased central and peripheral pro-inflammatory cytokine tumor necrosis factor alpha (TNFα). The hypothalamic neuropeptide orexin A (OXA, hypocretin) is neuroprotective through reducing lipid peroxidation and decreasing caspase-3/7 activity. In cortex, OXA acts through a microglial-mediated pathway to reduce inflammation and prevents neurodegeneration following ischemic injury. Whether endogenous orexin signaling is

altered in activated microglia in the hypothalamus is unknown. We hypothesize that PA induces changes in gene expression for the orexin receptors in microglial cultures. To test this, immortalized murine microglial cells (designated BV2) were treated with or without 0.1 mM PA for 4 h. Microglial cells were collected for gene expression analysis via qRT-PCR. Exposure to PA increased gene expression of orexin-1 receptor (OX1R; $p<0.05$ vs. control) but not orexin-2 receptor (OX2R; $p>.05$ vs. control). To our knowledge, this is the first report demonstrating that PA increases microglial OX1R and the presence of OX2R in a microglial cell line. These data support the idea that OX1R in microglia are responsive to PA. We are currently evaluating OXA's role in microglial activation following exposure to PA in the presence or absence of OXA by profiling inflammatory cytokines using both qRT-PCR and ELISA. The results from these experiments will provide novel insight into the mechanisms by which excess dietary fatty acids provoke inflammatory responses, and how endogenous hypothalamic peptides such as OXA may function as central immunomodulators.

Title: Excessive dietary α-tocopherol increases post-stroke microglial activation and contributes to brain injury

Authors: *C. L. RINK, S. GNYAWALI, M. HEIGEL, S. ROY, C. K. SEN, S. KHANNA; Surgery, The Ohio State Univ. Wexner Med. Ctr., Columbus, OH

Abstracts: Clinical trials testing the α-tocopherol form of vitamin E (αTOC) against a range of diseases, from cancer to heart disease, have largely failed or reported negative outcomes when a "more is better" approach to supplementation was employed. A 2005 meta-analysis of clinical trials testing high-dose αTOC (≥400 IU/d) reported significantly increased risk for all-cause

mortality in 9 of 11 clinical trials reviewed (Miller et al, Ann Intern Med., 2005). In the context of stroke, the Alpha-Tocopherol, Beta Carotene (ATBC) trial reported significantly increased risk for hemorrhagic stroke among participants assigned to αTOC supplementation. While the antioxidant properties of αTOC at physiological levels are widely regarded to attenuate stroke-induced injury, pathological effects of excessive αTOC have yet to be addressed. In this light, the current work was focused to determine the effects of high-dose αTOC on ischemic stroke outcomes in a pre-clinical setting using the intraluminal thread model of middle cerebral artery occlusion. In this work we demonstrate that excessive αTOC supplementation exacerbates stroke-induced lesion volume via increased microglial activation. Elevated brain αTOC levels are associated with increased S100B-mediated microglial activation and iNOS activity in the stroke-affected brain. *In vivo* outcomes are validated in microglial cell culture systems. Taken together, this work identifies new mechanisms by which excessive αTOC supplementation contributes to pathological brain injury.

Title: Tocotrienol vitamin E induces arteriogenesis and protects against ischemic stroke brain injury

Authors: *S. TEPLITSKY, S. KHANNA, M. HEIGEL, K. OLICKAL, C. K. SEN, C. RINK; The Ohio State Univ., Columbus, OH

Abstracts: Cerebrovascular collaterals refer to an interconnected group of blood vessels that anastomose and are capable of retrogradely perfusing the stroke-affected brain. Importantly, cerebrovascular collaterals have been clinically documented to protect the brain from ischemic

stroke brain injury. While there is interest in identifying therapies to improve collateral blood flow, mechanisms and a means to do so remain poorly studied. The current work rests on a key *in vivo* observation that supplementation of lesser-characterized vitamin E family members, tocotrienols (TCT), successfully improves cerebrovascular collateral blood flow (Rink et al., JCBFM 2011). Here, we employ TCT as a tool to study mechanisms of vascular remodeling, termed arteriogenesis, for improved collateral blood flow during acute ischemic stroke. C57/BL6 mice (N=24, 5 wks old) were orally gavaged 5d/week with TCT (50 mg/kg) or a volume-matched vehicle control placebo (PBO). After 4 and 10 weeks of supplementation, mice were subjected to ischemic stroke using the intraluminal thread method of middle cerebral artery occlusion (MCAO). Successful MCAO was validated by laser Doppler flowmetry. While ischemia persisted (30min after onset of MCAO), intracardiac injection of a FITC-conjugated Lycopersicon esculentum lectin (FITC-lectin, 0.5 mg/ml) enabled selective staining of patent vessels in stroke-affected and contralateral control brain. On the basis of staining, TCT supplementation increased collateral perfusion in stroke-affected S1 cortex. FITC-tagged collaterals were then cut (mean = 1.8x10^5 μm^2) and collected using laser capture microdissection. From laser-captured samples, RNA isolation was performed followed by cDNA synthesis and real-time PCR. Compared to placebo controls, TCT supplementation significantly affected expression arteriogenic targets associated with vascular proteolysis (MMP2 and TIMP1), and shear stress (DLL4). No significant difference in arteriogenic targets related to tubulogenesis (CLIC1 and CLIC4) were observed. Taken together, outcomes identify novel TCT-sensitive mechanisms that enable arteriogenesis for protection against acute ischemic stroke.

Abstracts: Multiple Sclerosis (MS) is driven by the infiltration of CNS specific lymphocyte cells that are peripherally activated by antigen presenting cells and transmigrate into the CNS resulting in chronic inflammation and demyelination. Here, we explore the association of disease stage identified by the behavioral phenotype with cortical neuronal microcircuit activity in the mouse brain *in vivo*. We utilized *in vivo* two-photon Calcium imaging in the visual cortex of experimental autoimmune encephalomyelitis (EAE) animals, the well-established animal model of MS. Upon a cranial window preparation, the fluorescent Ca2+ indicator Oregon Green Bapta1 (OGB-1) and Sulforhodamine 101 (SR101), a specific astrocyte marker, were injected using the multi-cell bolus loading technique. By a dedicated 2-photon microscope equipped with a resonant scanner, we simultaneously recorded up to 100 neurons at 30-Hz temporal resolution in layer II/III of the primary visual cortex. Since spontaneous activity reflects the basic architecture of cortical circuitry, whereas stimulus driven activity may predominantly be affected by subcortical inputs, we analyzed both spontaneous and evoked activity. Comparing healthy controls with EAE animals in remission phase, in which the animals do not exhibit an obvious behavioral phenotype, we find a differential pattern of spiking activity in the visual cortex.

Title: Blockade of L-VDCCs or RyRs during chronic neuroinflammation improves spatial memory, normalizes synaptic function, and reduces expression of inflammatory markers

Authors: *S. C. HOPP[1], H. M. D'ANGELO[1,2], S. E. ROYER[1], R. M. KAERCHER[2], L. ADZOVIC[2], A. M. CROCKETT[1,2], G. L. WENK[2,1];
[1]Neurosci., [2]Psychology, Ohio State Univ., Columbus, OH

Abstracts: Chronic neuroinflammation and calcium dysregulation are shared components of Alzheimer's disease and other neurodegenerative processes. Prolonged neuroinflammation produces elevation of pro-inflammatory cytokines and reactive oxygen species which are capable of altering neuronal calcium homeostasis via L-type voltage dependent calcium channels (L-VDCCs) and ryanodine receptors (RyRs). Chronic neuroinflammation also leads to deficits in spatial memory, which may be related to calcium dysregulation. The studies herein use an *in vivo* model of chronic neuroinflammation: rats were treated with intraventricular infusion of lipopolysaccharide (LPS) for 28 days. Synaptosomes from LPS-infused rats had increased calcium uptake, which was decreased by pharmacological blockade of the L-VDCC either *in vivo* or *ex vivo*. LPS-infused rats had significant memory deficits in the Morris water maze; this deficit was ameliorated by treatment with an L-VDCC antagonist. Taken together, these data indicate that calcium dysregulation during chronic neuroinflammation is at least partially dependent on increases in L-VDCC function. However, blockade of the RyRs also slightly improved spatial memory of LPS-infused rats, demonstrating that other calcium channels are dysregulated during chronic neuroinflammation. Calcium-dependent immediate early gene expression was reduced to control levels in LPS-infused rats treated with L-VDCC or RyR antagonists, indicating normalized synaptic function that may underlie improvements in spatial memory. Pro-inflammatory markers are also reduced in LPS-infused rats treated with either drug. Overall, these data suggest that calcium dysregulation via L-VDCCs and RyRs plays a crucial role in neuroinflammation-induced memory deficits.

Title: The role of TNF in pain induction and secondary consequences in the hippocampus following peripheral nerve injury

Authors: *T. DEL RIVERO[1], A. DELLAROLE[3], J. BETHEA[2];
[1]Drexel Univ., Philadelphia, PA; [2]Drexel Univ., philadelphia, PA; [3]Univ. of Miami, Miami, FL

Abstracts: Tumor Necrosis Factor (TNF) is a proinflammatory cytokine which is involved in physiological and pathological processes, systematically and within the central nervous system (CNS). There are two biologically active forms of TNF, soluble TNF (solTNF) and transmembrane TNF (tmTNF) that preferentially bind to TNFR1 and TNFR2 respectively. Recent studies have focused on targeting TNF for neuropathic pain treatment due to the involvement of the immune response in pain propagation. Following peripheral nerve injury, an increase in TNF levels has been observed in the sciatic nerve, spinal cord, and different brain regions. Although anti-TNF drugs such as etanercept and infliximab are currently used to treat pain, they are not completely effective and have some deleterious side effects. Recent studies have shown that certain types of TNF signaling (TNF receptor 1 signaling) are directly associated with an increase in pain following injury while other distinct types of TNF signaling (TNF receptor 2 signaling) help to protect cells. The current anti-TNF drugs inhibit overall TNF activity, so although patients experience a slight alleviation of pain, they may also be deprived of beneficial effects of TNFR2 signaling. This is why in the current study we are interested in the effects of specifically blocking TNF receptor 1 (TNFR1) signaling on neuropathic pain following peripheral nerve injury in a mouse model with the use of both transgenic mice and drug therapy. After undergoing chronic constriction injury (CCI) in the sciatic nerve, knockout mice lacking TNFR1 (TNFR1 -/-) fail to develop a normal pain response in the injured paw compared to wildtype mice as measured by the Von Frey test. Furthermore, following CCI we observe a decrease in hippocampal neurogenesis which corresponds to the time course for pain sensation, but this decrease in neurogenesis is not observed in TNFR1-/- mice. To investigate the therapeutic effects of inhibiting TNFR1 signaling after injury, we delivered XPro1595, a novel drug which creates a biologically inactive form of solTNF, to mice following CCI. Inhibition of TNFR1 signaling via XPro1595 resulted in an accelerated recovery from neuropathic pain which began at 4 weeks following injury. At the 5 week time we see an increase in XPro1595 levels in the CNS as well as in the plasma, therefore the delay in recovery could be due to a requirement for sufficient levels of XPro1595 to accumulate in the CNS. Together, these results suggest that TNFR1 signaling in both the peripheral and central nervous system is necessary for pain induction following CCI, and that TNFR1 signaling additionally plays a role in hippocampal alterations due to the injury.

Title: Sex differences in immediate microglia and astrocyte responses in models of brain injury

Authors: *H. MORRISON[1], J. FILOSA[2];
[1]Univ. of Arizona Col. of Nursing, Tucson, AZ; [2]Georgia Regents Univ., Augusta, GA

Abstracts: Microglia cells possess the title of immune cell; however, the brain houses two inflammatory cell responders, astrocytes and microglia. Due to a parallel function, it is conceivable that these cells coordinate surveillance and inflammatory responses during health and disease via modalities of integrated microglia-astrocyte communication. Sex differences have been well described related to stroke prevalence and stroke outcomes, however, the combination of mechanisms that underlie these sex differences, to include microglia-astrocyte communication, are poorly understood. We tested the hypothesis that lipopolysaccharide (LPS) induced microglia activation would differentially stimulate astrocyte activation in adult male and female mice. Using calcium indicator Rhod-2AM and live imaging techniques, we show that 15-min LPS incubation of female acute brain slices significantly reduced intrinsic astrocyte activity by 36% (vs. aCSF, $p<0.05$) and the Ca2+peak frequency of these active cells was also reduced by 33% (vs. aCSF, $p < 0.05$). While male astrocyte intrinsic activity and peak frequency was unchanged vs. aCSF incubation, the Ca2+ peak amplitude of active cells was increased by 30% after 15-min LPS incubation ($p<0.05$ vs. aCSF). In an additional study, intrinsic Ca2+depended astrocyte activity was significantly increased by 20% in female ($p <0.05$, vs sham), but not male, contralateral and distal ipsilateral brain regions after 60-min focal ischemic stroke. Although the Ca2+ peak frequency of active cells in contralateral and ipsilateral brain regions were similarly unchanged (vs. sham) in both sexes after 60-min of focal ischemia, the coefficient of variability in female data was significantly increased vs. males ($p<0.01$). Together, these data illustrate immediate and diverse astrocyte Ca2+ dependent responses to LPS induced microglia activation. We suggest that LPS induced microglia activation initiates differing microglia-astrocyte signaling modalities between males and females. In addition, and independent of sex, we illustrate contrasting Ca2+ dependent astrocyte responses between LPS incubation and ischemic injury. These early sex differences will influence current and future events that define stroke outcomes.

Title: Exposure to HIV-1 Tat in brain impairs sensorimotor gating and activates microglia in medial prefrontal cortex of male mice

Authors: *J. J. PARIS[1], H. D. SINGH[2], A. N. CAREY[4], J. P. MCLAUGHLIN[3];
[1]Torrey Pines Inst. For Mol. Studies, Port Saint Lucie, FL; [3]Pharmacol. and Neurosci., [2]Torrey Pines Inst. for Mol. Studies, Port Saint Lucie, FL; [4]Psychology, Simmons Col., Boston, MA

Abstracts: Human immunodeficiency virus (HIV) infection is associated with a greater incidence of mood disorder and behavioral disinhibition. Recently, impairments in sensorimotor gating have also been described among HIV-infected individuals with associated neurocognitive disorders, but the identity of the HIV-proteins and the mechanisms involved are not known. The regulatory HIV-1 protein, Tat, is neurotoxic and its expression in animal models increases anxiety-like behavior concurrent with neuroinflammation and structural changes in limbic and extra-limbic brain regions. We hypothesized that conditional expression of Tat(1-86) in the GT-tg bigenic mouse model would impair sensorimotor gating and increase microglial reactivity in subregions of the medial prefrontal cortex. Conditional, astroglial-derived Tat induction via doxycycline (Dox) treatment (0-125 mg/kg, i.p., for 1-14 days) significantly potentiated the acoustic startle reflex of GT-tg mice and impaired prepulse inhibition of this response in a bimodal, dose-dependent manner. Effects were observed to peak at brief (Dox 100 mg/kg, for 1 day) or prolonged (Dox 100 mg/kg, for 7 days) conditions of Tat expression. A greater proportion of active/reactive Iba1-labeled microglia was also observed in the anterior cingulate cortex of GT-tg mice when Tat protein was induced under low expression conditions, and in the agranular insular, anterior cingulate, and prelimbic cortices when Tat was induced under high expression conditions. Pretreatment with indomethacin attenuated behavioral effects of brief (but

not prolonged) Tat-exposure. Differences were not observed on any measure among control mice lacking the Tat transgene. Overall, exposure to Tat protein induced sensorimotor deficits associated with HIV, perhaps involving acute neuroinflammatory responses in forebrain regions.

Title: IFNβ mediated neuroprotection in HIV-1 associated brain injury

Authors: *V. E. THANEY[1], M. M. HOEFER[1], M. KAUL[1,2];
[1]Infectious and Inflammatory Dis. Ctr., Sanford Burnham Med. Res. Inst., La Jolla, CA; [2]Dept. of Psychiatry, Univ. of California San Diego, San Diego, CA

Abstracts: HIV-1 is known to invade the CNS early following peripheral infection, however, neurologic symptoms are delayed until later in the progression of the disease. This delay has been explained by the ability of the innate immune system to effectively suppress viral replication during the initial stages of CNS infection. Type I interferons (IFNs), with both pro-inflammatory and anti-inflammatory roles, are critical mediators of this response in the brain, and are a major first line of host defense against viral infections. We hypothesized, that the differences in IFNβ production and signaling in the CNS might provide an explanation for progression of the neurological symptoms. Based on preliminary evidence we investigated the neuroprotective effects of IFNβ in the brain against toxicity of HIV/gp120 using *in vivo* and *in vitro* models. We used mixed rodent cerebrocortical cultures (RCC), containing neurons, astrocytes, and microglia, to show that concentration dependent treatment with IFNβ can provide sufficient neuroprotection against gp120-induced toxicity. Additionally, treatment with IFNβ of RCC increased levels of natural ligands of the HIV co-receptor CCR5 and up-regulated expression of anti-viral IFN-stimulated genes. In contrast, treatment with HIV viral envelope protein gp120 alone at neurotoxic concentration did not cause any comparable changes in gene expression. These ligands, MIP-1β and RANTES, are known to suppress HIV-1 infection;

disease progression and all can provide significant *in vitro* protection against gp120-induced injury. We further found that introduction of neutralizing antibodies against MIP-1β, but not RANTES completely abrogated the neuroprotective effect of IFNβ. These results suggest that MIP-1β is a critical part of IFNβ mediated neuroprotective mechanism. To investigate the neuroprotective effects of IFNβ against HIV/gp120-induced neurotoxicity *in vivo*, we performed intranasal IFNβ administration to transgenic mice expressing the viral envelope protein in the brain. HIV/gp120-tg animals manifest several neuropathological features observed in AIDS brains, such as decreased synaptic and dendritic density, increased numbers of activated microglia, and pronounced astrocytosis. After one month of once a week treatment, brains were analyzed by quantitative RT-PCR for specific changes in gene expression and by immunohistology for structural neuronal injury. We found that intranasal IFNβ application triggered a biological response that was detectable as IFN-induced gene expression and ameliorated neuronal damage in HIV/gp120-tg mice.

Title: Strain of LCM virus influences tropism and pathology in the developing brain

Authors: *J. M. PLUME[1], B. KARACAY[2], J. MAHONEY[1], D. BONTHIUS[2];
[2]Pediatrics, [1]Univ. of Iowa, Iowa City, IA

Abstracts: Lymphocytic Choriomeningitis Virus (LCMV) is a common congenital infection that damages the fetal human brain. However, the nature and severity of the injuries differ from case to case. This variability may be due, in part, to differences among LCMV strains. Here, we compare and contrast the patterns of infection and pathological effects of three previously unexplored LCMV strains. Lewis rat pups were injected on PD4 with 1,000 infectious viral particles of one of three LCMV strains (E350, Clone 13, or WE2.2) and monitored over the next two weeks. Brains were harvested at multiple time points for immunological, histological, and molecular studies. The neurotropic strain, E350, behaves similarly to the Armstrong strain, with early widespread infection of astrocytes, followed by restricted infection of mitotically active neuroblasts in the cerebellum, olfactory bulb, hippocampus, and ventricular zone. These animals

live to adulthood, but suffer permanent cerebellar destruction. The Clone 13 strain, which was previously believed to infect only lymphatic tissue, infects many cells of the cerebellum, but has no other neuron or astrocytic targets. These animals do not exhibit overt neurological disease, but die ~10 days after infection. In contrast, the WE2.2 strain does not infect the cerebellum, but shows widespread infection of cortical and hippocampal neurons. The WE2.2 strain produces fatal disease without obvious neurological symptoms. Thus, different strains of LCMV have markedly different cellular targets of infection and pathologic effects within the developing brain.

Title: Altered microglial gene expression suggests impaired microglial function in HIV infection, even in the absence of detectable virus in brain

Authors: *T. FISCHER-SMITH[1], S. D. GINSBERG[2], M. J. ALLDRED[2], S. GUNNAM[1]; [1]Neurosci., Temple Univ. Sch. of Med., Philadelphia, PA; [2]Ctr. for Dementia Res., Nathan Kline Inst., Orangeburg, NY

Abstracts: HIV-associated neurocognitive disorders (HAND) are a common complication of HIV. The neuropathogenesis of HAND is poorly understood, however, HIV-infected and non-infected activated macrophages (M)s and microglia are significant to HIV-related neuropathogenesis. Previously, we reported considerable accumulation of $CD163^+$/$CD16^+$ Ms and microglia in brains of patients with HIV encephalitis (HIVE), the neuropathological correlate of the most severe form of HAND, HIV-associated dementia (HIV-D). More recently, we have found HIV^+ subjects without encephalitis (HIV/noE) also show increased $CD163^+$ and $CD16^+$ brain Ms and microglia, even in the absence of detectable virus production in the brain. Accordingly, we hypothesize that microglial activation is a common mechanism between lesser and more severe HIV-associated neurodegenerative processes, regardless of virus production in the brain. To begin to explore this hypothesis, we investigated gene expression changes of specific classes of transcripts in parenchymal Ms and microglia from archival brain tissue of patients with HIVE, HIV/noE, and age-matched seronegative (HIV^-) controls. Microarray analyses were performed on ~2,500 laser capture microdissected $CD163^+$, $CD16^+$ or $CD68^+$ Ms/microglia per case, using terminal continuation (TC) RNA amplification and a custom-designed array platform. Preliminary data demonstrates massive changes in gene expression between HIV^- and the two HIV studied conditions, HIVE and HIV/noE. Consistent with our hypothesis, altered expression of several classes of transcripts, including cell death genes, immediate-early genes, and inflammatory-based markers, suggestive of progressive M/microglial activation with disease severity, is seen in Ms/microglia recovered from HIVE brain, relative to HIV/noE and HIV^- subjects. We also see evidence for transcripts that are typically associated

with neurons and neurotransmission enriched in microglia, suggesting an important support role of these cells for proper neuronal activity in human brain. These preliminary results indicate the utility of profiling Ms/microglia in the brain in HIV infection to ascertain alterations in specific genes, signaling pathways, and presumably, encoded proteins that may be amenable to targeted treatment modalities. In addition, these studies provide additional insight into the diverse roles microglia play in "normal" brain homeostasis, as well as alterations in microglial function that likely contribute to neuronal injury and cognitive impairment.

Title: Alterations in mitochondria biogenesis during HIVE: Implications for mechanisms of neurodegeneration

Authors: *J. A. FIELDS[1], E. MASLIAH[2];
[1]Pathology, UCSD, La Jolla, CA; [2]Neurosci., UCSD, San Diego, CA

Abstracts: Approximately 50% of HIV+ persons are afflicted by some variant of HIV-associated neurocognitive disorders (HAND), and prevalence is increasing as patients live longer with disease. HIV enters the brain causing infection of resident CD4+ cells, viral replication, viral protein/toxin production and neuroinflammation. Some, or all, of these mechanisms culminate in neurodegeneration and HAND. We hypothesized that HIV proteins released from infected CNS cells enter bystander neurons and affect mitophagy and mitochondria biogenesis. To test this we assayed brain tissues from a well-characterized cohort of HIV- and HIV+ donors for expression of key mitophagy and mitochondria biogenesis proteins and complimented these studies with *in vitro* assays using HIV proteins, lentiviral vectors and neuroblastoma cells. The

mitochondrial fusion protein mitofusin (MFN) 1 was significantly increased in brains of HIVE donors, while dynamin-related protein 1 (DRP1) levels were decreased. Immunostaining showed altered DRP1 association with mitochondria and enlarged and abnormal mitochondria in neurons of HIV versus HIVE brains. These findings were recapitulated in the brains of transgenic mouse expressing gp120. HIV gp120 caused increased MFN 1 expression accompanied by changes in mitochondria morphology; overexpressing DRP1 reversed this effect. These data suggest HIV gp120 may interact with CNS neurons and subsequently disrupt mitochondria biogenesis leading to neurodegeneration and HAND. Interfering with this neurodegenerative mechanism may provide relief for HAND patients.

Title: Cysteinyl leukotrienes are essential to neurotoxicity of HIV-infected macrophages

Authors: ***A. B. SANCHEZ**[1], C. M. DE ROZIERES[1], K. E. MEDDERS[1], R. MAUNG[1], M. KAUL[1,2];
[1]Sanford-Burnham Med. Res. Inst., La Jolla, CA; [2]Univ. of California San Diego, San Diego, CA

Abstracts: Macrophages are the principal target of HIV-1 in the central nervous system (CNS). Activation of macrophages and microglia is critical for neuronal injury which is thought underlie the initiation and progression of neurodegenerative diseases such as HIV-1 associated neurocognitive disorders (HAND). Simultaneously, as a part of the innate and adaptive immune response, macrophages produce proinflammatory cytokines, chemokines and soluble proinflammatory lipid mediators, such us cysteinyl leukotrienes (cysLTs). Several studies have reported that leukotrienes, and their receptors, are expressed in the brain contributing to neurological disorders. A better understanding of the role of these proinflammatory lipid mediators in the neuronal toxicity will lead us to design new targets for protection of the CNS

from neurodegenerative diseases like HAND. In this study, we demonstrated that HIV-1 infection increased production of proinflammatory cysLTs by monocyte-derived macrophages (MDM). Next, neurotoxicity of HIV-infected MDM was assessed in the presence and absence of an inhibitor of cysteinyl leukotriene receptor-1 (cysLTR-1). Neuronal injury was evaluated after 24 hours treatment in fixed cells using specific markers for neuronal dendrites (MAP-2) and pre-synaptic terminal (synaptophysin) in combination with nuclear DNA staining and fluorescence microscopy. When rat cerebrocortical cells (RCC) were exposed to supernatant from HIV-infected MDM, but not uninfected cells, neuronal survival was significantly reduced. In contrast, the presence of the cysLTR-1 inhibitor completely prevented the neurotoxicity of supernatants from HIV-infected MDM. Altogether, our findings indicated that cysLTs originated in HIV-infected MDM and played a critical role in HIV-associated neuronal injury, since Montelukast, an inhibitor of cysLTR-1, protected cerebrocortical neurons against the toxicity of HIV-infected MDM

Title: TIA-1 orchestrates antiviral granule formation in vesicular stomatitis virus-induced encephalitis *in vivo* and *in vitro*

Authors: *Y. CHUNG[1], K. BULLOCH[2];
[1]Rockefeller Univ., New York, NY; [2]Lab. of Cell. Physiol. & Immunol., The Rockefeller Univ., New York, NY

Abstracts: Stress granules (SGs) are known for sequestering mRNA or reprogramming translation during stress, such as oxidative stress and heat shock. Viral infection is also known to induce a number of cellular stress responses and modulate stress granule (SGs) formation for maximizing replication efficacies, but mechanism of viral infection-induced SGs formation in the brain is still elusive. In the present study, we examine whether neurons could form SGs in

response to vesicular stomatitis virus (VSV) infection and its underlying mechanism. Immunohistochemical and immunoprecipitation results showed that VSV interacted with TIA-1 or G3BP and formed non-canonical SGs formation in E(t)C cerebellar granule neuronal culture. In VSV-infected olfactory bulb of *Cd11c/eyfp* transgenic mice, VSV also interacted with TIA-1 and co-localized with neuronal TIA-1 expression in glomeruli and granule cell layer. These TIA-1 positive granules were located in perinuclear region and sustained to 14 day of post-infection (d.p.i). In addition, TIA-1 positive granules were colocalized with cytoplasmic sensors for RNA viruses, such as retinoic acid inducible gene-1 (RIG-1) and melanoma differentiation-associated protein-5 (MDA-5), in the olfactory bulb of VSV-infected mice. These results suggest that TIA-1 positive granules might be an important place for antiviral immune response.

Title: Impact of SIV inoculation on cognitive performance in aged female rhesus monkeys

Authors: K. GURNSEY[1], N. NANIA[2], H. P. JEDEMA[1], *S. J. BISSEL[2], C. A. WILEY[2], C. W. BRADBERRY[1,3];
[1]Psychiatry, Univ. of Pittsburgh, PITTSBURGH, PA; [2]Neuropathology, Univ. Pittsburgh, PITTSBURGH, PA; [3]VA Pittsburgh Hlth. Services, Pittsburgh, PA

Abstracts: As part of ongoing studies into the effect of chronic SIV infection and antiretroviral therapy on cognition in the elderly, a cohort of 23 aged female rhesus macaques (16-23 years old) were trained and underwent neurocognitive assessments using a touch screen based stimulus response task designed to measure response latency and accuracy. Two performance-matched groups were established. One group was inoculated intravenously with SIVmac251 while the other group received saline. (Each group will be split later in the study to receive antiretroviral therapy or placebo). There were no measurable physiological consequences of acute inoculation; no differences in body temperature, animal activity or temperament. When performance immediately prior to infection (mean of 5-9 sessions) was compared to that following infection

(mean of 4-7 sessions after a one week hiatus) using a two way repeated measures ANOVA with group and time, there was no significant difference in response latency, but there was a significant difference in accuracy $F(1,21) = 9.2$, $p = 0.006$. Within each group, accuracy was not significantly different over time in control animals ($n = 11$, $p = 0.111$), but accuracy diminished over time in the inoculated group ($n = 12$, $p=0.015$). Thus the impact of SIV inoculation on cognition would not appear due to clinically measurable effects known to regulate body temperature and activity. The mechanism whereby cognitive performance was altered remains unclear. Whether these cognitive changes will persist or be impacted by antiretroviral therapy remains to be determined.

Title: Early host-pathogen interactions influence outcomes of herpes simplex encephalitis in the developing brain

Authors: *D. R. WILCOX[1], N. R. WADHWANI[3], D. E. ALEXANDER[4], D. A. LEIB[4], B. HE[5], R. M. LONGNECKER[2], W. J. MULLER[1];
[1]Pediatrics, [2]Microbiology-Immunology, Northwestern Univ. Sch. of Med., Chicago, IL; [3]Pathology, Ann & Robert H. Lurie Children's Hosp. of Chicago, Chicago, IL; [4]Microbiology-Immunology, Dartmouth Med. Sch., Lebanon, NH; [5]Microbiology-Immunology, Univ. of Illinois at Chicago, Chicago, IL

Abstracts: Background: Infection with herpes simplex virus (HSV) in adults is often subclinical, but is a significant cause of mortality and morbidity in the newborn. Although differences in the immune response have been implicated in the increased severity of disease in the neonate, the precise reasons remain unknown. The type I interferon response is important for controlling viral

replication in an adult mouse model of HSV encephalitis. This response is countered by the multifunctional HSV protein γ34.5, which acts to reverse host translational arrest, inhibit TBK1 function, and inhibit autophagy. The interactions between this viral protein and host responses to CNS infection, and their dependence on developmental age of the animal, have not been studied. Methods: We used mutant viruses and their corresponding rescue viruses in a model of HSV encephalitis to study host responses to CNS infection and their relationship to the different functions of HSV γ34.5 in newborn and adult mice. Mice were inoculated intracranially and followed over time for development of symptoms and mortality. Viral replication in the CNS was assessed by plaque assay. Results: Adult mice lacking an intact type I interferon response are significantly more susceptible to HSV CNS disease compared to wild-type (WT) mice, with a higher overall mortality, a shorter time to mortality, and increased viral replication. In contrast, newborn mice lacking a type I interferon response had no difference in mortality or viral replication compared to WT newborn mice. Based on these results, we hypothesized that HSV-1 γ34.5 would be dispensable for pathogenesis in the neonate. However, γ34.5 was required for disease in both adult and newborn mice, suggesting that modulation of the host by γ34.5 is a critical mechanism of pathogenesis. We dissected the specific functions of γ34.5 to determine the pathways in the developing brain important for viral disease. We have shown that the autophagy-inhibiting function of γ34.5, which is critical to pathogenesis in the adult, is dispensable in the newborn. In contrast, here we show that mutations in γ34.5 that disrupt the ability of HSV to counteract host translational shutoff, and mutations abrogating interaction with the host signaling protein TBK1, individually attenuate virulence in WT newborns. Conclusion: Host-translational shutoff and TBK1 activity are important innate responses to HSV infection in the newborn brain. Identification of factors important for HSV pathogenesis in the CNS provides insight into the unique innate immune responses of the developing brain, and offers a mechanism into the increase susceptibility of this population to viral encephalitis.

Title: Inflammatory profile in encephalopathy patients with a history of Lyme disease

Authors: *E. A. ECKMAN[1,2], J. PACHECO-QUINTO[1,2], J. J. HALPERIN[2,3];
[1]Biomed. Res. Inst. of New Jersey, Cedar Knolls, NJ; [2]Atlantic Hlth. Syst., Morristown, NJ;
[3]Neurosciences, Overlook Med. Ctr., Summit, NJ

Abstracts: As in other infections, some patients with Lyme disease have persistent nonspecific symptoms following appropriate treatment. The etiology remains to be identified. Emphasis on cognitive aspects of these symptoms has resulted in patients' fears that this reflects CNS infection. Despite absence of any evidence supporting this, such individuals often receive additional and inappropriate antibiotics. Controlled trials indicate such treatment is ineffective and has adverse effects. It is possible that a subset of patients recovering from Lyme disease may have an abnormal inflammatory response that could, in the absence of ongoing infection, cause symptoms ranging from fatigue to altered cognition. Improved diagnosis and differentiation between symptoms resulting from active nervous system Lyme infection, systemic infection, or an abnormal immune response could clarify pathogenesis and guide appropriate treatment. Published studies have attempted to correlate the initial type and extent of the inflammatory response to Lyme disease with the development of post-treatment symptoms. However, interpretation of the data is often complicated by the absence of an appropriate control population. The goal of our study was to characterize the inflammatory profile in CSF and serum from patients with encephalopathy or headache occurring after antibiotic treatment for Lyme disease. The levels of 18 cytokines and chemokines, including markers of Th1, Th2, and Th17-type inflammatory responses, were measured using multiplex assays. Results were compared to those from patients with similar symptoms unrelated to Lyme disease, to healthy controls, and to patients with active CNS infection. Consistent with published studies, we observed significant elevations in CSF inflammatory markers including CXCL13 in patients with nervous system infection. These elevations correlated with CSF pleocytosis and were not specific to Lyme disease. CSF inflammatory markers were not elevated in the majority of patients with post-treatment encephalopathy or headache, consistent with other evidence that such symptoms do not result from CNS infection. A subset of both Lyme seropositive and seronegative encephalopathy patients did show elevations in serum IL-23 and related cytokines indicative of a Th17-type inflammatory response. However, the relationship between this response and the type and duration of symptoms is unclear. Further studies with sera from a larger number of asymptomatic patients are required to investigate the possible significance of this finding.

Title: CCL5 activates a orphan G-protein coupled receptor 75 in human neuroblastoma SH-SY5Y cell line

Authors: *S. DEDONI[1,2], V. AVDOSHINA[2], I. MOCCHETTI[2];
[1]Biomed. Sci., Univ. of Cagliari, Cagliari, Italy; [2]Georgetown Univ., Washington, DC

Abstracts: The chemokine CCL5 inhibits entry of M-tropic HIV strains into macrophages/microglia by affecting the binding of the envelop protein gp120 to the co-receptor CCR5. Interestingly, CCL5 also prevents neuronal cell death mediated by the T-tropic gp120 and the viral protein Tat, which have no affinity for CCR5. Thus, CCL5 could be used to reduce HIV-associated neurocognitive disorder (HAND). Nevertheless, the mechanism of action of CCL5 remains to be fully characterized. Recent studies have shown that CCL5 activates a G-protein coupled receptor 75 (GPR75) which encodes for a 540 amino-acid orphan receptor of the Gq α family. In the present study, we examined the interaction of CCL5 and GPR75 in neuroblastoma SH-SY5Y cells that do not express other receptors for CCL5, such as CCR5, CCR3, and CCR1. CCL5 then promoted GPR75 internalization within few minutes. In addition, CCL5 elicited a significant dose-dependent increase in pro-survival pathways, such as the phosphatidylinositol 3-kinase (PI3K) and the extracellular signal-regulated kinases (ERK1/2). Akt and ERK1/2 phosphorylation were blocked by the specific pathway inhibitors, Wortmannin and U73 122, respectively, but not by pertuxin toxin, suggesting that CCL5 activate a Gq-coupled receptor. In conclusion, we hypothesize that CCL5-GPR75 signaling could further activate a neuroprotective mechanism that could explain the multiple pro-survival roles of CCL5 in reducing gp120 and Tat cell death.

Title: Efavirenz promotes β-secretase expression and increased Aβ1-40,42 via oxidative stress and reduced microglial phagocytosis: Implications for HIVassociated neurocognitive disorders (HAND)

Authors: *D. FERRELL[1], L. BROWN[2], J. JIN[2], B. GIUNTA[2];
[1]Univ. of South Florida Col. of Medicine, D, Tampa, FL; [2]Dept. of Psychiatry, USF Hlth., Tampa, FL

Abstracts: Efavirenz (EFV) is among the most commonly used antiretroviral drugs globally, causes neurological symptoms that interfere with adherence and reduce tolerability, and may have central nervous system (CNS) effects that contribute in part to HIV associated neurocognitive disorders (HAND) in patients on combination antiretroviral therapy (cART). Thus we evaluated a commonly used EFV containing regimen: EFV/zidovudine (AZT)/lamivudine (3TC) in murine N2a cells transfected with the human "Swedish" mutant form of amyloid precursor protein (SweAPP N2a cells) to assess for promotion of amyloid-beta (Aβ) production. Treatment with EFV or the EFV containing regimen generated significantly increased soluble amyloid beta (Aβ), and promoted increased β-secretase-1 (BACE-1) expression while 3TC, AZT, or, vehicle control did not significantly alter these endpoints. Further, EFV or the EFV containing regimen promoted significantly more mitochondrial stress in SweAPP N2a cells as compared to 3TC, AZT, or vehicle control. We next tested the EFV containing regimen in Aβ - producing Tg2576 mice combined or singly using clinically relevant doses. EFV or the EFV containing regimen promoted significantly more BACE-1 expression and soluble Aβ generation while 3TC, AZT, or vehicle control did not. Finally, microglial Aβ phagocytosis was significantly reduced by EFV or the EFV containing regimen but not by AZT, 3TC, or vehicle control alone. These data suggest the majority of Aβ promoting effects of this cART regimen are dependent upon EFV as it promotes both increased production, and decreased clearance of Aβ peptide.

Title: Helix-A peptide blocks HIV gp120 neurotoxicity by restoring microtubular transport in neurons

Authors: V. AVDOSHINA[1], F. TARABALLI[3], P. CASTELLANO[4], S. DEDONI[1], A. KALLARAKAL[2], A. UREN[2,5], E. EUGENIN[4], E. TASCIOTTI[3], *I. MOCCHETTI[1]; [1]Dept Neurosci, [2]Dept Oncology, Biochemestry and Mol and Cell Biol, Georgetown Univ. Med. Ctr., WASHINGTON, DC; [3]Dept Nanomedicine, The Methodist Hosp. Res. Inst., HOUSTON, TX; [4]Dept Microbiology and Mol Genet, Rutgers University, The State Univ. of New Jersey, NEWARK, NJ; [5]Lombardi Comprehensive Cancer Ctr., Washington, DC

Abstracts: The HIV envelop protein gp120 can be secreted by infected cells and internalized by neurons. This phenomenon promotes reduction of dendritic and synaptic connections both *in vitro* as well as in HIV-positive individuals who develop cognitive and motor abnormalities. One of the mechanisms that could explain gp120-mediated synaptic damage is the blockade of the intracellular transport of mitochondria. Such transport relies on microtubule (MT) integrity, a critical step of synaptic stability. Neuronal MTs contain tubulin-β3 (TUBB3), a specific isoform of β-tubulin expressed only in neurons. Using *in vitro* studies we have found that various strains of gp120 bind to recombinant TUBB3, tubulin dimers, and assembled MTs. However, gp120 did not bind to any other isoforms of tubulin. Gp120 binding occurs by a twenty amino acid domain of the α-helix region (Helix-A). The aim of the present study was to evaluate the neuronal protective effect of Helix-A peptide from gp120 toxicity. To address this hypothesis we examined the displacement of gp120 from TUBB3, tubulin dimers, and assembled MTs by synthetic Helix-A peptide. Because this peptide does not penetrate cell membrane we have synthetized Helix-A peptide linked to porous silica nanoparticles (nHelix-A peptide) for intracellular delivery. In primary rat cortical neurons nHelix-A peptide prevented gp120-mediated decrease in mitochondrial function (MTT) as well as alteration in mitochondrial morphology. In addition, nHelix-A peptide prevented gp120-mediated neuronal loss (Hoechst/PI). Since Helix-A peptide did not bind to gp120 the proposed mechanism of neuroprotection of Helix-A involves its competitive binding to TUBB3 and MTs. Indeed, nHelix-A peptide restored mitochondrial transport that was impaired in neurons exposed to gp120. Thus, neuroprotection conferred by Helix-A peptide strongly suggests that the direct interaction of gp120 with tubulin is one of the main central mechanisms by which gp120 promotes axonal degeneration. The interaction of gp120 with MTs could be a new target for the

development of alternative therapeutic strategies to reduce synaptic simplification observed in HIV positive subjects.

Title: Delayed virus clearance and immune cell infiltration in a mouse model of alphavirus encephalomyelitis treated with a glutamine antagonist

Authors: *V. BAXTER[1,2], M. C. POTTER[3], B. S. SLUSHER[3], D. E. GRIFFIN[1];
[1]Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD; [2]Mol. and Comparative Pathobiology, [3]Brain Sci. Inst., Johns Hopkins Sch. of Med., Baltimore, MD

Abstracts: Encephalomyelitis induced by arthropod-borne alphaviruses is an increasingly important cause of significant disease and disability in people, and no treatments beyond supportive care or licensed vaccines are currently available. Infection of mice with the TE strain of Sindbis virus (SINV) produces a model of nonfatal alphavirus encephalomyelitis with which to study the immune response to infection and the mechanisms of virus clearance. While infectious virus is cleared within a week of infection, viral RNA persists in the brain beyond recovery from clinical disease. Neuronal damage during SINV infection is due primarily to inflammation and glutamate toxicity rather than the virus itself. 6-diazo-5-oxo-l-norleucine

(DON), a glutamine antagonist, inhibits both of these mechanisms, providing a tool with which to examine the pathogenesis of disease. In this study, our objective was to examine the effect of DON administration on CNS pathology and SINV clearance. Five-week-old male C57BL/6 mice were infected intranasally with 10^5 pfu SINV or mock-infected with PBS and then treated for seven days intraperitoneally with either a high (0.6 mg/kg) or low (0.3 mg/kg) dose of DON or PBS vehicle. Tissues were collected both during treatment at 5 and 7 days post infection (DPI) and following treatment at 9 and 11 DPI. Brains were examined for infectious virus titers by plaque assay and viral RNA by RT-qPCR, and immune cell infiltration was evaluated by flow cytometry and histopathology. Infectious virus and viral RNA levels were increased in DON-treated mice at 7, 9, and 11 DPI in a dose-dependent manner compared to untreated SINV-infected mice, indicating impaired virus clearance. Inflammation and cell death in the brains of DON-treated, SINV-infected mice were reduced compared to untreated mice. Mononuclear immune cell infiltration was markedly decreased in the brains of treated mice compared to those of untreated mice throughout the course of DON administration. T lymphocyte numbers increased and virus clearance was initiated in DON-treated, SINV-infected mice following cessation of treatment. These findings demonstrate the dual-role the immune response plays in alphavirus encephalomyelitis: while inflammation contributes to the neuronal damage and CNS pathology seen during infection, the immune response is also required for effective virus clearance.

Title: Glial M1/M2 balance in morphine-potentiated LP-BM5 murine AIDS

Authors: *V. D. MCLANE, L. CAO, C. L. WILLIS;
Col. of Osteo. Med., Univ. of New England, Biddeford, ME

Abstracts: Of the 1.1 million people infected with human immunodeficiency virus (HIV-1) in the United States, nearly 20% will develop cognitive deficits ranging from mild memory impairment to dementia. Over 30% of HIV-1 patients abuse opiates such as heroin, which increases the risk and severity of HIV-associated neurocognitive disorders. Morphine mediates this effect through its influence on glia, the initiators of innate immune defense against viral infection in the central nervous system (CNS). Through the LP-BM5 murine acquired immunodeficiency syndrome (MAIDS) model, we have shown that morphine suppresses proinflammatory (M1) cytokine RNA expression, correlating to a significant increase in viral RNA in the hippocampus. We hypothesize that this increase in viral RNA is the result of the synergistic effects of morphine and LP-BM5 viral infection on the M1/M2 balance of the CNS. To investigate this, we infected male C57BL/6 mice with LP-BM5 (5e4 plaque-forming units, intraperitoneal injection). At 7 weeks post-infection, animals received 1 week of subcutaneous morphine (25 mg) or placebo pellet implantation. We measured expression of anti-inflammatory (M2) markers and type 1 interferons in key regions of interest - hippocampus, striatum, and frontal cortex - through quantitative real-time PCR and immunohistochemistry. We observed region-specific decreases in expression of M1 (c-c motif ligand 5, CCL5) markers and type 1 interferons (interferon-β). Morphine treatment increased the proportion of M2 to complementary M1 marker expression (arginase-1/inducible nitrous oxide synthase; interleukin (IL)-10/IL-12 p40; IL-1 receptor antagonist/IL-1β), suggesting a trend towards M2 activation, which could favor faster viral replication. Through the LP-BM5/MAIDS model, we aim to provide a fresh perspective on the role of morphine in HIV-1 infection in the CNS and identify new pathways for the prevention of opiate-accelerated neurocognitive disorders.

Title: HIV-1 Tat protein induces microglial neurotoxic activity via potassium channel Kv1.3

Authors: J. LIU[1], H. LIU[1], J. ZHANG[1], *H. (. XIONG[2];
[1]Univ. of Nebraska Med. Ctr., Omaha, NE; [2]Univ. of Nebraska Med. Ctr., OMAHA, NE

Abstracts: Microglia playa an important role in the pathogenesis of HIV-1-associated neurocognitive disorders (HAND). Increasing evidence indicates the voltage-gated potassium (K_V) channels are involved in the regulation of microglia function. We hypothesize that microglia K_V channels are involved in microglia-mediated neurotoxic activity in HIV-1-infected brain. To test this hypothesis, we examined the involvement of Kv channels in microglia response to HIV-1 Tat protein. Treatment of rat microglia with HIV-1 Tat protein (200ng/ml) resulted in microglia activation, reflected by an increased production of TNF-α, IL-1β, reactive oxygen species, and nitric oxide, which were associated with enhanced outward K^+ current and K_V1.3 channel expression. Suppression of microglial K_V1.3 channel activity, either with Kv1.3 channel blockers Margatoxin, 5-(4-Phenoxybutoxy)psoralen, or broad-spectrum K^+ channel blocker 4-aminopyridine, or by knockdown of K_V1.3 expression via transfection of microglia with K_V1.3 siRNA, was found to abrogate microglia neurotoxic activity induced by HIV-1 Tat exposure. Further studies revealed an involvement of Erk1/2 mitogen-activated protein kinase signaling in HIV-1 Tat - microglia K_V1.3 - microglia neurotoxicity. These results indicate that microglial K_V1.3 may be a potential therapeutic target for HAND and other inflammation-associated neurological disorders.

Title: Mechanism of astrocyte activation during the pathogenesis of HIV-associated pain

Authors: *Y.-M. ZHANG[1,2], Y. SHI[2], B. LI[2], W. RU[2], S.-J. TANG[2];
[1]Xuzhou Med. College,Laboratory of Anesthesiol., Jiangsu Province Key Lab. of Anesthesiol., Jiangsu, China; [2]Dept. of Neurosci. and Cell Biol., Univ. of Texas Med. Br., Galveston, TX

Abstracts: Chronic pain is one of the most common neurological disorders, affecting over 60% of HIV-1-infected patients, but the underlying pathogenic mechanism is unclear. Our recent

work reveals astrocyte activation in the spinal cord dorsal horn (SDH) specifically from the HIV patients with chronic pain but not from the patients without pain. This finding indicates a critical role of reactive astrocytes in the pathogenesis of HIV-associated pain. How astrocytes are activated under this condition is not known. We are interested in testing the role of Wnt signaling in the astrocyte activation using a gp120 mouse model. Our preliminary data indicate that Wnt5a, which is predominantly expressed in SDH neurons and secretes in response to neuronal activation, up-regulates GFAP in the SDH; conversely, Wnt5a antagonist blocks gp120-induced GFAP up-regulation. Since Wnt5a receptor ROR2 is expressed in astrocytes, we reason that the Wnt5a/ROR2 signaling pathway plays an important role in gp120-induced astrocytes activation. We will use conditional knockout approaches to determine the contribution of neuronal Wnt5a and astrocytic ROR2 to the gp120-induced astrocyte activation. Results from our studies are expected to improve the mechanistic understanding of HIV-associated pain pathogenesis.

Title: Effect of 17-β estradiol and progesterone on Toxoplasma gondii infection in astrocytes *in vitro*

Authors: *A. F. GUTIÉRREZ MALDONADO, J. DUEÑAS JIMENEZ, L. RODRÍGUEZ–PÉREZ, M. GALVÁN-RAMÍREZ;
Univ. of Guadalajara, Guadalajara, Mexico

Abstracts: INTRODUCTION. Toxoplasmosis is a disease caused by an obligate intracellular parasite called Toxoplasma gondii. In humans, proliferating tachyzoites have been detected in glial cells in patients developing toxoplasmic encephalitis. The progesterone and 17-β estradiol have different effects on infection, may exacerbate or reduce parasite replication, however the participation of these hormones in astrocytes infected is no known. OBJECTIVE. Know the

effect of 17-β estradiol and progesterone on Toxoplasma gondii infection in astrocytes *in vitro*. MATERIALS AND METHODS. Astrocytes were obtained from rat cortex and were pre-treated with 17-β estadiol and progesterone at concentrations (10, 20, 40 and 80 nM/mL) for 48 hours, then were infected 24 hours with 14,375 Toxoplasma gondii tachyzoites. The effect of hormones on Toxoplasma gondii infection in astrocytes was evaluated by immunocytochemistry using anti-Toxoplasma antibody to identify the parasite and anti-GFAP to identify astrocytes. Cellular viability was measured with MTT. RESULTS. The 17-β estradiol increased the number of intra and extra cellular parasites at concentrations of 20 and 80 nM/mL versus control. Progesterone decreased the number of intra and extra cellular parasites at all concentrations compared to the control. Finally, the parasite viability was reduced to concentrations of 20, 40 and 80 nM/mL of 17-ß estradiol by MTT. CONCLUSIONS. 17-β Estradiol exacerbates Toxoplasma gondii infection at 20 and 80 nM/mL, while that progesterone at 10, 20,40 and 80 nM/mL had a reduced effect on T. gondii proliferation in astrocytes infected.

Title: Microglia Contribute to HIV1-gp120Bal- induced synapse loss

Authors: *W. RU[1], S. TANG[2];
[1]Neurosci. and Cell Biol., [2]Univ. of Texas Med. Br., Galveston, TX

Abstracts: HIV-1 infection of the central nervous system (CNS) may lead to synaptic degeneration that is implicated in the pathogenesis of cognitive impairments in HIV-1/AIDS patients. However, the mechanism(s) by which HIV-1 causes the synaptic degeneration is unclear. We hypothesize that microglia, which are the major phagocytes in the CNS, contribute to removing the damaged synapse on live neurons after HIV-1 infection. As an initial step to test

this hypothesis study, we have determined the effects of HIV-1 coat protein gp120 on synapses of cortical neurons in culture. Using western blotting analysis, we found that gp120Bal decreased the protein levels of pre- and post-synaptic makers synapsin I and PSD95 in a time-dependent manner. Confocal imaging revealed a decrease of synapses following gp120 application. These data suggest that gp120 induces synaptic loss on the cultured neurons. Interestingly, we found that pretreating the primary cultures with minocycline, an inhibitor of microglia activation, abolished the gp120Bal-caused synapse loss. In addition, we also observed that pharmacological blockers of either NMDA or AMPA receptor abolished gp120-induced decrease of PSD-95 and synapsinI. These preliminary findings indicate that HIV-gp120 induces synapse loss via a biological process that depends on microglial activation and synaptic activity. We will perform additional studies to test this hypothesis.

Title: Amyloid beta reduces cytopathic effects of Herpes Simplex virus type I

Authors: *J. MERRITT[1], A. ANGAJALA[1], J. R. BABU[2], G. GRIFFIN[1];
[1]Biol., Tuskegee Univ., Tuskegee, AL; [2]Nutrition, Dietetics, and Hospitality Mgmt., Auburn Univ., Auburn, AL

Abstracts: Alzheimer's disease (AD) is a neurodegenerative disorder that is characterized by memory loss and other types of dementia. Amyloid β (Aβ) is a main cause of senile plaques detected in the brains of patients with AD and other forms of dementia. Recent evidence suggests that the buildup of Aβ is may be in response to microbial infections in the central nervous system. Aβ has been shown to inhibit the growth of bacteria and yeast; however, little work has tested its role in reducing viral activity. The present work tests the hypothesis that Aβ suppresses the cytopathic effects induced by the neurotropic Herpes Simplex Virus Type I (HSV-1). To test

this hypothesis, we treated SH-SY5Y neuroblastoma cells with varying concentrations of Aβ one hour before HSV-1 infection (1716 strain). Forty-eight hours after infection, cell viability and morphology was assayed. First we determined cell viability by utilizing the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. The MTT assay indicated that pretreatment of Aβ (100nM, 1μM, 10μM) reduced HSV-1 induced cell death by 40% ($p<0.01$). Photomicrographs of neuroblastoma cells infected with HSV-1 (multiplicity of infection; MOI=1) also demonstrated that Aβ pretreatment reduced cytopathic effects of HSV-1. To more directly test HSV-1 activity, plaque formation assays are ongoing. These data indicate that the antimicrobial activities of Aβ are not limited to bacteria. Overall, the results provide another link connecting HSV-1 infection and the progression of AD.

Title: Rats reared in isolation from weaning show decreased expression of NMDA receptors in the medial prefrontal cortex

Authors: ***G. G. BORGES**[1], M. FERREIRA[1], J. RODRIGUES[1], K. MORIYAMA[1], M. SANTOS[1], H. FACHIM[2,3], M. IYOMASA[1], M. ROSA[3,4];

Abstracts: Dysfunction of the prefrontal cortex (PFC), where the excitability of the microcircuits has been demonstrated to occur through the NMDA glutamate (Glu) receptors, has been reported to contribute to symptoms of the schizophrenia such as cognitive deficits, thought disorders, delusions and hallucinations. It has been shown that Glu neurotransmission is decreased in the PFC of both schizophrenics and rats reared in isolation from weaning, a model

of this disease. The aim of this study was to evaluate the changes on the expression of NMDA receptors (NR1 and NR2) in the PFC (primary somatosensory cortex), sub-regions infralimbic (IL) and prelimbic (PrL) of the medial PFC (mPFC) and in entorhinal cortex (EC) induced by isolation rearing. Two groups of Wistar rats (n=5-8/each) were used. In both groups the pups remained with their mothers (6/mother) until weaning (21 days - 40g) when they were allocated randomly to one of two conditions: grouped (housed 3/cage, handled 3 times/week) or isolated (housed individually, handled once/week for cleaning purpose) for 10 weeks. The animals were anaesthetized, perfused and their brains sectioned (40μm) in the PFC and EC for immunohistochemistry. The number of immunopositive cells (IC) or the optical density (OD) was quantified bilaterally in 3 sections/rat. Data were compared by Student t-test ($p<0.05$). In contrast, the expression of NR2 was decreased significantly in both mPFC-PrL (25%, $p=0.003$) and EC (25%, $p<0.001$) of rats reared in isolation from weaning. The number of NR2-IC did not change in the PFC and mPFC-IL of rats reared in isolation when compared to grouped rats ($p>0.05$). The decreased expression only in NR2 found in the mPFC-PrL and EC of rats reared in isolation suggest that specific subtypes of Glu receptors underlie the alterations on the Glu neurotransmission reported in schizophrenia. These findings also suggest that Glu hypofunction occur in specific brain regions in schizophrenia as previously reported for sub-regions of the PFC. Understanding the altered PFC circuits in schizophrenia may improve the knowledge of the pathophysiology of this disease and contribute to the development of treatments that can retard the onset of the symptoms. **Support:** Capes; FPA.

Title: The NMDA receptor GluN2C subunit regulates behavioral and cellular phenotypes relevant to schizophrenia

Authors: *A. RAVIKRISHNAN, B. G. HILLMAN, S. C. GUPTA, R. PAVULURI, D. J. STAIRS, S. M. DRAVID;
Creighton Univ., Omaha, NE

Abstracts: The NMDA receptor (NMDAR) hypofunction hypothesis in schizophrenia posits that reduced NMDAR function leads to behavioral abnormalities observed in schizophrenia. Lower expression of GluN2C subunit of NMDAR has been reported in the cortex and thalamus in postmortem brains from schizophrenic patients, however its exact functional implications remain unknown. With the GluN2C heterozygous and knockout (GluN2C HET and KO) mouse model we tested whether a deficit in GluN2C expression leads to schizophrenia-like phenotypes. Moreover, using a GluN2C/GluN2D-subunit selective potentiator (CIQ) together with the GluN2C genetic model we tested whether facilitation of GluN2C-containing receptors can prevent schizophrenia-like behavior. GluN2C HET and KO mice were more sensitive to phencyclidine (PCP)-induced hyperlocomotion and working memory deficit in a Y-maze test compared to wildtype (WT) mice. CIQ attenuated PCP-induced hyperlocomotion and working memory deficit in WT and GluN2C HET but not in GluN2C KO. Furthermore, GluN2C KO had a modest deficit in prepulse inhibition and CIQ prevented dizocilpine (MK-801)-induced prepulse inhibition deficit in WT and GluN2C HET but not in GluN2C KO. Moreover, social isolation-induced stress led to emergence of hyperlocomotion and social interaction and working memory deficits in GluN2C KO. GluN2C KO also exhibited lower dendritic spine density in pyramidal neurons and higher expression of a marker for oxidative stress, 4-hydroxy-2-noneal in the medial prefrontal cortex. These results demonstrate that a deficit in GluN2C-containing NMDARs leads to schizophrenia-like phenotypes, and indicate that pharmacologic enhancement of GluN2C-containing NMDARs may lead to beneficial effects for behavioral and cognitive deficits in schizophrenia.

Title: Epigenetic regulation of NMDAR expression in prefrontal cortex and hippocampus during development in the methylazoxymethanol model and Disrupted-in-Schizophrenia-1 model for schizophrenia

Authors: *Y. GULCHINA[1], M. A. SNYDER[1], M. V. PLETNIKOV[2], W.-J. GAO[1];
[1]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Psychiatry and Behavioral Sci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstracts: The glutamate hypothesis demonstrates the importance of the NMDA receptor in the pathological process of schizophrenia, however the question of how mis-regulation of the NMDA receptor occurs remains unclear. One potential mechanism underlying aberrant NMDA receptor function is epigenetic control of transcription wherein gene product levels are altered without direct modification of the DNA sequence. To explore this possibility, we have employed two animal models: the neurodevelopmental methylazoxymethanol (MAM) acetate rat model and the transgenic mutant Disrupted-in-Schizophrenia-1 (mDISC1) mouse model. We have characterized NMDA receptor subunit protein levels through development, and we observed reduced NR2B protein levels in the prefrontal cortex (PFC) of both MAM-treated rats and mDISC1 mice in juvenile stage (p21) of development. Corresponding to the reduced NR2B, we identified an upregulation of H3K27me3, a histone marker indicative of repressive transcription, in the PFC of juvenile (p21) MAM-treated animals. In addition, HDAC4, a protein involved in regulating synaptic plasticity, was upregulated in adolescent (p45) MAM-treated hippocampus, where NR2B levels were similarly decreased as was observed in the PFC. We are currently evaluating the role of repressive transcriptional proteins, such as repressor element 1 silencing transcription factor (REST/NRSF), as well as histone marks of global changes in gene expression in the nuclei of PFC and hippocampus neurons in these animal models. In addition, we are investigating whether these epigenetic modifiers actively repress NR2B expression in juvenile and adolescent MAM-treated and mDISC1 animals, respectively.

Title: Reversion of behavior deficits with nitric oxide synthase inhibitor and gene expression in MAM schizophrenia model

Authors: *C. SALUM[1,2], M. C. BROSCO[2], O. M. LIMA-FILHO[2], G. S. V. HIGA[2], A. H. KIHARA[2];
[1]Univ. Federal Do ABC, Sao Paulo, Brazil; [2]Cognition and Complex Systems Group, UFABC, São Bernardo, Brazil

Abstracts: Gestational methylazoxymethanol acetate (MAM) exposure has been suggested to produce neural and behavioral abnormalities which model some aspects of schizophrenia. Some of the behavior deficits observed are reduced prepulse inhibition (PPI) and social interaction. Nitric oxide (NO) is altered in schizophrenic patients and we have shown that NO synthase (NOS) inhibitor, NG-nitro-L-arginine (LNO), was able to prevent PPI deficits caused by dopamine agonists and NMDA antagonists in rats. Our aims were to investigate if LNO was able to improve the behavior deficits of PPI and social interaction observed in MAM offspring and investigate gene expression of receptors DRD2, DRD1, NMDAR1 and enzymes nNOS and iNOS. Nine pregnant Wistar rats were treated with ip injection of either Saline or 22mg/kg of MAM on the 17th day of pregnancy. Male rats of the offspring (N=38) were used with approximately 90 days of age. Twelve of them, after the behavioral testing, were euthanized and their brains were removed and for dissection of four brain regions: prefrontal cortex (PFC), striatum (CPU), midbrain, and hippocampus. After RNA extraction, the expression of DRD2, DRD1, NMDAR1, NOSn, NOSi were examined by quantitative reverse transcription polymerase chain reaction. Other 26 rats of that offspring received an ip injection of Saline or LNO (40mg/kg) 1h before testing and were tested on PPI and then on social interaction. PPI test consisted on 64 stimuli presentations: pulse (120 dB), prepulse (PP, 69, 73 and 81dB), PP+P and null (no stimuli). %PPI and amplitude startle response (ASR) were registered. Social interaction test consisted on the exposure of two unfamiliar rats for 5min to the open field registering: sniffing, following and genital inspection. MAM-saline group presented significant lower %PPI and higher ASR to all stimuli compared to Saline-Saline group also showed significantly. Analyses detected reduced social behaviors for MAM-saline rats compared to Saline-Saline animals. In all behaviors there was no difference between MAM-LNO rats compared to Saline-Saline ones. PCR results showed lower expression of DRD1 at CPU and hippocampus, of DRD2 at CPU and midbrain and of NMDAR1 at hippocampus and midbrain in MAM rats compared to control ones. No difference was found in expression of nNOS and iNOS. Results suggest that LNO is able to restore some behavior deficits in MAM rats which may not be accounted by higher levels of nNOS. These findings and the genes expression alterations may be relevant for the study of schizophrenia. Financial **Support:** FAPESP (2011/09548-3), CNPq 476162/2011-4 and UFABC

Title: Untangling GSK3β, DISC1 and NMDAR interactions in prefrontal cortical neurons

Authors: *S. MONACO[1], W.-J. GAO[2];
[2]Neurobio. and Anat., [1]Drexel Univ. Col. of Med., Philadelphia, PA

Abstracts: Cognition is a fundamental neurological process mandatory for successfully navigating through a persistently changing environment. The ability to perceive, filter, prioritize, update and ultimately respond to incoming stimuli requires efficient cognitive processing. NMDA receptors are considered the cellular constituents associated with learning, memory, and higher order cognition. Disruption of NMDA receptors is strongly implicated in several disorders characterized by cognitive impairments, particularly schizophrenia. Schizophrenia is a neurodevelopmental disease with combined environmental and genetic factors that converge and thus affect susceptibility. DISC1 is recognized as a candidate risk gene linked to schizophrenia and has been found to directly interact with GSK3β as well as regulate NMDA receptors. The goal of this study is to further elucidate the signaling mechanism at play among DISC1, GSK3β, and NMDA receptors with a particular focus on prefrontal cortical neurons. We hypothesize that interaction of GSK3β and DISC1 affects the expression of NMDA receptors via regulation of β-catenin signaling. Preliminary results indicated that pharmacological inhibition of GSK3β lead to increased NR2B, NR2A, and β-catenin expression levels at 4 hours post-treatment, with no change in NR3A protein levels. pGSK3βser9 levels were reduced both at 4 and 24 hours following SB216763 treatment. We predict that DISC1 serves as an intermediate factor, linking environmental perturbations to genetic alterations. Gaining a better grasp on this cellular

signaling cascade will help provide an essential framework for understanding how the DISC1/GSK3β complex regulates NMDA receptor changes in prefrontal cortical neurons.

Title: "Two-hit" developmental model of schizophrenia (prenatal Poly I:C and neonatal PCP): Transient effects on microglia activation

Authors: C. SCHIFANI, A.-L. RELO, *C. KLEIN, A. Y. BESPALOV;
Neurosci. Discovery Res., AbbVie, Ludwigshafen, Germany

Abstracts: The neurodevelopmental hypothesis of Schizophrenia describes the disease onset as an interplay of at least two genetic or environmental 'hits' during development. Present research focused on an animal model combining two environmental factors known to be at risk for schizophrenia, maternal immune activation during pregnancy (polyinosinic-polycytidylic acid, Poly I:C, infusion on gestation day 15) and early life insult (neonatal exposure of offsprings to glutamatergic insult by repeated treatment with the NMDA receptor antagonist phencyclidine, PCP, on postnatal days 7, 9 and 11). This treatment leads to changes in behavior and metabolic brain activity in puberty and adulthood. More specifically, treated rats showed increased engagement in play behavior during puberty as well as increased exploratory activity during adulthood. Furthermore, adult hippocampal brain activity was reduced. At least some of the observed effects in the adult animals were correlated with the alterations in play behavior during late adolescence. Therefore, a separate series of studies addressed effects of Poly I:C/PCP treatment in late adolescent rats. To assess the potential neuroinflammatory state, hippocampal brain slices of 48-day old rats were stained with Iba-1, a marker for microglia. Treated rats showed a very strong increase of the number of microglia compared to controls. To characterize this effect further, OX-42 staining was used for the same slices to measure potential elevated

microglia activation. However, this was not shown to be different between groups. One possible explanation for this outcome could be that the microglia activation is already gone in late adolescent rats but number of microglia is still increased. To conclude, combined prenatal Poly I:C and early postnatal PCP treatment increases the number of microglia but, in this model, pathophysiological contribution of neuroinflammation appears to decline as the animals become adult.

Title: Which acetylcholine receptors participate to the lurasidone-induced improvement in novel object recognition subchronic phencyclidine model of cognition in schizophrenia?

Authors: *M. MIYAUCHI[1,2], L. RAJAGOPAL[1], M. HUANG[1], S. KWON[1], Y. OYAMADA[2], H. Y. MELTZER[1];
[1]Northwestern Univ., Chicago, IL; [2]Dainippon Sumitomo Pharma Co., Ltd., Osaka, Japan

Abstracts: Background: Both nicotinic acetylcholine (ACh) receptors (nAChR) and muscarinic Ach receptors (mAChR) are critical components of cognitive function. Under normal condition, nAChR and mAChR agonists generally improve cognition, while antagonists have the opposite effect. Lurasidone is a novel atypical antipsychotic drug, with high affinity for dopamine (DA) D2, serotonin 5-HT2A, 5-HT7, and 5-HT1A receptors. We have previously shown that acute lurasidone significantly reversed declarative memory deficits induced by subchronic treatment with the N-methyl-D-aspartate receptor (NMDAR) antagonist, phencyclidine (PCP) in a novel object recognition (NOR) paradigm, and also increased DA and ACh release in the medial prefrontal cortex (mPFC). The role of DA (via D1 receptor stimulation) in reversing the deficit in

NOR resulting from subchronic PCP is well established but the contribution of cholinergic mechanisms to this effect requires further study. Thus, the aim of the present study was to investigate the role of nAChR and mAChR in the ameliorating effect of acute lurasidone treatment in subchronic PCP treated rats. Materials and Methods: Female Long-Evans rats received vehicle or PCP (2 mg/kg, b.i.d.) for 7 days, followed by a 7-day washout. Groups of six normal rats received a single dose of the non-competitive nAChR antagonist, mecamylamine (MEC) (4 mg/kg) or the mAChR antagonist, scopolamine (SCO) (0.1 mg/kg) 15 min prior to acquisition. Another group of rats, following washout of subchronic PCP, received MEC (4 mg/kg) or SCO (0.1 mg/kg) 15 minutes prior to an effective dose of lurasidone (0.1 mg/kg). Results: Normal rats who received acute MEC (4 mg/kg) or SCO (0.1 mg/kg) showed significant NOR deficits. MEC (4 mg/kg) 15 minutes prior to lurasidone showed significant deficits; i.e. the ameliorating effect of lurasidone was blocked by pretreatment with MEC. SCO (0.1 mg/kg) pretreatment did not prevent the effect of lurasidone. Discussion: This study demonstrates that: 1) both MEC and SCO induce significant deficits in NOR in normal rats; 2) MEC, a nAChR antagonist, but not SCO, a mAChR antagonist, blocked the ameliorating effect of lurasidone following subchronic PCP treatment in rats; 3) endogenous ACh efflux in cortex and probably hippocampus induced by acute lurasidone plays a crucial role in its effect on subchronic PCP-induced NOR deficits via nAChR stimulation. Further studies with selective nAChR agonists and antagonists in subchronic PCP-treated rats in combination with lurasidone is needed to establish which nAChRs are involved in its ability to improve NOR.

Title: Examining the effects of a chronic exposure to phencyclidine on a rodent system: An analysis of functional network connectivity, behavioral performance, and mRNA expression

Authors: *C. M. MAGCALAS[1], N. I. PERRONE-BIZZOZERO[2], V. D. CALHOUN[4], J. BUSTILLO[2], E. E. PEREZ[2], D. A. HAMILTON[3];
[2]Neurosciences, [3]Psychology, [1]Univ. of New Mexico, Albuquerque, NM; [4]The Mind Res. Network, Albuquerque, NM

Abstracts: Chronic administration of phencyclidine (PCP) generates neurobiological and behavioral changes that mimic symptoms and micro-levels changes found in schizophrenia (sz). PCP impairs spatial learning and memory performance and flexibility of learning in addition to decreasing mRNA expression of markers including parvalbumin, NR2B, mGluR2, and $GAD_{65/67}$. The neuropathology responsible for the onset of sz is still unknown. Thus, establishing valid animals models plays a vital role in characterizing the processes involved. A growing interest in quantifying functional network connectivity (FNC) has yielded clinical studies, which have identified abnormal activation in sz patients. The current study aims to evaluate the effects of chronic PCP exposure on resting state FNC in the rat. Adult male rats (N=40) were pre-trained in the Morris Water Task (MWT) prior to a 4-week injection regimen. Rats received 14 intraperitoneal injections of either PCP (2.58 mg/kg) or 0.9% saline solution (1 mL/kg). Rats were anesthetized 72-hrs after their final injection & imaged in a 4.7T Bruker Biospin MRI scanner. Resting state fMRI BOLD data were collected after which rats were retested in the MWT to investigate long-term spatial memory and behavioral flexibility. Tissue punches from the medial and ventral frontal cortex, cerebellum, and parietal cortex were collected following the MWT retest. cDNA was synthesized from total RNA and RT-PCRs were performed in order to examine gene expression for parvalbumin, calbindin, GAD67, ErbB4, NR2A, and NR2B. EPI image sequences were normalized. Group independent component analysis implemented in Group ICA of fMRI Toolbox (GIFT) was used to identify resting state networks. A total of 27 non-artifactual components were retained and consisted of 14 cortical, 7 amygdala/hippocampal, 2 thalamic, 2 striatal, and 2 midbrain components. PCP exposed rats displayed more negatively correlated hippocampal-cortial and midbrain-cortial components, primarily for cortical components localized in the frontal cortex. Increases in positive correlations were observed in PCP exposed rats within hippocampal-hippocampal components. Performance during the MWT retesting phase indicated that PCP exposure induced a long-term spatial memory deficit but did not impair subsequent spatial learning. RT-PCR analysis determined that rats exposed to PCP show decreased expression for GAD67 in the ventral frontal cortex. These results indicate that chronic PCP exposure causes widespread alterations in FNC including constituents of the default mode network and other subcortical and cortical regions implicated in sz.

Title: Psychosis-Like behaviors in rats induced by toluene exposure: Role of NMDA receptors

Authors: *M. T. RIVERA, C. LÓPEZ-RUBALCAVA, S. CRUZ;
Farmacobiologia, Cinvestav, México, Mexico

Abstracts: Toluene is a volatile hydrocarbon found in a variety of chemical compounds that is commonly misused by inhalation for recreational purposes. The misuse of this solvent exacerbates psychosis symptoms in patients but the mechanism through which it exerts this effect is unknown. Toluene has a complex mechanism of action that includes NMDA receptor antagonism, among other effects. It has been described that other NMDA receptor antagonists like phencyclidine or ketamine induce psychotic like symptoms in healthy people. In preclinical research, these compounds are used to mimic a psychotic-like state. The main objective of the present study was to analyze if toluene could induce psychosis-like behaviors and to characterize the participation of the NMDA receptors in these actions. To this aim, male Wistar rats were exposed to toluene (500 -8000 ppm) for 30 min and immediately after were evaluated in social interaction and prepulse inhibition (PPI) tests. On the other hand, head-twitch response (HTR), a behavior related to hallucinogenic-like effects, was analyzed during toluene exposure. Our results show that there were a concentration-dependent decrease of cumulative interaction time and percent inhibition of the startle response in PPI test, while there was an increase in the number of HTR. In a second part of the study we analyzed the role of NMDA receptor antagonism in toluene´s effects, for this purpose rats were treated with D-serine 20 min before toluene exposure and tested in different trials. Results showed that co-activation of NMDA receptors prevent the deficit induced by toluene in social interaction and PPI test, and reduce the HTR. In conclusion, toluene exposure induces psychotic-like behaviors; the NMDA receptor antagonism is relevant in toluene's effects.

Title: Changes in NMDA receptor subunits following developmental ketamine administration

Authors: *V. JEEVAKUMAR[1], S. KROENER[2];
[1]The Univ. of Texas At Dallas, Richardson, TX; [2]The Univ. of Texas at Dallas, Richardson, TX

Abstracts: The NMDAR-hypofunction theory postulates that schizophrenia is associated with alterations of NMDARs in parvalbumin (PV)-expressing GABAergic interneurons, causing deficits in the function of those interneurons, leading to disinhibition of glutamatergic cells and cortical desynchronization. We recently characterized a developmental NMDAR antagonism model of the disorder in which mice are treated with ketamine (KET) (30 mg/kg) on PND 7, 9 and 11. We observed enduring cognitive deficits and negative-like symptoms of schizophrenia in adult animals. In the medial prefrontal cortex (mPFC) NMDAR blockade increased excitatory inputs onto PV interneurons, but did not change GABAergic inputs onto pyramidal (PYR) cells. Unexpectedly, we also observed a homeostatic upregulation of NMDARs in PV cells. Here, we further explore the alterations at NMDARs in PV cells of adult animals by examining subunit-specific changes in NR2A and NR2B contribution. We used whole-cell patch-clamp recordings to study pharmacologically isolated NR2A and NR2B currents by bath-applying either the NR2B blocker Ro25-6981 or the NR2A blocker PEAQX, respectively. The percentage change in amplitude of the response gave an estimate of the contribution of each subunit. We found that in KET-treated animals NR2A subunit contribution was unaltered (SAL = -46.38 ± 5.21%, n = 5; KET = -50.81 ± 4.01%, n = 5; p = 0.52); whereas NR2B-mediated currents were increased (SAL = -20.49 ± 4.4%, n = 7; KET = -35.35 ± 5.22%, n = 8; p = 0.03). This indicates that the upregulation of NMDAR currents in PV cells caused by developmental KET treatment is mainly due to an increase in NR2B subunits. Because we saw no enduring changes in IPSCs onto PYRs in adult animals, we investigated whether disinhibition of PYRs occurs transiently following KET administration. Thus mice treated with KET or saline on PND 7, 9 and 11 were sacrificed on PND 12 for sIPSC recordings from layer 5 PYRs in the mPFC. In a second experiment, the acute effects of KET were studied by recording sIPSCs from layer 5 PYR cells following a single injection of KET (or saline) on PND 7. Surprisingly, under both conditions we observed no changes in the amplitude or frequency of sIPSCs. Ongoing experiments explore the possibility that disinhibition of PYR cells in the PFC following both acute and chronic NMDAR

antagonism is layer-specific. Specifically, selective disinhibition of PYR cells in layers 2/3 may contribute to the increase in sEPSCs seen in layer 5 PV cells. Taken together, our results demonstrate paradoxical effects of developmental KET treatment on PV cells that alter mPFC network function and lead to persistent schizophrenia-like behavior in adult animals.

Title: Dose-dependent effects of repeated ketamine administration on novelty detection and cognitive processes

Authors: *A. SCHUMACHER, E. C. TOLLEDO, B. SIVANANDAN, J. WOLDEGABRIEL, R. ITO;
Psychology, Univ. of Toronto Scarborough, Toronto, ON, Canada

Abstracts: Ketamine is a non-competitive antagonist of the NMDA receptor, known to elicit strong psychotomimetic effects. Repeated exposure to sub-anesthetic doses of ketamine in rats has previously been shown to induce cognitive deficits, as well as behavioural changes akin to the negative symptoms of schizophrenia, giving much validity to the use of ketamine administration as a pharmacological model of schizophrenia. This study sought to further characterize the behavioural effects of two different ketamine pre-treatment regimens, focusing primarily on the effects of repeated ketamine administration on novelty processing, which is known to be dependent on the integrity of the hippocampus. Given existing evidence of reduced hippocampal recruitment in schizophrenia, we predicted that repeated ketamine pre-treated rats would demonstrate impaired novelty detection. Male Long Evans rats received either 5 or 14 intra-peritoneal injections of 30mg/kg ketamine or saline. After a withdrawal period of 10 days, rats were tested in an associative mismatch detection task. Rats were habituated to two audiovisual sequences, and subsequently presented with novel and familiar stimulus configurations to examine their ability to detect novel sequences. Furthermore, rats underwent a novel object detection task, in which they were habituated to four objects presented in a plus

maze. Subsequently, one object was replaced, and the spatial locations of two familiar objects were switched. Rats also underwent testing in various other tasks such as the delayed matching to place T maze task, sucrose preference task and locomotor tests involving administering a challenge dose of amphetamine (AMPH). As predicted, we found that the high-dose ketamine pre-treatment regimen elicited impairments in mismatch detection, spatial novel object detection and working memory. In contrast, the low-dose ketamine pre-treatment regimen improved performance of novelty detection. In addition, low-dose ketamine pre-treated rats showed enhanced locomotor activity following an AMPH challenge, indicative of locomotor sensitizaton, while the high-dose ketamine pre-treated rats showed decreased locomotor activity, compared to saline rats. These data demonstrate that different regimens of repeated ketamine administration can induce behavioural alterations in opposite directions, and that neural adaptations occurring in the mesolimbic dopamine system may underlie these effects. These findings have important implications not only for the use of repeated ketamine as an animal model of schizophrenia, but also for recent studies demonstrating ketamine to have antidepressant properties.

Title: Inhibition of D-amino acid oxidase does not increase D-serine plasma levels in monkey or dog

Authors: J. ALT[1], N. ATOR[2], T. TSUKAMOTO[1], C. ROJAS[1], *B. S. SLUSHER[1];
[1]John Hopkins Brain Sci. Inst., Baltimore, MD; [2]Psy Bay Behavioral Biol., John Hopkins, Baltimore, MD

Abstracts: D-serine administration has been shown to be effective for the treatment of schizophrenia symptoms. However, D-serine has to be administered at high doses in order to observe clinical effects. This is thought to be due to D-serine undergoing oxidation by D-amino

acid oxidase (DAAO) before it reaches the brain. Consequently, co-administration of D-serine with a DAAO inhibitor has been suggested as a way to lower the dose of D-serine required to treat schizophrenia. Early studies to evaluate this hypothesis showed that concomitant administration of DAAO inhibitors with D-serine significantly enhanced D-serine plasma levels in rodents compared to administration of D-serine alone. In a follow-up effort we wanted to demonstrate a corresponding enhancement of D-serine levels in larger mammals. We evaluated D-serine plasma levels in baboons for 24 h after 30 mg/kg oral administration in the presence or absence of 5- chloro-benzo[d]isoxazol-3-ol (CBIO), a prototype DAAO inhibitor. CBIO was administered by intravenous infusion at 0.1 mg/kg/h for 24 h. Even though CBIO reached concentrations in plasma at about 4-6 μM, well above its binding affinity for DAAO (200 nM), plasma D-serine levels were the same in the presence or absence of CBIO. Similar results were obtained when the same experiment was carried out with dogs instead of monkeys or when using other DAAO inhibitors instead of CBIO. We conclude that in contrast to rodents, DAAO inhibition in monkeys or dogs does not increase levels of D-serine in plasma. The difference in results among the different species could be due to differences in D-serine metabolism and/or clearance mechanisms. It is also possible that the role of DAAO is different in rodent versus non-rodent mammalian species.

Title: Age-dependent effects of mGluR2 agonist LY395756 on NMDA receptor expression and function in the rat prefrontal cortex

Authors: *M. LEE[1,2], B. XING[1], W.-J. GAO[1], X.-Q. HU[2], F. LI[3];
[1]Anat. and Neurobio., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Dept. of Rehabil., the Third Affiliated Hosp. of Sun Yat-Sen Univ., Guangzhou, China; [3]Dept. of Neurobio. and Anat., Zhongshan Col. of Med., Guangzhou, China

Abstracts: Pharmacologically targeting the group II metabotropic glutamate receptor (mGluR2/3) has been reported to be effective in alleviating symptoms of multiple neurological and psychiatric disorders, including persistent pain, drug addiction, and schizophrenia. It is widely believed that mGluR2/3 agonists mainly affect presynaptic release to regulate synaptic function. However, we recently reported that mGluR2/3 agonist also exhibit strong postsynaptic regulation of both AMPA and NMDA receptor function. Because its antipsychotic effect is mainly through activation of mGluR2, we explored the effects of LY395756 (LY39), a compound that is selective for mGluR2 as an agonist and mGluR3 as an antagonist, on NMDAR expression in the prefrontal cortex (PFC) of both juvenile and adult rats. We found that LY39 induced dose-dependent changes of synaptic membrane proteins in NMDAR subunits. It significantly increased the expression of NR1, NR2A, NR2B and NR2B phosphorylations Tyr1472, Ser1303 at high dose of 3 mg/kg in adult rats, but had no significant effect on NMDAR subunits at all 3 doses (0.3, 1, 3 mg/kg) in juvenile rats. Moreover, there were significant decreases in total protein level of mTOR and pGsk3β-Ser9/Gsk3β ratio at a high dose of 3.0 mg/kg LY39 in adult rats. It is therefore likely that LY39 exhibits distinct actions in NMDAR expression and function in young vs. adult animals. We are currently investigating this possibility and the potential mechanisms by using electrophysiological recording.

Title: Characterization of a subchronic PCP rat model of shizophrenia and evaluation of effects of Bitopertin and Tolcapone

Authors: *V. ANGLADE[1], D. PARACHOU[1], E. CAYRE[1], E. R. DETRAIT[2], C. DRIEU LA ROCHELLE[1];
[1]Biotrial Pharmacol., Rennes, France; [2]CNS Research, UCB S.A., Braine-l'Alleud, Belgium

Abstracts: Classical antipsychotics such as haloperidol are known to treat only the positive symptoms of schizophrenia (hallucinations, paranoid delusion, language disorder) whereas certain atypical antipsychotics have been proposed for the treatment of negative (social withdrawal, anhedonia) and cognitive (impaired attention, memory, executive function)

symptoms. In humans, the non-competitive NMDA antagonist phencyclidine (PCP) produces a schizophrenic-like psychosis including positive and negative symptoms and cognitive dysfunction. In animals, repeated PCP treatment produces long term behavioral and pathophysiological deficits that correlate with those reported in schizophrenia. We recently presented data (405.09, SFN 2013) on an animal model of schizophrenia, evaluating social withdrawal using the social interaction (SI) test and memory impairment using the novel object recognition (NOR) test in rats treated subchronically with PCP followed by withdrawal. The goal of the present study was to extend validation of this model by characterizing the duration of the PCP-induced deficits and evaluating the efficacy of bitopertin (RG1678, a highly potent GlyT1 inhibitor) and tolcapone (a COMT inhibitor) in reversing the deficits. Long Evans rats received a 7-day subchronic treatment with PCP (5 mg/kg twice a day, ip). In the first experiment, animals were tested in social interaction 1, 4 and 9 weeks after the end of PCP treatment or in the NOR test 1, 2 and 4 weeks after the end of PCP treatment. In the second experiment, the efficacy of acute treatment with bitopertin (1, 3 and 10 mg/kg, ip) and tolcapone (7.5, 15 and 30 mg/kg, ip) in reversing the deficits were assessed. The results show that PCP-induced reproducible social withdrawal lasts around 9 weeks post-treatment and the deficit in the NOR test lasts around 4 weeks post-treatment. Moreover, bitopertin (3 and 10 mg/kg) dose-dependently reversed the PCP-induced SI deficit and all three doses of tolcapone reversed the recognition memory impairment. In conclusion, subchronic treatment with PCP followed by withdrawal induces a deficit in novel object recognition and social withdrawal in rats which last up to four and nine weeks, respectively. These symptoms can be reversed by treatment with pharmacological agents such as the GlyT1 inhibitor bitopterin and the COMT inhibitor tolcapone.

Title: Effects of electroconvulsive seizure on the neonatal MK-801 treatment-induced long-term changes in behaviors and protein translation signal pathway in the rat frontal cortex

Authors: *S. KIM[1], H. PARK[2], Y. KIM[3];
[1]Dept Psychiatry (Institute of Human Behavioral Medicine), Seoul Ntl Univ. Col. Med., Seoul, Korea, Republic of; [2]Seoul Ntl Col. Med., Seoul, Korea, Republic of; [3]Dongguk Univ. Med. Sch., Goyang-si, Gyeonggi-do, Korea, Republic of

Abstracts: Systemic injections of MK-801, a selective NMDA receptor antagonist, into neonatal rats induce long-term neurochemical and behavioral changes. It has been suggested that these changes form the neurodevelopmental basis for schizophrenia-like behavior in rats. In this study, postnatal 7-day (PN7) rats were treated with MK-801, and their frontal cortices at PN60 were examined to investigate the long-term effects on the molecules in signal pathway of protein translation. At PN60, the rats treated with MK-801 at PN7 showed increased locomotor activity and deficits in prepulse inhibition, as reported previously. Accompanied with the behavioral changes, the phosphorylation level of S6 at S240/244, which promotes protein translation initiation, was increased, and the phosphorylation of raptor at S792, which inhibits the activity of mTOR signal pathway, was reduced in the rat frontal cortex at PN60. Repeated treatments of electroconvulsive seizure (ECS) from PN51 to PN60 ameliorated the increased locomotor activity and prepulse inhibition deficits of PN7 MK-801-treated rats. In addition, ECS treatments recovered the PN7 MK-801-induced increase in the phosphorylation of S6 at S240/244 and decrease in the phosphorylation of raptor at S792. In summary, long-term behavioral changes induced by neonatal MK-801 treatment was accompanied with the increased phosphorylation of S6 in the brain, which were recovered by ECS treatments. These findings could suggest an important role of aberrant long-term activation of protein translation machinery in the MK-801 neurodevelopmental animal model of schizophrenia.

Title: Effects of chronic prenatal MK-801 treatment on behaviour and dopamine functioning in the adult rat offspring

Authors: *S. GALLANT, L. WELCH, P. MARTONE, U. SHALEV;
Psychology, Ctr. For Studies In Behavioral Neurobio. - Concordia Univ., Montreal, QC, Canada

Abstracts: Patients with schizophrenia display impaired cognitive functioning, increased social withdrawal, and increased sensitivity to psychomimetic drugs. The neurodevelopmental hypothesis of schizophrenia posits that disruption of the developing brain predisposes neural networks to lasting structural and functional abnormalities resulting in the emergence of such symptoms in adulthood. Given the critical role of the glutamatergic system in early brain development, we investigated whether chronic prenatal exposure to the glutamate NMDA receptor antagonist, MK-801, induces behavioural and neurochemical changes in adult rats. Pregnant Long-Evans rats were administered saline or MK-801 (0.1 mg/kg; s.c.) at gestation day 7-19. Object recognition memory and cognitive flexibility were assessed in the adult male offspring using a novel object preference task and a maze-based set-shifting procedure, respectively. Social behaviour was assessed in pairs of rats interacting in an open-field box. Locomotor-activating effects of acute amphetamine (0.75, 1.0, 1.5 mg/kg) and MK-801 (0.1, 0.4 mg/kg) were also assessed. To investigate differences in dopamine (DA) utilization, rats were decapitated following an amphetamine challenge (0.75 mg/kg) and levels of DA and DA metabolites were assessed in the nucleus accumbens, striatum, and prefrontal cortex using HPLC. Adult, prenatally MK-801-treated rats failed to show novel object preference after a 90 min delay, suggesting that they did not recognize the familiar object. In addition, the set-shifting task revealed impaired acquisition of a new rule in prenatally MK-801-treated rats compared to controls. This deficit appeared to be driven by regression to the previously learned behaviour. Furthermore, in the social interaction task, prenatally MK-801-treated rats spent less time sniffing and more time wrestling with a novel rat compared to controls. There were no significant differences in locomotor activity following acute amphetamine challenges. Unexpectedly, MK-801-induced locomotor activity in prenatally MK-801-treated rats was lower compared to controls. Prenatally MK-801-treated rats appeared to have lower DA utilization in the nucleus accumbens and dorsal medial striatum compared to saline rats, though these differences were not statistically significant. These findings suggest that glutamate dysfunction during early development may mediate behavioural deficits in adulthood and may therefore shed light into the role of neurodevelopmental adaptations in schizophrenia.

Title: Sub-chronic ketamine effects in the rodent odor span task

Authors: D. PANOZ-BROWN, C. ANDERSON, R. WELCH, M. DEAL, K. GOBENCIONG, S. HANNAH, S. HESS, C. MYERS, K. E. BRUCE, A. PRICHARD, *J. GALIZIO;
Univ. North Carolina, Wilmington, NC

Abstracts: A number of studies have shown that sub-chronic exposure to NMDA antagonists (e.g., ketamine) impairs performance on a variety of cognitive tasks and may provide a model for the cognitive impairments in schizophrenia. The present study evaluated the effects of sub-chronic ketamine in a rodent model of working-memory capacity, the odor span task (OST). Rats were trained to stability on the OST and then exposed to five daily injections of saline, 10 mg/kg or 30 mg/kg ketamine. After exposure to sub-chronic ketamine, OST performance was evaluated along with the capacity to learn an olfactory discrimination reversal. Some reduction in span length and longest run of consecutive responses was observed in ketamine-treated rats, but these effects were relatively small and short lived. Overall OST accuracy did not show significant impairment and there was no effect on either the performance of a simple discrimination or on the reversal learning task. The present results were not consistent with previous studies showing large and persistent effects of sub-chronic ketamine and indicate the importance of task variables in the assessment of residual effects of NMDA antagonist treatment.

Abstracts: The present study extends the successful development of an apparatus and methodology to conduct fMRI studies in conscious rhesus monkeys in order to evaluate the CNS effects of antipsychotics. The dosing regimen employed a single bolus i.v. injection of ketamine followed by a continuous i.v. infusion over one hour in five adult female subjects. Prior to the fMRI protocol, multiple doses of ketamine were administered on separate occasions and plasma levels of ketamine were determined to establish dosing that approximated plasma levels (93-106 ng/mL at the low dose, 120-216 ng/mL at the high dose) reported in human studies. Behavioral observations indicated that dosing was well below the anesthetic range and all subjects were responsive to tactile and auditory stimulation. MRI scans were conducted in a Siemens Trio 3 Tesla magnet using a custom-designed transmit-receive volume NHP head coil. The monkeys lay prone in a custom-built restraint cradle optimized for acquiring MRI data from conscious monkeys attached to the NHP head coil, and physiological data, including heart rate, mean arterial blood pressure, and respiratory rate were monitored and collected continuously. BOLD fMRI images were collected utilizing a whole-brain gradient echo single-shot echo planar imaging sequence (TR/TE/FA = 3000ms/32ms/90; 1.5mm X 1.5mm X 1.5mm resolution). Each monkey underwent one 55-minute fMRI scan (2 minute baseline; followed by 53 minute infusion of ketamine). High-resolution (0.5mm X 0.5mm X 0.5mm) T1-weighted MPRAGE scans were acquired for anatomic reference. Statistical parametric maps were obtained with appropriate GLM models incorporating motion and hemodynamics of ketamine infusion. Ketamine induced a very robust ($p < 10\text{-}7$), dose-dependent activation in several brain regions, including dorsolateral prefrontal cortex, anterior cingulate, inferior parietal lobule and thalamus, and regional specificity declined with increased dose. Clinical fMRI studies have reported activation by ketamine in each of these brain regions, documenting the remarkable concordance between the nonhuman primates and human subjects. Ongoing studies are evaluating the interaction of ketamine with a standard antipsychotic drug in clinical use, risperidone. The results obtained will provide a metric to evaluate novel antipsychotics.

Title: Impaired Social activity in NMDA receptor GluN3A (NR3A) subunit knockout mice

Authors: *J. LEE, X.-Y. JI, L. WEI, S. P. YU;
Dept. of Anesthesiol., Emory Univ., Atlanta, GA

Abstracts: The N-methyl-d-aspartate receptor (NMDAR) has been implicated in the pathophysiology of neuropsychiatric disease, including schizophrenia and autism spectrum disorders (ASD), which has impaired social behaviors as a unique feature. For example, the glycine binding site in NMDARs can regulate social behavior in schizophrenia and ASD. In addition, the level of NR2 subunit tends to increase after administration of antipsychotic drugs for patients with schizophrenia and ASD. These results suggest that NMDA receptors play important roles in social activity. GluN3A or NR3A is a unique inhibitory subunit in the NMDAR complex. The role of GluN3A in social behavioral activities is unclear. In this study, we sought to determine altered social activities in GluN3A knockout (KO) mice. Wild type (WT) and GluN3A KO mice were tested for social transmission ability in a food preference task, the social interaction test, and the three-chamber social interaction test. Although GluN3A KO mice displayed normal social transmission of food preference, these mice spent less time in reciprocal social interaction in the social interactions test compared to WT mice. The three-chamber social test confirmed that mice lacking GluN3A had lower sociability and did not show a preference for social novelty. In addition, using a home cage monitoring system we observed reduced grooming and sniffing behaviors in GluN3A KO mice. To determine cellular signals that might mediate the altered social behaviors in GluN3A KO mice, we examined the expression of some social behavior-related genes including serotonin receptor, serotonin transporter, vasopressin, vasopressin receptor, oxytocin, oxytocin receptor, brain-derived neurotropic factor (BDNF), and cluster of differentiation 73 (CD73) in the prefrontal cortex, hippocampus, and thalamus. Among

these genes, the expressions of oxytocin and its receptor were significantly lower in the prefrontal cortex in GluN3A KO mice than that in WT mice. These initial findings suggest that GluN3A expressed in the adult prefrontal cortex plays a significant regulatory role in the social activity. Reduced expression levels of oxytocin and its receptors may contribute to the impaired social behavior and imply a link between GluN3A, oxytocin system and some psychiatric disorders such as schizophrenia and ASD.

Title: Evaluation of the effect of sarcosine, an endogenous glycine transporter 1 inhibitor, on behavioral performance and the glutamate hypothesis of schizophrenia in mice

Authors: ***W.-L. HUNG**[1], W.-S. LAI[1,2,3];
[1]Psychology, [2]Grad. Inst. of Brain and Mind Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan

Abstracts: The hypofunction of the NMDA glutamate transmitter system is emerging as a potentially more promising hypothesis for schizophrenia, especially for cognitive deficits. There is a growing interest in the development of pharmacological agents with potential antipsychotic properties that enhance the activity of the NMDA receptor via glycine modulatory site. Glycine is a coagonist at the NMDA receptor complex and glycine levels are regulated by glycine type I transporters, which serve to maintain low sub-saturating glycine levels in the vicinity of the NMDA receptor. Sarcosine (N-methylglycine), a naturally occurring selective glycine type I transporter inhibitor, can increase the concentration of glycine within the synaptic cleft and

potentiate NMDA receptor function. Emerging studies suggest that sarcosine might be useful for the restoration of NMDA hypofunction and the treatment of schizophrenia. However, the effective dose and the mechanism for the therapeutic effect of sarcosine remains much unclear. In this study, a series of experiments was conducted to evaluate the effect of sarcosine in male mice and MK-801 was used to induce acute NMDA receptor hypofunction in these mice. We found that (1) a single dose of sarcosine (except the highest does) did not affect basic locomotor activity in mice; (2) a single administration of sarcosine (except the highest dose) had no effect on MK-801 induced hyperlocomotion and stereotypy; (3) among these doses we selected, no obvious toxic effect was found in the blood biochemical analysis except the highest dose; (4) a reduction of brain activity was found after a single injection of sarcosine using microPET scan with 18F-fluorodeoxyglucose; and (5) MK-801 induced behavioral deficits in the prepulse inhibition and holeboard task can be normalized by sarcosine pre-injection. Behavioral data collection and further analyses are still in progress. Findings from this study provide some clues to understanding the effect of sarcosine and its therapeutic potential in the treatment of schizophrenia.

Title: Neural mechanisms of empathy in autism and aggressive conduct disorder

Authors: ***E. T. KLAPWIJK**[1,3], M. AGHAJANI[1,3], O. F. COLINS[1,3], N. D. J. VAN LANG[1,3], N. J. A. VAN DER WEE[3,2], R. R. J. M. VERMEIREN[1,3];
[1]Leiden Univ. Med. Ctr., Oegstgeest, Netherlands; [2]Psychiatry, Leiden Univ. Med. Ctr., Leiden, Netherlands; [3]Leiden Inst. for Brain and Cognition, Leiden University, Netherlands

Abstracts: Empathy, the ability to share and understand the feelings of other people, is a crucial aspect of human social interactions. Diminished empathy is thought to be central in autism spectrum disorders (ASD) and may also underlie aggressive and antisocial behavior in individuals with conduct disorder (CD). Using an fMRI paradigm, we investigated the neural

mechanisms underlying empathy in a sample of adolescents with ASD, a group of aggressive CD adolescents and a group of matched healthy controls. Thirteen male adolescents (15-19 years old) with ASD, 26 male adolescents with aggressive CD and 33 healthy control subjects were scanned using fMRI while completing an explicit empathy task (Schulte-Ruther et al., 2007). In this task emotional faces (angry, fearful and neutral) from the Radboud Faces Database (Langner et al., 2010) were presented. Participants were asked to either infer the emotional state from the face (other-task) or to judge their own emotional response to the face (self-task). A perceptual decision on the width of neutral faces was included as a control condition. FMRI data processing was carried out using FEAT Version 6.00, part of FSL (www.fmrib.ox.ac.uk/fsl). Behavioral results suggested that all participants were faster and better at recognizing other's fear compared to other's anger in the other-task ($p < .001$). No significant group differences in behavior were found. Neuroimaging results (all $p < .05$ cluster-corrected) showed higher activation in the dorsal anterior cingulate cortex (dACC) in the control group compared to the ASD group and in the posterior cingulate cortex (PCC) in the CD group compared to the ASD group during the self-task. Furthermore, higher activation in the left and right amygdala and thalamus was found for the control group compared to the CD group in this condition. The dACC is an important region for higher-order social cognition and empathy. Decreased activity in this area and in the PCC in the ASD group is in line with previous studies suggesting problems with cognitive processing of empathy in ASD. The amygdala and thalamus are important affective regions and decreased activity in these regions in the CD group is thought to reflect diminished affective reactions to other's emotions. Our results underline the importance of distinguishing between cognitive and affective aspects of empathy in ASD and CD groups.

Title: Enigma schizophrenia working group findings from 2,028 cases and 2,540 controls

Authors: *T. G. VAN ERP[1], D. P. HIBAR[2], P. M. THOMPSON[2], J. A. TURNER[3], T. ENIGMA SCHIZOPHRENIA WORKING GROUP[4];
[1]Dept. of Psychiatry and Human Behavior, Univ. of California Irvine, Irvine, CA; [2]Dept. of Neurol., Imaging Genet. Center, Univ. of Southern California, Los Angeles, CA; [3]Georgia State Univ., Atlanta, GA; [4]Dept. of Neurol., Univ. of Southern Calornia, Los Angeles, CA

Abstracts: Introduction The profile of brain structural abnormalities in schizophrenia is not fully determined, despite years of structural brain imaging research. To avoid the low statistical power obtainable with small samples analyzed using a variety of methods, here we analyzed brain magnetic resonance imaging (MRI) scans from 15 centers worldwide using standardized methods. Our ultimate goal is to identify biomarkers for use in schizophrenia imaging-genetics studies. Here we ranked subcortical brain abnormalities by effect size and identified sources of effect size heterogeneity across samples. Methods This ENIGMA (Stein et al. 2011) Schizophrenia Working Group project pooled, via meta-analysis, structural magnetic resonance imaging (MRI) brain scans from 15 sites across the globe. Data from 4,568 individuals, including 2,028 patients and 2,540 controls, were analyzed using standardized image analysis (FreeSurfer), quality assurance, and statistical methods. Bilateral accumbens, amygdala, caudate, hippocampus, pallidum, putamen, and thalamus as well as ventricular volume and total intracranial volume (ICV) were obtained. Group contrast effect sizes were estimated controlling for age, sex, and intracranial volume (ICV). Meta-regression analyses were performed to identify effect size moderators. Results Compared to healthy controls, patients with schizophrenia had smaller hippocampus (Cohen's d=-0.46), amygdala (=-0.31), thalamus (d=-0.31), accumbens (d=-0.25), and intracranial volumes (d=-0.12) and larger pallidum (d=0.21) and lateral ventricle

volumes (d=0.37). Putamen and pallidum volume exacerbations were positively associated with duration of illness; hippocampal deficits scaled with the proportion of not-medicated patients in each cohort. Conclusion This first ENIGMA Schizophrenia Working Group cooperative analysis of brain imaging data supports a consistent profile of subcortical abnormalities in schizophrenia. The largest effect size was observed for hippocampal deficits followed by lateral ventricle enlargement. Overall, the profile of subcortical abnormalities is consistent with a large meta-analysis of structural brain abnormalities in schizophrenia (Haijma et al. 2012). Patients with schizophrenia showed significantly smaller hippocampus, amgydala, thalamus, accumbens, and intracranial volumes and significantly larger pallidum and lateral ventricle volumes.

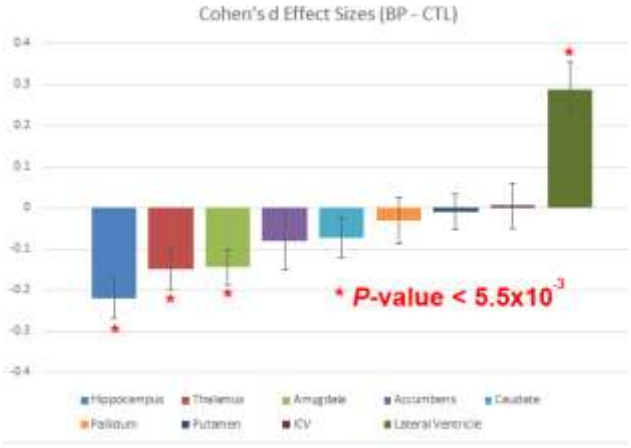
Title: ENIGMA Bipolar disorder working group findings from 1,745 cases and 2,613 controls

Authors: *D. P. HIBAR[1], L. T. WESTLYE[2], P. M. THOMPSON[1], O. A. ANDREASSEN[2], .. FOR THE ENIGMA BIPOLAR DISORDER WORKING GROUP[3];
[1]Dept. of Neurology, USC, Imaging Genet. Ctr., Marina Del Rey, CA; [2]Div. of Mental Hlth. and Addiction, Norwegian Ctr. for Mental Disorders Res. (NORMENT), KG Jebsen Ctr. for Psychosis Research, Oslo Univ. Hosp., Oslo, Norway;
[3]http://enigma.ini.usc.edu/ongoing/enigma-bipolar-working-group/, Los Angeles, CA

Abstracts: Introduction The pattern of effects on the brain in bipolar disorder (BP) has proven heterogeneous, and volumetric comparisons of brain structures theorized to be involved in the pathophysiology of BP have yielded mixed results. To investigate sources of uncertainty, we have formed an international collaboration for the study of BP as part of the Enhancing Neuroimaging Genetics through Meta-Analysis (ENIGMA) Consortium (Stein et al., 2012). In this initial ENIGMA-Bipolar effort, we perform the largest ever study of subcortical brain volumes in BP cases and healthy controls, by analyzing MRI scans from a total of 4,358 participants. Methods The ENIGMA Bipolar disorder working group brings together structural

MRI brain scans from 4,358 subjects - 1,745 cases and 2,613 healthy controls. We examined the mean volumetric differences between BP cases and healthy controls in seven subcortical brain structures: nucleus accumbens, amygdala, caudate, hippocampus, pallidum, putamen, and thalamus as well as ventricular volume and total intracranial volume (ICV). All effect sizes were estimated while controlling for age, sex, and differences in head size (ICV). Results BP cases had significantly lower volumes of the hippocampus (d = -0.221 ± 0.049; P = 6.62x10-6), thalamus (d = -0.150 ± 0.051; P = 3.21 x10-3), and amygdala (d = -0.143 ± 0.043; P = 9.44 x10-4) but larger lateral ventricles (d = 0.289 ± 0.066; P = 1.29x10-5) than healthy controls. None of the other five structures was significantly different between BP cases and controls using a Bonferroni corrected significance threshold p* < 0.05/9 = 5.6x10-3 (Figure 1). Conclusions Here we performed the largest ever study of neuroimaging measures in BP, enabling robust estimates of brain structure abnormalities. Patients with BP had significantly enlarged ventricles, which is the most consistently reported finding in the BP literature (Hallahan et al., 2010). Patients with BP have significantly smaller hippocampus, amygdala, and thalamus volumes - findings that have not been consistently shown in previous



reports.

Utrecht, Utrecht, Netherlands; [6]Vanderbilt Univ., Nashville, TN; [7]INSERM-CEA-Faculté de Médecine Paris-Sud, Orsay, France; [8]VU Univ., Amsterdam, Netherlands

Abstracts: The role of genes on risk for changes in brain anatomy is a challenge faced by neuroscientists and geneticists. To date it has been found that the majority of common genetic variants exert only a small effect on anatomical traits derived from brain imaging, if at all. Discovering the specific role of genes in these highly heritable brain traits is particularly confounded by the fact that study populations vary greatly across basic demographics, neurological conditions, and imaging acquisition methods, making critical replication and validation attempts a near impossible task. The Diffusion Tensor Imaging (DTI) Working Group in the Enhancing Neuro-Imaging Genetics through Meta-Analysis Consortium (ENIGMA-DTI) has developed image processing protocols and analysis methods that reliably pool data from heritable imaging phenotypes across various cohorts regardless of demographic and technical variability. To evaluate the effects of 16 common genetic variants previously reported to associate to white matter microstructural variation, we pooled the average fractional anisotropy data from 4314 scans from 6 various cohorts. Individuals ranged in age from 11 to 85. Data was pooled across populations through a mega analysis (all data were considered simultaneously in

the model) as well as a meta- analysis (results from individual cohort analyses were pooled) after covarying for linear and quadratic effects of age, sex, their interaction, as well as components from multi-dimensional scaling to reduce population stratification effects. Mega analysis showed more promise for detection of effects than meta-analysis. Polymorphisms for three genes showed nominally significant associations with global FA values *ADAMTS18*, *DISC1*, and *ZNF804A*. Despite this being the largest study of its kind for DTI, no variant survived multiple comparisons correction for the number of variants tested, let alone at the genome-wide statistical threshold for significance. This study validates the need for large-scale collaborative efforts for discovering genetic influences over brain connectivity.

Title: Subcortical brain volume abnormalities in major depressive disorder: Prospective meta-analytic findings from the enigma major depressive disorder working group

Authors: *L. SCHMAAL[1,2], D. J. VELTMAN[2], D. P. HIBAR[3], ;. FOR THE ENIGMA-MDD WORKING GROUP[4];
[1]GGZ Ingeest, Amsterdam, Netherlands; [2]Dept. of Psychiatry, VU Univ. Med. Ctr., Amsterdam,

Netherlands; [3]Imaging Genet. Ctr., USC, Los Angeles, CA;
[4]http://enigma.ini.usc.edu/ongoing/enigma-mdd-working-group/, Amsterdam, Netherlands

Abstracts: Despite overwhelming evidence that major depressive disorder (MDD) is heritable, intensive efforts to elucidate genetic variation underlying MDD have yielded only modest success, perhaps partly because genetic effects do not directly translate into dichotomous clinical phenotypes. Biomarkers, for instance measures of brain structure and function, may represent an intermediate step in the causal pathway from genetic variation to distal clinical phenotypes and may therefore help to resolve questions about the etiology of depression. The goal of our ENIGMA-Major Depressive Disorder (ENIGMA-MDD) consortium, a network of 14 research institutes from 7 different countries (for a full list of participating institutes, see: http://enigma.ini.usc.edu/ongoing/enigma-mdd-working-group/) with overlapping neuroimaging data from around 1800 MDD patients and 7200 controls, is to identify imaging markers that robustly discriminate MDD patients from healthy controls using a prospective meta-analytic approach employing the same analysis techniques and statistical models across all participating centers. Here we present the results of the first meta-analysis on differences in subcortical volumes between MDD patients and controls. MDD patients showed robust hippocampal volume reductions compared to healthy individuals (Cohen's d=-0.14), whereas other subcortical volumes seemed to be preserved. However, when examining subcortical volume differences between healthy controls and patients with recurrent MDD and patients experiencing their first MDD episode at time of scanning, more widespread subcortical volume abnormalities were observed in recurrent MDD patients including the hippocampus (Cohen's d=-0.14), amygdala (Cohen's d=-0.11), caudate (Cohen's d=0.21) and lateral ventricles (Cohen's d=0.16). In contrast, no differences between first episode patients and healthy individuals were observed. No associations between age of onset and use of antidepressant medication and subcortical volumes were observed. In conclusion, this currently largest worldwide effort to identify subcortical structural brain alterations showed robust reductions in hippocampus volume in MDD patients, with more widespread subcortical volume abnormalities in MDD patients with more than one depressive episode.

Title: Brain structure in ADHD across the life span: The ENIGMA ADHD working group

Authors: *B. FRANKE[1], M. HOOGMAN[2], M. ZWIERS[2], M. MENNES[2], .. FOR THE ENIGMA-ADHD WORKING GROUP[3];
[1]Departments of Human Genet. (855) and Psychiatry, Donders Inst. For Brain, Cognition and Behavio, Nijmegen, Netherlands; [2]Donders Inst. for Brain, Cognition and Behaviour, Nijmegen, Netherlands; [3]http://enigma.ini.usc.edu/ongoing/enigma-adhd-working-group/, ., Netherlands

Abstracts: Introduction Neuroimaging studies in ADHD show structural alterations of various brain regions in affected children and adults (Frodl and Skokauskas, 2012; Nakao et al., 2011; Valera et al., 2007). It is unclear, however, how these differences develop across the lifespan, and whether they are global effects or area-specific. To clarify brain changes across the lifespan, an ADHD Working Group was formed within the ENIGMA consortium (http://enigma.ini.usc.edu/). Within the working group, we are sharing brain imaging data from children and adults with ADHD and healthy comparison subject. Our first aim is to study subcortical brain differences in ADHD across the lifespan, and the potential effects of medication and co-morbidity. A second aim is to investigate effects of gender. **Methods** The ENIGMA-ADHD Working Group has adopted a rolling mega-analysis design: new groups can join at any time, and fixed data "freezes" allow analysis at different time points. Images are analyzed using fully automated and validated neuroimaging segmentation algorithms (FSL FIRST or FreeSurfer), for which protocols are available on the ENIGMA website. For all subjects, we collect volumetric data for hippocampus and the following subcortical structures: nucleus accumbens, amygdala, caudate nucleus, putamen, pallidum, and thalamus. We also share information on co-morbidity, ADHD symptoms, IQ, and medication use. The database currently includes 1640 cases and 1503 controls. **Results** So far, 22 international sites have joined the working group (see the ENIGMA website for a full list). Data from 452 ADHD cases and 405 controls have been analyzed to date. This sample has an age range of 6-63 years and includes 60% males. Our first analysis showed subtly but significantly smaller volumes for the left and right nucleus accumbens (*d*: 0.16 and 0.26), left amygdala (*d*: 0.16), right caudate nucleus (*d*: 0.16), and left putamen (*d*: 0.15) for cases compared to controls. These differences were independent of age. **Conclusions** The developmental trajectory of alterations in brain structure of individuals with ADHD remains largely unknown. This is due to the scarcity of large, well-powered longitudinal studies. Through data sharing, the ENIGMA-ADHD Working Group, with a sample of over 3000 cases and controls across the lifespan, will begin to address this gap. With sample sizes already similar to those of previous neuroimaging meta-analyses upon first data-freeze and analysis of the enlarged sample currently ongoing, our mega-analysis will help to

clarify outstanding questions regarding age, medication and gender effects on brain-developmental trajectories.

Title: Neural correlates of implicit face-emotion processing in youth with severe irritability

Authors: B. SHARIF-ASKARY[1], *J. STODDARD[2], P. KIM[4], J. Y. YI[1], K. HINTON[5], M. A. BROTMAN[1], D. S. PINE[3], E. LEIBENLUFT[1];
[1]Section on Bipolar Spectrum Disorders, [3]Section on Develop. and Affective Neurosci., [2]NIMH, Bethesda, MD; [4]Dept. of Psychology, Univ. of Denver, Denver, CO; [5]Vanderbilt Univ., Nashville, TN

Abstracts: Background: Pathologically irritable youths exhibit impairments in face-emotion processing. However, the neural basis of this impairment is unknown. One report found amygdala hyperactivity to increasingly angry affect during implicit face-emotion processing in pathologically irritable youths compared to healthy comparison youths (HC). Here, we examine the neural correlates of implicit face-emotion processing in youths with chronic and severe irritability [operationalized as severe mood dysregulation; SMD]. Methods: During fMRI, 85 youths (ages 8-18 years) completed an implicit face-emotion processing task by identifying the gender of faces varying in affect and intensity of expression. Acquisition occurred on a 3T750 GE scanner. Participants were excluded for excessive motion (5 SMD, 2 HC) and low behavioral accuracy <65% (3 SMD, 7 HC), leaving 34 SMD and 34 HC for group analysis. Group differences in BOLD signal response to affects (angry, fearful, or happy) at different intensities (0=neutral affect, 50%, 100%, and 150%) were compared by ANOVA. We used standard procedures in Analysis of Functional Neuroimages to identify significant clusters, thresholded voxelwise at $p<.005$ and cluster corrected to $\alpha \leq 0.05$ whole-brain. Results: Relative to HC youths, SMD were less accurate ($p=0.03$) and slower to respond ($p<0.001$), but did not differ in accuracy

or reaction time by type of emotion or emotional intensity. HC and SMD youths differed in BOLD responses to facial affects at different intensities in bilateral fusiform gyri [right: $F(6,396)=8.3$, $p<0.001$, $k=170$, peak coordinates=44,59,-11; left: $F(6,396)=7.2$, $p<0.001$, $k=114$, peak coordinates=-49,56,-11], right precuneus [$F(6,396)=5.1$, $p<0.001$, $k=76$, peak coordinates=24,61,-29], and two cerebellar areas. In the fusiform gyri, SMD youths had a greater BOLD response to angry faces at 150% emotional intensity, relative to both HC youths ($p's \leq 0.05$) and themselves at other intensities of angry ($p's \leq 0.01$), while HC youths had more BOLD responses in the fusiform gyri to happy faces at the 150% intensity relative to both SMD youths ($p's<0.05$) and themselves at all other intensities of happy ($p's<0.03$). Conclusions: In regions mediating attention to facial features, SMD youth show hyperactivation in response to intensely angry affect, whereas HC youth show such hyperactivation in response to intensely happy affect. These results expand the prior literature of atypical neural responses to increasing angry affect in pathologically irritable youths and suggest a neural correlate to the social threat attention bias found in these youths.

Title: Aberrant striatal functional connectivity in schizophrenia patients and unaffected first-degree relatives

Authors: ***P. LI**[1], R.-J. ZHAO[2], L. SHI[1], Y.-L. FAN[2], H.-Q. SUN[3], L. LU[3];
[1]Natl. Inst. On Drug Dependence,Peking Unive, Beijing, China; [2]Dept. of Alcohol and Drug Dependence, Beijing Hui-Long-Guan Hospital, Peking Univ., Beijing, China; [3]Inst. of Mental Health/Peking Univ. Sixth Hosp. and Key Lab. of Mental Health, Ministry of Health,Peking Univ., Beijing, China

Abstracts: The striatum, where antipsychotic drugs mainly act, interacts with cortical areas involved in the affective and cognitive control. A large body of research has revealed aberrant

functional and structural connectivity of striatum in schizophrenia. However, it remains unclear whether connectivity between subdivisions of striatum and cortex is differentially affected in schizophrenia, and whether certain altered striato-cortical connectivity represents a valid intermediate phenotype of the disorder. We examined spontaneous functional connectivity between striatal subdivisions and the cortex using resting-state functional MRI (rs-fMRI) in patients with schizophrenia (n=50), unaffected first-degree relatives of patients (n=25), and healthy controls (n=48). Patients with schizophrenia mostly exhibited decreased functional connectivity between nearly all striatal subregions and the prefrontal cortex, temporal lobe and limbic cortex. Furthermore, both patients with schizophrenia and their unaffected first-degree relatives showed reduced functional connectivity between limbic striatum and orbitofrontal cortex compared with healthy controls, and meanwhile the reduction level in patients was higher than that in unaffected first-degree relatives. Our findings demonstrated that schizophrenia was characterized in part by abnormalities in the functional connectivity within the striato-cortical system. Especially, altered functional connectivity between limbic striatum and orbitofrontal cortex was related to the genetic risk of schizophrenia, which makes it a potential biological marker for schizophrenia.

Title: Probing electrophysiological and behavioral correlates of working memory deficits in schizophrenia

Authors: S. FISH[1,2], E. PAPPA[1,2], M. TOUMAIAN[1,2], T. DAVIES[1,2], *C. G. THELERITIS[3], C. SAVILLE[2], M. ECONOMOU[4], C. KLEIN[2], N. SMYRNIS[4,1];
[1]Lab. of Sensorimotor Control, Univ. Mental Hlth. Res. Inst., Athens, Greece; [2]Sch. of Psychology, Bangor Univ., Bangor, United Kingdom; [4]Psychiatry, [3]Univ. Athens Med. Sch., Athens, Greece

Abstracts: Schizophrenia has previously been associated with a number of cognitive deficits. Research has consistently demonstrated deficits in working memory (WM) including increased error rate as well as higher and more variable reaction time (RT) in schizophrenia patients. Furthermore, patients have been shown to demonstrate decreased amplitude and increased latency of the P3b event-related potential (ERP). The present study combines these behavioural and electrophysiological findings in schizophrenia patients (n=22) and healthy controls (n=19). Accuracy, RT and variability of RT, as well as P3b amplitude and latency were measured for all participants during an n-back WM task consisting of two conditions (0-back and 1-back). ERP measures were obtained via 64 channel electroencephalographic (EEG) recording. Patients' responses were significantly more erroneous ($F(1, 39) = 7.42$, $p = .01$), RTs were greater ($F(1, 39) = 19.95$, $p < .001$), and more variable ($F(1, 39) = 13.36$, $p < .001$) than controls. Patients' accuracy ($F(1, 39) = 8.34$, $p = .006$) and RT ($F(1, 39) = 5.92$, $p = .02$) decreased more drastically than controls as WM load increased. Patients' P3b latencies were significantly more prolonged for both tasks in comparison to controls ($F(1, 39) = 7.07$, $p = .01$). The results demonstrate a WM deficit as well as increased P3b latency in patients with schizophrenia. Additionally, an increase in WM load was associated with increased latency for all participants. However, the absence of a significant effect of WM load on latency between the two groups, suggests that P3b may not explain the confirmed WM deficits in schizophrenia. Future research may investigate alternative electrophysiological markers for this cognitive deficit and have implications for the development of more specific endophenotypes of psychotic disorders.

Italiano di Tecnologia, Trento, Switzerland; [7]Psychiatric Hospital, Univ. of Zurich,, Zurich, Switzerland; [8]Inst. of Psychology, Univ. of Zurich,, Zurich, Switzerland; [9]Dept. of Psychology,, Univ. of Bern, Bern, Switzerland

Abstracts: Background: Major depressive disorder (MDD) is associated with structural and functional alterations in fronto-cingulate regions of the default mode and the task-positive networks (DMN, TPN). Enhanced activity in the anterior cingulate cortex (ACC) at rest is found in treatment-responsive patients, and may foster higher adaptive rumination. However, how structural changes affect functional coupling between the TPN and DMN, ACC activity, and how these functional changes are related to adaptive rumination is still unclear. Methods: Cortical thickness and regional homogeneity (ReHo) maps were calculated and compared between unmedicated depressed patients and healthy controls. Regions with reduced cortical thickness defined seeds for subsequent functional connectivity (FC) analyses. Results: Compared to healthy controls, depressed patients showed bilateral thinning of the dorsolateral prefrontal cortex (DLPFC) extending into the right frontopolar cortex (FPC), higher ReHo of the supragenual ACC and increased FC of the FPC with the midcingulate cortex (MCC) and the orbitofrontal cortex/ACC. In patients, higher supragenual ACC ReHo values were related to higher levels of adaptive rumination and stronger FPC - MCC connectivity. Moreover, in depressed patients greater adaptive rumination was also associated with stronger connectivity between the right DLPFC and the dorsal nexus, and higher connectivity strength correlated with increased ACC ReHo, even though DLPFC - dorsal nexus connectivity did not differ between patients and controls. Conclusions: Our findings suggest that bolstering the function of the supragenual ACC via the FPC/MCC and via the right DLPFC/dorsal nexus may foster adaptive rumination and potentially help treatment's response.

Title: Impact of smoking and age on WM compared to GM of schizophrenia

Authors: *H. SAMPATH[1,2], P. KOCHUNOV[1,2], F. MUELLERKLEIN[1,2], L. E. HONG[1,2]; [1]Neuroimaging Res. Program, Maryland Psychiatric Res. Ctr., Catonsville, MD; [2]Univ. of Maryland Ctr. for Brain Imaging Res., University of Maryland School of Medicine, MD

Abstracts: Patients with schizophrenia (SZ) have steeper age-related decline in white matter (WM) (Kochunov et al 2013; Wright et al 2014). This finding may share some common pathways linked to the 20% shorter life expectancy in SZ compared with the general population. SZ are also associated with 3-fold increase in the rate of smoking. We hypothesized that the abnormally steeper WM decline in SZ may be associated with abnormal aging and smoking. In comparison, cortical gray matter(GM) is known to be reduced early in the disease, and the impact of aging and smoking during adulthood could be less obvious. The study included 30 SZ smokers, 30 SZ nonsmokers, 30 normal control (NC) smokers, 30 NC nonsmokers. They underwent a MPRAGE T1 protocol for calculating GM voxel-based morphometry (VBM) and a diffusion tensor imaging protocol (DTI) for fractional anisotropy (FA), as indices of GW and WM integrity, respectively. Nicotine addiction severity was assessed by cigarette per day (CPD). GW VBM was assessed by SPM8+ DARTEL algorithm. FA was calculated by tract-based-spatial-statistics. Regression analyses were performed where brain index (VBM or FA) was the dependent variable, and age, CPD the predictors. Compared with NC, SZ showed reduced VBM in 9 cortical areas (corrected $p<0.05$). Age was associated with whole brain VBM in NC ($R^2=0.22$, $p<0.001$) and SZ ($R^2=0.25$, $p<0.001$), which were not significantly different ($z=0.26$, $p=0.80$), suggesting that VBM does not follow a precipitous decline in SZ. In NC smokers, the whole brain VBM was contributed by age ($t=-7.0$, $p<0.001$) but not CPD ($t=-0.76$, $p=0.45$). In SZ smokers, it was also contributed by age ($t=-2.8$ $p=0.008$) but not CPD ($t=-0.12$, $p=0.90$). For WM, we found age ($t=-6.92$, $p<0.001$) and a trend of CPD ($t=-1.79$, $p=0.076$) effect on whole brain FA in NC smokers. In SZ smokers, we similarly found age ($t=-4.18$, $p<0.001$) and a trend

of CPD (t=-1.89, p=0.076) contribution to FA. Previously we reported that the genu of the corpus callosum (GCC) was most severely associated with SZ and aging (Kochunov et al 2013), hence we re-test this in GCC. Here, we found significant effect of age (t=-4.11, p<0.001) but not CPD (p=0.74) on GCC FA in NC smokers. In SZ smokers, we found significant age (t=-3.23, p=0.003) and CPD (t=-2.26, p=0.032) effect on GCC FA. Age remains a key factor in the GM and WM decline overtime. Increased age-related decline was seen only in WM but not GM in SZ. In WM, nicotine addiction appeared to play a modest additional role to the FA reduction besides age. The effect was stronger in SZ, especially in GCC that provides connecting fibers between the frontal lobes. The potential underlying neurobiology of the joint age and smoking effects are considered.

Title: The impact of onset age on intrinsic functional connectivity of amygdala in major depression

Authors: *D. L. CLARK[1], A. KEMP[1], N. KONDURU[1], F. CORTESE[1], S. BRAY[2], I. GAXIOLOA-VALDEZ[1], B. GOODYEAR[1], R. RAMASUBBU[1];
[1]Univ. of Calgary, Calgary, AB, Canada; [2]Alberta Children's Hosp., Calgary, AB, Canada

Abstracts: Major depressive disorder (MDD) is the leading cause of disability worldwide. Advances have been made in the treatment of MDD, but it is not a homogenous disease, and because of its many subgroups - each with a unique etiology and most likely a distinct optimal treatment - it is difficult to achieve patient remittance. Early-onset MDD is associated with more illness burden and an increased risk of relapse. Previously our group found reduced resting state functional connectivity of the amygdala in MDD. Since there is limited data on the effect of MDD onset age on the intrinsic connectivity (IC) of the amygdala in adult patients, we examined the relationship between age of onset and IC of amygdala in MDD. Resting state functional

magnetic resonance data were collected from 55 medication-free, right handed Caucasian adults with MDD and 19 healthy controls. Patients were separated into two groups based on the age of onset of MDD: Early (≤18 years of age; n=21) and Adult (>18 years of age; n=33). Amygdala seed based resting state functional connectivity or IC maps were generated for patients with MDD using age, sex, depression duration and number of episodes as covariates. Similar maps were generated for healthy controls using age and sex as covariates. Overall, compared to healthy controls, patients with early onset MDD showed reduced IC in only two regions: the caudate and cerebellum; whereas, patients with adult onset depression showed widespread reduced IC of the amygdala with fusiform, temporal and occipital regions, subgenual cingulate, insula, caudate, and the cerebellum and compensatory increases in IC with prefrontal and premotor regions. Early onset MDD, when compared to adult onset, resulted in extensive increases in amygdala IC with areas related to both top-down and bottom-up regulation of emotional processing, including the dorsolateral prefrontal cortex, supplementary motor area, insula, temporal, fusiform and occipital regions, anterior cingulate and thalamus. The results were corrected at $P<0.05$ for multiple comparisons using false discovery rate estimations. Here we show that overall reduction in IC of amygdala in MDD is primarily driven by adult-onset MDD patients, while early onset MDD appears to result in a distinctive pattern of amygdala IC. Our data, together with previous structural findings, support that early onset MDD is a distinct subgroup with unique neural features. Our study is limited by a small and unbalanced sample size, but we hope it will motivate examination of onset age in larger clinical samples. Characterization of early-onset MDD might serve to inform targeted treatment strategies in the future.

Univ. of Athens Med. Sch., Athens, Greece; [4]Res. Ctr. of Radiology and Imaging, Natl. and Kapodistrian Univ. of Athens, Athens, Greece

Abstracts: There is a wealth of evidence that decision processing is impaired in patients with schizophrenia. In previous studies we have confirmed that these patients present significant differences in Reaction Time distribution in simple visuomotor tasks that have been interpreted as deficits in speeded decision processing. In this study 14 patients and 14 age and sex matched healthy individuals performed 300 trials of a forced 2-choice RT task (a version of the Eriksen Flanker task) in two conditions of easy and difficult perceptual decision while fMRI data were acquired. Our results confirmed that patients had slower ($F_{1,25} = 5.6$, $p=0,02$) and more variable ($F_{1,25}=15,7$, $p=0,0005$) RTs compared to controls while there were no error differences ($F_{1,25} =0,1$, $p=0,7$) between the two groups indicating that the difference in the speed of decision processing in patients was not related to performance differences. A specific difference in decision processing between patients and controls was also confirmed by the neuroimaging results showing that the contrast between difficult and easy decision trials resulted in an increased activation only at the Right Precuneus in controls while in patients a large network of areas were significantly more active, including the Left Precentral Gyrus, the Left Supplementary Motor Area, the Left and Right Occipital Middle Area and the Right Inferior Frontal Gyrus. These results favor the hypothesis that speeded decision processing is a very demanding task for patients with schizophrenia resulting in slowed and variable RT as well as the increased activation of a network of sensory, motor and frontal cortical areas.

Title: Smooth eye pursuit and fixation endophenotypes in schizophrenia and obsessive compulsive disorder

Authors: A. DAMILOU[1], C. THELERITIS[2], *G. V. PANTES[3], I. EVDOKIMIDIS[3], N. SMYRNIS[2,1];
[1]Lab. of Sensorimotor Control, Univ. Mental Hlth. Res. Inst., Athens, Greece; [2]Psychiatry, Natl. Univ. of Athens Med. Sch., Athens, Greece; [3]Univ. Athens Med. Sch., Athens, Greece

Abstracts: It is well established that smooth eye pursuit deficits are present in patients with schizophrenia and other psychotic disorders. It has also been shown that patients with schizophrenia present deficits in sustaining visual fixation especially in conditions of increased difficulty (such as in the presence of visual distracting stimuli). This study examines the specificity of these oculomotor endophenotypes for psychotic disorders by examining the performance of male patients with schizophrenia (N=38) and male patients with Obsessive Compulsive Disorder(OCD) (N=34) versus normal male controls(N=50).The participants performed smooth eye pursuit with increasing speed (10,20 and 30deg/sec) and a sustained visual fixation task (50sec duration) in three conditions (simple fixation, fixation with visual distractors and fixation in the dark with no fixation target).Smooth eye pursuit gain decreased with increasing pursuit speed ($F_{2,238} = 53.5$ $p<10\text{-}5$) and it was lower for patients with schizophrenia than in both OCD patients and healthy controls, while the later groups did not differ from each other ($F_{2,238} = 6.8$ $p<10\text{-}5$). The specific decrease in gain that was observed in schizophrenia was evident only for the higher pursuit speeds of 20 and 30degrees/sec as indicated by the significant speed by group interaction ($F_{4,238} = 2.9$ $p<10\text{-}5$). Saccade frequency in the fixation tasks was significantly higher for patients with OCD and patients with schizophrenia compared to controls ($F_{2,238} = 12.8$ $p<10\text{-}5$)and it was higher for the fixation condition with distraction and for the no target fixation condition compared to the simple fixation condition ($F_{2,238} = 7.8$ $p<10\text{-}5$). Finally a highly significant group by condition interaction ($F_{4,238} = 3.6$ $p<10\text{-}5$) was related to the fact that there was a specific increase in saccade frequency observed in the simple fixation task for the OCD patient group while patients with schizophrenia behaved as normal controls in the same fixation condition. In contrast both patients with schizophrenia and patients with OCD had higher saccade frequencies compared to healthy controls for the other two fixation conditions. These results indicate specific deficits in the pursuit system in schizophrenia and specific deficits in the visual fixation system for OCD that are different from those observed in schizophrenia, suggesting that oculomotor endophenotypes for schizophrenia and OCD are dissociable.

Title: Cognitive bias for negative information in women with and without past depression correlates with differences in brain network activity and functional connectivity

Authors: *K. ALBERT[1], V. GAU[1], B. BOYD[1], E. EISENBERG[2], P. NEWHOUSE[1]; [1]Vanderbilt Univ. - Ctr. For Cognitive Med., Nashville, TN; [2]Dept. of Obstetrics and Gynecology, Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstracts: Women have a greater risk of depression than men and women with a past history of major depressive disorder (MDD) have a high risk of recurrence, even after menopause. Cognitive biases towards negative information that persist during remission may contribute to cognitive vulnerability to depressive symptoms or MDD recurrence. In this study we examined whether attentional bias for negative information differs between postmenopausal women with and without a history of MDD. 19 euthymic postmenopausal women were screened and MDD history was determined using the SCID. 11 women had no history of MDD (*Control*), and 8 women had a history of unipolar MDD (*MDD-Hx*), but were euthymic for at least 1 year. All of the women were at least one year from final menses, with no hormone or antidepressant treatment for at least one year. Subjects then completed an Emotion Dot Probe (EDP) task and resting state scan during an fMRI session. Average Beck Depression Index was 1.86 (SD = 2.41), with no significant difference between groups. Behavioral results for the EDP task revealed that the MDD-Hx group had greater negative facilitation (faster RT for negative than neutral images) than the Control group. During the EDP task the MDD-Hx group had greater left amygdala activity for negative images and greater activity in a number of brain areas than the Control group during negative switch trials, including the temporal parietal junction (TPJ). For all subjects, the functional connectivity strength between the left amygdala and medial orbital prefrontal cortex (moPFC) was inversely correlated with left amygdala activity during negative images. The Control group had greater functional connectivity between the left amygdala and moPFC than the MDD-Hx group. By contrast, the MDD-Hx group had greater functional

connectivity between right anterior insula and the TPJ (salience network). The strength of connectivity between these two regions was highly correlated with activity of the TPJ during "negative switch" trials of the EDP and negative facilitation only in the MDD-Hx group. In this study, women with past depression showed an attentional performance bias and increased limbic activity for negative images. These differences were correlated with functional connectivity differences in salience and emotional response brain networks, suggesting that changes in brain network connectivity may underlay a continued cognitive bias towards negative information in women with past depression. This persistent bias in women with past depression may indicate an underlying cognitive processing deficit that may increase salience of negative information conveying vulnerability to MDD recurrence.

Title: Abnormal functional interactions of sensorimotor and social association networks in childhood-onset schizophrenia

Authors: *R. A. BERMAN[1], H. M. MCADAMS[1], D. GREENSTEIN[1], A. MARTIN[2], S. J. GOTTS[2], N. GOGTAY[1], J. L. RAPOPORT[1];
[1]Child Psychiatry Br., [2]Lab. of Brain and Cognition, NIMH, NIH, BETHESDA, MD

Abstracts: In recent years, the hypothesis of schizophrenia as a disorder of brain connectivity has regained considerable attention. Studies of adult-onset schizophrenia have shown mixed alterations in "functional connectivity" as measured by the covariation of spontaneous brain activity. Here we used resting-state functional magnetic resonance imaging to study network interactions in childhood-onset schizophrenia (COS), a rare, severe form of the disease that may have more salient neurobiological abnormalities. We addressed two major questions: 1) Do alterations in functional connectivity reveal disrupted interactions among specific brain networks in COS? 2) If so, do these alterations correspond to behavior? We used a data-driven approach

(Gotts et al., 2012) to analyze data from 19 COS patients and 26 healthy controls, group matched for age, sex, and handedness (all $p>.05$). Analysis produced 12 data-driven "seeds" with decreased functional connectivity in COS compared to controls (voxelwise threshold $p<0.0005$, cluster-corrected $p<.05$). A conjunction of resulting seed maps identified an additional 14 regions of altered connectivity in COS. All 26 ROIs had decreased functional connectivity in COS; we found no evidence for hyperconnectivity. Multi-dimensional scaling and k-means clustering of ROIs identified two major clusters. The first was comprised of social/limbic brain regions, including areas of the "default mode network" such as the posterior cingulate and medial prefrontal cortex. This social cluster also included higher-order association areas in parietal and dorsolateral prefrontal cortex. The second cluster was comprised of somatosensory and motor areas, including pre- and post-central gyrus, putamen, and inferior cerebellum. Matrix plots of ROI x ROI interactions revealed negative coupling of these two clusters in COS but not controls. Analysis of unaffected COS siblings (n=22) indicated that these alterations are state-specific, as siblings did not exhibit the decreased connectivity seen in COS. We then asked whether the network structure was related to positive and negative symptom scores in COS patients. Positive symptoms were associated with decreased across-cluster correlations, whereas negative symptoms were associated with decreased correlations within the social cluster. In summary, resting-state networks in COS are distinguished by a negative coupling between basic somato-motor areas and higher-order limbic / association areas. This opposing interaction suggests an abnormal integration of sensorimotor and social/cognitive processes and may relate to deficits in self-monitoring that are central to the disease.

Title: Effectiveness of fast mapping to promote learning of novel stimuli in schizophrenia

Authors: *S. A. KORENIC, S. J. NISONGER, C. M. SALTER, B. W. KRAUSE, S. A. WIJTENBURG, L. M. ROWLAND;
Univ. of Maryland Sch. of Med. (MPRC), Baltimore, MD

Abstracts: Research on fast mapping (FM), a process that promotes expeditious incidental learning of information, is thought to support rapid vocabulary acquisition in young children through the extra-medial temporal lobe (MTL) regions. Recent research suggests that patients with amnesia and profound MTL damage are able to learn novel word-image associations using an FM paradigm (Sharon et. al, PNAS 108:1146-1151, 2011), but also see (Smith et. al, PNAS 111:475-479). The present study aims to determine whether FM would be an effective learning strategy for individuals suffering from schizophrenia, a severe mental illness that is associated with compromised MTL functionality. Twenty-three patients with schizophrenia and 23 healthy control subjects between the ages of 18-55 years completed two tasks: FM encoding and an episodic encoding control. For visit 1, participants were shown novel word-image associations with the FM paradigm and tested for recognition after a 10 minute break. A delayed recognition trial was completed one week later (± 2 days). During the same visit as the delayed recognition trial for FM, participants were evaluated on their ability to retain novel word-image associations using a control episodic encoding condition that also included a 10 minute delay trail and a one week (± 2 days) delay recognition trial. Results indicated that both groups performed better on the explicit encoding recognition trials when compared to FM recognition trials (p's < 0.05). For the FM recognition trials, both groups performed similarly. However, participants with schizophrenia performed significantly worse on the explicit encoding recognition trials than control participants (p's < 0.05). While participants with schizophrenia did not perform significantly worse on FM recognition trials when compared to healthy controls, these results do not provide enough evidence to suggest that FM promotes learning in schizophrenia. Whether FM benefits select individuals with schizophrenia is currently a focus of further investigation.

Title: Left frontal peak alpha frequency correlates with depression in male combat veterans with mTBI or mTBI+PTSD

Authors: *J. A. ONTON[1], I.-W. SHU[2], S. C. MATTHEWS[2];
[1]Warfighter Performance Dept 162, Warfighter Performance, San Diego, CA; [2]Veterans Affairs San Diego Healthcare Syst., La Jolla, CA

Abstracts: Depression is a common comorbid disorder in combat veterans with posttraumatic stress disorder (PTSD) and/or mild traumatic brain injury (mTBI). Studies show that combined PTSD and depression results in more severe illness burden, poorer prognosis and increased suicidal ideation compared to depression alone. Much work has suggested frontal alpha power asymmetry correlates with depression, but little attention has focused on alpha frequency to address speed of processing. High density EEG was recorded from 33 OEF/OIF veterans (16 mTBI only; 17 mTBI+PTSD) during several behavioral tasks, between which were periods of rest when subjects sat quietly starring at a fixation cross. EEG data from the entire session was submitted to independent component analysis (ICA) to find areas of high variance independent activity. Independent components (ICs) were clustered across subjects based on scalp map similarity. Periods of rest were concatenated and spectral power was calculated for all clustered ICs. Three clusters showed slower peak alpha frequency in the mTBI groups compared to Controls. These clusters localized to bilateral occipital, mid-parietal and left fronto-temporal regions. None of the peak alpha frequencies correlated with PTSD severity, but the left fronto-temporal region peak alpha frequencies were significantly negatively correlated with depression severity according to the Beck Depression Inventory (BDI) ($p = 0.01$). Lower alpha frequency may contribute to compromised thalamo-cortical network activity resulting in greater difficulty reversing negative thought patterns or other depressive symptoms.

Title: Risk variants for bipolar disorder influence multiple cellular and molecular mechanisms leading to altered neuronal excitability

Authors: *S. A. AMENT[1], K. ROULEAU[2], J. PEARL[3], C. FUNK[2], M. SHELTON[2], R. GELINAS[2], J. C. ROACH[2], L. HOOD[2], N. D. PRICE[2];
[1]Dept Neurosci, Inst. For Systems Biol., Seattle, WA; [2]Inst. for Systems Biol., Seattle, WA; [3]Mol. and Cell. Biol. Grad. Program, Univ. of Washington, Seattle, WA

Abstracts: Very little is known about the genetic and neuronal mechanisms underlying risk for bipolar disorder. We recently discovered through whole-genome sequencing that multiply affected pedigrees with bipolar disorder have an elevated rate of rare coding and non-coding variants in calcium channels and other genes related to neuronal excitability. Here, we test the hypothesis that genomic variation found in bipolar disorder genomes influences neuronal excitability and cellular transcriptomic states. We tested our hypothesis at two levels: (i) by characterizing a novel role in calcium signaling for a top candidate gene, humanin, that had not previously been linked to calcium channel function; and (ii) by characterizing the functional effects of rare calcium channel variants found in bipolar disorder families in cultured neurons. Our approach combines RNA interference, CRISPR/Cas9 genome editing, pharmacology, neurophysiology, and molecular systems biology. We found that humanin influences calcium homeostasis by inhibiting neuroinflammatory cytokines, at least in part via interactions at the level of transcriptional regulation. Some calcium channel variants found in bipolar disorder genomes disrupt protein synthesis; mimicking disrupting variants in the Cav1.2 channel CACNA1C using RNAi suggested that this gene has shared transcriptomic effects with humanin but does not interact with cytokines. Other variants in calcium channels disrupt enhancer and promoter sequences recognized by transcription factors important for neuronal cell type specificity and plasticity. Based on our results and recent findings from other groups we propose that altered neuronal excitability may be a general mechanism underlying risk for bipolar disorder.

Title: Pupillary reactivity in subjects affected by Schizophrenia during free viewing of natural images of different complexity

Authors: C. ACEVEDO[1], K. MUÑOZ[2], S. MADARIAGA[2], R. MAYOL[1], *J. I. EGANA[3,4], P. MALDONADO[1];
[1]Fisiologia & Biofisica, ICBM / BNI / Univ. de Chile, Universidad de Chile, Chile; [2]Dept. Ingeneria Electrica, Univ. de Chile, Santiago, Chile; [3]Fisiologia & Biofisica, Facultad De Medicina / Univ. De Chile, Santiago, Chile; [4]Anestesiologia & Reanimacion, Hosp. Clinico Univ. de Chile, Santiago, Chile

Abstracts: Subjects affected by schizophrenia (SCZ) presents a wide range of dysfunctions in both cognitive and non-cognitive processes. The activity of the Autonomous Nervous System's (ANS) is one of non-cognitive mechanisms reported as altered in SCZ. However, cognitive processes are known to modulate ANS responses in healthy subjects. Most of these reports, both in SCZ and healthy people have used artificial experimental settings. We tested whether ANS activity, measured as pupillary reactivity, is modulated by cognitive load in SCZ. We used an ecological setting using free viewing of natural images. Different properties of pupillary dynamics were evaluated. 20 subjects with DSM-IV-R criteria for SCZ and 11 controls were evaluated. After written informed consent was obtained participants were exposed to a set of 70 natural images of 7 different visual complexities. All sets of images exhibited same luminance distribution. Images were displayed in a 21" screen located at 57 cm (40ºx30º visual field). Each image was presented between 4.5-5.5 seconds. Pupillary response was assessed using and EyeLink II/1000 eye-tracking device with a 500 Hz resolution. Participants were instructed to freely explore images. In order to proceed to the next image the subject had to perform a drift correction and press a button. Data was artifact-corrected and Z-score normalized. We found that SCZ group exhibited, in general, a smaller response (less amplitude) given mainly by a more contracted pupil at the start of trials (baseline). Patients also showed more pronounced maximum contractions and delays (time to max. contraction). Dilatation velocity after max contraction (1 sec after max contraction) was faster in the SCZ group and then slows down to catch-up with the control group by the end of the trial. When different images categories were, we found that complex images enhanced the differences in max contraction, delay and dilatation velocity between SCZ and control groups. When 500 ms before image start were considered (button pressing), two phenomena were observed. First, the baseline pupil diameter was the same for

SCZ and healthy control groups. Second, the dilatation velocity in control was faster so that at the start of image presentation baselines are separated. Taken together these findings support the idea that an SCZ patient exhibits both abnormal ANS basal tone and responses. Results also show that cognitive a process modulates ANS functioning in SCZ patients but in an abnormal way that increases differences with the control population. It remains open to further explore these and other ANS dysfunctions, as biomarkers of this condition.

NARSAD

Title: Blood glutathione predicts cortical glutamate levels and cognitive functions

Authors: *T. TANAKA[1], J. M. COUGHLIN[1], A. MARSMAN[2], H. WANG[1], S. BONEKAMP[2], P. K. KIM[1], C. HIGGS[1], S. POSPORELIS[1], M. VARVARIS[1], R. A. E. EDDEN[2], M. POMPER[2], D. SCHRETLEN[1], N. CASCELLA[1], P. B. BARKER[2], A. SAWA[1];
[1]Psychiatry, [2]Radiology, Johns Hopkins Med. Institutions, Baltimore, MD

Abstracts: Aberrant oxidative stress and glutamatergic pathways may underlie the pathophysiology of schizophrenia. In this study, we measured the level of total glutathione (GSH), a marker of oxidative stress, in plasma and lymphoblasts of patients with schizophrenia (SZ) and age-matched, healthy controls (HC). We also examined the levels of glutathione and Glx (the sum of glutamate and glutamine) in anterior cingulate cortex (ACC), expressed as ratios to creatine (Cr), using 3T brain magnetic resonance spectroscopy (MRS). In addition, we systematically assessed cognitive function in all study participants. First, we observed significant reduction in the levels of total GSH in plasma and lymphoblasts of patients with SZ compared with those levels in HC. Total GSH in plasma showed significantly positive correlation with the Glx/Cr in the ACC after adjusting for age and smoking status. Furthermore, the reduction in

peripheral GSH correlated with specific deficits in cognitive function, namely those within the domain of processing speed. These results suggest that blood measurement of GSH may be useful in predicting levels of brain chemicals in metabolically-related pathways (in particular glutamate) and neuropsychological deficits associated with SZ. We are further investigating the potential of GSH as a peripheral marker of the disease. In contrast, we did not observe a significant difference in ACC GSH/Cr ratios between SZ and control groups, and ACC GSH/Cr did not correlate with the levels of blood GSH. We conclude that (1) peripheral GSH is a promising candidate biomarker for key endophenotypes relevant to SZ, and (2) biochemical assays currently provide more reliable GSH measure than MRS at low magnetic field (e.g., 3T).

Title: Evaluation of redox dysregulation in the pathology of schizophrenia using induced pluripotent stem cell technology

Authors: *B. GIANGRECO[1], P. STEULLET[1], J.-H. CABUNGCAL[1], L. BARTESAGHI[2], N. TONI[3], R. CHRAST[2], K. Q. DO[1];
[1]Ctr. For Psychiatric Neurosciences, Prilly-Lausanne, Switzerland; [2]Dept. of Med. Genet., Lausanne, Switzerland; [3]Dept. of Fundamental Neurosciences, Lausanne, Switzerland

Abstracts: Background: Schizophrenia (SZ) is a disorder that involves genetic and environmental factors. A decrease of glutathione (GSH), a major cellular antioxidant, was shown in patient's brain and CSF. Furthermore, polymorphisms in the key synthetizing enzyme for

GSH were found associated with the disease. These observations lead to the hypothesis that redox dysregulation is a main hub in this disorder. In this study, we set up a method based on fluorescence imaging to identify the redox state of thiol residues in a GSH deficient mouse model (Gclm-/-). Our long-term objective is to use induced pluripotent stem cells (iPSC) to examine the impact of oxidative stress on neurons derived from a well-characterized cohort of SZ patients. Methods: We established the conditions for thiol labelling by fluorescence in WT mice brain slices and evaluated its sensitivity. Then, we investigated redox state of cells in WT and GBR-treated Gclm-/-mice, GBR being a dopamine reuptake inhibitor that induces additional oxidative stress. In parallel, we have started to generate iPSC from patient's fibroblasts and to derive them into neurons. Results: The ratio between oxidized and reduced thiols was increased in GBR-treated Gclm-/-compared to WT mice, suggesting a more oxidized cellular environment. This ratio will be measured in iPSC-derived neurons from patient's fibroblasts that we are currently producing. Conclusions: This method together with other approaches will allow to assess whether the redox state is also altered in iPSC-derived neurons from patients. Ultimately, application of this method to iPSC may pave the way to individualized therapies.

Title: Self-disturbances in schizophrenia: Models of hippocampal-dopamine interactions and their phenomenological correlates

Authors: *A. L. MISHARA;
Dept of Clin. Psychology, The Chicago Sch. of Professional Psychology: Sou, Los Angeles, CA

Abstracts: Background: Human-self is an important but elusive topic in neuroscience and its clinical application. Schneider (1959) described self-disturbances (Ichstörungen) as belonging to the first-rank symptoms and therefore pathognomic of schizophrenia, e.g., thought-withdrawal, thought-insertion, somatic-passivity, delusions of reference, mental/motor automatisms, and

break-down of unitary self-experience (Mishara et al., 2014). Nevertheless, whether self-disturbances are heterogeneous, specific to schizophrenia, and the underlying neurobiological mechanisms remain unclear (Mishara et al., 2014). Conrad subsequently found disrupted self-experience in early-schizophrenia: 1) random occurrences are seen as having special meaning directed towards self; 2) delusions spread from a few salient-events to ever greater scope of the patient's experience related back to the self; 3) the self is experienced as passive center-point of the Ichstörungen (Mishara, 2010). These observations provide a useful heuristic for considering plausible neurobiological mechanisms. Methods: Recent neurobiological-models of hippocampal dysfunction in psychotic-symptoms including Ichstörungen, were examined to see to what extent they could be mapped onto the phenomenology: 1) positive feedback in a thalamus-hippocampus-VTA circuit acts as trigger when NMDA-receptor deficiency is combined with a transient increase in dopamine release (Lisman); 2) Diminished Pattern-Separation/Increased Pattern-Completion (Tamminga, Stan and Wagner); 3) Aberrant salience mediated by dopaminergic dysfunction disrupts encoding of the delusional memories (Mishara and Fusar-Poli, 2013). Results: Each model provides plausible explanations for some Ichstörung-symptoms. However, the roles of neuroplasticity mechanisms, dopamine and antipsychotic medications in reducing symptom-phenomenology and improving memory performance in schizophrenia patients remain largely undetermined. Conclusions: Phenomenologic-analysis of self-disturbances in beginning-schizophrenia provides an initial step for developing neurobiological models, which implicate hippocampal dysfunction, and help explain and treat these disturbances. Title: Resting-state brain networks predict severity of auditory hallucinations in schizophrenia

Authors: E. S. FINN[1], F. TOKOGLU[2], X. SHEN[2], R. E. HOFFMAN[3], *R. T. CONSTABLE[2]; [1]Interdepartmental Neurosci. Program, [2]Dept Diagnos. Radiol, Yale Univ., New Haven, CT; [3]Psychiatry, Yale Univ. Sch. of Med., New Haven, CT

Abstracts: Background: Auditory verbal hallucinations (AVHs), or "hearing voices," are a prominent symptom of schizophrenia. We sought to identify biomarkers of various dimensions of AVH severity using functional connectivity analysis of resting-state fMRI data. **Methods:** Resting-state fMRI scans were acquired from hallucinating patients (HP, n = 28), non-hallucinating patients (NHP, n = 21), and healthy controls (C, n = 21). The two patient groups were matched on important demographic and clinical variables. Each patient received a clinical rating using the auditory hallucination rating scale (AHRS), a composite AVH scale that includes frequency, loudness, length, realness, number of voices, distress associated with voices, and degree to which voices alter actions and thoughts. To conduct connectivity analysis, a functional brain parcellation consisting of 162 regions was used to define network nodes across the whole brain. Matrices of correlation coefficients ("edges") between the timecourses of each pair of nodes were calculated for each subject, and the network-based statistic--a spatial correction algorithm yielding network results that are both biologically and statistically valid--was used to identify networks of fully connected edges whose strength differed significantly between groups. The two main contrasts of interest were HP vs NHP and HP vs C. Having identified group-difference networks, we then performed within-group correlations to relate connectivity strength in these networks to measures of AVH severity. **Results:** Overall, the HP group showed higher connectivity relative to the NHP group in a network of approximately 200 edges. Nodes with higher connectivity for HPs included the left inferior parietal lobule, right supplementary motor area, left superior temporal gyrus (STG) and left anterior cingulate cortex. Summing values of all edges within the HP > NHP network in individual HPs revealed that increased connectivity in this network predicted a higher total AHRS score ($r = 0.47$, $p = 0.01$), and especially the subscore for number of voices ($r = 0.57$, $p = 0.002$). The HP vs C contrast revealed differential connectivity patterns for left and right thalamus, primary sensorimotor and supplementary motor cortices, left posterior cingulate cortex, and right caudate, among other nodes. Interestingly, connectivity between the thalamus and left STG--a classic language region, and one that has been previously implicated in AVHs--was higher in HPs than Cs, yet *negatively* predicted AHRS score ($r = -0.57$, $p = 0.002$), suggesting that increased connectivity between these regions might reflect a compensatory mechanism in patients.

Title: The development of a computerized neurocognitive test as an objective functional biomarker of emotional distress

Authors: L. A. KING[1], *E. B. ROACH[2], C. E. LATHAN[3], J. L. SPIRA[1];
[1]US Dept. of Veterans Affairs, Natl. Ctr. for PTSD, Honolulu, HI; [2]Anthrotronix Inc, Silver Spring, MD; [3]AnthroTronix Inc., Silver Spring, MD

Abstracts: We examined the potential for using computerized neurocognitive tests (CNTs) as objective biomarkers of functional impairment in a functioning, non-clinical, military population in order to complement the subjective reporting of post-deployment distress symptoms. Due to difficulties in utilizing traditional neuropsychological assessments, there is a paucity of research on neurocognitive functioning in military members with post-deployment emotional distress. CNTs that use precise speed and accuracy measures hold the promise of being more sensitive than traditional paper and pencil tests and are more easily utilized in a variety of healthcare settings. The Defense Automated Neurobehavioral Assessment (DANA) was used to assess neurobehavioral functioning in 646 United States Marines, all of whom were fit for duty and currently functioning in their assigned duties. This research aimed to determine if neurocognitive functioning was associated with emotional and somatic distress in this sample of combat veterans. The marines were assessed for concussion history, postconcussive symptoms, emotional distress, neurocognitive functioning, and deployment history. Differences in those with and without significant symptoms of PTSD, Depression, Insomnia, and Anger were compared across seven neurocognitive tests, and sensitivity and specificity were also determined. Medium to small effect sizes were found on cognitive performance for all psychological factors. Marines with elevated PTSD scores had significantly slower and less accurate performance in Simple Reaction Time (SRT), Choice Reaction Time (CRT), Go-No/Go, Spatial Discrimination, and Symbol-Digit Delayed Memory, and decreased accuracy in Running Memory (all $p<.005$ with moderate effect sizes); elevated Depression and Anger scores were associated with similar findings (Depression: all but Choice RT, $p<.05$ with moderately small effect sizes; Anger: all but

Spatial Discrimination p<.05, moderate- small effect size). The DANA Attentional-Discrimination Composite Score was positive for PTSD, Depression and Anger (p<.05 with a small effect size). A receiver operator curve (ROC) analysis showed that the DANA Composite Score has adequate sensitivity and specificity for PTSD, Depression, and Anger (p<.05, Sensitivity and Specificity all >.80). These results suggest that the DANA NCT is a reliable, sensitive, and objective measure of the cognitive sequelae of emotional distress that has the potential for being utilized by clinicians for initial diagnosis, treatment disposition, and potentially assessing improvement and return to work determinations.

Title: An automated toolkit to generate Cerebral Blood Volume (CBV) maps of the hippocampal circuit applied to prodromal schizophrenia

Authors: *F. A. PROVENZANO[1], R. R. GIRGIS[3], N. BRUNO[1], U. A. KHAN[1], J. A. LIEBERMAN[2], S. A. SMALL[1];
[1]Taub Inst., [2]Dept. of Psychiatry, Columbia Univ., New York, NY; [3]New York State Psychiatric Inst., New York, NY

Abstracts: Introduction. Using Cerebral Blood Volume (CBV) fMRI, we have previously reported that selective hypermetabolism in the anterior CA1 region of the hippocampal circuit occurs in prodromal stages of schizophrenia and related psychotic disorders. To date, a manual approach was used to generate CBV maps of the hippocampal circuit. This approach is time consuming and introduces sources of noise. To address these limitations, over the last few years we have been developing and optimized an analytic toolkit that generates CBV maps of the hippocampal circuit in an automated fashion. Here, we unveil this toolkit and test its ability to detect anterior CA1 hypermetabolism in prodromal stages of disease. Methods. Recruited

patients (N=19) and controls (N=16) underwent a series of MRI scans, including a structural T1-weighted image (1x1x1 mm) as well as two T1-weighted scans (.68x.68x3 mm), acquired in the coronal plane along the long axis of the hippocampus prior to and after a bolus injection of a gadolinium based contrast agent. A template was created using the pre-contrast scans of these patients and a trained anatomist drew regions of interest of the hippocampus, including the anterior, middle and posterior left CA1. Our software was able to generate CBV maps for each patient and apply the template drawn ROIs to template co-registered CBV. Mean value differences reveal a significant increase in CBV signal, concordant with extant literature, in the prodromal group versus the age matched controls. Discussion. By detected anterior CA1 hypermetabolism, this study validates the capabilities of this automated toolkit. Achieving this goal is important as CBV-fMRI is being applied in different research centers, investigating a range of disorders that target the hippocampal circuit. Additionally, an automated toolkit is required if CBV-fMRI will turn out to become a biomarker of prodromal schizophrenia, as we are currently testing, and potentially used in clinical trials.

Title: Development of real-time fMRI neurofeedback attention training for depression

Authors: *D. M. SCHNYER[1], M. T. DEBETTENCOURT[2], C. G. BEEVERS[1], S. SHERMAN[1], J. D. COHEN[2], K. A. NORMAN[2], N. B. TURK-BORWNE[2];
[1]Univ. of Texas, Austin, Austin, TX; [2]Princeton Univ., Princeton, NJ

Abstracts: We applied a real-time fMRI attention-training (rtAT) intervention to help depressed individuals improve attentional control over negative information. Poor regulatory control over negative cognition is a central feature of the disorder. The rtAT task used a modified sustained attention to response task (SART) and multivoxel pattern analysis (MVPA) in real-time to provide timely feedback about moment-to-moment fluctuations in attentional states. Seven adults with high levels of depressive symptoms were trained across 3 days. Behavioral performance was measured in five separate sessions: a pre-training session, three fMRI neurofeedback

sessions, and a post-training session. Resting state fMRI was collected before and after rtAT training. Performance (d') in a pre-training laboratory-based SART task was associated with a standard measure of attentional bias for negative stimuli. Individuals with greater attention bias for negative stimuli (measured with eye tracking in a standard dot probe task) had poorer performance on the SART with sad face distracters (r = -.45) and attention bias for sad faces was uncorrelated with performance with neutral face distracters (r = -.02). Sustained attention improved over the course of 3 rtAT sessions and 5 of the 7 participants experienced significant improvement from the pre-training to post-training laboratory based assessments. Over the course of 4 weeks (rtAT plus weekly follow-up for three weeks), we observed a significant decline in depression symptoms and decreases in depression over time were strongly correlated with improved SART task performance over the same time period (r = .50). Across participants there was a relationship between the severity of the depression and the behavioral improvements observed in the task, such that participants who showed higher levels of depression improved more. Despite the small sample size, from pre to post training, all participants revealed increased resting state functional connectivity between the right middle frontal gyrus and left and right supramarginal gyrus - a key portion of a previously identified attention control network (ACN). These pilot data indicate that real-time attention training shows high promise for altering the neural networks that support the control of attention to affective stimuli. With only three sessions of rtAT we are seeing symptom improvement, reductions in attention bias, and functional connectivity changes within the ACN. Ongoing work will add additional patients and an appropriate control group.

Care Syst., San Diego, CA; [6]Veterans Affairs Ctr. of Excellence for Stress and Mental Hlth., San Diego, CA

Abstracts: Functional magnetic resonance imaging (fMRI) research suggests that both adult and adolescent major depressive disorder (MDD) is marked by aberrant connectivity of the default mode network (DMN) during resting-state (Greicius, 2008; Connolly et al., 2013). However, no studies to date have examined the influence of emotional processing on DMN pathology in adolescent depression. Here, we collected fMRI data from 27 medication-free adolescents (13-17 years) with MDD and 37 well-matched healthy controls (HCL) during an emotional identification task and also during rest. Emotion-dependent and resting-state functional connectivity analyses were assessed using functionally defined seeds of the primary nodes of the DMN: medial prefrontal cortex (mPFC) and posterior cingulate cortex (PCC). MDD showed comparatively elevated emotion-dependent functional connectivity between mPFC and PCC with regions in the default mode (precuneus), cognitive executive (cingulate gyrus, inferior parietal lobule), and salience and affective (striatum/subcallosal cingulate gyrus) networks (Figure 1). Furthermore, PCC-subcallosal cingulate connectivity remained elevated in MDD compared to HCL during rest ($F(1,54)=5.410$, $p=0.023$). Lastly, emotion-dependent functional connectivity patterns significantly correlated with depression severity ($r=0.436$, $p=0.029$; $r=0.483$, $p=0.014$) and age of depression onset ($r=-0.527$, $p=0.014$). Together, our findings suggest that depression may be characterized by non-adaptive functional coupling of brain networks that reflect fundamental differences in processing internal and external environments. Given that our study sample of depressed adolescents is free from possible confounds of chronic illness and medication usage, these patterns point to possible neural substrates underlying the cognitive processes initiating and maintaining depression and offer potential insight into how depression may alter the normal development of intrinsic brain networks.

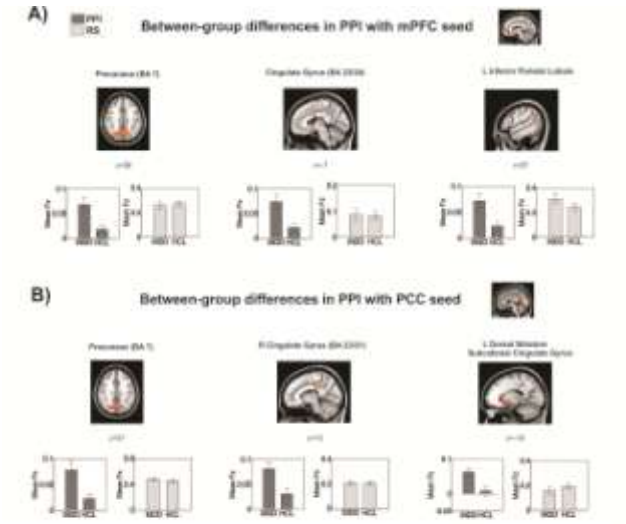

Figure 1. Regions showing significant between-group differences in emotion-dependent functional connectivity as measured using the psychophysiological interaction (PPI) method. Results are shown for the medial prefrontal cortex (mPFC) seed **(A)** and posterior cingulate cortex (PCC) seed **(B)**. All areas survived correction for multiple comparisons at a cluster-wise threshold of $p<0.05$. Mean functional connectivity values are reported as Fisher's z-scores (Fz). Mean resting-state (RS) Fz were extracted from the regions exhibiting significant between-group differences on the PPI analysis. Locations are reported in MNI coordinates (radiological convention).

Abstracts: BACKGROUND: Aberrant DNA methylation in the blood of patients with major depressive disorder (MDD) has been reported in several previous studies. However, no comprehensive studies using medication-free subjects with MDD have been conducted. Furthermore, the majority of these previous studies has been limited to the analysis of the CpG sites in CpG islands (CGIs) in the gene promoter regions. The aim of the present study is to identify DNA methylation markers that distinguish patients with MDD from non-psychiatric controls. **METHODS**: Genome-wide DNA methylation profiling of peripheral leukocytes was conducted in two set of samples, a discovery set (20 medication-free patients with MDD and 19 controls) and a replication set (12 medication-free patients with MDD and 12 controls), using Infinium HumanMethylation450 BeadChips. **RESULTS**: Significant diagnostic differences in DNA methylation were observed at 363 CpG sites in the discovery set. We were able to distinguish patients with MDD from the control subjects with a sensitivity of 100% and a specificity of 100% in the discriminant analysis using the DNA methylation markers. We validated these selected DNA methylation markers with 100% accuracy in the replication set. **CONCLUSION**: Our results indicate that multiplex DNA methylation markers may be useful for supporting the diagnosis of MDD.

Title: Dermal fibroblasts bring molecular insights into Major Depressive Disorder

Authors: *K. A. GARBETT[1], A. VERECZKEI[2], S. KÁLMÁN[4], G. FALUDI[3], Ž. KORADE[1], R. C. SHELTON[5], K. MIRNICS[1];
[1]Psychiatry, Vanderbilt Univ., NASHVILLE, TN; [2]Inst. for Med. Chemistry, Mol. Biol. and Pathobiochemistry, [3]Dept. of Psychiatry, Kútvölgyi Clin. Ctr., Semmelweis Univ., Budapest, Hungary; [4]Psychiatry, Univ. of Szeged, Szeged, Hungary; [5]Psychiatry, Univ. of Alabama, Birmingham, AL

Abstracts: Understanding the biological bases for Major Depressive Disorder (MDD) may be facilitated by the use of peripheral tissue. Primary dermal fibroblasts are easy to obtain and propagate, are not immortalized, and most importantly, after several cell divisions in controlled cell culture conditions, the effects of patients' environment and medication use are practically eliminated. In addition, fibroblast cultures allow us to study the cellular response to various challenges, which are particularly valuable for uncovering the disturbed molecular processes related to the disease. Primary fibroblast cultures were obtained from skin biopsies of subjects with MDD and matched healthy controls (n=16). Cultures were maintained in standard (STD) medium. Metabolic stress was evoked by glucose substitution with galactose (GAL) and with lipid reduced (RL) media. In all conditions mRNA and miRNA expression levels were simultaneously measured by gene expression microarrays and qPCR. In STD conditions fibroblasts from MDD patients, when compared to matched controls (CNTR), revealed a strong disease-associated mRNA expression pattern of genes related to molecular pathways involved in cell communication, immunity and cell proliferation. Furthermore, the MDD-associated miRNA expression signature appeared to be functionally connected with the mRNA expression pattern. Next, to evaluate the response of MDD and CNTR fibroblasts to a metabolic stress (and reveal molecular deficits that are not obvious under resting conditions), we compared the mRNA/miRNA profile of MDD and CNTR cells grown in galactose and reduced lipids media. Culturing mammalian cells in GAL is a mitochondrial oxidative phosphorylation challenge, while RL exposure strongly engages de novo lipid biosynthesis. GAL challenge in MDD patients resulted in enrichment of molecular pathways involved in cell cycle regulation, apoptosis, cell survival and inflammation. RL exposure in MDD caused increased expression of genes participating in cell survival, migration, proliferation, and regulation of metabolism, but also decreased expression in pathways regulating energy production. Many of these disturbed processes have been also previously observed in postmortem brain tissue of subjects with MDD. From these experiments we conclude that dermal fibroblasts are useful and informative biomaterial for studying psychiatric disorders. Furthermore, it appears that challenging patient

cells with stressors is essential for revealing the underlying molecular deficits that characterize the disorder.

Title: Genetic variation in adenosine A2A receptor gene (rs2298383) is associated with peripheral levels of TNF-α and major depression in women

Authors: *M. P. KASTER[1,2], M. GAZAL[2], F. N. KAUFMANN[2], K. JANSEN[2], J. P. OSES[2], L. D. M. SOUZA[2], R. A. SILVA[2], D. C. MOREIRA[3,4], D. R. LARA[4], G. C. GHISLENI[2,3]; [1]Dept. de Bioquímica, Univ. Federal De Santa Catarina, Florianópolis, Brazil; [2]Life and Hlth. Sci., Univ. Católica de Pelotas, Pelotas, Brazil; [3]Hosp. de Clínicas de Porto Alegre, Univ. Federal do Rio Grande do Sul, Porto alegre, Brazil; [4]Pontifícia Univ. Católica do Rio Grande do Sul, Porto Alegre, Brazil

Abstracts: Introduction: Major depressive disorder (MDD) has been a growing public health concern estimated to become the second leading cause of disability by the year 2020. Recently, polymorphisms in genes involved in adenosine metabolism and adenosine receptors were associated with vulnerability to psychiatric disorders including depression (Biochim. Biophys. Acta. 1808:1380-99, 2011). Objective: The aim of our work is to identify a possible association between the 23155511C/T single nucleotide polymorphism (SNP) in exon 1 of the adenosine A2A receptor gene, ADORA2A (rs2298383), located in a potential promoter region, peripheral inflammatory cytokines (TNF-α, IL-1β and IL-6) and MDD in a southern Brazilian population. Methods: This work is part of a population-based study including 750 subjects (18 to 24 year-old) from the urban area of Pelotas, RS (Brazil). MDD diagnosis was made with the Mini

International Neuropsychiatric Interview 5.0. DNA was extracted from peripheral leucocytes and genotyping was performed using Real Time PCR. Serum cytokines were evaluated by ELISA. Results: Of the 750 subjects evaluated, we found 256 with MDD. Most of the MDD subjects were women (54%), caucasian (78.9%) and with a low use of psychiatric medication (8.3%). No differences were detected according to diagnosis and genotypic distribution ($\chi 2=0.211$) or levels of TNF-α (control: 104.90±15.41 vs MDD: 135.71±25.94 pg/mL, p=0.278), IL-1β (control: 9.09±1.77 vs MDD: 15.40±4.74 pg/mL, p=0.14) or IL-6 (control: 20.17±2.36 vs MDD: 18.15±1.25 pg/mL, p=0.45). However, after stratification by gender we observed an association between carriers of the T allele (C/T homo- and T/T heterozygotes) and MDD in women ($p<0.05$, Pearson's chi-squared test). In addition, there was a tendency to increased TNF-α levels in MDD women vs control (63.72±16.50 and 135.71±25.94 pg/mL, respectively, p=0.08, using Student' t test). No changes were observed IL-1β and IL-6 levels in women according to diagnosis. In addition, two-way ANOVA revealed significant differences for the interaction between genotype and diagnosis in the levels of TNF-α ($p<0.05$), but not IL-1β (p=0.56) and IL-6 (p=0.36). The post-hoc analysis indicated that in healthy control women the levels TNF-α were similar according to the genotype (CC: 60.05±42.90 pg/mL, vs CT/TT 77.75±23.64). However, the levels of TNF-α were significantly higher in MDD women with the CC genotype (241.32±50.15 pg/mL) when compared CT/TT genotypes (91.95±30.52 pg/mL). Conclusion: We concluded that there is an association between allele T of the ADORA2A SNP, lower levels of TNF-α and decreased risk for MDD in women.

Title: The inflammation-related gene CITED2 modulates the relationship between the dopamine-related gene NR4A2 and subgenual anterior cingulate cortical thickness in Major Depressive Disorder

Authors: *H. SUZUKI[1], J. MARINO[2], K. TEAGUE[2,3,4], M. MISAKI[1], T. VICTOR[1], J. SAVITZ[1,5], B. MCKINNEY[6], P. BELLGOWAN[1,5], W. DREVETS[1,7], J. BODURKA[1,8]; [1]Laureate Inst. For Brain Res., TULSA, OK; [2]Surgery, Univ. of Oklahoma Sch. of Community Med., TULSA, OK; [3]Pharmaceut. Sci., Univ. of Oklahoma Col. of Pharm., Tulsa, OK; [4]Biochem. and Microbiology, Oklahoma State Univ. Ctr. for the Hlth. Sci., Tulsa, OK; [5]Community Med., The Univ. of Tulsa, Tulsa, OK; [6]Mathematical and Computer Sci., The Univ. of Tulsa, TULSA, OK; [7]Janssen Pharmaceuticals, LLC, Johnson & Johnson, Inc., Titusville, NJ; [8]Univ. of Oklahoma Col. of Engin., Norman, OK

Abstracts: Chronic stress dysregulates neuroimmune balance facilitating our stress adaptation and leaves brain structure vulnerable to disorders. In Major Depressive Disorder (MDD), anhedonia has been separately associated with structural changes in the subgenual anterior cingulate cortex (sgACC), mesolimbic dopaminergic system, and innate immune system. This study examined neuroimmune interactions between MDD status and expression of two genes previously implicated in MDD, the dopamine-neuron trophic gene, NR4A2, and neuroinflammation-related gene, CITED2, on sgACC thickness. Twenty unmedicated adults with MDD (14 females, mean age = 38) and 25 healthy adults (18 females, mean age = 31) underwent blood sampling and MR imaging (3T GE MR750 scanner, including a structural T1-weighted scan). Monocyte RNA was extracted and reverse transcribed into complementary DNA; quantitative real-time polymerase chain reactions were used to determine NR4A2 and CITED2 relative transcript abundance. FreeSurfer was used to segment the bilateral subcallosal cortex (posterior sgACC), and mean cortical thickness was measured. Hierarchical regressions were performed to predict sgACC thickness: MDD status, NR4A2 levels, and CITED2 levels in the first model, all possible two-way interactions in the second model, and a three-way interaction in the third model. Age, gender, and body mass index were covaried in all models. The first and second models did not indicate any main effect or two-way interaction. However, the third model showed that the three-way interaction predicted left sgACC thickness significantly ($\beta = .85$, $t(34) = 2.75$, $p < .01$) and right marginally ($\beta = .67$, $t(34) = 1.91$, $p = .064$). A follow-up regression within each group revealed that reduced left sgACC thickness was associated with decreased transcript abundance of NR4A2 and CITED2 in MDD ($\beta = 2.75$, $t(16) = 2.51$, $p < .05$), but not healthy controls (see Fig. 1). These findings provided insights into the neuroimmune interactions in MDD, such that CITED2 expression modulates the effect of NR4A2 on the sgACC in MDD.

Title: The emotion and brain wave activity to stress for women with premenstrual syndrome

Authors: Q. LIU[1], *R. ZHOU, SR[1,2,3,4], W. CHEN[1];
[1]Sch. of Psychology, Beijing Normal Univ., Beijing, China; [2]State Key Lab. of Cognitive Neurosci. and Learning & IDG/McGovern Inst. for Brain Research, Beijing Normal Univ., Beijing, China; [3]Ctr. for Collaboration and Innovation in Brain and Learning Sciences, Beijing Normal Univ., Beijing, China; [4]Res. Ctr. of Emotion Regulation, Beijing Normal Univ., Beijing, China

Abstracts: The purpose of the present study was to investigate the relation between electroencephalogram (EEG) rhythm to stress and emotion for women with premenstrual syndrome (PMS). thirty women (18~30 years old, 22±2.19) took part in the study, among them, fifteen women were diagnosed to be PMS group, while the left formed the non-PMS group. The participants received the EEG stress evaluation test (eyes-open resting, eyes-closed resting, attention and cognition tests) and filled in the positive affect and negative affect scale (PANAS) in non-menstrual phase (luteal or follicular phase). The EEG brain wave rhythms (theta, alpha, sensorimotor and low beta rhythms) under stress test were recorded and analyzed. The results showed that compared to non-PMS group, the PMS group had higher negative affect and lower positive affect scores on PANAS. Moreover, the PMS group got stronger alpha rhythm than non-PMS group under the eyes-open resting and attention tests. Finally, under the stress evaluation test, the EEG rhythm was positively correlated to negative affect and negatively correlated to positive affect (Table 1). The results indicated that the PMS females had stronger EEG arousal under stress and this was correlated with their higher negative affect and lower positive affect. The emotion variation of PMS females may partly explain their sensitive EEG arousal to stress.
Key words: stress; premenstrual syndrome; EEG rhythm; positive affect; negative affect Table1 The correlations of the scores of positive affect and negative affect scale and EEG rhythms (theta, alpha, SMR and low beta) under different tasks (open eyes resting, closed eyes resting, attention test, and cognition test).

Tasks	**EEG Rhythms**	**Positive Affect**	**Negative Affect**
	Theta	-0.365 (0.048)	0.40 (0.028)
	Alpha	-0.40 (0.028)	
	SMR	-0.378 (0.039)	0.325 (0.080)
	Low Beta	-0.403 (0.027)	0.362 (0.050)
Open eyes resting	Theta	-0.467 (0.009)	
Closed eyes resting	SMR	-0.319 (0.085)	
Attention test	Low Beta	-0.485 (0.007)	0.339 (0.067)
	Theta	-0.464 (0.010)	
	Alpha	-0.358 (0.052)	0.562 (0.001)
	SMR	-0.396 (0.031)	0.440 (0.015)
	Low Beta	-0.373 (0.042)	0.450 (0.013)

Note: The unit of EEG rhythms (theta, alpha, sensorimotor and low beta rhythms) was Hz.

Title: Increased Toll-like receptor 2 and 6 protein expression in the depressed suicide brain

Authors: *X. REN, H. S. RIZAVI, G. N. PANDEY;
Psychiatry, Univ. of Illinois at Chicago, Chicago, IL

Abstracts: Abnormalities of the immune function in depression and suicide are based in part on the observation of increased levels of proinflammatory cytokines in the serum and in postmortem brain of depressed and suicidal patients. Several studies suggest dysregulation of the immune system in suicide as increased microgliosis has been reported in postmortem brain of suicide subjects and increased levels of proinflammatory cytokines in the CSF of suicidal patients. This observed abnormality of cytokines in suicide may be related to altered innate immune receptors known as Toll-like receptors (TLRs). In a recent study we reported a significant increase in the protein and mRNA levels of TLR3 and TLR4. To further examine the role of TLR in suicide we have now studied the expression of TLR2, TLR5, and TLR6 in depressed suicide subjects. We determined the protein expression of TLR2, TLR5, and TLR6 in the PFC of 24 depressed suicide victim and 24 normal control subjects. The postmortem brain tissues were obtained from the Maryland Brain Collection and the psychological autopsies were performed for the diagnosis of the subjects using DSM-IV-SCID. Protein expression was determined using Western blot technique. When we compared the protein expression of TLR2, we found that the protein expression of TLR2 was significantly increased in depressed suicide victims compared with

normal control subjects, while there was no difference in TLR5 protein expression in depressed suicide victims compared with normal control subjects. The protein expression of TLR6 was also significantly increased in the PFC of depressed suicide subjects compared with normal controls. These results suggest that overexpression of TLR2 and TLR6 protein may be in part related to the abnormalities of proinflammatory cytokines in the brain of suicide victims and that abnormalities of innate immunity are associated with suicide.

Title: Altered gene expression of proinflammatory cytokines and their receptors in the lymphocyte of depressed patients

Authors: *H. ZHANG[1], H. S. RIZAVI[2], X. REN[2], G. N. PANDEY[2];
[1]Univ. Illinois at Chicago, CHICAGO, IL; [2]Psychiatry, Univ. Illinois at Chicago, Chicago, IL

Abstracts: Abnormalities of the immune function have been implicated in the pathophysiology of depression. This is primarily based on the observation that treating cancer patients with a cytokine interferon(IFN)-α causes depression-like symptoms and that protein levels of proinflammatory cytokines and their soluble receptors are increased in the serum of depressed patients. The soluble receptors are derived from proteolytic degradation of membrane-bound cytokine receptors, which are involved in signal transduction and mediate the functional and biological effects of cytokines. Although soluble cytokine receptors have been studied in depression, to our knowledge membrane-bound cytokine receptors were not studied in depression or other psychiatric disorders. To examine if major depressive disorder (MDD) is also associated with abnormal gene expression of cytokines and their receptors, we determined mRNA expression of proinflammatory cytokines and their receptors in the lymphocytes of drug-free MDD patients and normal control subjects. We determined the protein and mRNA expression of proinflammatory cytokines, interleukin (IL)-1β, IL-6, and tumor necrosis factor (TNF)-α, and mRNA expression of their receptors IL-1R1, IL-1R2, IL-1R antagonist (IL-1RA),

IL-6R, glycoprotein (Gp)130, TNFR1, and TNFR2 in the lymphocytes from 26 drug-free, hospitalized MDD patients and 29 drug-free normal control (NC) subjects. The subjects were diagnosed according to DSM-IV criteria. Protein levels of cytokines were determined by ELISA, and mRNA levels of cytokines and cytokine receptors in lymphocytes were determined by the qPCR method. We found that the mean mRNA levels of the proinflammatory cytokines IL-1β, IL-6, and TNF-α were significantly increased in the lymphocytes of MDD patients compared with normal controls. The protein levels of the cytokines IL-1β, IL-6, and TNF-α were also significantly increased in the plasma of MDD patients compared with normal controls. The mRNA levels of IL-1R1, IL-1RA, TNFR1, and TNFR2 were significantly increased in the lymphocytes of MDD patients compared with normal controls. No significant differences were observed in mRNA levels of IL-1R2, IL-6R, or Gp130 between MDD patients and normal controls. These studies suggest that the reported abnormalities of cytokines and their soluble receptors observed in the plasma of MDD patients may be related to an abnormal gene expression of these cytokines and their receptors in the lymphocytes of MDD patients, and that their mRNA expression levels in the lymphocytes could be a useful biomarker for depression. To our knowledge, this is the first study of cytokine receptors in depressed patients.

Abstracts: Background: Application of genomes scale tools to study stimulant drug action is mostly limited to animal models due to lack of timely access to relevant neural cells in humans. Methods: Drug naive children with Attention Deficit Hyperactivity Disorder (ADHD) underwent a standardized prospective assessment of medication treatment response. Genome scale peripheral blood mononuclear cell (PBMC) expression reactivity was compared before and after acute (2 hours) and sub acute (2 weeks) MPH exposure, and correlated with prospectively documented response. Results: MPH induced PBMC expression changes among responders implicated several informative pathways, and previously described ADHD risk genes. Conclusions: Prospectively documented surrogate mononuclear cell genome scale transcriptional reactivity to MPH among previously drug naïve children with ADHD, may point to selective underlying molecular targets of MPH response.

Abstracts: [Background] Matrix metalloproteinases (MMPs) are implicated in remodeling synaptic circuits of neuron and glia in the brain as well as regulating to inflammation and immune system, which suggests a pathophysiology of psychiatric disorders. We have previously reported on two major gelatinases, MMP-9 and MMP-2, suggesting that serum levels of MMP-9

were treatment-specific markers for electroconvulsive therapy (ECT) and that serum levels of MMP-2 were disease-specific markers for mood disorders (Neuroscience 2013). [Purpose] We measured serum levels of MMP-3, a stromelysin, which is known to be involved in inflammatory and immune diseases, in patients with mood disorders and schizophrenia during ECT treatment. [Subject and Methods] This study was performed on depressed (N = 29) and schizophrenic patients (N = 19) following a course of ECT. We also compared the serum levels of these patients to those of healthy controls (N = 40). Serum MMP-3 concentrations were measured by enzyme-linked immunosorbent assay. The clinical severity was assessed using the 17-item Hamilton Rating Score for depression (HRSD) and the Brief Psychiatric Rating Scale (BPRS) for schizophrenia. The ethics Committee of NHO Kure Medical Center approved the study protocol, and all participants provided written consent. [Results] In healthy controls, the serum MMP-3 levels of male were significantly higher compared to those of female (24.4 [SD, 7.9] ng/ml vs 11.4 [SD, 3.7] ng/ml, $p < 0.05$). Serum MMP-3 levels were significantly lower in male patients with both mood disorders (16.8 [SD, 6.9] ng/ml) and schizophrenia (16.1 [SD, 9.4] ng/ml) at baseline before ECT compared to those of male control subjects. MMP-3 levels were not significantly associated with severity of symptoms and dose of psychotropic drugs. In contrast, there were no significant differences in serum levels of MMP-3 between the female patients groups and female control group at baseline. After ECT treatment, MMP-3 levels did not changed significantly across groups. [Conclusion] Our findings suggest that serum MMP-3 levels, without being influenced by ECT, were significantly lower only in males with both mood disorders and schizophrenia. Serum levels of MMP-3 might be a gender-specific marker for psychiatric disorders.

Abstracts: Background: A clinically significant depressive episode affects 14% of mothers, constituting the most common medical complication after delivery. The underlying mechanisms that trigger post partum depression (PD) among this susceptible minority have not been deciphered. Methods: We compared genome scale transcriptional profiles in peripheral blood mononuclear cells (PBMCs) sampled immediately after delivery, between drug naïve mothers prospectively diagnosed with a post partum onset depressive episode and resilient mothers who did not express depressive symptoms upon 6 months follow up. Results: Applying weighted gene correlation network analysis (WGCNA) and pathway analyses, we found replicated evidence for reduced mononuclear cell transcriptional engagement in cell proliferation and coupled histone synthesis among mothers entering a prolonged depressive episode. Pathway enrichment data suggest perturbed transcriptional reactivity to post partum hormonal changes, exert altered immune regulation among susceptible mothers. Discussion: Distinct mononuclear cell transcriptional changes during the triggering of a persisting PD episode suggest an altered immune reactivity, and point to relevant underlying molecular abnormalities

Title: Brain nerve growth-related gene NTRK2,BDNF is associated with amygdala and orbitofrontal volumes in the human brain and mood: A voxel-based morphometry (VBM) study

Authors: *S. AIZAWA, J. AKIYOSHI, H. HIRAKAWA, K. MASUDA;
Oita Univ. Fac. of Med., Yufu-Shi, Japan

Abstracts: [Introduction] Brain-derived neurotrophic factor (BDNF) is one of the neurotrophic factors that induce its actions through the neurotrophic tyrosine receptor kinase type 2 (NTRK2). Genetic variation in BDNF and NTRK2 has been associated with major depressive disorder (MDD) and anxiety disorders. These variations also have been correlated with brain variations including regions constantly associated with MDD and anxiety disorder. The aim of our study was to evaluate the association of regional gray matter (GM) volume within the amygdala and other unpredicted regions at the whole-brain level with the BDNF and NTRK2 polymorphism with depressive and anxiety symptoms. [Methods] We genotyped 112 healthy controls with respect to 6 at-risk reference SNPs (rs) of BDNF: rs6265, NTRK2はrs11140800,rs1187286,rs1867283,rs1147198,rs10868235. All participants underwent structural magnetic resonance imaging, and the data was statistically analyzed with voxel-based morphometry (VBM) using Statistical Parametric Mapping (SPM8). We examined the State-Trait Anxiety Inventory (STAI), Profile of Mood States (POMS) and Depression and Anxiety Cognition Scale (DACS), a Japanese psychological questionnaire, to assess automatic thoughts. We also examined Temperature Character Inventory (TCI) and Revised NEO Personality Inventory (NEO-PI-R). [Results] We found that there was a significant difference of Fatigue (F) of POMS, Neuroticism and Openness to experience and Agreeableness of NEO-PI-R, and Harm Avoidance of TCI between major-allele homozygote, heterozygote, and minor-allele homozygote in NTRK2. There was also Anger-Hostility (A-H), Fatigue (F) and Confusion (C) of POMS between major-allele homozygote, heterozygote, and minor-allele homozygote in BDNF. We found significant alterations in amygdala, orbitofrontal volumes with rs1187286 in NTRK2 and in insula with rs6265 in BDNF. [Discussion] The relationship between NTRK2,BDNF SNPs and psychological tests suggest that NTRK2,BDNF are associated with anxiety and depression. These effects of NTRK2,BDNF SNPs on brain morphology provide further evidence of its involvement in the neurobiology of depression and anxiety.

Title: Identical blood biomarkers in late-onset major depressive disorder patients and model mice

Authors: *S. MIYATA[1], M. KURACHI[2], N. SAKURAI[1], K. TAKAHASHI[1], H. YAMAGATA[3], K. MATSUO[3], K. NARITA[1], M. FUKUDA[1], Y. ISHIZAKI[2], M. MIKUNI[1]; [1]Gunma University, Psychiatry and Neurosci., Gunma, Japan; [2]Gunma University, Mol. and Cell. Neurobio., Gunma, Japan; [3]Yamaguchi University, Div. of Neuropsychiatry, Yamaguchi, Japan

Abstracts: The absence of objective biomarkers for major depressive disorder (MDD) is a central problem in the diagnosis and treatment. Additionally, the discovery of new antidepressants is desired, but the screening of antidepressant effects has largely relied on traditional behavioral tests in rodents, which have weak validation in human MDD. Here we identified objective and state-dependent biomarkers in blood cells of late-onset MDD patients (i.e., age at onset of MDD over 50 years) and its model mice by cross-matching with their gene expression profiles. Ten patients with MDD (DP), 10 patients with MDD in a remitted state (RM) and 12 healthy controls (HC) were enrolled. Mean ages, sex composition and Mini Mental State Examination score did not differ between the three groups, but the Structured Interview Guide for the Hamilton Depression Rating Scale scores were significantly higher in DP than HC and RM. The age at onset was not different between DP and RM. By the microarray analysis, the expression of 3,066 probes (2,207 up/859 down) was significantly changed in DP vs. HC and RM vs. DP, but not RM vs. HC, indicating that the expression of these probes was state-dependently changed in the blood cells. Next, we generated the animal model of late-onset MDD; ovariectomized (OVX) mice with chronic exposure to unpredictable mild stress (CUMS), which have a pathophysiological similarity to late-onset MDD. OVX+CUMS mice exhibited the depression-like behavior in the forced swimming test and the anxiety-like behavior in the open-field test. The expression of 637 probes (338 up/299 down) was the specific change in the blood cells of OVX+CUMS mice in the microarray analysis. The differentially expressed genes from patients were cross-matched with those in the animal model by reference to each gene symbol, and we found the identical 14 genes. We suggest that these genes in blood cells will be helpful for properly diagnosing late-onset MDD and bridging the gap between animal studies and human clinical trials.

Abstracts: Bipolar disorder (BD) is a psychotropic disorder that causes unusual shifts in mood from the manic to the depressive state. Genetic linkage studies have shown that TRPM2, a Ca2+-permeable cation channel is associated with BD, but the nature of this linkage is not known. Here we show that the genetic ablation of Trpm2 elicits altered stress-related innate behaviors and social behaviors. In addition, Trpm2-/- mice exhibited abnormal oscillation and synchronization of electroencephalogram, such as reduced value of entropy, decreased correlation coefficient values, lower coherence between the two regions. These EEG traits are frequently emerged in BD patients. Interestingly, amphetamine administration to wild-type mice evoked a large increase in open-field activity, which was reversed by lithium. However, the anti-manic action of lithium was not observed in the Trpm2-/- mice. Because TRPM2's dysfunction in mice provides several symptoms frequently emerged in BD patients, Trpm2-/- mice may be useful for animal model for BD as well as mechanistic study for its etiology in future. Title: Neural correlates of successful psychotherapy of depression in adolescents

Authors: J. STRAUB[1], P. L. PLENER[1], N. SPRÖBER[1], L. SPRENGER[4], M. G. KOELCH[1], *T. KAMMER[2], G. GRÖN[3], B. ABLER[3];

Abstracts: Introduction: While major effort has been invested in investigating the neural correlates of depression and their modulation by treatment in adults, less is known about the effects of psychotherapy in adolescents. Given the concordance of the amygdala, hippocampus and the subgenual anterior cingulate cortex (sgACC) as correlates of depression and their involvement in reward processing, we used functional magnetic resonance imaging during performance of a monetary reward task in an intervention vs. waitlist-control design to investigate the clinical and neural effects of cognitive behavioural group therapy (CBT-G). Methods: We investigated 22 medication naïve adolescents with major depressive disorder. Participants were scanned before and after five sessions of 90 minutes of CBT-G (PAT-I), or before and after a five weeks of waiting (PAT-W) with treatment as usual. Symptoms were assessed using the Children's Depression Rating Scale and the Beck Depression Inventory Revision. Changes in symptom scales were analyzed along with neural activation changes within the three independent regions of interest (ROI). Results: Pre-post-test psychometric assessments were insignificant in PAT-W but significant in PAT-I for BDI-II and CDRS-R. Time by group interaction effects were significant with respect to BDI-II ($t(20) = -1.82$, $p = .042$) and CDRS-R ($t(20) = -2.05$, $p = .027$). Pre-post-test ROI activation also stayed constant in PAT-W in the sgACC, Hippocampus und Amygdala. In PAT-I, pre-to-post-test brain activation was significantly altered in the left amgygdala, left hippocampus and bilateral sgACC. Time by group interaction effects were significant for the right sgACC ($t(20) = -1.89$, $p = .037$), left Amygdala ($t(20) = -2.49$, $p = .011$) and left Hippocampus ($t(20) = -1.74$, $p = .049$). In line with previous findings in adults, pre-to-post symptom improvement in the BDI-II correlated with pre-to-post activity change in the bilateral sgACC (left sgACC: $r = .57$, $p = .01$; right sgACC: $r = .54$, $p =$

.02). Correlation coefficients further increased with pre-to-follow-up difference scores in the BDI-II (left sgACC: r= .69, p = .002; right sgACC: r = .73, p = .001). Furthermore individual pre-to-follow-up symptom change, assessed by means of BDI-II, was significantly related to baseline sgACC activation (left sgACC: r = -.56, p = .02, right sgACC: r = -.59, p = .01). Conclusions: Successful group psychotherapy of depression in adolescents was related to signal changes in brain regions previously demonstrated to be reliably linked with successful, particularly pharmacological treatment in adults.

Title: High-resolution functional mapping of the human habenula in depression

Authors: *B. A. ELY[1], K. A. B. LAPIDUS[2], D. L. ROSENTHAL[3], K. E. SIP[3], J. XU[4], E. R. STERN[2];
[1]Neurosci., [2]Neuroscience, Psychiatry, [3]Psychiatry, [4]Radiology, Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstracts: Background: Recent studies have suggested that the habenula (Hb), a pair of small grey matter nuclei bordering the dorsomedial thalamus, may play an important role in depression. Animal studies have indicated that projections from the Hb act to inhibit the reward system through modulation of midbrain dopaminergic and serotonergic signaling. In a case study following Hb deep brain stimulation, a patient with treatment-resistant depression reported remission. However, the small size of the human Hb has limited *in vivo* investigation via standard neuroimaging methods. Using novel high-resolution resting-state fMRI (rfMRI) approaches, we aim to address this hurdle and examine Hb connectivity in a group of subjects with major depression (MDD), treatment-resistant depression (TRD), and healthy controls (HC). **Methods:** Subjects (two HC and one MDD) underwent 15-minute rfMRI scans at both 3T and 7T using 32-channel head-coils. Isotropic high-resolution multiband accelerated gradient echo EPI images of 2.1mm^3 at 3T (one run) and both 1.6mm^3 and 1.28mm^3 (two runs each) at 7T were acquired. Left and right 2mm-radius spherical Hb regions-of-interests (ROIs) were identified based on anatomical landmarks using FSL software. Spatial and temporal preprocessing of the time series were conducted using SPM12/FSL, followed by functional connectivity analysis via the CONN toolbox. **Results:** A consistent pattern of bilateral association of Hb connectivity was seen for all three subjects at 3T, with each ROI positively correlating with the contralateral Hb as well as the bilateral thalamus and insula. Hb connectivity in the two controls appeared more widespread, including the midbrain and prefrontal cortex. In the MDD subject, stronger connectivity between the left and right Hb was observed. These results from 3T were corroborated by ultra-high-resolution rfMRI data acquired in the same subjects at 7T (both 1.6mm^3 and 1.28mm^3) with exquisite spatial specificity. **Conclusions:** These preliminary findings demonstrate the ability to detect expected patterns of Hb connectivity using high-resolution 3T rfMRI and the added benefits of spatial specificity using ultra-high-resolution 7T rfMRI. The higher bilateral Hb functional association in the MDD subject is consistent with the literature and will be verified in this pilot case-control study (MDD, TRD, and HC, 10 subjects each).

Title: Glutamatergic levels in the healthy and depressed brain: An ultra-high field 1h-mrs ketamine treatment study

Authors: *N. LALLY[1,2], L. AN[3], A. NUGENT[1], D. BANNERJEE[1], J. SHEN[3], C. ZARATE[1]; [1]NIH, Bethesda, MD; [2]Inst. of Cognitive Neurosci., Univ. Col. London, London, United Kingdom; [3]Magnetic Resonance Spectroscopy Core, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstracts: Recent evidence has highlighted aberrant glutamatergic-signalling in patients diagnosed with depression. Additionally, evidence suggests that ketamine, a non-competitive N-Methyl-D-Aspartate antagonist, may possess rapid acting antidepressant efficacy mediated through the enhancement of glutamatergic transmission. However, due to technical limitations, it has not been possible to reliably determine whether such alterations in the glutamatergic system occur in the in-vivo in the human patients and whether successful treatment with ketamine resolves any dysfunction. Here, using a 7 Tesla Siemens MRI, we acquired baseline 1H-MRS data, using an adapted point resolved spectroscopy sequence, from the pregenual anterior cingulate in healthy volunteers (N=18) and also at baseline and 24 hours post-ketamine and -placebo infusions in medication free treatment-resistant patients with major depressive (N=7) and bipolar disorder (N=2) in a double-blind, randomized, placebo controlled investigation. A water linewidth of < 16Hz was required for data points to be included in the analyses and 1H-MRS metabolites were referenced to creatine. In contrast to previous reports, we found no statistical difference in pregenual glutamate levels between patients with depression (M=1.33) and healthy volunteers (M=1.43; $t(25)=1.64$, $p=0.11$, $d=0.69$). In congruency with previous investigations, there was no significant difference between glutamate levels post-ketamine (M=1.38) and post-placebo (M=1.33; $t(7)=0.77$, $p=0.47$, $d=0.27$). These results attenuate the emphasis of the glutamatergic system, as measured by 1H-MRS, in the neurobiology of depression. However, the current sample size precludes any firm deductions surrounding the pathophysiology and treatment mechanisms of depression; effect sizes suggest that increasing the sample size may yield statistically significant differences between healthy and depressed subjects.

Title: FKBP5 is associated with amygdala volumes in the human brain and mood: A voxel-based morphometry (VBM) study

Authors: *J. AKIYOSHI, H. HIRAKAWA, K. MASUDA, S. AIZAWA;
Oita Uiniversity Fac. of Medicine, Dept. of Neuropsychiatry, Oita, Japan

Abstracts: Introduction: The FK506 binding protein 51 (FKBP5) genes control the stress hormone system and are associated with mental illness due to stress. Genetic studies suggest that FKBP5 plays an important role in depression, post-traumatic stress disorder, and anxiety disorder. The aim of the present study was to investigate the effects of 6 FKBP5 single nucleotide polymorphisms (SNPs) on human amygdala volumes, using voxel-based morphometry (VBM). Methods: We genotyped 112 healthy controls with respect to 6 at-risk reference SNPs (rs) of FKBP5: rs3800373, rs992105, rs9296158, rs1360780, rs9470080, and rs2766534. All participants underwent structural magnetic resonance imaging, and the data was statistically analyzed usingVBM. We analyzed the association between VBM, mood and anxiety. Results: We found significant alterations in amygdala volumes with rs 3800373, rs992105, rs1360780, and rs9470080. According to the Profile of Mood States (POMS), rs992105 and rs9470080 were associated with tension-anxiety, depression-dejection, anger-hostility and Vigor. Discussion: These effects of FKBP5 SNPs on brain morphology provide further evidence of its involvement in the neurobiology of depression and anxiety.

Title: Selective serotonin reuptake inhibitor, electro-convulsive therapy, and repetitive transcranial magnetic stimulation treatments affect distinct neural systems in Major Depressive Disorder: A comprehensive meta-analytic investigation

Authors: *D. T. CHAU[1], P. FOGELMAN[1], W. C. DREVETS[1,2], P. J. HAMILTON[1];
[1]Laureate Inst. For Brain Res., Tulsa, OK; [2]Janssen Res. & Develop., Janssen Pharmaceuticals of Johnson & Johnson, Titusville, NJ

Abstracts: A large number of functional neuroimaging studies have investigated the neural mechanisms of conventional interventions for Major Depressive Disorder (MDD). Unfortunately, the results of these studies have been mixed and, correspondingly, have been equivocal with respect to the primary mechanisms underlying the specific modes of treatment for MDD. In the present study, we conducted voxel-wise, whole-brain meta-analytic syntheses of studies reporting changes in resting-state brain activity, as indexed by regional cerebral blood flow or regional glucose usage, in MDD. Studies included in the present meta-analysis employed one of three distinct classes of intervention: selective serotonin reuptake inhibitor (SSRI)-based pharmacotherapy, electro-convulsive therapy (ECT) or repetitive transcranial magnetic stimulation (rTMS). In addition to investigating concomitant changes associated with each modality, we examined these results relative to each other and to reliable resting-state baseline activation abnormalities in MDD. Our meta-analytic study revealed the following: 1) SSRIs decrease activity in the left mid and posterior insula in MDD; 2) ECT decreases activity in MDD in the right posterior cingulate gyrus and left medial frontal gyrus (primary nodes of the brain's default network); and 3) rTMS decreases activity in the left ventral anterior cingulate and right thalamus. Interestingly, there was no overlap across treatment modalities in brain regions exhibiting decreased activity as a result of treatment. Moreover, regions exhibiting decreased activity following SSRI, ECT, and rTMS treatments did not overlap with regions showing abnormal baseline activity in MDD _ increased activity in the right subcallosal gyrus and right and left pulvinar and decreased activity in the right and left fronto-insular, right dorsal anterior cingulate, and left dorsolateral prefrontal cortex. The current data suggest that SSRIs, rTMS, and ECT work by targeting neural mechanisms that do not exhibit abnormal resting activity in MDD. Specifically, SSRIs exert their effects via the mid and posterior insula, which receive major afferents from the vagus nerve, possibly reducing the flow of viscero-motor information to the cerebral cortex in MDD; alternatively, ECT may alleviate persistent and treatment-resistant negative mood by dampening activity in default network nodes postulated to subserve ruminative, self-referential processing in MDD. Finally rTMS may, through indirect pathways,

normalize dysfunctional activity increases in limbic cortico-striatal-pallido-thalamic circuitry that contributes to motivational deficits and anhedonia in MDD.

Title: Associations between oxytocin-related genes, anxiety, depressive, cognitive symptoms and neuroimaging

Authors: *H. HIRAKAWA, J. AKIYOSHI, K. MASUDA, S. AIZAWA;
Hasama-Machi, Yufu-Shi, Japan

Abstracts: [Introduction] Oxytocin (OT) has been studied reported widely in the neuroendocrine system. Some reports have indicated extensive behavioral influences and various possible effects. Association between OT and social functioning is very important in this system. Animal studies showed that central OT receptor distributes the critical regions in relation to couple attachment and maternal maintenance. We examined the association between the associations between oxytocin-related genes, anxiety, depressive, cognitive symptoms and neuroimaging such as fMRI and VBM. [Methods] The study included 610 healthy participants. We examined the State-Trait Anxiety Inventory (STAI), Profile of Mood States (POMS) and Depression and Anxiety Cognition Scale (DACS), a Japanese psychological questionnaire, to assess automatic thoughts. We also examined Temperature Character Inventory (TCI) and Revised NEO Personality Inventory (NEO-PI-R). OT gene SNP rs53576 was selected according to their minor allele frequency. Linear regression models were used to test association of mean psychological scores with each allele (major-allele homozygote, heterozygote, and minor-allele homozygote). All participants underwent structural magnetic resonance imaging, and the data was statistically analyzed using SPM8 and VBM. We analyzed the association between fMRI, VBM, mood, anxiety and cognition. [Results] We found that there was a significant differences of Tension-Anxiety (T-A), Anger-Hostility (A-H), and Vigor (V) of POMS between major-allele homozygote, heterozygote, and minor-allele homozygote. There was a significant differences of Novelty seeking (NS), Harm avoidance (HA) and Reward dependence (RD) in TCI between

major-allele homozygote, heterozygote, and minor-allele homozygote. We also found significant alterations in hippocampus, cingulate, insula, orbitofrontal, thalamus, caudate, pallidum volumes between major-allele homozygote, heterozygote, and minor-allele homozygote. [Discussion] We found significant differences of VBM, psychological, and personality test between major-allele homozygote, heterozygote, and minor-allele homozygote. These results suggest that OT gene SNP rs53576 has influenced anxiety and depressive symptoms in conjunction with brain volume change.

Title: MGAT4A gene is associated with anxiety, depressive symptoms and self-denial

Authors: *K. MASUDA, J. AKIYOSHI, H. HIRAKAWA, S. AIZAWA;
Oita Univ. Fac. of Med., Yufu-Shi, Japan

Abstracts: [Introduction] Epigenetic alterations suggest explaining the mechanism of disease and describing the pathophysiology of epigenetic disruptions. Single-gene interruptions of the epigenetic organization have long been identified to induce bipolar disorders. Relationship between MGAT4A gene and bipolar disorder has been reported recently (Gamazon et al., 2013). The SNP regulates the methylation of inositol polyphosphate phosphatase 4A (INPP4A) in cis. The gene INPP4A encodes one of the enzymes comprised in the phosphatidylinositol signaling pathway, which is a target for the effects of lithium. We examine the relationship between MGAT4A gene, salivary amylase response, salivary cortisol response, personality and psychological tests (include self-denial) for depressive and anxiety symptoms. [Methods] The study included 593 healthy participants. We collected saliva samples from participants before after, electrical stimulation and TSST to measure the concentrations of salivary alpha-amylase (sAA) and salivary cortisol. Profile of Mood State (POMS) and State-Trait Anxiety Inventory (STAI) scores and Heart Rate Variability (HRV) were also determined following stimulation. MGAT4A gene (rs12618769) was selected according to their minor allele frequency. Linear regression models were used to test association of mean psychological scores with each allele (major-allele homozygote, heterozygote, and minor-allele homozygote). The significant α-value

was set at $\alpha < 0.0025$. Statistical analysis was conducted using SNPStats. Call rates for all genotypes were > 98%. [Results]There was a significant differences of state and trait anxiety in each allele in MGAT4A gene (rs12618769). Tension-Anxiety (T-A), Depression-Dejection (D) and Fatigue (F) scores of POMS in heterozygote and minor-allele homozygote were more than that in major-allele homozygote. Vigor (V) scores of POMS in minor-allele homozygote were less than that in heterozygote and major-allele homozygote. Future denial (FD), threat prediction (TP), self-denial (SD), and past denial (PD) in minor-allele homozygote were more than that in heterozygote and major-allele homozygote. [Discussion]Our results demonstrated that DACS scores showing significant interaction with the MGAT4A gene SNPs may be regarded as appropriate traits to detect the diathesis of automatic thoughts. The MGAT4A gene SNPs may be important loci in research on cognitive vulnerability to depression and anxiety.

Title: A delayed brain-derived neurotrophic factor response to ketamine infusion: Implications for rapid symptom improvements in treatment-resistant depression

Authors: *A. P. ALLEN[1], M. NAUGHTON[2], G. CLARKE[1], J. DOWLING[3], A. WALSH[3], F. ISMAIL[2], G. SHORTEN[3], L. SCOTT[2], J. F. CRYAN[4], T. G. DINAN[1];

Abstracts: Introduction: Ketamine is associated with rapid antidepressant efficacy, but research is required to unearth the underlying biological mechanisms. Brain derived neurotrophic factor (BDNF), a neurotrophin associated with hippocampal neurogenesis, is reduced in depression and can be normalised following antidepressant treatment. Previous research has shown that ketamine enhancement of plasma BDNF four hours post-infusion in patients with treatment-resistant depression (TRD) was associated with symptomatic response to ketamine treatment . However, although the clinical response to ketamine can persist for one week or longer, it is unknown if BDNF increases are stable over this time period. It is also unknown if multiple infusions are additive or lead to sustained effects on BDNF levels. This study aimed to examine the effect of multiple ketamine infusions on serum BDNF and severity of depressive symptoms. Methods: Patients with TRD (N = 17) and healthy controls (N = 20) were recruited. Between 1 and 3 infusions of ketamine (0.5mg/kg) were administered to TRD patients at visits one week apart. Blood samples were collected at baseline in all participants, and within the TRD cohort at 24 hours following the first infusion and at 2 hours and 1 week following each infusion. Symptomatic response to ketamine was assessed using the Hamilton Depression Rating Scale (HDRS). Patients who showed a 50% or greater reduction in HDRS score were classified as responders. BDNF levels were assessed in serum using MesoScale Discovery custom assays. For each sampling time, to assess the effect of ketamine treatment on BDNF, post-ketamine BDNF data were compared to corresponding baseline data for patients who responded symptomatically. Results: Ketamine was associated with a significant clinical response; a majority of patients showed a clinical response at all sampling time points. At baseline the TRD group had significantly lower BDNF (M = 13.3 ng/ml, SD = 6.6) compared to the healthy controls (Mean = 19.6, SD = 8.9, p = 0.03). Those who responded clinically at 2 hours post-infusion did not have higher BDNF at 2 hours following any infusion. However, patients who responded clinically to ketamine at 1 week post-infusion showed enhanced BDNF at 1 week post-infusion compared to baseline (Mean increase = 4.6, SD = 4.3, p = .03), but only for the first infusion. Conclusions: We found a delayed rather than immediate effect of ketamine treatment on circulating BDNF levels. Ketamine infusion may be associated with enhanced serum BDNF, although this may not occur as rapidly as the clinical response, and may not persist over multiple infusions of ketamine.

Title: Whole blood microRNAs as biomarkers of treatment-resistant depression? Effects of ketamine and electroconvulsive therapy

Authors: *K. A. SCOTT[1], G. M. MOLONEY[1], M. NAUGHTON[2], R. M. O'CONNOR[1], D. M. MCLOUGHLIN[5], J. DOWLING[3], G. SHORTEN[3], A. WALSH[3], L. SCOTT[2], F. ISMAIL[2], G. CLARKE[2,4], T. G. DINAN[2,4], J. F. CRYAN[1,4];

Abstracts: Major depressive disorder (MDD) is a debilitating and potentially life-threatening illness that affects nearly 1 in 5 individuals during the course of a lifetime. A significant number of patients fail to experience remission of symptoms in response to traditional antidepressant therapies such as those targeting the serotonergic system. Two therapies that have shown much promise for treatment resistant depression (TRD) are ketamine (KET) and electroconvulsive therapy (ECT), although their exact mechanisms of action are not clear. Understanding the molecular mechanisms underlying their effects may provide insight into the development of novel therapeutic strategies for depressive illness while minimizing adverse side effects often associated with antidepressant treatments. There has been an increasing emphasis on the role of microRNAs in brain function and behavior and their potential as biomarkers in addition to mediators of pathology. MicroRNAs (miRNAs) are small, endogenous, non-coding RNAs that affect gene expression, typically by targeting mRNAs for degradation or by preventing their translation to protein. In the current study we have assessed miRNA expression in whole blood from healthy controls and compared it with miRNA of patients with TRD prior to and following KET or ECT treatment. Whole blood was collected in PAXgene blood RNA tubes and total RNA was isolated using the PreAnalytiX Blood miRNA Kit. RNA quantity and quality were assessed using a Nanodrop 2000 spectrophotometer and Agilent Bioanalyser. A microRNA microarray analysis was then performed to identify miRNAs that differed between groups. We have identified a number of potential miRNA biomarkers in the whole blood of TRD patients that differ from those of controls. Furthermore, we have identified miRNAs that change in response to successful treatment with ECT or KET. Further validation of these findings using real time qPCR is now warranted. Our preliminary findings suggest that circulating miRNAs differ between healthy controls and patients with TRD, suggesting that miRNAs may be an

effective biomarker of depressive illness. Furthermore, successful treatment of depression also alters blood miRNAs. Understanding the roles of these miRNAs may in turn inform novel and more efficacious treatments for stress-related disorders such as depression and anxiety.

Title: Cingulo-frontal network dynamics explains the correlation between EEG theta and treatment outcome in depression

Authors: J. RAMIREZ-MAHALUF[1], A. ROXIN[2], H. S. MAYBERG[3], *A. COMPTE[1]; [1]IDIBAPS, Barcelona, Spain; [2]Ctr. de Recerca Matemàtica, Bellaterra, Spain; [3]Emory Univ., Atlanta, GA

Abstracts: Major depression disease (MDD) has been associated with a dysfunction of cingulo-frontal networks following glutamate metabolism dysfunction in the ventral anterior cingulate cortex (vACC), but theoretical frameworks do not yet provide a principled approach to MDD treatment. Recently, electroencephalography (EEG) is increasingly viewed as a promising

neurophysiological biomarker of treatment outcome: resting ACC activity in the θ band (4-8 Hz) predicts treatment response (Pizzagalli, Neuropsychopharmacol 2011). We provide here a physiological interpretation in terms of the dynamics of the cingulo-frontal network. We built a biophysical computational model of 2 cortical areas (vACC, and dorso-lateral prefrontal cortex, dlPFC) that acts as a bistable switch between emotional and cognitive processing: the two areas cannot be co-active due to effective mutual inhibition. dlPFC activates persistently in response to brief external cognitive signals, and deactivates vACC by means of dlPFC-vACC disynaptic inhibition. Reciprocally, emotional signals activate vACC directly and deactivate dlPFC. In such networks of coupled excitatory and inhibitory neurons, we found a regime characterized by θ oscillations when the system operated as a switch, in line with midline θ characterizing executive processes in healthy humans. We simulated MDD by slowing down glutamate re-uptake in vACC. Excessive excitation led to non-switchable, constant vACC activation, and this prevented dlPFC from responding to cognitive signals, mimicking sustained sadness and cognitive dysfunction in MDD. Interestingly, these dynamics were reflected in the model-derived EEG: MDD models had reduced θ and increased β oscillations, similar to MDD patients (Knott et al., Psychiat Res 2001). We modeled serotonergic treatments (SSRI) through hyperpolarization of vACC neurons, based on the high incidence of 5-HT_{1A} receptors in vACC. SSRI counteracted aberrant vACC activity and impacted the EEG: oscillations at β (θ) decreased (increased) in amplitude, mirroring EEG β in patients after treatment (Tarn et al. J Affect Disorders 1993). Importantly, because the strength of θ oscillations indicated in our network the proximity of the system to the switch mode, there was a correlation between the amplitude of θ oscillations and the effective deactivation of vACC after a given dose of SSRI. This provides a biophysical explanation for the experimentally observed correlation between θ activity before treatment and treatment outcome (Pizzagalli, 2011). In this view, EEG theta measures how close the cingulo-frontal network is to the switch regime that underlies healthy function.

Title: Brain responses to unpredictable threat in individuals at high risk for depression

Authors: *N. KIRLIC[1,3], M. MISAKI[3], J. BODURKA[3], W. C. DREVETS[4], R. P. ALVAREZ[3,2];
[2]Fac. of Community Med., [1]The Univ. of Tulsa, Tulsa, OK; [3]Laureate Inst. for Brain Res., Tulsa, OK; [4]Res. and Develop., Janssen Pharmaceuticals, Titusville, NJ

Abstracts: First-degree relatives of individuals with mood disorders are at increased biopsychosocial risk for psychopathology. Exaggerated emotional reactivity and dysregulation to aversive stimuli pose as risk factors for depression. Using an instructed threat paradigm and high resolution fMRI, we investigated the neurocircuitry underlying responses to unpredictable threat in 21 psychiatrically-healthy individuals at risk for depression by virtue of family history (HR) and 21 age- and gender-matched controls with no family history of mood disorders (LR). Subjects virtually navigated two computer-generated contexts, one where unsignaled shocks on the ankle could occur at any time (Threat), and one where no shock was ever delivered (Safe). Subjects were presented with 20 Threat and 20 Safe contexts over 4 scans lasting 6 min each. Context presentations lasted 18 sec and were followed by a 14-18 sec inter-stimulus interval during which subjects performed a low-level vigilance task. Subjects received 1-2 shocks per scan for a total of 5. Fear ratings and skin conductance responses (SCRs) indexed anxiety reactivity to Threat compared to the Safe condition. Scanning was performed using a GE MR750 3T scanner, a 32-channel phased-array coil, and parallel imaging. A gradient echo EPI sequence with Sensitivity Encoding and FOV/slice thickness=24/2.9mm was used (TR=2000ms, TE=25ms, acceleration=2, image matrix=96x96, flip=40°, and 35 axial slices). Advanced normalization tools with symmetric diffeomorphic image registration was utilized for spatial normalization. Fear ratings and SCRs indicated that anticipation of unpredictable shock elicited sustained apprehension in both HR subjects and LR controls. Correspondingly, whole brain analyses revealed that anxious reactivity to Threat compared to Safe elicited activation in a broad neural network associated with emotion and pain processing, including anterior cingulate, insula, bed nucleus of the stria terminalis, and periaqueductal gray. Compared with the LR group, the HR group displayed significantly increased activity in subgenual anterior cingulate (sgACC) and orbitomedial prefrontal cortex (omPFC) to Threat compared to the Safe condition. These data suggest that sustained anxiety in HR and LR individuals elicits activity in common and distinct neurocircuitry. The sgACC and omPFC have been implicated in emotion regulation and commonly show hyperactivity in depressed patients during emotional processing. Dysfunction in these prefrontal regions in high-risk individuals may be a marker of vulnerability for subsequent development of depression particularly when facing adverse life experiences.

Title: Effects of vagus nerve stimulation on pupil function

Authors: V. DESBEAUMES[1], D. K. NGUYEN[2], M. PHILIBERT[1], M.-P. FOURNIER-GOSSELIN[3], P. LESPÉRANCE[4], *F. RICHER[5];
[1]Psychology, Univ. du Québec à Montréal, Montreal, QC, Canada; [2]Neurol., [3]Neurosurg., [4]Psychiatry, Univ. de Montréal, Montreal, QC, Canada; [5]Psychology, Univ. Quebec at Montreal, Montreal, QC, Canada

Abstracts: Background: Vagus nerve stimulation is a recognized treatment for refractory epilepsy and depression. The main site of innervation of the vagus nerve is the nucleus of the tractus solitarius (NTS). NTS is connected to the locus coeruleus (LC), which in turn, projects to preganglionary parasympathetic nuclei of the brain stem, including the Edinger-Wesphal (EW) nucleus controlling the pupil. Pupillary effects of vagus nerve stimulation have not yet been examined in humans. The objective of this study is to evaluate the acute effects of VNS on baseline pupil size and the pupillary light reflex. Method: We studied 25 patients (10 with major depression, 15 with partial epilepsy) treated with chronic VNS (30 sec ON stim, 5 min OFF stim). Patients fixated a dark screen where a light disc appeared during 500ms. Pupil recordings (3.4 s, infrared head-mounted video camera) started 1.5 s before visual stimulation. Six trials were presented ON VNS stimulation and 6 trials OFF. Results: VNS stimulation was associated with a significant increase in baseline pupil diameter ($t(24)=-4.3$; $p<0.01$) and a smaller amplitude of peak constriction ($t(24)=-5.0$;$p<0.001$) compared to unstimulated periods. There was no difference between the patient groups on any of the pupil measures. Conclusion: Trains of stimulation of the vagus nerve produced a significant increased in pupil diameter during resting state and reduced the amplitude of the pupillary light reflex. These effects are compatible with the known connectivity between LC and EW nuclei and could serve as markers of autonomic effects of VNS.

Title: Depression and Alzheimer's Disease: Novel postmortem brain studies reveal a possible common mechanism

Authors: *Y. TATEBAYASHI, N. NIHONMATSU-KIKUCHI, Y. MATSUDA;
Affective Disorders Res. team, Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan

Abstracts: The relationship between depression and Alzheimer's disease (AD) has always been relevant and controversial. Recent large-scale epidemiological studies, however, have supported the possibilities that major depressive disorders (MDD) that occur during adolescence or middle age represent a risk factor for AD and/or diagnoses of MDD in the elderly often constitute a prodrome of AD. Here, we introduce our recent research about postmortem brains from patients with MDD. Our novel methodological approaches have revealed that MDD may be associated with an unknown type of myelin/myelination abnormalities in the frontopolar cortex. Based mainly on our findings, as well as on neuropathological observations by Braak & Braak (Acta Neuropathol 9, 197-201, 1996), we discuss the possible existence of an as yet unknown common mechanism linking the pathophysiologies underlying both depression and AD.

Title: Involvement of reactive oxygen species in cocaine taking-behaviors in rats

Authors: *S. CHANG[1], E. JANG[2], Y.-H. RYU[3], B. LEE[1], R. J. FOLSOM[2], N. D. SCHILATY[2], K. KIM[1], C. YANG[1], S. C. STEFFENSEN[2], H. KIM[1];
[1]Col. of Korean Med., Daegu Haany Univ., Suseong-Gu Daegu, Korea, Republic of; [2]Brigham Young Univ., Provo, UT; [3]Korea Inst. of Oriental Med., Daejeon, Korea, Republic of

Abstracts: Reactive oxygen species (ROS) have been implicated in the development of behavioral sensitization following repeated cocaine exposure. We hypothesized that increased ROS following cocaine exposure would act as signaling molecules in the mesolimbic dopamine (DA) system, which might play an important role in mediating the reinforcing effects of cocaine. The aim of this study was to evaluate cocaine enhancement of brain metabolic activity and the effects of ROS scavengers on cocaine self-administration behavior, cocaine-induced ROS production in the nucleus accumbens (NAc) and cocaine enhancement of DA release in the NAc. Metabolic neural activity monitored by temperature and oxidative stress were increased in NAc following cocaine exposure. Systemic administration of the ROS scavenger PBN or TEMPOL, either pre- or post-treatment, significantly decreased cocaine self-administration without affecting food intake. Infusion of TEMPOL into the NAc inhibited cocaine self-administration. Increased oxidative stress was found mainly on neurons, but not astrocytes, microglia or oligodendrocytes, in NAc of rats self-administering cocaine. TEMPOL significantly attenuated cocaine-induced enhancement of DA release in the NAc, compared to saline control. TEMPOL had no effect on the enhancement of DA release produced by the DA transporter (DAT) inhibitor GBR12909. Taken together, these findings suggest that enhancement of ROS production in NAc neurons contributes to the reinforcing effect of cocaine.

Title: Evidence for tuning to preferred drug levels during cocaine self-administration by nucleus accumbens neurons

Authors: *O. A. KIM[1,2], K. R. COFFEY[1], D. J. BARKER[1], S. MA[1], A. P. PAWLAK[1], A. T. FABBRICATORE[1], M. O. WEST[1];
[1]Dept. of Psychology, Rutgers Univ., Piscataway, NJ; [2]Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstracts: Drug consumption can transition from recreational use to abuse when individuals repeatedly consume the substance in bouts or "binges," leading to severe negative consequences for the user. However, there is evidence that drug abusers remain sensitive to the immediate consequences of drug consumption. During a binge, animals work to maintain stable, "preferred" brain concentrations of cocaine. Each injection leads to a rapid rise in drug level followed by a gradual pharmacokinetic decay, allowing animals to "titrate" their cocaine levels by spacing self-infusions according to dose. A binging animal responds each time drug level decays to a level termed the "maintenance threshold." The present report sought to characterize the relationship of drug level to firing rates in the Nucleus Accumbens (NAcc), a component of dopaminergic pathways implicated in drug self-administration (SA) and motivated behaviors. Following two weeks of cocaine SA training, single-unit recordings of NAcc neurons in male, Long-Evans rats were taken and analyzed in relation to calculated drug levels and observed drug consumption. A subset of neurons (15%) exhibited tuning to the maintenance threshold. These data suggest that the NAcc, via its downstream connections to motor areas, is involved in synthesizing information regarding proximity to preferred drug levels and influencing the occurrence of drug consumption.

Title: Exploring individual differences in rats' addiction susceptibility: drug level titration ability is inversely related to cue induced responding

Authors: *K. COFFEY[1], D. SHOLLER[2], M. WEST[2];
[1]Psychology, Rutgers Univ., Piscataway, NJ; [2]Rutgers, Piscataway, NJ

Abstracts: While only a sub-population of humans show substance abuse or dependence potential, methods for differentiating sub-populations of addiction-prone animals are lacking. In the present study, we sought to effectively characterize subjects who were susceptible to cue induced responding, a maladaptive trait which promotes substance dependence and relapse in humans. Animals were trained on a variable interval schedule of cocaine self-administration with a discriminative stimulus (SD) tone signaling drug availability. Animals' response variance was modeled with respect to calculated brain drug concentration and SD latency. Results demonstrate that animals' abilities to effectively titrate drug are learned and inversely related to responsiveness to the SD. Specifically, poor titration of drug levels is linked to higher cue-reactivity while animals that are better able to titrate their drug levels show little SD-driven responding. Moreover, subjects failed to respond during roughly 50% of signaled availability periods, with drug levels at missed availability periods consistently greater than drug levels at hit availability periods. A custom normalized titration metric (NTM) was calculated from the distribution of differences between drug levels during missed and hit trials for each animal. Low titration ability using this NTM also predicts SD-induced responding. Animals' titration abilities and SD-responsivity exist along a spectrum that is captured by our response variance calculation and NTM. These metrics may be adapted for use with many self-administration paradigms to determine addiction susceptibility, potentially facilitating future studies of behavioral, psychological, or genetic differences among individuals. Such endeavors could be used to characterize addiction susceptibility in humans or to develop more effective genetic or behavioral therapies.

Title: Potentiation of the expression of cocaine-induced sensitization by a conditioned stressor

Authors: *A. SASAKI[1], A. HUSSAIN[2], P. SHANMUGANATHAN[2], A. SIVAKUMARAN[2], S. SIVANATHAN[2], S. ERB[1,2];
[1]Dept. of Cell and Systems Biol., [2]Dept. of Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstracts: Stress is a major factor contributing to drug craving and relapse in humans, and in rodent models of drug seeking. Stress has also been found to cross-sensitize to the locomotor activating effects of psychostimulants in rodent models. In the present study, we examined the effect of a conditioned stressor on the expression of cocaine-induced sensitization in rats. More specifically, we determined whether a mint odor cue previously paired with footshock stress would elicit a sensitized locomotor response in rats previously given repeated exposures to cocaine. To this end, male Wistar rats were given once daily injections of cocaine (30mg/kg, i.p.) or saline for 6 days in locomotor monitoring chambers. Subsequently, equal numbers of rats in each drug condition were exposed to 15 min of brief, intermittent footshocks or no footshocks, either in the presence or absence of a mint odor cue. Odor-footshock pairing sessions occurred once daily sessions for 3 days. Approximately 5 days after the last of these sessions, all rats were given 3 locomotor tests for sensitization. The first was a test for conditioned locomotion, in which all rats were returned to the locomotor chambers in which cocaine or saline injections had been administered, and activity was monitored for 30 min; no injections or stress manipulations were given during this test. In the second test, all rats were exposed to the mint odor in the context of the locomotor chambers, in order to test for the cross-sensitizing effects of a conditioned stressor. In the third test, all rats were given a challenge injection of cocaine (10mg/kg, i.p.), either in the presence or absence of the mint odor. Irrespective of the prior stress condition, cocaine pre-exposed rats showed a robust conditioned locomotion effect upon re-exposure to the activity chambers in Test 1, and a sensitized locomotor effect in response to a challenge injection of cocaine in Test 3. Although the conditioned stressor itself did not elicit a cross-sensitized locomotor response in Test 2, it strongly potentiated the effect of a cocaine challenge in cocaine-sensitized rats in Test 3. That is, rats that had been given repeated cocaine injections followed by odor-footshock pairings showed a much higher level of activity in response to a cocaine challenge at test than did any other group. To our knowledge, this is the first report of a facilitation of cocaine-induced locomotor sensitization by a conditioned stressor.

Title: Aversive taste reactivity predicts escalation of cocaine self-administration behavior and preference in rats

Authors: *E. M. COLECHIO[1], D. N. ALEXANDER[2], C. G. IMPERIO[1], K. JACKSON[3], P. S. GRIGSON[2];
[1]Dept Neurosci, [2]Neural & Behavioral Sci., Penn State Hershey, HERSHEY, PA; [3]Lebanon Valley Col., Annville, PA

Abstracts: Addiction is a disease of chronic relapse, often elicited by drug-associated cues even after prolonged periods of abstinence. Therefore, understanding the link between cues and drugs of abuse is of great interest. Our central hypothesis focuses on elucidating the predictive value of early cue reactivity for later cocaine intake and addiction-like behaviors in a rodent model. Specifically, we tested whether taste reactivity (TR) to a drug-paired cue relatively early in acquisition can predict later escalation of cocaine self-administration behavior. Phase I. Rats received 6 TR-self-administration sessions. During each session, a Kool-Aid flavored saccharin solution was intraorally infused at a rate of 1 infusion/min for 30 min followed by a 2 h opportunity to self-administer 0.33 mg/infusion cocaine (n=17) or saline (n=5). Phase II. Thereafter, the rats were given 15 daily trials of 6 h access to cocaine (0.66 mg/infusion), after which the willingness to work for cocaine was assessed using progressive ratio (PR). Phase III. The relative value of the Kool-Aid-flavored saccharin cue vs. cocaine was assessed in a single 6-h two-choice test. Results. The results showed that greater aversive TR during Phase I was associated with escalated cocaine self-administration during the extended-access phase, a greater willingness to work for cocaine (PR), and an increased preference for cocaine over Kool-Aid-flavored saccharin when both were available. Thus, TR to the drug-paired cue early in training predicts later drug-taking behavior: eg., how fast a rat will take cocaine, how much cocaine the rat will take, whether drug-taking will escalate over time, how hard a rat will work for drug, and

whether a subject will prefer drug or the Kool-Aid flavored natural reward cue. This work was supported by DA009815.

Title: The modulating effects of rottlerin on psychostimulant-induced conditioned place preference

Authors: *T. LIAO, L. YU;
Inst. of Behavioral Medicine, Natl. Cheng K, Tainan, Taiwan

Abstracts: Brain-derived neurotrophic factor (BDNF) has been known to regulate cocaine-seeking behavior. Rottlerin can increase brain BDNF levels in a long-lasting manner. We hypothesized that rottlerin can decrease psychostimulant-induced conditioned place preference (CPP). To test this hypothesis, C57BL/6 mice were pretreated with single intraperitoneal rottlerin injection (5 mg/kg) immediately after the unconditioned place preference pretest. We found that such a treatment effectively decreased methamphetamine (MA)- (1 mg/kg/conditioning) and cocaine (10 mg/kg/conditioning)-induced CPP as three drug-place and vehicle-place conditionings were employed. Likewise, pretreatment with 7,8-dihydroxyflavone (10 mg/kg, i.p.), a selective TrkB agonist, prior to each cocaine-place conditioning was found to decrease cocaine-induced CPP. In an attempt to characterize the modulating effects of rottlerin on the maintenance of psychostimulant memory, single rottlerin injection was given approximately 24 hours before the 3-day forced extinction trainings. Rottlerin (5 mg/kg) did not affect the extinction of the psychostimulant-induced CPP but to significantly decrease the drug-primed reinstatement of psychostimulant-induced CPP. These results, taken together, suggest that systemic rottlerin administration may be beneficial in decreasing the hedonic value of psychostimulants and facilitating the forgetting of the psychostimulant-associated memory.

Title: The development of novel dopamine D3 receptor-selective partial agonists as potential medications to treat psychostimulant abuse

Authors: *C. A. BOATENG[1], O. M. OKUNOLA-BAKARE[1], T. M. KECK[1], C. BURZYNSKI[1], C. SCHWEPPE[1], R. RAIS[2], B. SLUSHER[2], P. DONTHAMSETTI[3], J. A. JAVITCH[3], W. JOHN[4], P. CZOTY[4], M. A. NADER[4], A. H. NEWMAN[1];

Abstracts: The dopamine D3 receptor (D3R) is involved in brain reward pathways and is a promising therapeutic target for treatment of substance abuse and other neuropsychiatric disorders. Several highly selective D3R antagonists and partial agonists based on the 4-phenylpiperazine scaffold have been discovered. One of the most selective and high affinity D3R partial agonists, (±)PG648 (N-(4-(4-(2,3-dichloro-phenyl)piperazin-1-yl)-3-hydroxybutyl)-1H-indole-2-carboxamide; Newman et al. 2009) and its enantiomers were selected as leads for behavioral evaluation, first in a quinpirole-elicited yawning model of D3R *in vivo* activity and later in both rodent and nonhuman primate models of psychostimulant abuse. Although microsomal stability, pharmacokinetic and behavioral data in rodents looked promising, PG648 was not active in nonhuman primates. We hypothesized that either bioavailability/metabolism in the rhesus monkeys was different from rodents or its very high D3R selectivity was problematic. In order to address these questions, we have prepared analogues in which the 2,3-diCl-phenyl

piperazine was replaced with either a 2-OMe, -3-Cl- or a 2,3-naphthyl-substituent. In addition, bioisosteric replacement of the indole in PG648 with quinoline was also explored. We also prepared analogues with either the unsubstituted or the 3-OH substituted 4-carbon linker between the arylpiperazine and aryl amide to determine its effects on D3R affinity, selectivity, efficacy and metabolic stability. Thirty-two novel ligands were synthesized by conjugating 4-bromobutyl- or epoxideethylphthalimide with the substituted arylpiperazines. The resulting intermediates were deprotected to give the primary amines, which were coupled with the arylcarboxylic acids to give the desired 3-OH-substituted or unsubstituted carboxamides. Binding affinities were determined using [3H]NMS radioligand binding competition assays in membranes prepared from HEK293 cells expressing human dopamine D2-like receptors. By varying the arylpiperazine substitution, we found several ligands displayed high affinity (Ki=0.1-3.6 nM) and (20-100-fold) selectivity profiles at the D3 versus D2 receptors. Based on binding profiles, a subset of analogues was evaluated in a D3R BRET1-based GαoA activation functional assay and for mouse microsomal stability. These new lead compounds are currently being evaluated in models of psychostimulant abuse and preliminary data suggest that chemical modification of PG648 has resulted in promising behavioral activity in nonhuman primates.

Title: The use of 6Beta Naltrexol to treat anxiety and depression during acute cocaine withdrawal

Authors: *M. J. MUELLER[1], T. DEYOUNG[2], J. BOYETTE-DAVIS[2];
[1]York Col. of Pennsylvania, New Park, PA; [2]York Col. of Pennsylvania, York, PA

Abstracts: Cocaine addiction has been and continues to be an issue in today's society with 16.5% of those aged 26 and older using cocaine at some point in their lifetime. Withdrawal symptoms are unpleasant and include an overwhelming craving for the drug as well as fatigue,

anxiety, sleeplessness, irritability and depression. Naltrexone has been used to decrease withdrawal from various addictive substances, including alcohol and narcotics. Unfortunately, various reports have found that withdrawal symptoms may temporarily increase with the use of Naltrexone. More recent reports have found that 6Beta Naltrexol, a novel neutral receptor antagonist, lessens withdrawal symptoms for alcohol cessation. This study investigated the effects of Naltrexone and 6Beta Naltrexol on cocaine withdrawal. Twenty-seven male Sprague Dawley rats received injections of 15mg/kg of cocaine for 14 consecutive days. The rats were withdrawn from the drug for 24 hours prior to the beginning of behavioral testing. Anxiety and depression were assessed in the rats using the elevated plus maze (EPM) and the forced swim test (FST), respectively. The results showed that half of the rats responded to the drugs while the other half did not. When the rats were split into high-responders and low-responders, it was found that those who were high-responders to the drugs experienced significantly less anxiety and depression. This study may have implications for the medications given to an addict when they are experiencing cocaine withdrawal.

Title: Neuronal correlates of resilience to cocaine addiction in rats

Authors: ***Y. VANDAELE**, S. NAVAILLES, A. DURAND, K. GUILLEM, S. AHMED; Gironde, IMN UMR 5293, Bordeaux, France

Abstracts: When faced with a choice between two competing actions, taking cocaine or drinking sweet water, most rats prefer the nondrug activity, even after prolonged drug use. Only few rats prefer the drug. These findings suggest that, like in people, most rats would be resilient to addiction while a minority would be vulnerable. Here we sought to unravel the neuronal correlates of resilience to addiction. We imaged brain activity in the majority of nondrug-preferring rats in response to cocaine versus sweet water (the preferred activity), using large-scale Fos mapping. Rather surprisingly, we found that the preferred activity induced little specific brain activity, except in the thalamocortical gustatory pathway. In contrast, cocaine taking elicited more brain activity; particularly in brain regions involved in reward omission and frustration (e.g., the lateral habenula and the tail of the VTA). We hypothesize that this result likely reflects the frustration of not having access to the preferred reward during testing. We are currently testing this hypothesis by imaging brain activity in nondrug-preferring rats in experimental conditions that rule out the involvement of preferred reward omission and frustration. We will also compare and contrast the obtained pattern of brain activity to that observed in drug-preferring rats. Ultimately, this work will identify specific neuronal correlates of resilience and vulnerability to cocaine addiction.

Title: The modulating effects of companions on cocaine-induced conditioned place preference

Authors: *W.-Y. TZENG[1], L. YU[2];
[1]Inst. of Basic Med. Sci. of NCKU, Tainan, Taiwan; [2]Inst. of Behavioral Med. of NCKU, Tainan, Taiwan

Abstracts: A number of social factors have been known to affect drug use and the development of drug dependence. Lately, we found that the presence of three cocaine-free or -treated companions in cocaine conditionings reliably decreased the magnitude of cocaine-induced

conditioned place preference (CPP) especially as moderate doses (10 and 20 mg/kg/conditioning) of cocaine were used. We hereby further showed that the presence of three methamphetamine (MA)-treated (1 mg/kg) companions also decreased cocaine (20 mg/kg/conditioning)-induced CPP. Likewise, the presence of three saline-treated companions during the MA (1 mg/kg/conditioning) conditionings significantly decreased the magnitude of MA-induced CPP. Finally, ibotenic acid (5 μg/side) infusion-produced lesion was performed in bilateral dorsal hippocampus (DH) and amygdala (Amg) three days prior to the unconditioned preference pretest. The results showed that bilateral amygdalar or hippocampal lesion per se did not affect the magnitude of cocaine-induced CPP. Nonetheless, bilateral amygdalar, not hippocampal, lesion abolished the companion-produced decreasing effects on cocaine-induced CPP. The results, taken together, suggest that the presence of companions during psycho-stimulant conditionings can diminish the psycho-stimulant-induced CPP. Moreover, Amg is necessary for mediating the companions' decreasing effects on cocaine-induced CPP.

Title: Effects of Δ^8-Tetrahydrocannabivarin (Δ^8-THCV) on appetitive effects of cocaine and nicotine in rodents

Authors: *E. L. GARDNER[1], P. MULDOON[2], X.-F. WANG[1], G.-H. BI[1], M. DAMAJ[2], A. H. LICHTMAN[2], R. G. PERTWEE[3], Z.-X. XI[1];
[1]Chem Biol Res. Br., NIDA/IRP, BALTIMORE, MD; [2]Dept. of Pharmacol. and Toxicology, Virginia Commonwealth Univ., Richmond, VA; [3]Sch. of Med. Sciences, Inst. of Med. Sci., Univ. of Aberdeen, Aberdeen, United Kingdom

Abstracts: Growing evidence suggests that blockade of brain cannabinoid CB_1 receptors or activation of brain cannabinoid CB_2 receptors attenuates the rewarding effects of cocaine or other addictive drugs such as nicotine. Δ^8-Tetrahydrocannabivarin (Δ^8-THCV) is a synthetic analogue of the plant cannabinoid Δ^9-tetrahydrocannabivarin (Δ^9-THCV), which exhibits CB_1

receptor antagonist and CB_2 receptor agonist profiles. Thus, dual CB_1 receptor blockade and CB_2 receptor activation might produce an additive or synergistic therapeutic anti-reward effect. To test this hypothesis, we observed the effects of Δ^8-THCV on cocaine and on nicotine self-administration and other addiction-related behavior. We found that systemic administration of Δ^8-THCV (3, 10, 20 mg/kg, i.p.) failed to alter intravenous cocaine self-administration in wild-type or CB_2 receptor-knockout mice, but dose-dependently inhibited intravenous nicotine self-administration in alcohol-preferring rats and wild-type mice. Co-administration of Δ^8-THCV and AM630, a selective CB_2 receptor antagonist, blocked Δ^8-THCV's action in alcohol-preferring rats, and genetic deletion of CB_2 receptors (in CB_2 receptor-knockout mice) partially attenuated Δ^8-THCV's action on nicotine self-administration. Also, systemic administration of Δ^8-THCV (0.3-3 mg/kg, i.p.) inhibited nicotine-induced conditioned place preference and nicotine-seeking behavior in wild-type mice during extinction in the absence of nicotine and nicotine-associated cues. Further, CB_2 receptor-knockout mice show significantly lower levels of nicotine self-administration with longer inter-infusion intervals than their wild-type littermates, an effect similar to drug-taking behavior maintained by a higher dose of nicotine. Taken together, these findings suggest that: 1) Δ^8-THCV may have anti-nicotine, but not anti-cocaine, therapeutic effects - partially mediated by activation of CB_2 receptors; and 2) deletion of CB_2 receptors appears to enhance nicotine's rewarding effects. Further studies are required to confirm these findings.

Title: Taking cocaine versus staying on task: Drug cue-evoked competition for attention and individual differences in vulnerability to cue-evoked task shifts

Authors: *K. PITCHERS, C. J. SKRZYNSKI, T. E. ROBINSON, M. SARTER;
Psychology, Univ. of Michigan, Ann Arbor, MI

Abstracts: Subjects vulnerable for addiction-like behavior have a propensity for transforming conditioned reward cues to cues that capture their attention and instigate cue-directed behavior. The goals of this research are to develop a behavioral paradigm for determining the power of drug cues to shift subjects from performing a food-rewarded attention task to taking drug, to determine individual variation in the power of drug cues to do so, the neurobiological mediation of such variation, and to find treatments that increase the resistance of subjects to disengage from the task. Rats acquired an operant sustained attention task (SAT), which involved the reporting of hits and correct rejections (water-rewarded), and misses and false alarms (not rewarded) via retractable levers. Next, they were trained to self-administer cocaine, and after the acquisition of stable self-administration behavior, were either maintained on a FR schedule (nose-pokes; infusion criterion 40; IC40) or shifted to a second self-administration procedure: intermittent access (IntA). For IntA training, cocaine access was limited to 5-min periods cued by a tone (DS+), alternating with 25-min timeout periods (DS-, white noise). After stable behavior the propensity to shift from one task (SAT) to self-administration was assessed in chambers equipped with nose-poke ports placed at the opposite wall of the SAT intelligence panel. In IC40 animals, the presence of the nose-poke ports and concomitant availability of cocaine did not immediately disrupt SAT performance as rats only gradually switched to drug-taking late during SAT session. In contrast, in IntA rats, the presentation of the DS+ at the 10 min mark evoked an immediate switch away from SAT to drug-taking. Ongoing research will determine whether rats classified as sign- and goal-trackers differ in their vulnerability to DS+-evoked task shifts and whether this vulnerability can be improved with enhancement of the cholinergic system. Our paradigm models the power of drug cues, as opposed to unrestricted access to drug-taking, to deprioritize SAT performance and thus, is suitable for studying the cognitive and neurobiological mechanisms via which drug cues trigger drug-taking and relapse.

Title: Effects of sensory overstimulation in early life on vulnerability to cocaine addiction

Authors: *S. RAVINDER, D. A. CHRISTAKIS, J. M. RAMIREZ, S. M. FERGUSON; Seattle Children's Res. Inst., Seattle, WA

Abstracts: We have previously developed a rodent model of "excessive non-normative stimulation" which mimics excessive media use in infants and toddlers whereby mice are exposed to audio stimuli (clips from the cartoon network channel) paired with visual stimulation (flashing lights) for six hours per day, starting at P10, for a total of 42 days. When tested subsequently, overstimulated mice demonstrate increased risk taking, decreased anxiety, poorer short-term memory and impaired learning relative to controls. In this study, we investigated the relationship between excessive non-normative stimulation early in life and vulnerability to drugs of abuse in adulthood by studying cocaine-induced psychomotor sensitization. Following sensory overstimulation, male CD-1 mice received 10 daily injections of cocaine (15mg/kg) or saline over a 2-week treatment period. After a 2-week withdrawal, all mice received an escalating dose challenge of cocaine (saline, 10mg/kg, 20mg/kg). Locomotor activity, monitored for 60 mins after each injection, was used as an index of psychomotor sensitization. We found that saline-treated overstimulated mice were hyperactive compared to controls, yet there did not appear to be differences between groups in locomotor responses following cocaine treatment. However, when normalizing to the hyperactive baseline, overstimulated mice displayed blunted locomotor sensitization to cocaine. Nonetheless, because of the differences in locomotor baselines we are currently conducting conditioned place preference experiments to further assess whether overstimulated mice show differences in drug abuse vulnerability. Our results suggest that non-normative overstimulation modifies the dopaminergic system leading to a blunted cocaine response and studies are underway to assess physiological changes in the VTA dopaminergic neurons of overstimulated mice to examine this. These findings are interesting in the context of ADHD, as Ritalin treatment blunts hyperactive responses in patients but has the opposite effect in controls. In addition, our observations are consistent with a large body of literature which suggests that exposure to positive as well as negative experiences early in life can have a profound impact on behavioral traits and can modulate vulnerability to developing neuropsychiatric illnesses.

Title: Psychopharmacological responsiveness to cocaine across early ontogeny: possible role of D2High receptors

Authors: *S. E. EATON, A. MOHD-YUSOF, C. A. CRAWFORD, S. A. MCDOUGALL; Dept. of Psychology, California State Univ., San Bernardino, CA

Abstracts: Research suggests that sensitivity to dopaminergic drugs varies across ontogeny, with behavioral responsiveness to psychostimulants being greater during the preweanling period than in adulthood. Adolescence, which is a developmental epoch that falls between the preweanling period and adulthood, is a time of unique behavioral responsiveness to psychostimulant drugs. It is most frequently reported that cocaine and amphetamine produce a hypoactive behavioral response in adolescent animals when compared to younger and older age groups. Curiously, other researchers report a nearly opposite pattern of effects, with acute and repeated cocaine treatment causing hyperresponsiveness during the adolescent period. The neural mechanisms responsible for these age-dependent differences in behavioral responsiveness are uncertain, but they cannot be explained in terms of ontogenetic changes in dopamine receptor numbers (i.e., maturational changes in D1 and D2 receptor densities do not correspond to alterations in drug sensitivity). Instead, it is possible that age-dependent differences in the percentage of high affinity D2 receptors, rather than overall receptor numbers, might account for ontogenetic changes in drug sensitivity. To test this hypothesis, $D2^{High}$ receptors in the dorsal striatum of male and female rats were measured during the preweanling period (i.e., PD 5, PD 10, PD 15, and PD 20), adolescence (PD 40), and adulthood (PD 80). Behavioral responsiveness to cocaine was assessed at PD 20, PD 40, and PD 80. D2 specific binding and the ratio of $D2^{High}$ receptors was measured in the dorsal striatum using [^{3}H]-domperidone; whereas, behavioral responsiveness to cocaine (0, 2.5, 5, 10, or 20 mg/kg) was assessed in automated activity chambers during a 120 min testing session. On the two days prior to cocaine testing, rats were injected with saline and habituated to the activity chambers for 60 min. Results showed that the percentage of dorsal striatal $D2^{High}$ receptors was significantly greater in preweanling rats (48.78%) than in adolescent (24.06%) or adult (24.39%) rats. Among the various preweanling age groups (PD 5, PD 10, PD 15, and PD 20) there was no difference in the percentage of $D2^{High}$ receptors. In terms of the behavioral data, rats tested with cocaine on PD 20 exhibited greater

behavioral responsiveness than the two older age groups. This pattern of results is consistent with the hypothesis that age-dependent changes in the percentage of $D2^{High}$ receptors are responsible for ontogenetic differences in sensitivity to psychostimulant drugs.

Title: A novel neuropeptide regulator of behavioral responses to cocaine

Authors: *J. KASPER[1], C. R. BENZON[2], D. L. MCCUE[3], J. D. HOMMEL[2];
[1]Univ. Texas Med. Br., Galveston, ; [2]Pharmacol. and Toxicology, [3]Neurosci., Univ. of Texas - Med. Br., Galveston, TX

Abstracts: Neuromedin U (NMU) is a neuropeptide expressed in the brain, including the mesolimbic pathway. While NMU has been studied for its ability to regulate food reward, NMU has not been studied in the context of drugs of abuse (e.g., cocaine). Therefore, we evaluated the effects of NMU on behavioral sensitization to cocaine, a behavior that is dependent on neural plasticity in the nucleus accumbens shell (NAcSh). In this study, NMU was microinjected directly to the NAcSh of cocaine sensitized and non-sensitized rats shortly before a cocaine challenge. NMU was found to decrease acute, but not sensitized, cocaine-evoked locomotion. This suggests that NMU signaling regulates the acute locomotor response to cocaine. In a separate experiment, NMU blocked cocaine-evoked locomotion on challenge day when administered throughout sensitization. Taken together, these data indicate that NMU signaling in the NAcSh modulates the development of behavioral sensitization to cocaine. The neural pathways that might underlie the change in locomotor activity were investigated using confocal microscopy with immunofluorescence. The primary receptor for NMU in the brain, NMU

receptor 2 (NMUR2) was found in the NAcSh and colocalizes with synapsin I and GAD67, markers of synapses and GABAergic neurons respectively. Furthermore, anterograde viral tracers injected into the dorsal raphe nucleus suggest that synaptic NMUR2 in the nucleus accumbens is associated with dorsal raphe neurons. This work suggests a novel NMU pathway from the dorsal raphe to the nucleus accumbens which is capable of regulating behavioral responses to cocaine.

Title: Synergistic effects of pilocarpine and tacrine on cocaine-reinforced behavior

Authors: *F.-C. YANG, H. XU, K. GRASING;
Dept. of Res. and Develop., Kansas City VA Med. Ctr., Kansas City, MO

Abstracts: Muscarinic agonists cause pronounced reductions in drug-reinforced responding, especially if they exhibit selectivity for the M1 muscarinic receptor subtype. Pilocarpine is a muscarinic agonist which shows good M1 selectivity in transformed cells, and has an acceptable safety profile in humans. Tacrine is an additional agent that strongly attenuates drug-reinforced behavior. To compare their respective mechanisms, we evaluated intravenous self-administration of cocaine after separate or combined treatment with pilocarpine and tacrine. METHODS: Rats were trained to self-administer cocaine under a fixed-ratio-5 (FR-5) schedule during two-hour multiple-component sessions in which 0.1, 0.2, and 0.4 mg/kg per injection of cocaine were each available for 40 minutes (low, intermediate, or high doses, respectively). Following intraperitoneal treatment with test compounds at low, intermediate, or high doses (1.0, 3.2, or 10 mg/kg-injection), rats were allowed to self-administer intravenous cocaine. RESULTS: Pretreatment with either pilocarpine or tacrine caused linear reductions in cocaine-reinforced responding, with high doses attenuating responding by more than 80% for low-dose cocaine.

After receiving combined treatment attenuation of responding for intermediate-dose cocaine was greater than additive effects of either agent. CONCLUSION: Based on this, we propose that the different mechanism underlying pilocarpine and tacrine effects on cocaine-reinforced responding exhibit synergism. Future studies should investigate the neurotransmitter changes underlying these actions. Because they are clinically available, pretreatment with pilocarpine and an monoamine oxidase inhibit may be a productive avenue for therapy of substance abuse disorders.

Title: Cocaine induces a persistent dose-dependent place-preference response in marmoset monkeys

Authors: ***A. C. BORGES**[1], R. B. M. DUARTE[2], L. L. NOGUEIRA[2], A. BORGES[2], M. BARROS[3];
[1]Univ. De Brasília, Brasilia, Brazil; [3]Dept. of Pharmaceut. Sciences, Sch. of Hlth. Sci., [2]Univ. de Brasilia, Brasília, Brazil

Abstracts: Place conditioning (CPP) using psychostimulant drugs has been extensively used in rodents, but few studies have analyzed drug-induced CPP in non-human primates. A previous study in our lab showed that a daily 5mg/kg i.pinjection of cocaine induced CPP in marmosets after nine consecutive sessions. Here we tested the influence of doses and the number of drug-context pairings on the magnitude and the duration of retention of cocaine-induced CPP in ten adult male marmoset monkeys (Callithrix penicillata). The CPP box consisted of a rectangular box with two compartments with different tactile and visual cues. A central door allowed the subjects entered to the apparatus. Tests were held from 13:00 to 17:00 h. The procedure was divided into three phases: Habituation: consisting of two consecutive 20-min sessions (days 1 and 2) with free access to both compartments. Conditioning: training was conducted for twelve

days (six drug sessions and six saline sessions) in which subjects received cocaine (3 or 7 mg/kg/i.p. according to their group) or saline (1ml/kg/i.p.) injections and were immediately confined in the drug- or the saline-paired compartments for 20 min. Tests: conducted on days 9 and 16. Animals were allowed to explore both compartments of the apparatus for 20 min. The preference was assigned by comparing the time spent in the drug-paired compartment in the habituation with total time spent during tests sessions. Results from habituation showed that the subjects had no inherent preferences for one specific compartment. We found that, after three cocaine-pairing sessions, a CPP response was observed only for the group that received the lower dose. The higher dose tended to increase time in the conditioned compartment but it did not reach statistical relevance. On the other hand, after the 6th drug-pairing session, there was a CPP of similar magnitude for both doses of cocaine tested. Fifteen days after the last drug-conditioning training, CPP remained only for the higher dose of cocaine tested. It is possible that the higher dose of cocaine initially caused aversion and CPP was only established when the aversive effect of the higher doses has been decreasing or changes in the brain occurred. The lower dose, although initially creating CPP, might not have long-lasting effects on the brain's circuitry.

Title: Ceftriaxone attenuates acquisition and facilitates extinction of cocaine-induced suppression in C57BL/6J mice

Authors: *C. S. FREET[1], A. L. LAWRENCE[2];
[1]Dept Neural & Behav Sci., Penn State Coll Med., HERSHEY, PA; [2]The Lincoln Univ., Lincoln University, PA

Abstracts: Rodents avoid intake of a palatable natural reward when paired with a drug of abuse such as cocaine (Cappell, LeBlanc, & Endrenyi, 1973; Carey & Goodall, 1974; Goudie, Dickins, & Thornton, 1978). As such, cocaine-induced suppression models an important criterion for

substance use disorder found in the DSM-5 (i.e., loss of important or desired activities due to drug use). Growing evidence implicates glutamate homeostasis in a number of behaviors observed in addiction such as acquisition of drug taking, motivation and reinstatement (Ward et al., 2011; Knackstedt et al., 2010). The aim of the current study was to evaluate the beta-lactam antibiotic, ceftriaxone, which has been shown to normalize disrupted glutamate homeostasis associated with exposure to drugs of abuse, in the acquisition and extinction of cocaine-induced suppression in C57BL/6J mice. Individual differences in cocaine-induced suppression were observed (i.e., low and high suppressors) with differential effects of ceftriaxone. Ceftriaxone delayed suppression of saccharin intake in high suppressors but eliminated suppression in low suppressors. In addition, ceftriaxone history facilitated extinction in the high suppressors. These data suggest that changes in glutamate homeostasis may be involved in the development of cocaine-induced suppression of saccharin intake and that individual differences significantly influence the response of this system to cocaine.

Title: Rats with a cocaine history develop compulsive appetite due to disruption in non-homeostatic control of food intake

Authors: *F. WEISS[1], Y. HAO[1], A. MATZEU[1], G. DE GUGLIELMO[1], P. PANDAY[1], T. KERR[1], R. MARTIN-FARDON[1], T. C. JHOU[2], R. C. RITTER[3], N. SUTO[1];

Abstracts: Obesity and pathological overeating have received increasing recognition as disorders of 'food addiction' because of their similarities to substance dependence in behavioral manifestations and neurobiological underpinnings. However, the applicability of this nosology remains a matter of debate. We hypothesized that a cocaine history known to result in addiction-like drug motivation and corresponding brain changes would result in similar addiction-like motivation for food. Separate groups of rats were allowed to self-administer saccharine or cocaine. Extended daily access to cocaine (6h/day or 'long access' [LgA]) resulted in escalated cocaine intake, whereas limited access (1hr/day or 'short access' [ShA]) did not, as previously reported. All rats then were given the opportunity to self-administer a food reward, sweetened condensed milk (SCM). A cocaine (both LgA and ShA) but not saccharine history was associated with heightened SCM seeking and intake, characterized by heightened resistance to extinction, increased workload, and punishment, as described for drug addiction. Importantly, this occurred without significant changes in bodyweight and baseline feeding. The failure to show weight gain and overeating per se suggests that the addiction-like appetitive behavior or 'compulsive appetite' that developed in rats with a cocaine history is due to dysregulation of non-homeostatic (non-metabolic) rather than homeostatic (metabolic) control of food intake. Consistent with this hypothesis, rats with a cocaine history exhibited heightened resistance to punishment when responses reinforced by a non-caloric palatable reinforcer, saccharine, were paired with electric footshock. Moreover, rats with a cocaine history showed functional upregulation of group II metabotropic receptors (mGluR2/3) in the medial prefrontal cortex (mPFC) and amygdala, brain sites implicated in non-homeostatic control of food intake. These receptors negatively modulate neural excitability, possibly contributing to the impaired functional connectivity between mPFC and amygdala observed in drug addicts. Overall, the current findings suggest that the nosology of addiction is most applicable to phenotypes of eating disorders that are characterized by compulsive appetite such as binge-eating disorder and bulimia nervosa. Neurobiological irregularities in the non-homeostatic pathway - abnormalities akin to those observed in drug addicts - possibly provide a neuroregulatory basis for compulsive appetite. **Support:** NIDA/NIH DA007348 (F.W.), DA008467 (F.W.), DA033533 (N.S), DA033344 (R.M.F.), DA032898 (T.C.J.).

Title: Cocaine-conditioned locomotor response is mediated by reactive oxygen species signaling

Authors: *J. D. NGUYEN, M. J. FORSTER;
Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstracts: We have previously shown that compounds that produce alterations in cellular redox state can modulate the cocaine-conditioned locomotor response; however, the role of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase-generated reactive oxygen species (ROS) has not been well characterized. Compounds that modulate intracellular and extracellular ROS signaling mechanisms were tested for their effects on the acquisition and expression of context-dependent increases in locomotion produced by a single exposure to cocaine. Cocaine (40 mg/kg) was administered to different groups of Swiss-Webster mice via intraperitoneal injection (i.p) in either a locomotor activity testing apparatus or the home cage, 2 hours following an activity test under saline. Mice placed in the testing chambers were given 30 minutes to explore freely and locomotion was monitored. A conditioned effect of cocaine was inferred by an increase in horizontal activity counts relative to home cage cocaine controls during a test in the same apparatus on the following day. N-acetylcysteine (10-250 mg/kg), dimethylthiourea (5-50 mg/kg), L-ascorbic acid (25-500 mg/kg), alpha-tocopherol (25-100 mg/kg), apocynin (1-50 mg/kg), or vehicle was administered prior to placement into the activity chamber on the test day. N-acetylcysteine and dimethylthiourea inhibited the expression and the acquisition of cocaine-conditioned locomotion, L-ascorbic acid and apocynin increased acquisition and expression of the conditioned effect, respectively, and alpha-tocopherol failed to affect the conditioned response. These results suggest that (i) attenuation of cocaine-conditioned behavior may be achieved by modulation of cellular redox state, (ii) a facilitation of the conditioned response may be due to pro-oxidizing redox state or inhibition of NADPH oxidase, and (iii) attenuation of the actions of ROS in cell membranes is not sufficient to prevent conditioning. Thus, ROS signals may mediate context associations during the development of addiction. These findings further support the potential value of redox modulating compounds as targets for addiction treatment.

Title: Cocaine pre-treatment induces a shift in the balance of motivational control over behavior in approach-avoidance conflict paradigms

Authors: *D. NGUYEN, S. ERB, R. ITO;
Psychology, Univ. of Toronto Scarborough, Toronto, ON, Canada

Abstracts: Addiction is a disease characterized by persistence to seek drug reinforcement despite negative consequences. Such maladaptive behaviors are attributable to drug-induced neuronal adaptations in the cortico-limbic-striatal circuitry implicated in learning, motivation, inhibitory control, and decision making. Dysregulation of neurotransmission in this circuitry is suggested to contribute to aberrant approach and avoidance processing for motivationally relevant stimuli, thus producing a bias towards appetitive behaviors and facilitating the development and sustenance of an addiction phenotype. Although enhanced reward seeking may result from a shift in balance of behavioral control by competing neuronal processes, the effects of repeated drug exposure on the resolution of motivational conflict under conditions wherein appetitive and avoidance motivations are simultaneously evoked have yet to be thoroughly investigated. In the present study, male Long Evans rats received daily IP injections of 30 mg/kg cocaine or saline for 7 d. Following a 10 d drug-free period, rats were tested in one of three behavioral paradigms. In the runway paradigm, rats learned that entering the goal compartment of a runway apparatus would lead to sucrose reward along with shock administrations. Latency to enter the goal compartment was taken as a measure of motivational conflict. In our radial arm maze paradigm, rats were conditioned to associate separate texture bar cues with either the delivery of sucrose or shock in the arms in which the cues were presented. Exploration time was then assessed in a final conflict test during which rats freely explored two maze arms containing either a neutral cue or a superposition of the appetitive and aversive cues for 5 min. For our active avoidance paradigm, rats were conditioned to lever press to avoid impending shock upon presentation of a conditioned tone stimulus. They were then tested in a conflict situation in which they could lever press to either avoid impending shock or to receive sucrose reward. Our results revealed that cocaine pre-treated rats display lower latencies to enter the mixed valence goal compartment in the runway. Cocaine pre-treated rats also showed a delay in learning for the aversive cue association in the radial arm maze. Finally, our preliminary data suggest that

cocaine pre-treated rats show impairment in acquisition of avoidance responding when motivational conflict is evoked in the active avoidance paradigm. Together, we conclude that neuronal imbalances induced by repeated cocaine exposure allow appetitive motivations to gain greater influence over behavioral output *in situ*ations of motivational conflict.

Title: Exposure to a high-fat diet attenuates the locomotor-stimulating effects of cocaine

Authors: *P. M. DINGESS[1], B. J. ANDERSON[2], A. E. CREAGER[2], R. A. DARLING[1], E. K. DOLENCE[2], T. E. BROWN[1];
[1]Neurosci., [2]Pharm., Univ. of Wyoming, Laramie, WY

Abstracts: According to the National Institute of Health over consumption of diets rich in high-fat (HF) is one of the contributing factors to the obesity epidemic. Various laboratories have shown that exposure to a HF diet evokes changes in dopaminergic signaling within the reward circuitry. However, the effect HF has on general reward processing is still unclear. In our first set of experiments, we examined the effects of HF diets on cocaine-induced locomotion to assess whether HF may influence the sensitivity to the stimulating effects of cocaine. Rats were placed on either a normal chow (NC), HF *ad libitum*, or HF calorically restricted diet for 1 or 3 weeks. Animals were then tested in locomotor boxes to assess activity via photobeam breaks. Cumulative activity induced by novelty, saline injection (intraperitoneal (i.p.)) or cocaine (5 or 15mg/kg, i.p.) was assessed for each dietary condition. At 1 week there was a significant gain in body weight but no significant differences in any of the dietary groups with regard to locomotor activity. However at 3 weeks, there was a significant increase in body weight and decrease in beam breaks in the HF group injected with 15 mg/kg cocaine (21,128 ± 1,721, n=14) compared to NC (33,705 ± 2,965, n=8). The same reduction in cocaine-induced (15mg/kg) locomotor

activity was observed in the HF calorically restricted group (20,286 ± 2,623, n=14) when compared to normal chow controls (30,342 ± 3241, n=9). Our results indicate that the HF diet is having an effect on cocaine-induced locomotor activity and this effect is independent of body weight. To address whether there is a general hypo-responsiveness of the reward circuitry in animals exposed to a HF diet an additional set of rats were placed on *ad libitum* HF or NC diets for 3 weeks, fasted for a 24-hr period and subsequently tested in an overnight sucrose self-administration task. Our results show that rats fed a HF diet have a significant attenuation in lever responses (429 ± 50, n=6) compared to the NC controls (858 ± 45, n=8). In our final experiment, animals were fed either a HF calorically restricted or NC *ad libitum* diet for 3 weeks. Following dietary exposure, extracellular basal dopamine levels were assessed using high-performance liquid chromatography (HPLC) in the prefrontal cortex (PFC), nucleus accumbens (NAc), ventral tegmental area (VTA), hippocampus, and amygdala. Our results demonstrate a significant increase in basal dopamine in the PFC in the HF group (979.487 ± 410.584, n=8) relative to NC controls (100.000 ± 40.176, n=8). Overall, our results lead us to conclude that exposure to the HF diet elicits changes in reward processing that manifests as a reduction in reward sensitivity.

Title: Characterization of the role of limbic p11 on addiction and depression

Authors: *M. ARANGO[1], J. T. SCHWARZ[3], M. VERNOV[4], I. NINAN[5], R. MARONGIU[4], F. JEANNETEAU[2], E. J. NESTLER[6], P. GREENGARD[7], S. RUSSO[6], M. G. KAPLITT[3]; [1]Neurolog. Surgery, [2]Inst. of Functional Genomics, Montpellier, France; [3]Neurolog. Surgery,

[4]Weill Cornell Med. Col., New York, NY; [5]New York Univ., New York, NY; [6]Friedman Brain Institute, Icahn Sch. of Med. at Mount Sinai, New York, NY; [7]Rockefeller Univ., New York, NY

Abstracts: The high rate of comorbidity between depression and cocaine addiction suggests shared molecular mechanisms and anatomical pathways. Here we investigate the contribution of p11 (S100A10) in two limbic structures, the Nucleus Accumbens (NAc), and the infralimbic Cortex (ILc) in both disorders. We have previously shown that downregulation of p11, a critical adaptor protein, specifically in the NAc elicits depressive-like behaviors in mice but its role in drug addiction is unknown. Conversely, human imaging has evidenced the involvement of the NAc and ILC on depression, yet the contribution of ILc p11 on depression is unknown. We combine mouse genetics and viral strategies to titrate p11 levels within the ILc, the NAc or its specific cell types. We investigate how p11 in the NAc affects the rewarding actions of cocaine on behavior and molecular correlates; and how ILc p11 contributes to ILc connectivity and tricyclic antidepressant response. We demonstrate that p11 knockout mice have enhanced cocaine conditioned place preference, which is reproduced by the focal downregulation of p11 in the NAc of wild-type mice. In wild-type mice, cocaine inhibited p11 expression in the NAc, while p11 overexpression exclusively in the NAc reduced cocaine CPP. Finally, we identify dopamine receptor-1 expressing medium spiny neurons as key mediators of p11's effects on cocaine reward. We show that ILc p11 does not mediate depressive-like phenotypes, but ILc p11 defficiency facilitates rapid onset antidepressant effects of imipramine, and mimic the effect of chronic imipramine treatment on the novelty induced hypophagia test. Our data provide evidence that disruption of p11 homeostasis in the NAc and ILc may underlie pathophysiological mechanisms of comorbid ailments as depressive disorders and of cocaine addiction.

Title: Epigenetic readers of lysine acetylation regulate cocaine-induced behavioral plasticity

Authors: *G. C. SARTOR, S. K. POWELL, S. P. BROTHERS, C. WAHLESTEDT;
Univ. of Miami Miller Sch. of Med., Miami, FL

Abstracts: Epigenetic processes that regulate histone acetylation play a critical role in behavioral and molecular responses to cocaine. However, to date, only a small fraction of the mechanisms involved in the addiction-associated acetylome have been investigated. 'Readers' of acetylated histone, referred as bromodomain containing proteins, have recently been shown to be key regulators of chromatin dynamics and disease state, but their role in addiction is unknown. Here, we found that chronic cocaine exposure and cocaine self-administration significantly increased expression of the BET bromodomain protein, Brd4 (but not Brd2 or Brd3) in the nucleus accumbens (NAc) of rats and mice. Behaviorally, we found that systemic and intra-accumbal administration of the BET bromodomain (BRD2, BRD3, BRD4, and BRDT) inhibitor, JQ1, reduced acquisition of cocaine conditioned place preference (CPP) in mice, whereas a similar bromodomain inhibitor that does not cross the blood brain barrier (I-BET 151, 50 mg/kg, i.p.) had no affect on cocaine CPP. JQ1 (50 mg/kg, i.p.) alone did not produce a condition place preference or aversion, nor did JQ1 (50 mg/kg, i.p.) alter LiCl-induced (150 mg/kg, i.p.) conditioned place aversion, indicating that JQ1 does not affect all types of contextual learning. Additionally, JQ1 attenuated the expression of brain-derived neurotrophic factor (BDNF) in the NAc. Ongoing studies are investigating potential mechanisms by which BETs regulate BDNF expression in response to cocaine. In summary, these observations support a role for BET bromodomain proteins as novel epigenetic regulators of cocaine-induced behavioral plasticity.

Title: The role and regulation of histone deacetylase 4 (HDAC4) in cocaine-related behaviors

Authors: *R. D. PENROD[1], M. B. CARREIRA[1,2], J. KUMAR[1,3], M. TANIGUCHI[1], C. W. COWAN[1];
[1]Psychiatry, Harvard Med. School, McLean Hosp., Belmont, MA; [2]Psychiatry, [3]Mstp, UT Southwestern Med. Ctr., Dallas, TX

Abstracts: Repeated exposure to drugs of abuse alters the function of the nervous system and produces states that encourage continued drug use. Changes to chromatin landscape and transcriptional accessibility, mediated in part by nuclear enzymes such as histone deacetylases (HDACs), are thought to play important roles in the development and persistence of addiction-related behaviors. HDAC4, a member of the Class IIa HDAC family, shuttles between the nucleus and cytoplasm in response to neuronal activity, and overexpression studies have implicated it in drug-related behaviors in the nucleus accumbens (NAc). As such, we sought to determine whether and how HDAC4 is regulated by cocaine, and whether this regulation is important for its suspected role(s) in addiction-related behavioral plasticity. Our findings indicate that acute and chronic cocaine differentially regulates HDAC4's phosphorylation state and nuclear/cytoplasmic localization, suggesting that the change in cellular localization might contribute to changes in cocaine-induced behaviors. We find that nuclear, but not cytoplasmic, HDAC4 suppresses cocaine reward behavior, and this was associated with strong repression of MEF2-dependent transcription activity. As a complementary approach to mutant expression within the NAc, we generated conditional gene deletion of HDAC4 from the adult nucleus accumbens using viral-mediated expression of Cre recombinase. Our preliminary findings indicate that HDAC4 regulates sensitivity to cocaine and the development of psychomotor sensitization, and ongoing work is evaluating its role in the extinction and reinstatement of cocaine conditioned place preference.

Title: A role for natural antisense transcripts in cocaine reward and addiction

Authors: *S. K. POWELL[1,2], G. C. SARTOR[2], D. VELMESHEV[2], S. P. BROTHERS[2], C. WAHLESTEDT[2];
[2]Dept. of Psychiatry and Behavioral Sci., [1]Univ. of Miami, Miami, FL

Abstracts: Growing evidence indicates an important role of epigenetic regulation in the mechanisms of cocaine addiction. Chronic cocaine use causes long-lasting changes in gene expression in the brain's reward areas that contribute to persistent drug-seeking and drug-taking behaviors. Recent reports indicate that epigenetic processes are key factors in such neuroadaptations and behaviors. Thus, understanding epigenetic mechanisms of addiction is crucial to develop targeted therapeutic interventions. However, the majority of epigenetic regulators and associated mechanisms have yet to be investigated. Representing an unexplored yet promising addiction-related target, natural antisense transcripts (NATs), transcripts encoded on the strand opposite to the sense strand on either protein-coding or non-protein coding genes, have recently been shown by our laboratory and others to be key regulators of chromatin state. However, to date, little is known about the expression of NATs in the context of addiction. Here, we investigated a role for NATs in response to cocaine by injecting c57bl/6 male mice with cocaine (20 mg/kg, i.p.) or saline once a day for 10 days. The nucleus accumbens (NAc) and other brain regions were collected at multiple time points after the last injection. Of addiction-related genes investigated, many were found to have natural antisense transcripts, and the expression of several of these antisense transcripts was also found to be significantly altered following chronic cocaine administration. These data indicate that cocaine disrupts the expression of addiction-related NATs, and that NATs may play an important role in cocaine addiction. Ongoing studies will determine the role of these NATs in the molecular mechanisms of cocaine reward and to explore their functions in animal models of addiction.

Title: Involvement of Wnt/βcatenin pathway in cocaine induced sensitization

Authors: *S. CUESTA, S. B. ROSSO, A. M. PACCHIONI;
Lab. de Toxicología Exptl., Facultad De Ciencias Bioquímicas Y Farmacéuticas,, Rosario, Argentina

Abstracts: Wnt factors are cistein rich secreted proteins which interact with one of 2 membrane receptors: Frizzled and Ryk. As a result of the interaction Dishevelled (DVL) is activated, and consequently, one of three pathways: canonical or Wnt/βcatenin, Planar Cell Polarity, and Wnt/calcium pathways. These three ways participate in different cell fates decisions like synaptogenesis, cell and tissue polarity and cell movement. Despite all the information about these factors in mammalian brain development, little is known regarding its role in adulthood. In the last years it has been revealed that Wnt pathways are involved in neuropsychiatric diseases. In schizophrenia, antipsychotic and amphetamine treatments lead to opposite changes in Wnt's effectors. Taking into account that all these evidence involves the dopaminergic pathways, our main goal was to evaluate the role of Wnt pathway in the long-lasting neuroadaptations induced by cocaine. According to recent evidence, we started evaluating the Wnt/βcatenin pathway, where the activation of DVL inhibits GSK3β and lead to the stabilization of βcat. We have already found that development of cocaine induced sensitization after 7 days of cocaine treatment (2x15 mg/kg i.p and 5x30 mg/kg i.p.) is associated with modifications in βcatenin (βcat) levels in prefrontal cortex (PFC), amygdala (Amyg) and dorsal striatum (DS). Moreover we have also found that a systemic treatment with a non-specific inhibitor of the Gsk3β blocks the development of cocaine sensitization by restoring βcat´s modifications. Our new data reveals that changes in βcat levels are only present when an animal showed behavioral sensitization after a cocaine treatment. On the other hand, we found that behavioral sensitization is not only related to a reduction in βcat in PFC, DS and Amyg, but also to an increase in Gsk3β activity and a reduction in Axin2 mRNA levels (target gene of the pathway) in PFC, suggesting an inhibition of Wnt/βcatenin pathway in this area. Then, we evaluate if these PFC changes were necessary for cocaine sensitization. In order to do that, rats received an intra-PFC infusion of Sulindac an hour before cocaine between day 2 and 6 of a 7 i.p. injections, administered once a day, of 15mg/kg of cocaine. The results showed that blocking PFC Wnt/βcatenin pathway with Sulindac, prior to cocaine injections, enhances the development of behavioral sensitization. So far our data suggests that cocaine sensitization is associated with modifications of Wnt/βcatenin pathway, and particularly, with an inhibition in PFC.

Title: CLOCK interacts with co-repressor protein complexes to negatively regulate tyrosine hydroxylase: Mechanisms underlying the circadian control of dopamine and cocaine reward

Authors: *R. W. LOGAN[1], W. P. WILLIAMS, III[1], S. WAPLINGER[1], S. SPENCER[2], M. M. SIDOR[1], C. A. MCCLUNG[1];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstracts: Mood and addiction disorders are associated with disruptions to the circadian system, although the mechanisms underlying these associations are poorly understood. The circadian gene, Clock, is highly expressed in the ventral tegmental area (VTA), a brain region that sends major dopaminergic projections with the mesocorticolimbic system that is implicated in mood and drug circuitry. Previously, we showed that mice carrying a mutation in exon 19 of this gene, ClockΔ19, exhibited increased levels of tyrosine hydroxylase (TH), the rate-limiting enzyme in dopamine synthesis, and enhanced sensitivity to rewarding stimuli, including cocaine. Here, we sought to determine the precise regulatory mechanisms by which CLOCK impacts the dopaminergic system that may be critical for behavioral responses to cocaine reward. Under normal conditions, CLOCK acts as a transcription factor by binding to enhancer elements (E-boxes) within gene promoters to promote transcription. However, we found that CLOCK may act as a transcriptional repressor of TH in the VTA, potentially through interactions with phosphoactive CRE-element binding protein (pCREB), the principle driver of TH transcription, and the recruitment of repressor proteins, Cryptochrome 1 (CRY1), and the histone deacetylase, sirtuin 1 (SIRT1). Using chromatin immunoprecipitation (ChIP) assays in wild-type mice, we found that CLOCK and pCREB bound the TH promoter in antiphase_maximum CLOCK and pCREB binding at ZT4 and ZT16, respectively. In the VTA of ClockΔ19 mice, however, pCREB binding was constitutively high, which was mirrored by elevated expression of TH mRNA across the entire day. Additionally, we found that mutation of the E-box sites in the TH promoter significantly increased TH-Luciferase reporter activity *in vitro*, suggesting CLOCK binds to these loci to repress TH transcription. In the cocaine conditioned place preference test, we also found that viral-mediated gene transfer of mutant CREB (mCREB) into the VTA normalized the enhanced reward sensitivity to cocaine of ClockΔ19 mice. To determine whether

CLOCK may recruit co-repressor proteins, we measured the protein levels of CRY1 and SIRT1, along with their protein-protein interactions. Both CRY1 and SIRT1 levels were reduced in the VTA of ClockΔ19 mice. Ongoing studies are investigating whether these proteins are recruited by CLOCK and/or pCREB to regulate TH transcription. Together, these experiments provide a molecular mechanism by which diurnal rhythms of TH expression are regulated by CLOCK and may represent a circadian-regulated pathway of drug reward.

Title: Inositol polyphosphate multikinase regulates cocaine-induced behavioral effects

Authors: *M. M. HARRAZ, R. XU, I. AHMED, S. H. SNYDER;
Dept. of Neurosci., Johns Hopkins Univ., BALTIMORE, MD

Abstracts: Transient induction of immediate early genes in response to various stimuli mediate synaptic plasticity and long-term changes in neural function. Drugs of abuse including cocaine induce immediate early genes expression. However, the molecular signals that link cocaine to immediate early genes induction are not well characterized. Recently, we demonstrated that the inositol polyphosphate multikinase (IPMK) is required for immediate early genes induction. Here we investigated the role of IPMK signaling pathway in cocaine-mediated actions utilizing IPMK conditional knockout mice. Our findings demonstrate that IPMK regulates cocaine-induced behavioral effects and suggest that IPMK signaling is a potential therapeutic target in cocaine abuse disorders.

Title: Investigation of the PFC-amygdala pathway and its role in addiction in serotonin transporter knockout rats

Authors: *P. KAREL[1], A. VAN DER TOORN[2], R. M. DIJKHUIZEN[2], L. J. VANDERSCHUREN[3], J. R. HOMBERG[1];
[1]Cognitive Neurosci., Radboudumc, Nijmegen, Netherlands; [2]Image Sci. Inst., Univ. Med. Ctr. Utrecht, Utrecht, Netherlands; [3]Animals in Sci. and Society, Utrecht Univ., Utrecht, Netherlands

Abstracts: During their lifetime only a subset of cocaine users make the transition to true addiction. One factor that may contribute to individual differences in liability to this transition is the serotonin transporter polymorphism (5-HTTLPR). Indeed, it has been demonstrated that the low activity short (s) allelic variant of this polymorphism increases risk for cocaine addiction. It has also been observed that carriers of the s-allelic version show an uncoupling between their prefrontal cortex (PFC) and the amygdala. Here we hypothesize that vulnerability to cocaine addiction in low 5-HTT expressing individuals is at least in part caused by this uncoupling. To test this hypothesis we use the 5-HTT knockout (5-HTT-/-) rat, an extreme model for 5-HTTLPR s-allele carriers. These animals model the human s-allele carrying population in many of their behaviors. In light of addiction these animals show increased responding to drugs as mirrored by the human DSM IV criteria. More specifically, we previously showed that these 5-HTT-/- rats show increased cocaine self-administration under short (1 hour, regular drug taking) and long access (6 hours, compulsive drug taking) conditions, an increased motivation to self-administer the drug under a progressive ratio schedule of reinforcement, and a failure to extinguish cocaine-seeking behavior. To test whether this increased addictive phenotype is caused by PFC-amygdala uncoupling, 5-HTT-/- and wild-type rats were trained in the long access paradigm of cocaine self-administration for 4 weeks. As controls a naïve group and a group trained to self-administer sucrose were included. All animals were perfused using 4% paraformaldehyde and brains were analyzed using a 9.4 Tesla rat MRI scanner focusing on the PFC and amygdala volumes and pathways connecting these areas. Here, we present the preliminary findings of this work.

Title: Loss of control over cocaine intake: The subthalamic nucleus as the critical actor

Authors: Y. PELLOUX[1], C. COHEN[1], A. TIRAN-CAPPELLO[1], S. LARDEUX[2], O. GEORGE[3], G. F. KOOB[4], S. H. AHMED[5], *C. BAUNEZ[1];

Abstracts: The subthalamic nucleus (STN) is critically involved in reward-related behavior. Lesion or high frequency stimulation (HFS) of the STN decreases the motivation to obtain cocaine, without decreasing that to obtain more natural rewards (Baunez et al., 2005; Rouaud et al., 2010). This selective reduction in the motivation for cocaine use suggests that the STN might be necessary for reinforcement sustained by drug of abuse and suggests that it could represent a promising brain target for therapy against cocaine addiction. The present study sought to further validate this hypothesis by testing the effects of bilateral inactivation of STN, by either lesions or high frequency stimulation (HFS), on establishment of escalation of cocaine self-administration. Escalation of cocaine use is a hallmark of drug addiction that is observed in rats when availability of the drug increases (Ahmed and Koob 1998). Here we show first that both STN lesions and HFS prevent escalation of cocaine intake. By recording local field potentials within the STN of rats escalating their cocaine intake, we also show that increased oscillations in the STN could serve as a marker of loss of control over cocaine intake. This outcome suggests a role

for the STN in the development of cocaine addiction and confirms that acting at the level of STN may be an interesting strategy for the treatment against cocaine addiction.

Title: Optogenetic stimulation of red nucleus glutamate neurons inhibits cocaine self-administration in mice

Authors: Y. HE, H.-Y. ZHANG, G.-H. BI, H.-J. YAU, H. SHEN, E. GARDNER, A. BONCI, *Z. XI;
NIDA, IRP, BALTIMORE, MD

Abstracts: It was recently reported that optogenetic activation or inactivation of glutamate neurons in the prefrontal cortex, ventral hippocampus (VH) or amygdala alters cocaine-seeking and reward-seeking behavior. However, little is known as to whether activation or inactivation of glutamate neurons in these and other brain regions similarly alters cocaine self-administration. The red nucleus (RN) in the midbrain is a structure anatomically adjacent to both the ventral tegmental area (VTA) and substantia nigra pars compacta (SNc), and the majority of RN neurons are glutamatergic. Interestingly, while RN neurons have been shown to modulate locomotion, little is known on which RN neurons modulate locomotion and whether RN glutamate neurons modulate drug-taking and drug-seeking behavior. In the present study, we used optogenetic strategies to explore these questions. We delivered Cre-dependent adeno-associated viral (AAV) vectors [AAV-EF1a-DIO-hChR2 (H134R)-EYFP] into distinct brain regions of vGluT2-IRES-cre mice to selectively express light-sensitive channelrhodopsin-2 (ChR2) in glutamatergic neurons. We found that, 1) optogenetic activation of glutamate neurons in the RN (targeted by both the AAV and optical fibers) significantly inhibited intravenous cocaine self-administration. 2) photostimulation of ChR2-containing glutamatergic terminals in the nucleus accumbens (NAc) in mice that had received intra-VTA AAV microinjections produced a similar inhibitory

effect on cocaine self-administration; 4) optogenetic activation of RN glutamate neurons failed to alter basal or cocaine-enhanced locomotion; and 5) photostimulation of glutamate neurons in the RN or glutamatergic terminals from the VTA to NAc failed to maintain intracranial self-stimulation behavior. Taken together, these behavioral findings suggest that RN glutamate neurons appear to play an important role in cocaine self-administration, and therefore, may constitute a new therapeutic target for treatment of drug abuse and addiction.

Title: GABA uptake changes in mice prefrontal cortex after a cocaine Exposure: effects on anxiety-like behavior

Authors: ***M. P. CARVALHO**[1], R. MARTINS[2], N. PENICINALLI[1], A. C. MANHÃES[3], R. C. C. KUBRUSLY[1];
[1]MFL, Univ. Federal Fluminense, Rio De Janeiro, Brazil; [2]Univ. Federal Fluminense, Rio de Janeiro, Brazil; [3]Univ. Estadual do Rio de Janeiro, Rio de Janeiro, Brazil

Abstracts: Aim: Cocaine is a psychostimulant, which acts in central nervous system, increasing the levels of catecholaminergic neurotransmission. Moreover, this drug can modulate different neurotransmitters systems, like GABAergic synapses. We are investigating the molecular mechanisms related to GABA uptake induced by acute cocaine (COC) exposure and its effects on anxiety-like behavior in adolescent mice. Methods: Swiss Webster mice in P40 were treated with cocaine (10; 20; 25; 30 mg/kg/ip) or saline. The pre frontal cortex (PFC) was used for [3H]-GABA uptake. To evaluate the anxiety-like behavior we use elevated plus-maze apparatus (EPM). Animals were randomly selected into four groups: (A) saline, (B) treated with COC 20

mg/kg/ip, (C) treated with 25 mg/kg/ip, (D) cocaine 30 mg/kg/ip. The animals were free to explore the apparatus for 5 minutes. To estimate the locomotor activity Open Field apparatus (OF) was used. All experiments were conducted in accordance with ethical committee, under the protocol CEUA/065/2012. Results: The % of time in open arms in all of the groups tested were not different (A: 8.959 ± 1,941 B: 15.35±3.33; C: 11.12±2.25; D: 14.67±2.84; n=16). The % of entries in the open arm had no difference between the groups (B: 26.57±5.57 C: 27.06±4.84 D: 34.17±4.62; n=16) compared to group A; (25.64±3.06; n=16). The % of time in Center has showed no modifications among the groups (B: 21.27±4.03; C: 25.11±2.952; D: 19.07±2.44; n=16) and saline (17.46±1.60; n=16). Although the analysis in the OF to the distance traveled revealed no differences among the tested groups (A: 79.31±11.87; b: 102.0±10.4; C: 103.2±8.81; D: 80.85±7.25; n=16) the rearing analyses showed that groups B (49.40±2.75; n=16) and C (37.19±4.13; n=16) had an increase in this behavior compared to saline group (18.86±3.22; n=16). Moreover, the % of time in the Center demonstrated that animals in group C (62.56±3.31; n=16) spent higher time than control group (35.65±8.2 n=16). COC 25mg/kg inhibited GABA uptake (97.93±6.95 n=14) compared to control group (148.4±7.80 n=14). After a short withdraw 24h or 48h GABA uptake levels were restored (24h: 188.0±18.83; 48h: 182.4±12.13; n=8) Conclusion: The acute cocaine exposure inhibited GABA uptake just after its administration however after a short-withdrawal GABA uptake levels were similar to the saline group showing that the system seems to be sensitized. This changes in the uptake could lead to an anxiolytic and impulsive behavior as was shown in the OF apparatus.

Title: Estradiol rapidly enhances dopamine in nucleus accumbens shell of female but not male rats

Authors: K. E. YOEST[1], J. A. CUMMINGS[1], K. N. CHAMBERLAIN[4], Y. A. ALONSO[2], B. J. ARAGONA[1], *J. B. BECKER[3];
[1]Psychology, [2]Neurosci. Grad. Program, [3]Univ. Michigan, Ann Arbor, MI; [4]Psychology, Kalamazoo Col., Kalamazoo, MI

Abstracts: There are well established sex differences in the susceptibility to addiction, where women show faster escalation of drug use and are more prone to relapse than their male counterparts. Similar findings have been reported in rodent models, where female rats acquire cocaine-taking behavior more rapidly than males. Gonadal hormones modulate this sex difference, as the positive subjective effects of psychomotor stimulants are enhanced by estradiol treatment in women, and estradiol also enhances the acquisition of and motivation for cocaine self-administration in female rats. Our laboratory has demonstrated that acute estradiol administration also enhances cocaine-induced dopamine in the striatum, but not the nucleus accumbens (NAc) measured via microdialysis, (Cummings et al., Drug and Alcohol Dependence, 135:22-28, 2014). In this previous experiment, the microdialysis probe was in the boundary of the core and shell of the NAc. We postulated that our failure to see an effect of estradiol in the NAc was due to probe placement, since estradiol has been reported to have opposite effects in the NAc core and shell. With this experiment, we tested the effect of acute estradiol treatment on stimulated cocaine-induced dopamine release and reuptake in the NAc shell. Ovariectomized females and intact males were anesthetized with urethane and treated with estradiol benzoate (EB) or vehicle 30 min prior to administration of cocaine (10 mg/kg i.p.). Fast scan cyclic voltammetry (FSCV) was used to measure stimulated dopamine release in the NAc shell both prior to and after cocaine administration. We found that acute EB treatment significantly increased stimulated dopamine release as measured by FSCV in females but not males after cocaine. We also found that acute EB significantly reduced reuptake of dopamine after stimulation in cocaine-treated males but not females. These findings demonstrate a significant sex difference in the mechanism by which estradiol enhances dopamine release in NAc shell. Importantly, dopamine signaling in the NAc has been implicated in acquisition and escalation of drug taking behaviors, aspects of addiction that are more pronounced in female addicts. Elucidating the mechanism by which estradiol may render women more susceptible to compulsive drug use will help to develop gender-specific treatments in clinical settings.

[2]Dept. of Physiol., Med. Sci. Campus, Univ. of Puerto Rico, San Juan, Puerto Rico

Abstracts: The ventral tegmental area (VTA) plays an important role in reward and motivational processes that facilitate drug addiction. Previous investigations indicate that presynaptic alpha1-adrenoreceptors (α1-AR) modulate glutamate and GABA release on VTA dopaminergic (DA) neurons. We hypothesized that chronic but not acute cocaine treatment alters presynaptic α1-AR modulation of glutamate and GABA neurotransmission on VTA DA neurons. We recorded VTA DA neuronal excitatory (EPSCs) and inhibitory postsynaptic currents (IPSCs) using whole-cell voltage clamp in brain slices from male rats previously treated with one or five daily cocaine injections. We also recorded EPSCs from brain slices of animals after a 7 day withdrawal period. After acute cocaine treatment, α1-ARs increased EPSCs amplitude. In contrast, following chronic cocaine injections α1-ARs failed to increase EPSCs amplitude. Therefore, subsequent to a chronic cocaine administration paradigm, α1-ARs were desensitized and their pharmacological stimulation did not augment EPSCs amplitude. Moreover, PKC stimulation with phorbol 12-myristate 13-acetate failed to increase glutamate release in slices obtained from cocaine sensitized animals. However, after acute or chronic cocaine treatments α1-ARs stimulation decreased IPSCs amplitude. , α1-ARs actions on glutamatergic transmission on VTA DA neurons were desensitized following a 7 day withdrawal period. These data suggest that α1-ARs enhance DA neuronal excitability after repeated cocaine administration most probably by reducing GABA inhibition onto VTA DA neurons. A better understanding of α1-AR modulatory changes in cocaine sensitization will increased our knowledge of the role of the noradrenergic system in cocaine addiction and might provide possible avenues for therapeutic pharmacological interventions (Supported by GM-08224 to CAJR and R25 GM-061838 to MVH).

Title: Sex differences in hypocretin modulation of dopamine signaling in the nucleus accumbens

Authors: ***J. K. SHAW**, R. A. ESPAÑA;
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstracts: Women progress to cocaine dependence more rapidly and are more prone to stress-induced relapse than men. Preclinical evidence is consistent with this, indicating that females acquire self-administration more readily, display higher motivation for cocaine and are more likely to reinstate cocaine use than their male counterparts. The mechanisms underlying these sex-differences have yet to be fully elucidated but likely involve the mesolimbic dopamine (DA) system_a pathway that is modulated by hypocretin (HCRT) projections to DA neurons in the ventral tegmental area (VTA). Although increased HCRT expression in the female hypothalamus has been described, sex differences in HCRT regulation of dopamine transmission have not been sufficiently investigated. Here we used *in vivo* voltammetry to detect HCRT-mediated sex differences in DA release and uptake. We implanted HCRT knockout (KO) or wild-type (WT) male and female mice with a bipolar stimulating electrode in the VTA and a carbon fiber electrode in the caudate and nucleus accumbens (NAc) core, where DA release was electrically evoked every 5 minutes. Following collection of at least three stable baseline samples we administered 10mg/kg cocaine i.p. and monitored subsequent DA transmission. Results from a subset of animals confirm data in rats that females demonstrate higher concentrations of DA in caudate relative to males regardless of genotype. In the NAc, our data suggest an interaction between sex and genotype in regulating DA transmission; whereas HCRT KO males demonstrate reduced evoked DA relative to WT males, KO females instead demonstrated higher

concentrations of evoked DA that WT females. Our results also indicate an interaction between sex and genotype on DA responses to cocaine. Taken together, these observations suggest a differential role for HCRT regulation of DA reward pathways based on sex.

Title: Isoflurane is an alternative anesthetic for *in vivo* voltammetry

Authors: *Z. D. BRODNIK[1], K. HARRIS[2], R. ESPANA[3];
[1]Drexel Univ., Philadelphia, PA; [2]Drexel Univ. Col. of Med., Philadelpha, PA; [3]Drexel Univ. Col. of Med., Philadelphia, PA

Abstracts: Electrophysiology and voltammetry experiments in anesthetized animals commonly use urethane as an anesthetic of preference. Urethane produces an extended surgical-level anesthesia with only modest changes in circulation, respiration, and reflex responses, and therefore is thought to minimally interfere with the physiological relevance of data. Despite these benefits, there are also disadvantages to the use of urethane for *in vivo* experiments. In particular, urethane is considered to be cytotoxic, carcinogenic and immunosuppressive and thus is limited to use in terminal experiments. Isoflurane is an inhalation anesthetic drug that holds advantages over injectable agents. For example, isoflurane anesthesia requires minimal animal handling, has a large margin of safety, and can be rapidly adjusted to maintain an appropriate level of anesthesia throughout an experiment. To examine whether isoflurane could serve as an anesthetic for use during *in vivo* voltammetry experiments, we tested the effects of isoflurane on the uptake kinetics of stimulated dopamine release in the nucleus accumbens and compared results to those obtained with urethane. Uptake parameters Km and V_{max} were modeled, and we determined that these parameters did not differ between low doses of isoflurane and urethane. Furthermore, we found that the same dose of isoflurane did not alter changes in dopamine uptake

in response to intravenous cocaine. Together these data identify isoflurane as viable for use in anesthetized voltammetry experiments.

Title: Ventral tegmental area regulation of the prefrontal cortex is superactivated by chronic cocaine self-adminstration

Authors: *W. BUCHTA[1], A. RIEGEL[2];
[1]Dept. of Neurosci., [2]Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstracts: Dopamine (DA) release in the prefrontal cortex (PFC) is thought to gate sensory information important for interpreting the saliency of environmental stimuli. In addiction, the prefrontal cortex (PFC) becomes hyper-responsive to drug-associated sensory cues, disrupting executive function. Although DA terminals emanating from the Ventral Tegmental Area (VTA) participate in cue processing, the underlying mechanism and its role in addiction remains unclear. To investigate this relationship, Cre-dependent AAVs were injected into the VTA of transgenic (TH:Cre) rats to selectively transfect VTA DA cells with channel rhodopsin (ChR2) or Gs/Gq-coupled synthetic receptors (DREADDs). After ~30d, PFC (prelimbic area) brain

slices were prepared. Whole cell patch clamp electrophysiological recordings were performed in L5 pyramidal cells and VTA terminals were stimulated with either transient pulses of blue light (to activate ChR2) or bath application of CNO (to activate DREADDs). Under baseline conditions, cells displayed robust spike-frequency adaptation (accommodation) and a large slow after-hyperpolarization (sAHP). Activation of ChR2 or DREADDs reduced the sAHP, reduced accommodation, and increased firing. Similar changes were observed with bath application of DA, the D1 agonist SKF81297 or direct activation of cyclase activity with forskolin. Co-application of cocaine increased the percentage of responsive cells, but not the magnitude of firing. D1-antagonism or depletion of intracellular Ca2+ stores blocked the actions of DA. Thus, VTA terminals regulate PFC accommodation via a DA/D1/AC/PKA/Ca2+ cascade, and DA's influence is expanded during an acute application of cocaine. To evaluate this mechanism in a model of addiction, recordings were made in slices from animals with a history of chronic cocaine self-administration. Under these conditions, cells demonstrated (a priori) a compromised sAHP and accommodation, as well as hyperexcitable firing rates_an adaptation that was absent in slices from matched yoked-cocaine animals that received identical amounts of cocaine but were not subjected to drug-related cues. Acute blockade of DA-D1 receptors, inhibition of PKA, depletion of intracellular Ca2+, or stabilization of KCNQ (KV7) ion channels restored accommodation following chronic cocaine self-administration. Taken together these data suggest that VTA terminals utilize a DA-D1 receptor mechanism to regulate PFC excitability and this mechanism is superactivated following chronic cocaine self-administration. This neuroadaptation may underlie the enhanced saliency of drug-related cues that trigger relapse in cocaine addicts.

Abstracts: Methylphenidate (MPH), a drug widely used to treat children diagnosed with ADHD, and cocaine (Coc) inhibit the re-uptake of dopamine and norepinephrine. Cocaine, unlike MPH, also inhibits the re-uptake of serotonin (5-HT). Previously, we observed that the frequency of spontaneous GABA release from thalamic reticular nucleus (Ret) neurons is increased in slices from mice treated with a Coc binge (3 i.p. injections, 15mg/kg each, 1 hour apart) but not in those from animals treated with an MPH binge, suggesting that the effect of Coc is mediated by changes in serotonergic transmission. Thus, we investigated the effect of 5-HT receptors agonists and antagonists in control and Coc treated thalamocortical slices from mice using patch clamp. Additionally, we administered Coc to mice lacking 5-HT2A receptors. We first recorded miniature inhibitory post-synaptic potentials (mIPSPs) from ventrobasal neurons using thalamocortical slices from control mice in the presence of 5-HT and 5-HT1A or 5HT2A/2C agonists ((±)-8-OH-DPAT, (±)-DOI hydrochloride; both 10μM) and antagonists (NAN-190 hydrobromide, ketanserin; both 25μM). Our results show that the effect of bath-applied 5-HT (100 μM, >15min) on mIPSP frequency resembles that of Coc (5-HT, Coc vs. control, Kruskal Wallis test, $p<0.05$), and that even though both types of agonists led to an increase in frequency, the effect of the 5-HT1A agonist was stronger (8-OH-DPAT=347% increase, DOI=129% increase; 8-OH-DPAT vs. DOI vs. control, Kruskal Wallis test, $p<0.05$). Surprisingly, the 5HT2A antagonist also had the same effect (Kruskal Wallis test, $p<0.05$), which could be explained by a biphasic action of 5HT2A receptors at the GABAergic afferents terminals from Ret neurons. We then analyzed the effect of 5-HT 100 μM applied locally ("puff") onto ventrobasal neurons during recordings of mIPSCs from mice lacking 5-HT2A receptors (both control or injected with a Coc binge). In both cases, the application of 5-HT resulted in a reduction of the mIPSPs frequency that after the puff recovered to initial values only in the control group (post-puff frequency was 96% of the initial value in control group vs. 58% in Coc binge group, Wilcoxon Mann-Whitney test, $p=0.0075$). Our findings suggest that Coc-induced effects on thalamic serotonergic transmission might be mediated by presynaptic 5-HT receptors (on the terminals of Ret neurons), and that these effects could be responsible for thalamocortical abnormalities observed in cocaine addicts and animal models of Coc intake.

Title: Fluoxetine potentiates methylphenidate-induced gene regulation in the striatum: Role of 5-HT1B serotonin receptor

Authors: V. VAN WAES, S. EHRLICH, J. BEVERLEY, *H. STEINER;
Chicago Med. School/RFUMS, North Chicago, IL

Abstracts: The psychostimulant methylphenidate (Ritalin) is used in the treatment of attention-deficit hyperactivity disorder (ADHD) and as a cognitive enhancer in the healthy. Methylphenidate, like cocaine, acts by blocking the reuptake of dopamine. However, unlike cocaine, methylphenidate does not affect serotonin. Serotonin contributes to addiction-related gene regulation by cocaine. Thus, the lack of a serotonin effect may explain methylphenidate's more moderate gene regulation effects and addiction liability. Our previous studies indeed show that enhancing serotonin action by adding a selective serotonin reuptake inhibitor (SSRI), fluoxetine (Prozac), to methylphenidate potentiates methylphenidate-induced gene regulation in the striatum. The 5-HT1B serotonin receptor subtype facilitates cocaine-induced gene regulation. Here, we investigated a role for 5-HT1B in the SSRI potentiation of methylphenidate-induced gene regulation, by *in situ* hybridization histochemistry. Our results show that repeated methylphenidate treatment (5 mg/kg, 5 days) induces a minor increase in 5-HT1B expression in the striatum. Repeated fluoxetine treatment (5 mg/kg) by itself had no effect, but fluoxetine significantly potentiated the methylphenidate-induced increase in 5-HT1B expression. We also assessed the effects of 5-HT1B receptor-selective agents on methylphenidate-induced gene regulation. The 5-HT1B antagonist GR 55562 (2 mg/kg) attenuated the fluoxetine potentiation of methylphenidate-induced zif 268 expression. Conversely, the 5-HT1B agonist CP94253 (3-10 mg/kg) alone had minimal effects on zif 268 expression but dose-dependently potentiated

methylphenidate-induced zif 268 induction, thus mimicking the fluoxetine effects. Methylphenidate plus SSRI concomitant therapies are indicated in ADHD/depression comorbidity and other disorders, and co-exposure also occurs with cognitive enhancer use by patients on SSRIs. Our findings demonstrate that SSRIs potentiate addiction-related gene regulation by methylphenidate; SSRIs may thus enhance the addiction liability or other behavioral effects of methylphenidate. Our results show that the 5-HT1B receptor contributes to this SSRI potentiation of gene regulation. The 5-HT1B receptor may thus serve as a pharmacological target to prevent SSRI-induced behavioral effects.

Title: The role of 5-HT-mediated Glycogen synthase kinase 3β signaling pathway in the nucleus accumbens core in cocaine addiction

Authors: *I.-J. YOU, S. WEE;
Dept. of Mol. Therapeut., The Scripps Res. Inst., Jupiter, FL

Abstracts: In our previous study, we hypothesized that enhanced 5-HT_{1A} autoreceptor activity with chronic cocaine use underlay cocaine addiction and found that the inhibition and deletion of 5-HT_{1A} autoreceptors attenuated motivation for compulsive cocaine seeking behavior and cocaine reward, respectively. However, the key signaling components in the forebrain that mediate cocaine addiction via the increased 5-HT_{1A} autoreceptor function have not been examined. The present study, therefore, examined whether decreased serotonergic output in the nucleus accumbens (NAc) by the increased 5-HT_{1A} autoreceptor function is related to compulsive cocaine seeking and reward. The literature suggests that the increased activity of glycogen synthase kinase (GKS)-3β in the NAc is associated with synaptic plasticity in psychiatric disorders and addictive behaviors. Serotonin (5-HT) negatively regulates the activity of GSK3β. Accordingly, we also investigated the role of GSK 3β in the NAc core in cocaine addiction. Using the DREADD (designer receptors exclusively activated by designer drug)

technique, we determined the effect of the stimulation of the raphe to the nucleus accumbens 5-HT circuit on cocaine-induced conditioned place preference in mice. In a rat model of cocaine self-administration with extended access, which mimic compulsive cocaine intake in humans, we measured the level of phosphorylated GSK3β, an inactive form, and the total GSK3β in the NAc core. Lastly, we determined whether a selective GSK-3β inhibitor in the NAc core decreased cocaine self-administration in rats with extended access. The stimulation of the raphe to the nucleus accumben 5-HT projection abolished cocaine-induced conditioned place preference in mice, similar to our previous finding with the deletion of 5-HT_{1A} autoreceptors. Additionally, we found that the level of phosphorylated GSK3β was significantly decreased in the NAc core of LgA rats compared with ShA rats. Moreover, the inhibition of GSK3β in the NAc core attenuated compulsive-like cocaine self-administration in LgA rats, but not in ShA rats. Altogether, these results show that increased motivation for cocaine is associated with increased 5-HT_{1A} autoreceptor function, resulting in decreased serotonergic output to the NAc and suggest that the increased activity of GSK3β as the downstream signaling of decreased 5-HT neurotransmission in the NAc contributes to the transition to cocaine addiction perhaps by promoting a pro-depressive state.

Title: Prefrontal correlates of addiction and the effect of subconvulsive electrical stimulation on cue-induced relapse in rats

Authors: *I. GOLDENBERG[1], R. GAL[2], S. ZIBMAN[2], N. BARNEA-YGAEL[2], A. ZANGEN[2];
[2]Life Sci., [1]Ben Gurion Univ., Beer Sheva, Israel

Abstracts: A major hallmark of drug (and especially cocaine-) addiction is relapse to drug use following a period of self-imposed abstinence. In humans and animal models, relapse can be reliably triggered by presenting cues previously associated with drug self-administration, a phenomenon termed cue induced relapse (CIR). It has been suggested that changes in neuronal activity in the medial prefrontal cortex (mPFC) following repeated drug use may play a key role

in CIR. Here we used a chronically-implanted bilateral linear microelectrode array (14 recording electrodes + 2 stimulating electrodes) to record local field potentials (LFPs) and induce subconvulsive electrical stimulations (SCES) in the mPFC of behaving rats. Following array implantation, rats were trained to self-administer cocaine by pressing a reinforcing lever, and each reinforcement was coupled with a light + tone cue. Next, 2/3 of the cage floor was electrified such that the rats had to tolerate a foot shock to reach and press the reinforcing lever. The shock intensity was increased over daily sessions until an individual Abstinence Threshold (AT) was reached and the rats abstained from lever pressing for 3 consecutive days. Next, mPFC-SCES (20 Hz, 0.01 ms pulse duration, 400 μAmp) was applied daily for two weeks. The rats then entered a 30 min CIR-test, during which the cues were non-contingently presented under 85% AT conditions. The CIR-test was repeated for 4 consecutive days and we recorded the number of lever presses each day. Cue-induced mPFC-LFP activity was recorded throughout the experiment. Whereas 36% of the rats that did not receive SCES (n=11) 'relapsed' to lever-pressing (i.e., pressed the lever at least twice during the CIR-test), only 16% of the rats that received SCES (n=6) 'relapsed'. Additionally, during the CIR-tests as compared with prior to the cocaine self-administration training, an increased power was observed in the theta and beta frequency ranges in response to the cues. This physiological response decreased in consecutive CIR-test days, suggesting extinction associated with the non-contingent cue presentation. It therefore seems that repeated cocaine self-administration is associated with increased saliency of the drug-associated cues manifested, at least, as increased cue-induced theta/beta mPFC activity. Results obtained in this study may provide insights to the mechanisms underlying CIR and offer novel therapeutics alternatives for relapse to drug use in human addicts.

Title: Blockade of TrkB receptors attenuates D-AMPH withdrawal-induced increases in dynorphin expression in the nucleus accumbens and striatum

Authors: *K. A. HORNER[1], R. C. MURRAY[2], J. J. L. FULLER[2];
[1]Div. Basic Med. Sci., Mercer Univ. Sch. Med., MACON, GA; [2]Mercer Univ. Sch. of Med., Macon, GA

Abstracts: Several lines of evidence suggest that withdrawal from chronic, escalating doses of D-amphetamine (D-AMPH) induces a syndrome with symptoms that are similar to those seen in major depressive disorder (MDD). Animals and humans undergoing psychostimulant withdrawal exhibit a loss of interest or pleasure in all or most activities (anhedonia) and depressed mood (dysphoria), which are also core symptoms of MDD. Increased dynorphin (DYN) expression in the nucleus accumbens (NAc) is thought to contribute to the anhedonia and dysphoria that is seen following psychostimulant withdrawal and in MDD. Brain derived neurotrophic factor (BDNF) is also increased in the NAc following psychostimulant withdrawal and in MDD, and is thought to have a pro-depressive effect in this region. Interestingly, increased BDNF in the NAc could contribute to the up-regulation in DYN that is observed with psychostimulant withdrawal and MDD. Specifically, activation of tropomyosin related kinase B (TrkB) receptors by BDNF increases *cAMP response element-binding (CREB)* protein activity via activation of the mitogen-activated protein/extracellular signal regulated kinase (MAP/ERK) pathway. Furthermore, CREB has been shown to positively modulate DYN levels in the NAc. Therefore, enhanced BDNF-CREB activity in the NAc may result in anhedonia and pro-depressive effects via up-regulation of DYN activity and abrogation of BDNF-CREB signaling may have a beneficial, antidepressant effect. However, it is not known whether blockade of TrkB receptors following psychostimulant withdrawal will alter DYN expression in the NAc. Thus, the goal of the current study was to determine the effects of TrkB receptor blockade on DYN expression in the NAc, as well as the adjacent striatum (STR) following withdrawal from D-AMPH. Animals were treated 3 times a day for 4 days with escalating doses of D-AMPH (1-10 mg/kg). Twenty-four hours after the final dose of D-AMPH, animals were treated with the TrkB receptor antagonist, ANA-12, sacrificed and the tissue processed for *in situ* hybridization histochemistry. Chronic, escalating doses of D-AMPH, coupled with 24h of withdrawal resulted in a significant increase receptor DYN mRNA expression in the core and shell of the NAc and the STR. Blockade of TrkB receptors attenuated D-AMPH-withdrawal induced increases in DYN expression in the core, but not shell of NAc, and in the STR. These data indicate blockade of BDNF receptors reverses the increase in DYN expression seen following chronic D-AMPH exposure and could alleviate the anhedonia and dysphoria observed during psychostimulant withdrawal, as well as in MDD.

Title: Transcriptome analysis and gene targeting of a QTL influencing methamphetamine sensitivity

Authors: *N. YAZDANI[1], Y. SHEN[2], W. JOHNSON[2], C. D. BRYANT[3];
[1]Pharmacol. & Exptl. Therapeut., Boston Univ. Sch. of Med., Boston, MA; [2]Dept. of Med., [3]Pharmacol. & Exptl. Therapeutics, Psychiatry, Boston Univ., Boston, MA

Abstracts: We previously utilized interval-specific congenic lines derived from C57BL/6J (B6) and DBA/2J (D2) alleles to fine map a quantitative trait locus (QTL) influencing methamphetamine (MA)-induced locomotor activity. We identified a 0.23 MB critical interval on chromosome 11 containing only two protein-coding genes, Rufy1 and Hnrnph1. Notably, Rufy1 contains three missense SNPs and Hnrnph1 contains 1 SNP near the 5' UTR. We are currently generating null mutant lines for both genes using transcription activator-like nucleases (TALENs) to determine the quantitative trait gene(s) that influence MA sensitivity. In an attempt to identify transcriptome signatures associated with strain differences in MA sensitivity, we carried out RNA sequencing (RNA-seq) with striatal samples from a B6.D2 congenic line (chr.11: 50-60 Mb) that captures the QTL and WT B6 littermates. Results depict an overrepresentation of cis-regulated, differentially expressed genes within the congenic interval (4 out of 92 differentially expressed genes; FDR < 0.05) and widespread genomic regulation on all autosomes. Using Ingenuity Pathway Analysis (IPA), the top canonical pathways were "glutamate receptor signaling" and "GalphaQ signaling," while our top gene networks were "Behavior, Nervous System Development and Function, Tissue Morphology" and "Behavior, Neurological Disease, Cell-to-Cell Signaling and Interaction." In B6.D2 congenics, we uncovered down-regulation in the expression of critical genes involved in midbrain dopaminergic neuron development (e.g. Nr4a2, Bdnf) and striatal glutamate neurotransmission (e.g. Slc17a6, Slc17a7, Homer2, Gls, Gng2, Gria4). Dopamine signaling in the striatum plays a modulatory role on innervating glutamatergic neuron synapses on principal medium spiny neurons (MSNs), and this interplay has been shown to be sensitive to acute MA. Thus, we hypothesize that Rufy1 is the quantitative trait gene (QTG) responsible for variation in behavioral sensitivity to MA, which is mediated by a mechanism involving decreased

dopaminergic striatal innervation and dampened glutamatergic neurotransmission, cumulating to altered MSN morphology and MA-induced function.

Title: Amphetamine-induced phasic dopamine release requires dopamine cell firing and endocannabinoid signaling

Authors: ***D. P. COVEY**[1], K. BUNNER[2], J. F. CHEER[1], P. A. GARRIS[3];
[1]Univ. of Maryland, Baltimore, MD; [2]Psychological and Brain Sci., Indiana Univ., Bloomington, IN; [3]Sch. of Biol. Sci., Illinois State Univ., Normal, IL

Abstracts: Similar to all other classes of abused drugs, the rewarding and reinforcing effects of amphetamine (AMPH) arise from its ability to increase dopamine levels in the nucleus accumbens (NAc). Recent *in vivo* measures showing AMPH to increase phasic dopamine release events - i.e., dopamine transients - challenge the accepted mechanism by which AMPH exerts this effect. Yet, the respective contributions of action potential-dependent transient signaling and non-exocytotic efflux to AMPH effects on NAc dopamine levels are unknown. These two processes were assessed by administering AMPH intravenously to awake rats while monitoring dopamine levels in the NAc with fast-scan cyclic voltammetry. AMPH elicited an immediate and robust increase in NAc dopamine concentration (Figure, A). This effect was abolished by intracerebral infusions of tetrodotoxin (TTX), but not vehicle (VEH), onto ventral tegmental dopamine cell bodies. Thus, cell activity is required for AMPH to increase NAc dopamine levels, indicating that non-exocytotic efflux is not the major action of AMPH in this region. Next, we assessed how AMPH elevates NAc dopamine concentration by administering the cannabinoid CB1 receptor inverse agonist/antagonist rimonabant (RIMO) prior to AMPH (Figure, B). In

contrast to TTX, which eliminates action potential generation in dopamine neurons, RIMO selectively disrupts the increase in dopamine transient frequency in the NAc - supporting similar work with cocaine, ethanol and nicotine. Terminal effects of AMPH remained intact following RIMO, as evidenced by persistence of AMPH-induced increases in the amplitude and duration of dopamine concentration transients. Thus, blocking CB1 receptors with RIMO selectively disrupt AMPH's ability to elicit dopamine transients. Collectively, these results provide strong evidence that a predominant action by which AMPH increases NAc dopamine levels is by activating dopamine cell firing through mobilization of endocannabinoid tone.

Title: M1 muscarinic and α4β2-containing nicotinic receptor ligands modulate oral methamphetamine self-administration in DBA/2 mice

Authors: *M. M. FORD;
Div. of Neurosci. (L-584), Oregon Hlth. & Sci. Univ., Beaverton, OR

Abstracts: Cholinergic transmission modulates several aspects of stimulant abuse, including initial exposure, transition to dependence, and relapse risk. Recent work from our laboratory determined that the discriminative stimulus effects of methamphetamine (MA) in mice is influenced by M1 muscarinic and α4β2-containing nicotinic receptor activities, but the potential

therapeutic value of drugs with activity at these receptor subtypes in reducing MA self-administration has yet to be evaluated. The goal of the current work was to evaluate the influence of the M1-preferring agonist xanomeline, the M1-preferring antagonist dicyclomine, the α4β2-preferring nicotinic antagonist DHβE, and the α4β2 nicotinic partial agonist varenicline in a binge-like model of MA consumption. Thirty-two male DBA/2 mice were exposed to progressively higher concentrations of MA (10, 20 and 40 mg/L) versus water over consecutive 5-day blocks during 2-hr limited access sessions, starting 2-hr into the dark phase. Drinking patterns were monitored in custom lickometer chambers. Following a 3-week maintenance period with access to 40 mg/L MA, sub-groups of mice were treated with multiple doses of a test drug (i.p.) in a Latin square design. Xanomeline reduced MA intake by 40% at each dose tested (1, 1.7 and 3 mg/kg), and this decrease was attributable to a comparable decline in the number of MA bouts per session. While dicyclomine treatment (10 and 17, but not 3 mg/kg) similarly decreased MA intake, this treatment effect was associated with a diminished latency to first MA bout and smaller mean bout size, but no difference in the number of bouts. In contrast, no dose of DHβE (0.3, 1 or 3 mg/kg) altered MA self-administration or underlying drinking patterns. Varenicline (2 mg/kg) attenuated MA intake by 40%, which was primarily attributable to a decreased mean MA bout size. Results are congruent with earlier evidence showing that xanomeline and dicyclomine elicited rightward and leftward shifts in the stimulus dose-response curve of MA, respectively. In conjunction with the present findings, xanomeline and dicyclomine treatment may diminish and enhance the reinforcing properties of MA, respectively, while similarly decreasing self-administration via distinct mechanisms. Supported by DA018165 and OD011092.

Title: Toll-like receptor 4 activation by methamphetamine contributes to increased dopamine concentrations

Authors: *T. A. COCHRAN[1], A. L. NORTHCUTT[1], T. J. FABISIAK[1], X. WANG[1], M. HAAS[1], J. AMAT[1], M. R. HUTCHINSON[2], S. F. MAIER[1], K. C. RICE[3], L. R. WATKINS[1]; [1]Univ. of Colorado, Boulder, Boulder, CO; [2]Discipline of Physiol., Univ. of Adelaide, Adelaide, Australia; [3]Chem. Biol. Res. Br., Natl. Inst. on Drug Abuse, Rockville, MD

Abstracts: Historically, the rewarding effects of drugs have been attributed to neuronal responses, particularly those of the mesolimbic dopamine pathway. Recent evidence suggests that CNS immune activation within the brain is also required for drug reward. Morphine and cocaine can activate Toll-Like Receptor 4 (TLR4), resulting in proinflammatory CNS immune signaling. TLR4 is an innate immune pattern recognition receptor, expressed principally on microglia and astrocytes in the CNS. In these instances, TLR4 appears to recognize morphine and cocaine as xenobiotics, or foreign invaders, triggering CNS immune signaling, akin to the immune response elicited by bacteria. The ensuing proinflammatory cascade can have neuroexcitatory consequences. In the case of morphine or cocaine, blockade of TLR4 (1) prevents induction of CNS immune activation, (2) suppresses conditioned place preference, (3) blocks drug-induced dopamine increases within the nucleus accumbens and (4) attenuates drug self administration. These findings provide the foundation for our recently proposed xenobiotic hypothesis. This hypothesis suggests that in serving its immune-surveillance role, TLR4 detects and identifies morphine and cocaine as foreign, invading compounds and initiates proinflammatory immune signaling in response to the perceived threat. Further, this drug-induced proinflammatory CNS immune signaling may be necessary for drug reward and reinforcement. Methamphetamine is thought to exert its rewarding effects via inhibition and reversal of dopamine transporters in the mesolimbic dopamine pathway. Repeated methamphetamine use is also associated with neurotoxicity. There is some indication that CNS immune activation may contribute to methamphetamine's rewarding and neurotoxic effects. However, the mechanism by which methamphetamine triggers a CNS immune response is unknown. Here, we demonstrate that methamphetamine can bind to TLR4 to initiate CNS immune activation. Systemic methamphetamine induces upregulation of proinflammatory markers in the brain, notably within the ventral tegmental area. Further, we demonstrate that systemic TLR4 antagonism attenuates methamphetamine-induced increases of dopamine within the nucleus accumbens. To date, our data suggest that methamphetamine-activation of TLR4 contributes to its dopaminergic effects, as well as implicating a possible mechanism underlying neurotoxicity. These findings also provide further support for the xenobiotic hypothesis, and indicate that TLR4 may be a promising target for pharmacological intervention to treat drug abuse.

Title: Acute high dose of methylphenidate increases the amount of synaptic NMDAR but decrease its association with lipid raft in nucleus accumbens

Authors: A. D. CABELLO ARREOLA, L. GARZA OCAÑAS, *I. DELINT-RAMÍREZ; Pharmacol., Univ. Autonoma De Nuevo Leon, Monterrey, Mexico

Abstracts: Methylphenidate is a stimulant drug with dopamine and noradrenaline reuptake inhibition properties. It is mainly prescribed for attention deficit hyperactivity disorder. However, high doses of methylphenidate are potentially addictive. Growing numbers of young people use high dose of this drug for pleasurable enhancement. It is known that acute administration of drugs of abuse, such as cocaine, increase synaptic NR2B containing NMDAR in nucleus accumbens. To address whether high doses of methylphenidate also induces insertion of NMDAR at synapses, we measured the amount of NMDAR in the synaptosomal fraction isolated from nucleus accumbens, 30 minutes after an intraperitoneal injection of 10mg/kg of methylphenidate or cocaine in rats. Like cocaine, methylphenidate treatment increased the amount of NR2B contain NMDAR in the synaptosomal fraction, which suggest an increase in the NMDAR signaling. Their association with lipid rafts also regulates NMDAR signaling. Previously, we have showed that spatial training increases the association of NMDARs with lipid raft, where they can interacts with proteins such as SRC family proteins, which regulates the NMDAR function. We measured the effect of Methylphenidate treatment on the association of NMDAR with lipid raft isolated by density gradient. Unlike what happen during spatial training, we found that the association of NMDAR with lipid rafts decreases after the acute injection of Methylphenidate.

Title: Differential effects on reward produced by synthetic cathinones

Authors: S. B. DOLAN, *M. J. FORSTER, M. B. GATCH;
Pharmacol. and Neurosci., Univ. North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstracts: Since 2007, there has been a dramatic rise in the frequency of abuse of and consequential emergency room visits related to synthetic cathinones, an emerging class of designer drugs. Despite the classification of a number of synthetic cathinones as Schedule I controlled substances, numerous analogs have been synthesized and continue to remain a popular legal alternative to methamphetamine and MDMA. Using a conditioned place preference assay, dose-response curves for the rewarding effects of four synthetic cathinones in male Swiss-Webster mice were generated: MDAI (0.1, 0.3, 1, 3, 10 mg/kg), flephedrone (4-FMC, 3, 10, 30 mg/kg), butylone (1, 3, 10 mg/kg), and naphyrone (0.3, 1, 3, 10 mg/kg). Conditioning with each of the drugs produced a significant increase in time spent on the drug-paired floor, which suggests that this class of drugs has a high potential for abuse. MDAI was the most potent compound tested, followed by naphyrone, butylone, then flephedrone. MDAI, butylone, and naphyrone produced a plateau in the dose-response pattern of reward, with significant effects across a broad range of doses. Flephedrone produced a narrow inverted-U-shaped dose-response curve with 10 mg/kg resulting in a significant increase in time spent on the drug paired floor, but not 3 or 30 mg/kg. These results suggest that, although each of these drugs produce rewarding effects, MDAI, naphyrone, and butylone may be more likely to be abused over flephedrone, given their broad range of effective doses compared to flephedrone's narrow window of efficacy. When considered together with previous findings that these compounds produce increases in locomotor activity and discriminative effects comparable to cocaine and methamphetamine, the synthetic cathinones pose a significant risk for abuse and warrant further study.

Title: Attenuation of the sleep-disrupting effects of methamphetamine by the selective 5-HT2C agonist WAY 163909 and the selective 5-HT2A antagonist M100907 in rhesus monkeys

Authors: *M. PEREZ DIAZ[1], M. ANDERSEN[2,1], L. L. HOWELL[1,3];
[1]Yerkes Natl. Primate Res. Ctr., Atlanta, GA; [2]Dept. de Psicobiologia, Univ. Federal de São Paulo (UNIFESP), São Paulo, Brazil; [3]Dept. of Psychiatry and Behavioral Sci., Emory Univ., Atlanta, GA

Abstracts: Methamphetamine (METH), one of the most widely abused illicit drugs, causes adverse mental, behavioral and physical effects. One of the most prominent symptoms of amphetamine use is sleep deprivation, which negatively impacts cognitive function and mood, and may contribute to on-going drug use. METH self-administration (SA) reliably disrupts measures of sleep in rhesus monkeys. Interestingly, evidence indicates that serotonin (5-HT) can modulate sleep and the neurochemical and behavioral effects of abused stimulants. Selective 5-HT2A inhibition attenuates the effects of acute amphetamine on arousal and dopamine overflow in rhesus monkeys, and selective 5-HT2C inhibition increases wakefulness and decreases REM sleep in rodents. In the present study, we investigated whether a selective 5-HT2C agonist, WAY163909, and a selective 5-HT2A antagonist, M100907, could attenuate the sleep-disrupting effects of METH SA. Four rhesus macaques with a previous history of METH SA self-administered 0.03mg/kg/injection of METH on a fixed ratio (FR) 20 schedule of reinforcement on Mon.-Fri. between 9-11am. Daily METH intake per subject was 8.97±0.11mg (mean ± SEM) and did not vary throughout study. Subjects then received I.M. injections of M100, WAY, or both between 6-6:15pm. Each dose (or combination of doses) was given for one week (Mon.-Fri.). Sleep was monitored using actigraphy-based monitors attached to the subjects' collars that measure slight changes in motion and translate these into measures of sleep using a temporal-smoothing algorithm. For all subjects, both WAY and M100 treatments decreased latency to fall asleep and increased sleep efficiency compared to vehicle. In addition, attenuation of sleep disruption did not decrease METH SA. These data further inform previous studies by demonstrating that 5-HT2C activation and 5-HT2A inhibition can improve sleep that has been disrupted by METH SA as well as sleep in general, suggesting effectiveness across different neurochemical states. The results of this study suggest that improved sleep may not be sufficient to disrupt ongoing drug-taking behavior. Further, results also suggest that these compounds may prove useful in the treatment of the sleep-related side-effects of psychostimulant abuse.

Title: Amphetamine-induced behavioral and neuronal plasticities are regulated by Parvalbumin-positive GABAergic interneurons of the nucleus accumbens

Authors: ***X. WANG**[1,2], J. DENG[3], A. WEST[2];
[1]Neurosci., [2]Neurobio., Duke Univ., Durham, NC; [3]Dept. of Psychiatry, Univ. of Florida, Col. of Med., Gaines Ville, FL

Abstracts: Psychostimulant drugs of abuse induce plasticity of the functional circuitry within the brain's reward circuits, leading to the expression of addictive-like behaviors. While the majority of the literature has focused on the plasticity of medium spiny neurons (MSNs) in the nucleus accumbens (NAc), as they are critical mediators of motivated behaviors, MSN firing is also gated by local interneurons. Parvalbumin (Pv)-containing GABAergic interneurons make strong inhibitory synapses onto the somata and proximal dendrites of MSNs. These interneurons fire strongly following psychostimulant administration and changes in their activity alter striatal circuit properties. However the functional impact of PV+ GABAergic interneuron in the induction or/and expression of addictive behavior remains unknown. We have shown that both acute and chronic exposure to psychostimulants induce phosphorylation of the methyl-DNA binding protein MeCP2 at Ser421 (pMeCP2), selectively in Pv+ GABAergic interneurons of the NAc. Genetic data show that MeCP2 functions in the NAc to limit the rewarding properties of psychostimulants. Thus these data have led us to investigate whether pMeCP2-dependent plasticity of the Pv+ GABAergic interneuron population in the NAc might underlie these effects. We find that mice bearing a germline MeCP2 knockin (KI) mutation in which Ser421 is replaced by a non-phosphoryatable Ala residue, show enhanced locomotor sensitization to repeated amphetamine injection. Therefore, pMeCP2 functions in the NAc to limit psychostimulant-induced behavioral plasticities. Consistent with the possibility that pMeCP2 regulates adaptations of NAc interneurons, we also find that amphetamine-induced expression of the immediate-early gene Fos is reduced in the Pv+ GABAergic interneurons of the KI mice

compared with their WT littermates. The correlation we observe between Fos regulation in NAc Pv+ GABAergic interneurons and locomotor sensitization in these mice suggests that adaptations in the Pv+ GABAergic interneuron may contribute to psychostimulant-induced behavioral plasticities in these mice. To test this hypothesis we are using an intersectional genetic strategy to express tetanus toxin light chain selectively in Pv+ interneurons of the NAc to determine the behavioral consequences of inhibiting the contribution of these neurons to NAc circuit regulation. These studies are increasing our understanding of the cellular mechanisms that underlie addictive behaviors.

Title: Tolerance to the locomotor-activating effects of 3,4-methylenedioxymethamphetamine (MDMA) predicts escalation of MDMA self-administration and cue-induced reinstatement of MDMA seeking in rats

Authors: *K. T. BALL, M. SLANE;
Dept Psychol, Bloomsburg Univ, Pennsylvania, BLOOMSBURG, PA

Abstracts: Pre-clinical studies of individual differences in addiction vulnerability have been increasing over recent years, but the amphetamine derivative 3,4-methylenedioxymethamphetamine (MDMA; ecstasy) has received relatively little attention in this regard. Previously, we reported large individual differences both in rats' initial behavioral response to experimenter-administered MDMA and their degree of behavioral sensitization to repeated administration. To determine whether these differences could predict subsequent patterns of MDMA-taking or -seeking behaviors we used the self-administration-extinction-reinstatement model to examine addiction-like behavior (i.e., escalation of MDMA self-administration and cue-induced reinstatement of MDMA seeking) in rats a priori characterized for either locomotor sensitization or tolerance to MDMA. Rats that developed tolerance to the locomotor-activating effects of MDMA had a significantly larger locomotor response to the first

MDMA injection relative to rats that developed sensitization. Importantly, rats that developed tolerance subsequently displayed an escalation of MDMA self-administration over days, as well as clear cue-induced reinstatement of MDMA seeking following extinction. Conversely, rats that developed locomotor sensitization to MDMA subsequently maintained relatively stable levels of MDMA self-administration over days and showed no cue-induced reinstatement of MDMA seeking. These results show that differences in the level of psychomotor activation following acute and repeated MDMA administration can reliably predict two important addiction-like behaviors in rats, which may have implications in the prediction of compulsive MDMA use in humans.

Title: The effects of repeated amphetamine exposure during adolescence on psychomotor activity and neuronal function in the medial prefrontal cortex in young adulthood

Authors: *L. K. SHERRILL, T. KRISHNAMANI, D. O'HEARN, M. WU, Y. KUDAIMI, J. M. GULLEY;
Dept. of Psychology, Univ. of Illinois, Urbana-Champaign, Champaign, IL

Abstracts: Amphetamine (AMPH) use typically begins in adolescence and a strong association exists between adolescent-onset drug use, cognitive dysfunction, and a high lifetime prevalence rate of drug dependence. Exposure to drugs during adolescence may have long-lasting neurophysiological effects given the significant, yet normal, changes in dopamine signaling and prefrontal cortex (PFC) development during this developmental time period. Previous studies from our lab and others indicate that repeated exposure to AMPH during adolescence produces long-lasting changes in executive function that may be mediated by alterations in dopaminergic circuits in the medial PFC. Here, we investigated the protracted effects of repeated AMPH exposure early in life on psychomotor behavior and dopamine function in the medial PFC using single-unit recordings from awake behaving male rats. During adolescence, all rats were given

10 injections of saline or AMPH (3.0 mg/kg, i.p.), once every other day, from postnatal day (P) 27-45. In Experiment 1, motor behavior was assessed in an open-field arena following challenges with dopamine D1 or D2 receptor-selective agonists (1.0 mg/kg SKF 82958 and 0.5 mg/kg quinpirole, respectively). In Experiment 2, separate rats were re-exposed to 3.0 mg/kg AMPH in the open-field and after 45 min were given a challenge injection of the D1 receptor antagonist (SKF 83566, 0.03 mg/kg, i.p.). A subset of these rats underwent stereotaxic surgery approximately one week prior wherein a microwire electrode array was implanted into the prelimbic or infralimbic medial PFC. Our preliminary results suggest that repeated AMPH exposure during adolescence produces sensitization to the motor stimulant effects of AMPH and D1- and D2-selective agonists. In the mPFC of AMPH pre-treated rats, neurons excited during AMPH challenge showed a greater increase in firing rate compared those from controls. In addition, this increased activity tended to persist during challenges with SKF 83566 in the AMPH pre-exposed group. Taken together, these preliminary findings provide evidence that exposure to AMPH during adolescence leads to long-lasting plasticity in the mPFC and may be mediated in part by increased responsiveness at D1 receptors. Follow-up studies are underway to assess the effects of repeated exposure to AMPH on D2 receptor function in the mPFC.

Title: Abuse liability and toxicity of synthetic cathinones (“bath salts”) as revealed by intravenous drug self-administration, *ex vivo* MRI, and immunohistochemistry

Authors: *L. R. WATTERSON[1], S. B. TAYLOR[2], F. BUDIN[3], S. F. ALI[4], P. KUFAHL[1], N. NEMIROVSKY[1], M. OLIVE[1];

Abstracts: In the last few years, designer drugs known as synthetic cathinones, often colloquially referred to as “bath salts”, have emerged as popular “legal high” replacements of illicit stimulants such as methamphetamine, cocaine, and MDMA (ecstasy). Acute use of synthetic cathinones has led to numerous documented incidences of intoxication and toxicity, adverse psychological and behavioral effects, and death. However, while adverse acute effects are well documented, little scientific data exists detailing their abuse liability or potential neurotoxic effects. In the first set of experiments, we present data collected in our laboratory using rodent intravenous self-administration (IVSA) showing that both MDPV and methylone, two first-generation synthetic cathinones, were both robustly self-administered during 2-hour limited access conditions. In 6-hour extended access conditions, however, only MDPV led to escalated intake, a pattern most similar to that of methamphetamine. This finding suggests that MDPV has a higher degree of addiction potential compared to methylone. In addition, we show that self-administration of both MDPV and methylone intake is highly correlated with alterations in monoamine and monoamine metabolite levels in both cortical and hypothalamic brain tissue. Next, in a separate set of experiments, we present additional evidence of toxicity with *ex vivo* MRI data revealing macro-scale changes in brain structures resulting from chronic self-administration of MDPV and methamphetamine as compared to sucrose controls. Furthermore, brains that underwent MRI imaging were further processed in histological procedures to assess changes in the expression of dopamine and serotonin transporters, microgliosis, and neurodegeneration. Collectively, these results indicate that synthetic cathinones possess a significant abuse liability and exert numerous CNS effects on both macro-structural and micro-structural levels.

Title: The role of trace amine associated receptor 1 in behaviors

Authors: X. SHI[1], N. WALTER[1], K. J. BUCK[1], J. K. BELKNAP[1], T. J. PHILLIPS[1], *A. J. JANOWSKY[2];
[1]Oregon Hlth. & Sci. Univ., Portland, OR; [2]VA Med. Ctr., PORTLAND, OR

Abstracts: Trace amine associated receptor 1 (TAAR1) is a G-protein coupled receptor and is activated by a number of endogenous ligands including tyramine and β-phenethylamine. The receptor is also a direct target of psychostimulants, including methamphetamine (MA), amphetamine, and 3,4-methylenedioxymethamphetamine (MDMA). Despite a growing number of studies, the role of this receptor in specific symptoms of drug abuse is not well understood. Interestingly, there is one nonsynonymous single nucleotide polymorphism (SNP) in the TAAR1 that distinguishes various inbred mouse strains. One allele is apparently unique to the DBA/2J (D2) strain, while an alternative allele is shared by C57BL/6J (B6) and at least 17 additional strains. This SNP (C229A) results in allelic isoforms with either proline or threonine at amino acid position 77. This amino acid residue is situated at the putative cytoplasmic end of the second transmembrane domain of TAAR1. This has tremendous implications for TAAR1 function and its role in behavioral and physiological phenotypes. To determine if there is a difference in function between the B6 and D2 TAAR1, site-directed mutagenesis was used to create the D2 construct. Both B6 and D2 constructs were stably transfected into HEK-293 cells, cells were prepared and treated with β-phenethylamine or tyramine, and cAMP accumulation was measured using ELISA. Both β-phenethylamine and tyramine elicited a dose-dependent response in cells expressing the B6-like TAAR1 (EC_{50}~100nM), and the effect was blocked by EPPTB, a TAAR1 antagonist. However, agonist effects were absent in the cells expressing the D2 TAAR1, suggesting that the receptor is non-functional. RT-PCR was used to verify that both receptors are transcribed. Additionally, confocal microscopic analysis of GFP-tagged constructs indicated that both B6 and D2 TAAR1 are cytosolic, consistence with previous reports. Correlational analyses of B6 x D2 recombinant inbred (BXD RI) strain data using published and unpublished behavioral trait databases indicated that TAAR1 function (or its absence) is strongly correlated with behaviors related to psychostimulant, opiate, and ethanol responses. These findings have significant implications for understanding the role of TAAR1 in drug seeking or withdrawal behaviors, as well as in normal physiology. This work was supported by the Department of Veterans Affairs, the Methamphetamine Abuse Research Center (P50DA018165), the Portland Alcohol Research Center (P60AA010760), and R24AA020245.

Title: Nicotine causes long-lasting behavioral sensitization and changes in accumbal neurotransmission

Authors: *J. E. MORUD, L. ADERMARK, M. ERICSON, B. SÖDERPALM;
Univ. of Gothenburg, Gothenburg, Sweden

Abstracts: Chronic tobacco use is often associated with life-long addiction as well as high risk of relapse after cessation. This is suggestive of persistent neural adaptations, but very little is known about the long-lasting effects of nicotine on neural circuits. In order to investigate the long-term effects of nicotine exposure Wistar rats were treated during three weeks with nicotine (0.36 mg/kg), and the duration of behavioral and neurophysiological adaptations were evaluated seven months later. We found that increased drug-induced locomotion persisted seven months after the initial behavioral sensitization. *In vitro* analysis of synaptic activity in the nucleus accumbens (nAc) revealed a decrease in nicotine-sensitized rats as compared to vehicle-treated control rats. In addition, administration of the dopamine D2 receptor agonist quinpirole significantly increased evoked population spike amplitude in nicotine-sensitized rats as compared to vehicle-treated control rats. These results suggest that nicotine sensitization produces long-lasting neural effects, which are detectable both in behavior and in field potential recordings.

Title: Role of histone modifying enzyme PRDM2 in alcohol-related behaviors

Authors: *C. PITCAIRN[1,2], E. BARBIER[2], A. BORICH[2], J. TAPOCIK[2], A. JOHNSTONE[2], J. SCHANK[2], Z. ZHOU[3], Q. YUAN[3], D. GOLDMAN[3], C. WAHLESTEDT[2], M. HEILIG[2]; [1]1-5288, NIH-NIAAA, Bethesda, MD; [2]Lab. of Clin. and Translational Studies, Natl. Inst. of Alcohol Abuse and Alcoholism, Natl. Inst. of Hlth., Bethesda, MD; [3]CTI, Dept. of Psychiatry, Univ. of Miami Miller Sch. of Med., Miami, FL

Abstracts: Exposing rats to repeated cycles of alcohol intoxication and withdrawal will produce persistent changes in voluntary alcohol consumption that model characteristics of human alcohol use disorder (AUD). Although the neural adaptations mediating these behavioral changes remain unclear, recent data suggest that modifications in histone and DNA methylation may play a role. Therefore, we wanted to investigate how the expression of enzymes related to such epigenetic modifications is changed following alcohol-exposure and whether these expression differences are associated with behaviors characteristic of post-dependent rats. To test this, alcohol dependence was induced in male Wistar rats by exposing them to alcohol vapor 14 hours a day for 7 weeks. Three weeks after conclusion of alcohol exposure, total RNA extracted from the dorsal medial prefrontal cortex (dmPFC) was sequenced using the whole transcriptome sequencing protocol (n=4/group). Whole transcriptome sequencing identified 783 genes that were differentially expressed between control and post-dependent rats, including several genes coding epigenetic enzymes that showed significantly decreased expression in rats chronically exposed to alcohol vapor. We chose to investigate the effect of reducing expression of one of these enzymes - the histone lysine 9 methyltransferase PRDM2. Thus, a shRNA lentivirus specific to prdm2 was injected into the dmPFC of naïve rats and behavioral tests for alcohol consumption, aversion resistant alcohol seeking, and stress induced reinstatement were performed. We found that inhibition of PRDM2 within the dmPFC was associated with increased alcohol self-administration, a resistance to quinine adulteration, and reinstatement of self-administration at a lower shock intensity. These results suggest that PRDM2 may regulate specific behaviors observed in post-dependent rats and suggest a role for histone methylation in alcohol-related behaviors more generally.

Title: Neuronal dna-methylation in the medial prefrontal cortex regulates alcohol-induced behavior and plasticity

Authors: *A. L. BORICH, E. BARBIER, J. TAPOCIK, N. JUERGENS, C. PITCAIRN, J. HANSON, J. SCHANK, H. SUN, A. THORSELL, K. SCHUEBEL, Z. ZHOU, Q. YUAN, M. EMMERT-BUCK, D. GOLDMAN, M. HEILIG;
Natl. Inst. On Alcohol Abuse and Alcoholism, Bethesda, MD

Abstracts: Recent studies have suggested an association between alcoholism and DNA methylation, a mechanism that can mediate long-lasting changes in gene transcription. Here, we examined the contribution of the DNA methyltransferase 1 (DNMT1) to the long-term behavioral and molecular changes induced by a history of alcohol dependence. In search of mechanisms underlying persistent rather than acute dependence-induced neuroadaptations, we studied the role of DNA methylation and DNMT1 activity for medial prefrontal cortex gene expression and for alcohol self-administration (SA) in post dependent (PD) rats. Male wistar rats (200-400g) became alcohol dependent with exposure to intermittent alcohol vapor for 14h each day for 7 weeks until a stable blood alcohol concentration (BAC) of 150-300 mg/dl was established. Controls were housed in identical chambers with normal airflow. Three weeks after exposure, baseline SA of 10% alcohol was measured. PD rats showed escalated alcohol intake, which was associated with increased DNMT1 expression as well as decreased expression of genes encoding synaptic proteins involved in neurotransmitter release in the mPFC. Infusion of the DNMT1 inhibitor RG108 prevented both escalation of alcohol consumption and dependence-induced down-regulation of 4 out of 7 transcripts modified in PD rats. Specifically, DNMT1 treatment directly reversed the down-regulation of syt2, which was caused by alcohol-induced hypermethylation on exon1. Lentiviral inhibition of syt2 expression in the mPFC increased aversion-resistant alcohol drinking, supporting a mechanistic role of syt2 in alcohol seeking. Treatment with the methyl-donor, L-Methionine, induced escalation in alcohol consumption in naïve rats similar to that of PD rats. Our findings show a functional role of DNMT1 in persistent alcohol-induced behaviors, and identify a candidate gene network that may mediate its effects. DNMT1 expression is persistently increased in mPFC with chronic intermittent exposure to

alcohol. Inhibition of DNMT1 normalized alcohol consumption and restored expression levels of neurotransmission-related genes, indicating that DNA hypermethylation is causally related to their suppressed expression in PD rats. Together, these data provide novel evidence for DNMT1 as a potential therapeutic target for alcoholism.

Title: GluN2B-NMDA receptor targeted proteomic approach unveils ethanol-induced changes in molecular signaling cascades involved in plasticity

Authors: ***T. A. WILLS**[1], K. M. LOUDERBACK[2], A. J. BAUCUM[3], R. J. COLBRAN[1], D. G. WINDER[1];
[1]Mol. Physiol. and Biophysics, [2]Neurosci., Vanderbilt Univ., Nashville, TN; [3]Dept of Biol., Indiana Univ. Purdue Univ. in Indianapolis, Indianapolis, IN

Abstracts: GluN2B-containing NMDA receptors (NMDARs) govern synaptic efficacy at glutamate synapses, and are major acute and chronic targets of alcohol. In the BNST, the acute and chronic effects of ethanol are dependent on the GluN2B subunit of the NMDAR. Further, withdrawal from chronic intermittent ethanol (CIE) in this region causes an enhancement of long-term potentiation (LTP) that may involve activation of extrasynaptic GluN2B-NMDARs. This enhancement was unexpected in light of the wealth of data suggesting that extrasynaptic GluN2B-NMDARs promote long-term depression (LTD) in regions like the hippocampus. To investigate how this plasticity might be differentially regulated in different regions by ethanol, we utilized a GluN2B-NMDAR-immunoprecipitation-based proteomic approach to identify GluN2B associated proteins. In the hippocampus, we find a constellation of ethanol-induced protein changes indicative of induction of group I mGluR regulated LTD (Arc, Homer, GluA2).

In support of this proteomic data, we find that the group I mGluR agonist DHPG fails to produce LTD in area CA1 following CIE. These data suggest *in vivo* induction of group I mGluR-LTD by CIE and a possible connection between NMDAR and mGluR signaling. Current proteomic work in the BNST will help determine whether divergent mechanisms I these two regions are responsible for the district regional influence on plasticity.

Title: Family history of alcohol use disorder and large-scale intrinsic network connectivity in adulthood

Authors: M. H. PARRISH[1], C. T. SMITH[2], M. MENCELOGLU[1], S. H. OPPLER[1], *C. A. BOETTIGER[4,3];
[1]Psychology, [2]Neurobio. Curriculum, [3]Bowles Ctr. for Alcohol Studies, Univ. of North Carolina, Chapel Hill, NC; [4]Psychology & BRIC, Univesity of North Carolina, CHAPEL HILL, NC

Abstracts: Alcohol use disorders (AUDs) are highly heritable, with 40-60% of AUD risk estimated to be genetic. Despite known heritability, to date, few biomarkers of family history of AUDs have been identified. Moreover, although a few neuroimaging studies have compared adolescent brain connectivity between those with a family history of AUD (FHP) and those without (FHN), no studies to date have compared intrinsic brain connectivity in FHP and FHN adults. Our objective in the present investigation was to identify differences in large-scale adult

brain network connectivity associated with AUD family history status. To do so, we used functional connectivity analysis of resting state fMRI data to quantify the coactivation of predefined brain regions in identified intrinsic functional networks (salience network: SN; central executive network: CEN; default mode network: DMN) in 58 healthy adults, comparing those classified as FHP (n=22) or FHN (n=36). Participants were screened for psychiatric diagnoses, including lifetime substance use disorders. The FHP and FHN groups did not differ significantly in terms of age, sex, socioeconomic status, education, IQ, or substance use. We first specifically compared covariation in the activity of a key SN node, the right frontoinsular cortex (rFIC), and frontoparietal nodes of the CEN between FHP and FHN groups. We observed significantly greater SN-CEN synchrony in the FHN group ($Z=0.23 \pm 0.03$) relative to FHP group ($Z=0.06 \pm 0.05$); $t(56)=3.24$, $p=.004$). We next compared coactivation of another SN seed, the ventral tegmental area (VTA) and the medial orbitofrontal cortex (mOFC) between FHP and FHN groups. We found significantly greater VTA-mOFC connectivity in the FHP group ($Z=0.24 \pm 0.03$) relative to the FHN group ($Z=0.11 \pm 0.03$); $t(56)= 2.85$, $p=.004$). Additional exploratory seed-to-voxel analyses evaluating the effect of FH status on connectivity with rFIC or VTA seeds identified multiple loci within the CEN and DMN that were differentially synchronous with the rFIC or VTA seeds between the FHP and FHN groups. Loci within the DMN showed greater synchrony with the VTA among the FHP group, whereas sites within the CEN were less coactive with the rFIC among the FHP group. These findings predict impaired switching between exogenous and endogenous attention in FHP relative to FHN individuals, an idea to be empirically tested. These data also suggest adult patterns of resting state connectivity between salience processing regions and the DMN and CEN as novel biomarkers for familial AUD risk or resilience. Future work to determine whether these patterns of network interconnectivity predict future alcohol problems may shed light on this issue.

Title: Exercise-induced positive activated affect is dependent on work intensity and modulated by opioid receptor system distributed in the mesolimbic pathway. A positron emission tomography study

Authors: *M. HIURA[1,2], T. NARIAI[3,2], K. ISHII[2], M. SAKATA[2], K. ODA[4,2], J. TOYOHARA[2], K. ISHIWATA[2];

Abstracts: [Introduction] The opioid receptor system is involved in the regulation of pain and emotion and the underlying mechanism has been studied using positron emission tomography (PET) with the selective μ-opioid agonist radiotracer [^{11}C]carfentanil (CFN). Physical exercise is associated with changes in mood states and altered pain perception, and the underlying mechanism has not been well elucidated. Considering that exercise is a physiological stressor, as with pain and emotion, it is speculated that exercise-induced mood change might share common neuroanatomical pathways of the opioid receptor system. The present study investigated the effect of exercise intensity on the μ-opioid receptor (MOR) availability in the brain by CFN PET and the association between the exercise-induced altered mood and the opioid receptor system. **[Methods]** Seven healthy young males performed two bouts of the constant work rate cycling exercise for 20 min on separate days with different intensities and underwent two CFN PET imaging sessions on each day: a resting state PET scan and a post exercise PET scan. The exercise of moderate and heavy intensities (ExM and ExH, respectively) was applied, which corresponded to 60% and 80% of their peak pulmonary oxygen uptake, respectively. Mood status was monitored before and after the exercise bouts. The binding potential (BP_{ND}) of CFN was determined by a modified Logan graphical analysis. For an anatomical reference, individual brain MRI scans were acquired and the image data were analyzed using Statistical Parametric Mapping software. **[Results]** Decrease of the BP_{ND} was identified in broad areas including the amygdala, insular cortex, anterior cingulated cortex, caudate nucleus, precuneus region and frontal and temporal cortexes ($P<0.001$, uncorrected) after the ExM but only in the anterior cortex, precuneus region and orbital gyrus after the ExH. With regards to the altered mood in the ExM, the scales of depression positively correlated with the BP_{ND} in the regions such as the amygdala and anterior cingulated cortex which are involved in the mesolimbic pathway ($P<0.001$, uncorrected). This correlation was not identified after the ExH. **[Discussion]** Decreased BP_{ND} was considered to reflect the endogenous opioid release as the main effect of the ExM and ExH as well. However, an anxiolytic effect was specific to the ExM which might be attributable to the MOR system in the mesolimbic pathway. The results of the present study suggest that leg movement, respiratory effort and elevation in body temperature caused by exercise might have effect on interoceptive network of feelings from the body which partially shares the mesolimbic pathway.

Title: Acute and long-term effects on neurotransmission and plasticity in striatal subregions after intermittent nicotine exposure

Authors: *L. ADERMARK[1], J. MORUD[1], K. DANIELSSON[1], M. PEREZ ALCAZAR[2], M. ERICSON[1], A. LOTFI[1], B. SÖDERPALM[1];
[1]Addiction Biol. Unit, Gothenburg, Sweden; [2]Neurosci. and Physiol., Gothenburg, Sweden

Abstracts: Repeated administration of drugs of abuse appears to recruit serial and dopamine-dependent striatal ascending spirals from the nucleus accumbens (nAc) to more dorsal regions of the striatum. This progressive shift might be of importance for the development of compulsive drug seeking and the high vulnerability to relapse. The aim of this study was to explore acute and long-term effects of repeated nicotine administration on synaptic efficacy and plasticity in striatal subregions of adult male Wistar rats. Daily nicotine injections for 3 weeks (0.36 mg/day s.c., 15 days) produced robust locomotor sensitization to the drug. Field potential recordings reviled a decrease in input/output function in the dorsomedial striatum (DMS) for up to one month after the nicotine sensitization-period, while the dorsolateral striatum (DLS) and nucleus accumbens (nAc) remained unaffected. After three, and up to six months of nicotine abstinence, however, synaptic efficacy was recovered in the DMS but significantly decreased in the nAc of nicotine-sensitized rats as compared to vehicle-treated controls. In parallel to the decrease in input/output function the number of dendritic spines was increased, suggesting that repeated administration to nicotine might increase the number of silent synapses in striatal sub-regions. Synaptic plasticity induced by high frequency stimulation sustained in nicotine-treated rats acutely after the sensitization-period, but was significantly impaired in the DLS following one and three months of nicotine abstinence. In conclusion, the data presented here indicates that repeated nicotine-

administration produces long-lasting, sub-region specific and time-dependent effects on striatal neurotransmission, which could be related to behavioral sensitization to nicotine and/or to the development of addiction.

Title: A hypo-status revealed by multi-modal neuroimaging in drug addicted Brain

Authors: ***Z. WANG**[1], J. SUH[2], C. P. O'BRIEN[2], T. FRANKLIN[2], A. R. CHILDRESS[2]; [1]Psychiatry, Univ. of Pennsylvania, PHILADELPHIA, PA; [2]Psychiatry, Univ. of Pennsylvania, Philadelphia, PA

Abstracts: Addiction is a chronic brain disorder. Finding brain signatures sensitive to disease is a high research priority. Previous studies suggested a reduced baseline activity in addicted brain, but it is unclear whether it is a static change or a dynamic baseline dysfunction and whether it overlaps with structural alterations related to drug use. The purpose of this study was to address these unexplored questions. We hypothesized that drug users have 1) tissue loss in orbitofrontal cortex (OFC), a critical area in the development of addictive behavior, and 2) hypo-perfusion in prefrontal cortex (PFC) and limbic area; 3) hypo-dynamic activity in PFC and limbic area; 3) the 3 modal brain alterations show overlaps. To test the hypotheses, we acquired structural MRI, arterial spin labeled (ASL) perfusion MRI, and resting state fMRI (rsfMRI) data from 23 cocaine treatment seeking patients and 25 race/education/age matched controls. Individual brains were registered into a standard space for group level analysis. Brain volume was measured using the voxel-based morphormetry technique. Static baseline activity was measured with cerebral blood flow using ASL MRI, which is known to be related to regional brain function. Dynamic baseline was characterized by rsfMRI reflected brain complexity, which has been shown to be altered in

disease conditions. Statistical results were collected using a threshold of p100 (corrected using Monte Carlo simulations with $\alpha<0.05$). Compared to controls, patients showed reduced grey matter volume in OFC, consistent with findings published by us and others; patients had hypo-perfusion in medial and bilateral OFC, ventral striatum (VS), anterior cingulate cortex (ACC), insula, temporal cortex, and dorso-lateral PFC (dlPFC), indicating a static hypo-activity in these mesa-limbic-cortical area, which is a major circuit involved in drug addiction; hypo-resting state functional complexity was found in mOFC, VS, insula, and dlPFC, but also in the sensory-motor system consisting of precentral cortex, parietal cortex, and thalamus. The hypo-complexity patterns indicate a loss of functional capacity of integrating either external or internal input such as inhibition or attentional control signal for drug use. Hypo-complexity in ACC/OFC and dlPFC was related to higher risk-taking (an addiction-relevant behavior). Hypo-perfusion and hypo-complexity overlapped with atrophy patterns only in the anterior part of mOFC. Suggesting a dis-association of structural and functional contribution to addiction related brain alterations. These multi-modal hypo- signatures may have potential clinical significance. Supported by the CURE grant.

Title: The transgenerational effects of nicotine and chronic stress in mice

Authors: *N. L. YOHN[1], C. KRAPP[2], M. S. BARTOLOMEI[2], J. A. BLENDY[1];
[1]Dept. of Pharmacol., [2]Cell and Developmental Biol., Univ. of Pennsylvania, Perelman Sch. of Med., Philadelphia, PA

Abstracts: Objective: Evidence suggests that nicotine and stress can influence behavior within and across generations. Thus, the goal of this work is to determine if nicotine and stress

administered in separate generations interact to influence behavioral manifestations of drug and stress response in subsequent generations. Methods: Male C57Bl/6 mice (F0) were administered chronic saline or nicotine via osmotic minipump for four weeks starting at 4 weeks of age. Following 1 month of nicotine administration, minipumps were removed and males were mated to produce F1 offspring. Half of the F1 males and females underwent chronic unpredictable stress (CUS) for 2 weeks starting at 4 weeks of age. Following CUS, both male and female mice were mated with naïve partners to produce the F2 generation and these offspring were used to produce the F3 generation. All generations (F1, F2, and F3) were administered a series of tests for anxiety-like phenotypes and stress responsivity between 10-14 weeks of age. Brain regions of interest were harvested from the F2 generation. A candidate gene approach was employed to determine the molecular changes in subsequent generations of offspring following parental nicotine exposure by probing for the expression of CRF, CRFR1, CRFR2, and GR in brain regions that directly influence behavior on the acoustic startle response (ASR) in F2 mice. Results: In F1 males, adolescent stress increased anxiety-like behavior in the MB and EZM. Increase in anxiety-like behavior extended to the F2 male offspring derived from F1 female mothers that received stress. In addition, in the male F1 mice a decrease in ASR was found due to stress and nicotine lineage. Finally, preliminary evidence suggests, the effect of stress in the F1 generation extends to males in the F3 generation. In F1 females, adolescent stress increased anxiety-like behavior in the EZM, however this phenotype was not transmitted to additional generations. Instead, in both F1 and F2 female mice, nicotine lineage increased startle amplitude in ASR. In addition, F2 male mice derived from stress and/or nicotine showed altered expression of CRFR1 and GR in the hypothalamus and amygdala in a region specific manner. Summary: The clinical and public health implications of life-long or transgenerational effects after preventable “exposures” such as nicotine indicate an urgent need to understand the mechanisms that mediate these effects. This work was supported by T32 DA28874 and R01 DA033646.

Title: Effects of adolescent exposure to morphine in female rats on cognitive function in male offspring

Authors: C. WEBBER[1], F. VASSOLER[2], R. DONAHUE[1], E. BYRNES[2], *W. A. CARLEZON, Jr[1];
[1]Dept Psychiat, Harvard Med. Sch./Mclean Hosp., BELMONT, MA; [2]Cummings Sch. of Vet. Med., Tufts Univ., North Grafton, MA

Abstracts: In humans, opiate use during adolescence is more common in girls than in boys. Previous research in rodents has determined that the male offspring of females exposed to morphine during adolescence show sensitized behavioral response to morphine. With acute morphine administration, prepubescent male offspring have prolonged sedation and adult male offspring have increased morphine analgesia. We explored the possibility that exposure to morphine in female adolescent rats may affect measures of cognitive function in male offspring. Female Sprague-Dawley rats were administered an increasing dose regimen of morphine (5-25 mg/kg; subcutaneously) or saline from post-natal day 30-40, and then allowed to recover for at least 3 weeks before mating with a naïve male. Differences between male offspring of saline-exposed females (SAL-F1) and male offspring of morphine-exposed females (MOR-F1) were assessed in the 5-Choice Serial Reaction Time Task (5CSRTT), a well-validated method of studying learning, impulsivity, and motivation. Specifically, 5CSRTT measures include %Correct, %Omitted, %Accuracy, head entries, response types, and latencies. Rats were first evaluated in terms of baseline (pre-drug) performance by 3 days at criteria (>60% Correct, <20% Omissions). Following baseline assessment, rats received intraperitoneal injections of cocaine (1.0, 3.0, 10.0 mg/kg) in ascending order. After cocaine administration rats were given at least one session to meet criteria before the next dose, if criteria was not met baseline was re-established. There were no inherent differences between MOR-F1 and SAL-F1 rats as assessed by 5CSRTT. On the day of cocaine treatment, both groups performed similarly in %Correct, %Omitted, and %Accuracy. There was a main effect of cocaine dose and of maternal treatment on head entries, often considered an index of stereotypic behavior. Post-hoc tests revealed that 10mg/kg cocaine increased head entries significantly in the MOR-F1 group when compared to SAL-F1. Moreover, MOR-F1 rats exhibited greater head entries than SAL-F1, independent of dose. Interestingly, on the day following cocaine treatment, the MOR-F1 group performed better in %Correct, %Omitted, and %Accuracy than while on cocaine. In contrast, the SAL-F1 group performed the same or worse the day following cocaine treatment than while on cocaine. One possibility is that performance on the day following cocaine reflects acute withdrawal, and the MOR-F1 rats are less sensitive to withdrawal-associated dysphoria. Further exploration into the transgenerational effects of female adolescent morphine use on responsiveness to adverse and rewarding stimuli is warranted.

Title: Alterations in cell proliferation following combined binge alcohol and chronic nicotine exposure in adult rats

Authors: R. T. LINGG[1], C. B. HARTLESS[1], K. Y. CHEN[2], K. NIXON[2], *D. M. HAYES[1]; [1]Radford Univ., Radford, VA; [2]Univ. of Kentucky, Lexington, KY

Abstracts: Excessive alcohol consumption has consistently been associated with drastic impairments in neurological functioning ranging from structural to complex behavioral abnormalities, but the long term cognitive effects of nicotine use are less clearly established. Within the adult brain, researchers have shown impairments from alcohol and nicotine abuse in neural progenitor cell (NPC) proliferation, as well as the subsequent differentiation, maturation, and integration of NPCs into existing neuronal functioning; a process known as neurogenesis. Specifically, research has shown that both binge alcohol consumption and chronic nicotine abuse result in a substantial depression of cell proliferation within the subgranular zone (SGZ) of the dentate gyrus of the hippocampus; an area associated with ongoing plastic developments involved in spatial memory and learning. Furthermore, reduced neurogenesis has been hypothesized to be a potential mechanism underlying impairments in structural and functional integrity seen in many chronic drug users. As alcohol and nicotine are the most commonly co-abused substances, further elaboration regarding the neural mechanisms of their combined use is critical. Adult male Sprague-Dawley rats were injected with nicotine (0.3 mg/kg in 0.9% saline) or vehicle every 8 hours for 10 days. For the final four days of exposure, rats also received intragastric intubations of an ethanol-containing diet (25% w/v in Vanilla Ensure Plus®) or control diet thrice daily (mean dose: 9.17 ± 0.31 g/kg/day, BEC: 276.07 ± 12.43 mg/dL). Immediately after the final drug administration, brains were extracted and coronal tissue sections (40 μm) were used for Ki67 immunohistochemistry in order to identify cells in all active phases of the cell cycle. As expected, cells expressing Ki67 were located in non-homogenous cell clusters along the SGZ of the dentate gyrus. Consistent with previous reports, a significant reduction in Ki67+ cells was observed following binge ethanol treatment as compared to

controls. Furthermore, exposure to nicotine expectedly resulted in significant reductions in cell proliferation in the SGZ. Importantly, the dual ethanol and nicotine treatment yielded substantially reduced numbers of proliferating cells as compared to all other groups. Thus, dual exposure to alcohol and nicotine resulted in enhanced deficits in cell proliferation, which may compromise hippocampal integrity more drastically than either drug alone. Future research will investigate whether the additive damage to hippocampal circuitry following dual drug exposure results in behavioral deficits on a Morris Water Maze task.

Title: Effects of chronic nicotine administration on hippocampal and striatal acetylcholinesterase activities

Authors: *P. U. NWOHA[1], O. M. IJOMONE, Male[2];
[1]Anat. & Cell Biol., Obafemi Awolowo Univ., Ile-Ife, Nigeria; [2]Human Anat., Cross River Univ. of Technol., Okuku, Nigeria

Abstracts: The present study investigated the effects of chronic administration of nicotine on the activities of acetylcholinesterase (AChE) in the hippocampus and striatum. Adult male albino Wistar rats, obtained from the Animal Holding of the Department of Anatomy and Cell Biology, Obafemi Awolowo University, Ile-Ife, Nigeria, were divided into two groups - experimental and control groups. Rats in the experimental group were given daily subcutaneous injections of nicotine at doses of 0.25, 2 or 4 mg/kg body weight for 28 days, while those in the control received similar injections of physiological saline for the same period. At the end, animals were anaesthetised and brains excised and processed for histochemical demonstration of AChE. Results obtained revealed significant decrease in AChE activities in the hippocampus and striatum following 2, and 4 mg/kg nicotine ($P < 0.01$) but not 0.25 mg/kg administration. This shows that nicotine may inhibit AChE activities in the brain, thereby affecting acetylcholine availability, with consequent motor effect.

Title: The gene expression response of Snca and Cdk5 to nicotine dosing is adolescent-specific and correlates with nicotine preference

Authors: R. T. HALLENBERG[1], N. S. DHARKER[1], *K. J. FRYXELL[2];
[1]Sch. of Systems Biol., George Mason Univ., Manassas, VA; [2]Sch. of Systems Biol., George Mason Univ., MANASSAS, VA

Abstracts: We injected inbred adolescent and adult mice (A/J and C57BL/6J strains) with a single subcutaneous dose of 0.5 mg/kg nicotine (or saline vehicle). We sacrificed them 3 hr or 24 hr later, and dissected specific brain areas for gene expression analysis. An additional set of mice were subjected to 4 injections at 2 day intervals, then sacrificed 24 hr after the last injection. Here we show that *Snca* and *Cdk5* were up-regulated in multiple brain areas of adolescent (but not adult) mice, by nicotine (but not saline) injections. In some cases, this up-regulation was significant after a single nicotine injection. After multiple nicotine injections, up-regulation was further increased, and was most pronounced in the mouse strains, ages, and sexes most vulnerable to nicotine dependence. In particular, *Snca* and *Cdk5* up-regulation was greater in adolescent mice than adults, greater in females than males, and greater in C57BL/6J than in A/J mice, all of which matched reported differences in nicotine preference. These observations, together with previous evidence that *Snca* and *Cdk5* were up-regulated by cocaine, suggest that both genes may have been up-regulated by nicotine-stimulated dopamine signaling. If so, then the probable result would be homeostatic reductions in dopamine signaling, which are among the best-documented functions of both *Snca* and *Cdk5*.

Title: Effects of kolaviron on the histology of the hypothalamus, pituitary, and testes of adult male Wistar rats

Authors: A. U. OBI[1], P. U. NWOHA[2], *C. A. ONYEKA[3,4];
[1]Dept. of Anat. and Neurobio., Imo State Univ., Owerri, Nigeria; [2]Dept. of Anat. and Cell Biol., Obafemi Awolowo Univ., Ile-Ife, Nigeria; [3]Dept. of Anat., Univ. of Lagos, Lagos, Nigeria; [4]Anat., Madonna Univ., Elele, Nigeria

Abstracts: Garcinia kola Linn is consumed widely in sub-Saharan Africa for various purposes, and kolaviron is its main product. This study determined the effects of kolaviron on the histology of organs of the hypothalamic-pituitary-gonadal axis, mainly the hypothalamus, pituitary and testis. The aim was to ascertain if its consumption has deleterious effects on these organs. Thirty-six adult male Wistar albino rats, obtained from the Department of Anatomy and Cell Biology, Obafemi Awolowo University, Ile-Ife, Nigeria, with mean weight of 220g, were divided into six groups (A, B, C, D, E, F) of six animals each. Groups A, B, C, and D were the experimental groups and were given 100, 200, 400 and 800 mg/kg body weight of kolaviron respectively. Animals in group E served as control 1 and were given physiological saline, while those in group F served as control 2 and were given corn oil in which the kolaviron was dissolved. All administration was done daily by gastric intubation for 8 weeks. Adequate care was taken of all the animals. At the end, animals were anaesthetised, and the organs processed, stained with H & E and studied. Cells were counted with Image J. Compared to the controls, results showed gross cellular depletion and desquamation in the testis of groups C and D. Also in groups C and D, but not A, and B, there was significant reduction in the number of cells of the hypothalamus, and pituitary, compared to the controls ($P<0.05$). These findings suggest that kolaviron, at high doses could affect these organs and be detrimental to the body.

Title: Chronic nicotine administration in adolescent C57BL/6J mice results in deficits in trace fear conditioning in adulthood

Authors: *D. A. CONNOR[1], T. J. GOULD[2];
[1]Temple Psychology, Philadelphia, PA; [2]Psychology, Temple, Philadelphia, PA

Abstracts: The consequences of nicotine exposure during adolescence on cognition are not well understood. However, according to the CDC, 23 percent of high school students currently use tobacco products. Therefore, there is a need to develop a better understanding of the immediate and long-lasting effects of nicotine exposure during adolescence on cognition. Previous work indicates that exposure to chronic nicotine during adolescence leads to long-lasting deficits in contextual fear conditioning, 30 days after cessation of nicotine treatment (in adulthood). In contrast, adult mice do not show long-term deficits in contextual fear conditioning 30 days after exposure to chronic nicotine. Previous work from our lab has shown that immediate abstinence results in deficits in trace fear conditioning in adult mice. Thus, we sought to investigate how chronic nicotine administration might alter learning in a different hippocampus-dependent task, trace fear conditioning. In addition to recruitment of the hippocampus, trace fear conditioning also requires the medial prefrontal cortex and is thought to share characteristics with declarative memory. Therefore, trace fear conditioning is a useful behavioral assay to assess changes higher order cognitive function. We tested both long-term (30 days) and immediate (24 hr) abstinence after chronic administration during either adolescence or adulthood. An age-dependent effect was seen after long-term abstinence from chronic nicotine. Adolescent mice chronically administered nicotine showed deficits in trace fear conditioning 30 days after cessation. However, when mice were chronically treated during adulthood, and tested 30 days after cessation, no deficit was observed. In contrast, adolescent mice showed no immediate abstinence deficit, while mice treated in adulthood did show immediate deficits. Our findings support previous data showing administration during adolescence leads to deficits in hippocampus-dependent conditioning and attention. However, our results diverge from work showing that chronic nicotine treatment during adolescence leads to immediate abstinence-associated deficits in hippocampus-dependent contextual fear conditioning. This difference may result from the recruitment of extrahippocampal prefrontal regions during trace fear conditioning. In sum, our results represent a novel assessment of the long and short-term effects of prior chronic nicotine administration in adolescent and adult mice on cognition. Furthermore, this work demonstrates

that abstinence-associated deficits in hippocampus/cortex-dependent conditioning may impact adolescents differently than adults.

Title: The role of context preference on single trial nicotine conditioned place preference, and the role of dosing context on MAPK activation in the ventral striatum

Authors: *G. M. FERNANDEZ[1], D. G. EHLINGER[1], H. C. BERGSTROM[2], C. G. MCDONALD[1], R. F. SMITH[1];
[1]George Mason Univ., Fairfax, VA; [2]Lab. of Behavioral and Genomic Neurosci., Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD

Abstracts: Adolescents are prone to risky behaviors that lead to experimentation with drugs, such as nicotine. This behavioral profile coincides with a sensitization of the dopamine reward pathway. Drug-seeking behaviors are also maintained through reinforced drug- cue associations, tested via conditioned place preference (CPP). CPP is a behavioral measure of drug reward where a drug- context relationship is established through associative learning. Developmental differences in the establishment of a nicotine- context association could be due to differences in the cellular mechanisms underlying plasticity. The mitogen activated protein kinase (MAPK) pathway has been implicated in drug-induced plasticity. Adult (~P70) and adolescent (P28) Sprague Dawley rats were trained for single trial nicotine CPP (0.5 mg/kg), and their initial CPP chamber bias was correlated with the strength of the drug-cue relationship. Adolescents with relatively higher dark chamber preference (HDP) on day 1 formed single trial nicotine CPP, an effect not seen in HDP adults. Adults with relatively lower dark chamber preference (LDP) on day 1 of testing also formed single trial nicotine CPP, an effect not seen in LDP adolescents. Single trial nicotine CPP was abolished in HDP adolescents administered a MAPK inhibitor (SL327; 50 mg/kg) prior to conditioning. Adult and adolescent Sprague Dawley rats were also exposed to either a single CPP conditioning session or a saline versus nicotine injection in the

homecage. Brains were processed for phosphorylated MAPK (pMAPK) immunohistochemistry in the nucleus accumbens (NA). In the NA shell, there was a trend for increased pMAPK in adolescence following a nicotine injection in the CPP chamber compared to the homecage. There was a significant increase in pMAPK labeled cell counts in adults after a saline injection in the CPP versus homecage context. In the NA core, there was a significant increase in pMAPK with CPP versus homecage dosing in both age groups, regardless of drug. Our results suggest that preexisting context preference modulates the strength of a drug cue relationship across age groups, and during adolescence, this modulation involves MAPK. Down regulation of the NA MAPK pathway may modulate age related differences in response to a stimulus by flagging the significance of a novel event within a context.

Title: Evidence for maternal deprivation stress and gestational nicotine exposure as risk factors for affective disorders and drug abuse

Authors: *M. C. GONDRE-LEWIS[1], K. WARNOCK[2], H. WANG[1], H. L. JUNE[2]; [1]Anat., Howard Univ. Col. of Med., WASHINGTON, DC; [2]Psychiatry and Behavioral Sci., Howard Univ. Col. of Med., Washington, DC

Abstracts: Individuals exposed to abuse, neglect, or drugs of abuse during gestational development and infancy are maladaptive to many social situations and are chemically sensitized to subsequent drug exposure. In addition, a high percentage of individuals receiving care for mood disorders like major depressive disorder, bipolar disorder and schizophrenia report experiencing these early life stressors during vulnerable periods of brain development. We have

previously shown that early postnatal maternal deprivation (MD) alone or in combination with prenatal nicotine (NIC) exposure alters neuronal development in the hippocampus, primarily the ventral hippocampus associated with emotional memory. Here, we explored the role of MD, NIC or the combination of the two in inducing behaviors correlated with neuropsychiatric disease and drug seeking in adolescents and adults. Pregnant Sprague Dawley female rats were prenatally exposed to saline or 4mg/kg/day of nicotine during the gestational period and their offspring were subjected to MD or normal maternal care at P2 until weaning. During adolescence, P28-P42, their performance on the open field test, elevated plus maze, forced swim test (FST), sucrose drinking, nicotine bottle drinking and alcohol binge drinking was assessed. NIC or MD exposure resulted in significantly increased locomotor activity. Subcutaneous nicotine during adolescence (sq-NIC) enhanced locomotor activity in controls, but NIC + sqNIC or MD + sqNIC were always significantly more active than sqNIC or sqPBS controls. NIC or MD exposure also decreased sucrose preference, and caused higher immobility times in the FST in adolescents. MD had a more robust effect on these parameters than NIC, and when combined the effect was mostly additive, but sometimes synergistic. Notably, both MD and NIC induced a high and sustained preference for nicotine by bottle drinking and alcohol via operant intracranial self-administration lever-pressing. Interestingly, MD binge drinking was elevated to levels close to that of alcohol-preferring rats. Neuroanatomical assessment of neurons in the amygdala or ventral tegmental area (VTA), brain loci associated with emotion and reward, showed an increase in the number of amygdala neurons in MD and NIC, and a decrease in VTA neurons of MD but not NIC groups, corresponding to dopamine neurons of alcohol preferring rats. We conclude that NIC and MD are confounders for behaviors associated with mood disorders and are risk factors for increased alcohol and nicotine substance use. We further conclude that the mechanisms for MD-induced drug seeking behavior may act through the dopamine reward pathway by a different mechanism than NIC.

Title: A single nicotine injection leads to neural tube defects in chicken model

Authors: V. HUMPHREY, N. BOHN, *N. V. OMELCHENKO;
West Liberty Univ., West Liberty, WV

Abstracts: A large proportion of the United States population has been exposed to maternal smoking *in utero*. Mounting data suggests that nicotine can have a negative impact on neural system development. There is a known list of negative consequences of nicotine exposure, including neural tube defects. The goal of this study was to evaluate effects of nicotine exposure on chicken neural system development. The early chick embryo is an established model of the first month of embryonic development in mammals. Nicotine (nicotine hydrogen bitartrate) or vehicle (sodium bitartrate monohydrate) solutions were injected in eggs prior to incubation to match blood plasma levels observed in heavy smokers. Three cohorts of 24 eggs distributed between treatment groups were generated. After injections, eggs were sealed and placed in the incubator (35.5°C). Embryos were harvested on day 5 after injections. Our data indicates that the nicotine treatment does not affect viability, weight, or length of the embryos. Nonetheless, nicotine notably affects the axial rotation of the embryos. Axial rotation is defined as a change in the dorsoventral orientation of the head during development ("head turning"). In our study, atypical axial rotation was observed in nicotine treated groups 4-5 times more often than in controls ($p<0.05$). In order to elucidate the mechanism of such changes, the animals were embedded in paraplast, sectioned, and stained with hematoxylin and eosin for histological analysis. Preliminary data indicates that altered axial rotation linked to incomplete closing of the embryonic neural tube in the cervical region, but not in other areas of the tube. The development of neural tube and surrounding mesoderm is currently being evaluated using modern techniques of stereological analysis.

Title: Epigenetic and mutant analysis of alcohol tolerance in *Drosophila*

Authors: *A. GHEZZI, N. S. ATKINSON;
Section Neurobiol, Univ. Texas Austin, AUSTIN, TX

Abstracts: Exposure to alcohol is known to trigger homeostatic adaptations in the brain that lead to the development of drug tolerance and dependence. These adaptations are believed to be of central importance in producing the addictive state. Accumulating evidence from genomic studies performed over the last several years suggests that these alcohol phenotypes are not the product of changes in the activity of single genes, but rather, these responses seem to be choreographed by multi-gene networks. It has thus become increasingly clear that proper understanding of these adaptations will require a comprehensive analysis of the molecular pathways that coordinate the regulation of these complex networks. Epigenetic histone modifications have recently emerged as important modulators of gene expression and are thought to represent a form of transcriptional memory that is directly imprinted on the chromosome. By altering the structural arrangement of chromatin regions, these modifications regulate the accessibility of transcription factors to the underlying DNA. Using a novel genomic approach that exploits the analysis of epigenetic modifications and the power of *Drosophila* genetics, we have recently identified a network of genes with a direct role on the development of alcohol tolerance. The genes in this network not only show a common alcohol-induced histone acetylation response but also share a highly correlated expression profile in response to distinct environmental stimuli. These results suggest that the genes in this network are coordinately regulated. Here, we explore the epigenetic landscape of a 'tolerance' gene network to decipher potential regulatory epigenetic signatures involved in adaptation to alcohol.

Title: Significant association of rs17189632 in the glutamate receptor subunit gene (GRIN3A) with heroin dependence

Authors: *X. XIE[1,2,3], H. LIU[1,2,3], W. ZHOU[1,2,3];
[1]Ningbo Inst. of Microcirculation and Henbane, Zhejiang, China; [2]Lab. of Behavioral Neuroscience, Sch. of Medicine, Ningbo Univ., Ningbo, China; [3]Ningbo Addiction Res. and Treatment Ctr., Ningbo, China

Abstracts: Objective The N-methyl-D-aspartate receptor is consisting of three subfamilies (NR1, NR2A, 2B, 2C, 2D and NR3A, 3B). The ability of NR3A to modulate the NMDAR function makes it an attractive candidate gene of heroin addiction. The purpose of this study is to explore the association between two single nucleotide polymorphisms (SNPs) (rs3739722, rs17189632) in the glutamate receptor subunit gene (GRIN3A) and heroin addiction. Methods The genotypes of the two SNPs (rs3739722, rs17189632) in 332 heroin dependent patients and 200 normal control subjects in the male Han Chinese population were detected by TaqMan SNP genotyping method, and the association between heroin dependence and the two SNPs was analyzed. Results The distributions of genotype and allele at rs3739722 were not significantly different between in the cases and in the control group (P> 0.05). The frequencies of genotype and allele at rs17189632 were significantly different between the cases and the controls (x2 = 7.237, P = 0.0268; x2 = 4.278, P = 0.0386). In addition, the A allele frequency of rs17189632 was significantly lower in cases compared with the control group (OR = 0.752, 95% CI 0.574-0.986, P = 0.0386). And the frequency of AA genotype of rs17189632 was significantly lower in cases compared with the control group (OR = 0.457, 95% CI 0.255-0.818, P = 0.0073). Conclusion Our study indicates that the rs17189632 of the glutamate receptor subunit gene (GRIN3A) play a major role in heroin dependence.

Title: Hybrid mouse diversity panel reveals genetic correlations between impulsivity and intravenous drug self-administration

Authors: *J. D. JENTSCH[1], M. C. CERVANTES[1], R. LAUGHLIN[2], A. S. JAMES[1];
[1]Univ. Calif, Los Angeles, Los Angeles, CA; [2]Williamette Univ., Salem, OR

Abstracts: Impulsivity, which often reflects a loss of inhibitory control over reward-seeking behaviors, has been implicated as a heritable risk factor for drug and alcohol use disorders. That said, impulsivity has often been conceived of as a multi-dimensional construct, spanning several partially related behavioral phenomena with separate biological substrates. For example, heightened propensity to engage in intravenous drug self-administration has been linked to an elevated tendency to respond early in a choice serial reaction time task (Dalley et al. Science, 15:1267-70, 2007) and to difficulty with suppressing or updating behavior in a reversal learning task (Cervantes et al. Psychopharmacol., 229:515-25, 2013). Yet other studies have linked the tendency to discount delayed rewards to self-administration. We sought to determine whether premature responding in choice reaction time tasks and/or response inhibition in a reversal test were genetically correlated with intravenous cocaine self-administration, using the hybrid mouse diversity panel - a large genetic reference panel consisting of inbred mouse strains. Published data on impulsive responding in a 5-choice serial reaction time from Loos et al. (Biol. Psychiatry, 2014; doi: 10.1016/j.biopsych.2014.02.011) were combined with novel data on reversal learning and intravenous cocaine self-administration acquired from many of the same strains. Genetic correlations were performed at the strain level to identify phentoypes with common genetic influences. Anticipatory responding in the 5-choice task (from Loos et al. 2014) and from our reversal learning task were negatively correlated with one another but each was positively correlated with a measure of response inhibition in reversal learning, suggesting that these measures index a common construct. Moreover, anticipatory responding and response inhibition in the reversal learning task were positively related to drug self- administration behaviors, while anticipatory responding in the 5-choice task was not. Gene co-expression network analyses revealed novel data about transcriptomic influences that mediate these relationships, and genome-wide scans for each phenotype reveals evidence for both conserved and distinct genetic determinants. These data provide new evidence suggesting that multiple measures of impulsivity are, in part, related to one another, while simultaneously having partially distinct genetic/genomic influences and relating to drug self-administration propensity in non-overlapping fashions.

Title: Studying the role of epigenetic marks in a gene cluster associated with alcohol use disorders using induced pluripotent stem cell-derived neural cultures

Authors: *M. GROSS, R. LIEBERMAN, J. COVAULT;
Univ. of Connecticut Hlth. Ctr., Farmington, CT

Abstracts: Alcohol use disorders affect approximately 8.5% of the US population during a one-year period. Studies have found strong genetic effects playing a role in the transition of heavy drinking to alcohol dependence; however, understanding the mechanisms behind this switch has been difficult. Induced pluripotent stem cells (iPSCs) have become a tremendous tool for studying neurological disease. Before their appearance, neurobiological disease was studied solely on the use of neuroimaging studies, post-mortem human tissue, and animal models, all of which have their limitations. Using iPSCs, our lab has differentiated iPSCs from control and alcoholic subjects into forebrain glutamatergic neurons. After examining mRNA expression of key genes involved with alcohol dependence susceptibility, it was discovered that a cluster of genes encoding four subunits to the $GABA_A$ receptor on chromosome 4p12 were expressed at low levels in close to half of the lines we examined. Further, this low expression was correlated with the presence of a synonymous *GABRA2* exon 5 T to C SNP (rs279858), which has been associated with alcohol dependence in several studies. However, mRNA for subunits encoded by $GABA_A$ receptor genes located on other chromosomes were expressed. Existing data shows that in embryonic stem cells and iPSCs, the promoter region of *GABRA2* is poised, meaning it has both repressive and active epigenetic chromatin/histone modifications, but that post-mortem neuronal tissue shows a loss of *GABRA2* promoter region repressive histone marks. We hypothesize that the low expression of the chromosome 4 $GABA_A$ receptor gene cluster in a subset of iPSC-derived neural cultures may be associated with the retention of repressive histone modifications, or possibly long distance chromatin looping by CTCF binding sites. Using chromatin immunoprecipitation followed by quantitative PCR, epigenetic marks commonly associated with activate gene expression (H3K4me3), marks associated with repressed gene

expression (H3K27me3 and H3K9me3), and CTCF binding sites were explored in subject's iPSCs and iPSC-derived neural cultures. Preliminary results show that 12-week old iPSC-derived neural cultures that show low expression of the chromosome 4p12 $GABA_A$ gene cluster and that also have the rs279858 C-allele have a greater amount of repressive histone marks than lines that express the $GABA_A$ gene cluster and have the TT genotype at rs279858. Our results suggest that the rs279858 polymorphism may moderate, via chromatin epigenetic mechanisms, the developmental regulation of the chromosome 4p12 $GABA_A$ gene cluster.

Title: Adolescent cocaine exposure alters acetylation and tri-methylation on histone 3 lysine 9 in the hippocampus and nucleus accumbens exclusively in selectively bred rats that are typically resilient to addiction

Authors: *A. PARSEGIAN[1], J. GARCIA-FUSTER[2], S. CHAUDHURY[1], P. BLANDINO[1], S. J. WATSON[1], S. FLAGEL[1,3], H. AKIL[1];
[1]The Mol. & Behavioral Neurosci. Inst., Ann Arbor, MI; [2]Univ. Res. Inst. on Hlth. Sci., Univ. of the Balearic Islands, Palma de Mallorca, Spain; [3]Dept. of Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstracts: Only a small minority of those who experiment with drugs of abuse goes on to become drug addicts. Although there is no single factor that confers addiction liability, it is clear

that genetic predisposition and prior experience with the drug have predictive validity. Notably, early initiation of drug use reliably predicts the likelihood of addiction in adulthood. Thus, adolescence may be a particularly critical period when drug use causes persistent neuroadaptations that might render one more susceptible to addiction. Recently, an important relationship has emerged between certain chromatin modifications, the genes they modify, and the enduring neurobiological impact of cocaine in promoting addiction. Here, we utilized a unique genetic rat model that captures individual differences in vulnerability to addiction to determine whether adolescent drug exposure alters their genetic predisposition via modification of epigenetic chromatin marks. Rats selectively bred based on locomotor response to novelty differ on a number of addiction-related traits. Specifically, relative to bred low-responder (bLR) rats, bred high-responders (bHR) are more sensitive to the psychomotor activating effects of cocaine and reinstate drug-seeking more readily following a prolonged period of abstinence. We exposed these bred rats to a sensitizing regimen of cocaine (15 mg/kg) or saline for 7 days during adolescence (PND 33-39) and assessed phenotypic differences in the acute and sensitized response to cocaine during this period. Further, we used a novel approach to measure two histone modifications, acetylation (ac) and tri-methylation (me3) on histone lysine 9 (H3K9), in the hippocampus (HC) and nucleus accumbens (NAc) during either adolescence, or after three weeks of abstinence. As expected, bHRs showed greater sensitivity than bLRs to both acute and repeated cocaine exposure during adolescence. In the saline-treated bLRs, expression of acH3K9 was higher and H3K9me3 was lower in the HC and NAc, as compared to bHRs. Interestingly, adolescent cocaine eliminated these differences, rendering bLRs more similar to bHRs. Further, these effects appear to be sub-region specific, as no differences were seen in the ventral HC, and epigenetic changes in the NAc shell were distinct from those in the core between the phenotypes. These findings suggest that adolescent cocaine exposure may render bLRs more susceptible to addiction, without affecting bHRs. Additional epigenetic and behavioral analyses will be performed to determine associations linking adolescent cocaine-induced epigenetic modifications to neurobiological and behavioral alterations that persist into adulthood

Title: Strain-specific differences in microrna expression in the hippocampus following exposure to stress and/or alcohol

Authors: *K. M. HAMRE, S. LATTIMER, J. INGELS, L. LU;
Univ. Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstracts: Genetic differences in response to stress and/or alcohol exposure are well documented although the specific genetic pathways that mediate these differences remain elusive. Moreover, it is becoming clear that these pathways include more than simply alterations in gene expression, but also include other changes such as differences in microRNA (miR) expression. The present experiment was conducted to determine whether there were strain-specific differences in miR expression following exposure to either stress and/or ethanol. Adult male C57BL/6J (B6) and DBA/2J (D2) mice were examined. Stress was given via a 4-week chronic, unpredictable mild stress paradigm that included tilted cages, wet bedding, mild restraint, exposure to odor from another male and 24- hour constant light. Alcohol was given as an acute exposure to 1.8 g/kg given via IP injection. Four groups were examined: 1) stress only, 2) ethanol only, 3) stress + ethanol, and 4) control given neither. Prior to tissue collection, mice were examined for anxiety phenotypes in an elevated plus maze, with bigger effects seen in the D2 than in the B6 mice. Hippocampal tissue was collected and expression of selected miRs was examined using real-time qPCR. MicroRNAs were selected because they had previously been shown to be altered following ethanol exposure or because they are proposed members of stress-related pathways such as the CRH pathways. As expected, the different groups exhibit differentially-expressed miRs. Interestingly, exposure to stress alters the miRs that change expression following alcohol exposure and this effect is observed in a strain-dependent fashion with more changes observed in the D2 mice than in the B6 mice. Analysis showed that miRs involved in several stress- or ethanol-related pathways showed changes following ethanol and/or stress treatment. For example, changes were found in 1) miR-206, a miR related to the BDNF (brain derived neurotrophic factor) signaling pathway, and 2) miR-335 that has strain-specific alterations in expression. These results demonstrate that microRNAs are excellent candidates for mediating genetic differences in responses to stress and ethanol. Future studies will expand these analyses to evaluate other miRs as well as their downstream mRNA targets.

Title: Examining regulators of the glucocorticoid receptor in human neural cells derived from alcoholics

Authors: *R. LIEBERMAN[1], E. S. LEVINE[2], H. R. KRANZLER[4], J. COVAULT[3]; [2]Neurosci., [3]Psychiatry, [1]Univ. of Connecticut Hlth. Ctr., Farmington, CT; [4]Univ. of Pennsylvania, Philadelphia, PA

Abstracts: The glucocorticoid receptor (GR) is a ligand-activated transcription factor that is the primary target for the glucocorticoid cortisol. Cortisol is released by the adrenal gland following hypothalamic-pituitary-adrenal (HPA) axis activation in response to stress. Termination of the stress response is facilitated by GR activation in the brain, which is a complex process involving numerous co-chaperones that can regulate activity of the GR by modulating folding, translocation into the nucleus, and affinity for cortisol. A common finding in psychiatric disorders including depression, post-traumatic stress disorder, schizophrenia, bipolar disorder, and alcoholism is an alteration in the subject's response to stress. Studies of human post-mortem brain suggest that differences in the expression of the glucocorticoid receptor and its regulatory co-factors between control and patient samples may underlie some of the alterations to the stress response observed in these psychiatric disorders. Alcohol use disorders are common in society, affecting 8.5% of the U.S. population. Recent RNA-seq findings from post-mortem hippocampal samples suggest that genes involved in the stress-response pathway, including the glucocorticoid receptor and its co-factors, are altered in alcoholics. Furthermore, alcoholics have higher basal levels of cortisol and a blunted cortisol response to acute stress, and dysregulation of the stress response can be seen in the children of alcoholics, suggesting a genetic component. To further elucidate differences in glucocorticoid receptor regulation in alcoholism, we examined human neural cells differentiated from induced pluripotent stem cells generated from 12 alcoholic and 10 non-alcoholic donor subjects. Using an established neural differentiation protocol, we generated mixed neural cultures containing physiologically active forebrain glutamatergic neurons and glial cells. After 6 weeks of neural maturation, cells were exposed for 6 hours to 10μM, 100μM, or 1000μM dexamethasone, a synthetic agonist with a high affinity for the glucocorticoid receptor. Following exposure, RNA was extracted and the expression of genes encoding the GR and its co-factors FKBP51, FKBP52, and Bcl-2-associated athanogene

(encoded by *NR3C1, FKBP5, FKBP4* and *BAG1*, respectively) was analyzed using quantitative PCR. Differences were observed in *FKBP5*, but not *NR3C1*, *FKBP4,* or *BAG1* gene expression following acute dexamethasone exposure between cells derived from alcoholic and non-alcoholic donor subjects. These results suggest expression of certain GR co-factors may be regulated differently in neural cells from alcoholics.

Title: A genetic reduction in the serotonin transporter differentially influences self-administration of 3,4-methylenedioxymethamphetamine (MDMA) and heroin

Authors: B. W. BROX, *B. A. ELLENBROEK;
Victoria Univ. of Wellington, Wellington, New Zealand

Abstracts: Addiction to drugs of abuse is a ubiquitous phenomenon that places a tremendous financial and psychological burden on society, families and the individual. Interestingly, only a small percentage of individuals (~20%) who use drugs of abuse go on to develop the compulsive behaviours that define addiction. Clinical studies have shown that there is a subset of the population with a genetically determined reduction in the serotonin transporter that may increase vulnerability to developing addiction. To investigate the influence of reduced serotonin transporter function in the laboratory we studied the reinforcing properties of MDMA ('ecstasy') and heroin in a genetically modified animal model: the serotonin transporter (SERT) knockout rat. Homozygous ($SERT^{-/-}$) animals lack SERT function completely while heterozygous ($SERT^{+/-}$) have about 50% SERT function compared to the wild type ($SERT^{+/+}$). Importantly, MDMA, in addition to its effects on the SERT, directly stimulates dopamine release. Heroin, on the other hand, via stimulation of μ-opioid receptors, indirectly stimulates dopamine release. To understand the interaction between reduced serotonin transporter function and the development of addictive behaviours we utilized a self-administration behavioural paradigm. One hundred per cent of $SERT^{-/-}$ and $SERT^{+/-}$ rats acquired MDMA self-administration compared to only 50% of $SERT^{+/+}$. Of the animals that met the criterion for self-administration the $SERT^{-/-}$ took more

infusions during maintenance as well as reached greater breakpoints when tested on a progressive ratio schedule compared to $SERT^{+/+}$. On the other hand, there were no significant differences between genotypes during acquisition and maintenance of heroin self-administration. These results clearly indicate that genetically reduced SERT function is a risk factor for the development of self-administration of some drugs and further underline the fact that significant differences exist between disparate drugs of abuse.

Title: Dorsal root ganglion development in nicotine-exposed zebrafish

Authors: *J. SCHULD[1], K. R. SVOBODA[2];
[1]Joseph J. Zilber Sch. of Publ. Hlth., Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [2]Joseph J. Zilber Sch. of Publ. Hlth., Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstracts: During vertebrate development including humans, multipotent cells known as neural crest cells (ncc) give rise to a variety of different cell types such as neurons, pigment/melanocytes, bone, cartilage, and glia. The development of ncc is likely altered in children born to mothers who smoke during pregnancy which could result in congenital birth defects. These birth defects may also be linked to nicotine, a main ingredient of cigarettes. Our research group utilizes zebrafish as a model to study nicotine toxicity, a phenomenon seen in humans. Our unpublished results reveal that embryonic nicotine exposure in zebrafish alters the development and migration of melanocytes and dorsal root ganglion (DRG) neurons. In zebrafish and other vertebrates, the dorsal root ganglia lie adjacent to the spinal cord and are segmentally positioned along the length of the body. We are utilizing Tg(Isl2B:gfp) transgenic zebrafish to study the consequences of nicotine exposure on DRG development. In non-exposed,

96 hpf larvae, cells within individual DRG are organized in a pattern that resembles either a cluster of grapes or in a more elongated pattern, resembling a chili pepper. About 50% of the ganglia analyzed exhibited the cluster of grapes phenotype, ~ 40% exhibited the chili pepper phenotype, and about 10% exhibited a phenotype not easily categorized. In nicotine exposed larvae, roughly 10% of the ganglia analyzed exhibited the cluster of grapes phenotype, whereas ~ 70-80% of the ganglia analyzed exhibited the chili pepper phenotype. When nicotine-exposed larvae were raised out to 1.5-3 weeks of age and imaged, the patterning of neural processes extending from DRG neurons and projecting within the skin was found to be altered. This analysis was done using a Zeiss, Axio Zoom.V16 Microscope. This imaging platform is designed for imaging in thick tissue with high-resolution. Our results show that an early exposure to nicotine during times when the dorsal root ganglia are developing, may permanently alter their development.

Title: Defining a novel intermediate progenitor cell class in the embryonic olfactory epithelium

Authors: *E. M. PARONETT, D. W. MEECHAN, T. M. MAYNARD, A.-S. LAMANTIA; Pharmacol. and Physiol., George Washington Univ., Washington, DC

Abstracts: The identity of olfactory epithelial (OE) intermediate progenitors remains uncertain, despite the potential role of this class of cells in ongoing OE regeneration. We addressed this issue in the early developing OE using inducible Cre-driven mouse lines for two critical proteins -Pax7 and Ascl1_that are likely associated with OE stem and transit amplifying precursors, respectively. Using brief exposure to tamoxifen, we induced Cre driver expression in a subset of cells expressing either Pax7 or Ascl1 at embryonic day 10.5 (E10.5) and studied lineage-derived cell expression patterns at E11.5 for early OE development, and E16.5 for late OE development. The numbers of Pax7 recombined progeny seen at E11.5 after E10.5 tamoxifen exposure is consistent with the slowly dividing stem cell identity of the Pax7 cells. Nevertheless, E11.5

Pax7-derived cells give rise to Ascl1-expressing cells. We are currently evaluating the fates of these Pax7 progeny at later survivals after E10.5 tamoxifen exposure. At E11.5, some, but not all, Ascl1-derived cells are proliferatively active. The proliferatively active cells are primarily located in the dorsomedial OE and are likely to be derived from the slowly-dividing Pax7 progenitors in the ventrolateral OE. They are proximal to differentiating neurons on either side of the zone in which they are actively dividing, suggesting that Ascl1 acts late in the transit-amplifying niche of the stem cell lineage. Discontinuous patterns of Ascl1 in the OE at E11.5 and E16.5 after E10.5 tamoxifen indicate that Ascl1-mediated expansion may reflect local morphogenesis that guides emergence of OE turbinates. These results indicate that there is a likely intermediate progenitor that emerges between the Pax7 slowly dividing stem cells and the Ascl1 near-terminally neurogenic intermediate progenitors. We are currently determining whether these novel intermediate progenitors are a subset of high Six1-expression proliferative cells in the E11.5 OE. Dissociated cells of the medial OE analyzed by pair cell assay show that cells expressing Six1 as well as Ascl1 are capable of both symmetric and asymmetric division and thus have the potential to be both self-renewing and terminally neurogenic. Therefore, it seems likely that there is a novel OE intermediate progenitor class that is essential for the progression from slowly-dividing stem cell to Ascl1-expressing late neural progenitor, and ultimately newly generated olfactory receptor, vomeronasal receptor and GnRH neurons. These precursors, or a closely related class, may be retained in the mature OE to facilitate ongoing regeneration.

Title: Genomic Plasticity in the olfactory epithelium is correlated with odorant exposure during early development in the zebrafish (Danio rerio)

Authors: C. CALFÚN[1], C. DOMINGUEZ[2], T. PÉREZ-ACLE[2], *K. E. WHITLOCK[1];
[1]Univ. de Valparaiso, Valparaiso, Chile; [2]Fundacion Ciencia y & Vida, Santiago, Chile

Abstracts: Zebrafish form olfactory memories of odors experienced during early development (imprinting) including the artificial odorant phenylethyl alcohol (PEA). Correlated with this olfactory memory we have shown that the transcription factor (TF) *otx2* is upregulated in the olfactory epithelium (OE) of PEA-imprinted fish, demonstrating a role for peripheral nervous system (PNS) in olfactory memory. In order to further analyze odorant modulation of the gene expression in the OE, we focused on the olfactory receptor (OR) as potential odorant regulated genes through regulation by *otx2.* We identified ORs containing Otx2 binding sites in their control regions and analyzed their expression by qPCR. Exposure to PEA resulted in the down regulation of five of the eight ORs analyzed. In order to identify regulatory sequences for ORs, we performed a bioinformatic analysis looking TF for binding sites. We observed multiple binding sites for transcription factors, including Otx2, in regions flanking ORs sequences. Interestingly, according the literature, some of these TFs can to form repressive complexes with Otx2 to control gene expression, and are located upstream the odorant-modulated ORs. Currently we are performing a RNA seq analysis at three weeks post fertilization and adult stage, in order to study odorant effects on the whole transcriptome of the zebrafish OE, including the OR repertoire. At three weeks post fertilization, our preliminary data show that the exposure to PEA is correlated with changes in different receptors expressed in the olfactory sensory neurons, including some genes of the OR family. This study supports the model where the odor environment can modulate gene expression during early development and suggests a role for the ORs in the memory formation.

Title: Crucial role of olfactory receptor accessory proteins RTP1 and RTP2 in receptor gene choice, development and odor detection

Authors: *R. SHARMA[1], Y. ISHIMARU[2], I. DAVISON[3], M. EHLERS[4], H. MATSUNAMI[1]; [1]Duke Univ., Durham, NC; [2]Univ. of Tokyo, Tokyo, Japan; [3]Boston Univ., Boston, MA; [4]Pfizer Neurosci., Cambridge, MA

Abstracts: Receptor transporting proteins (RTP1 and RTP2), specifically expressed in the olfactory sensory neurons (OSNs), have been shown to greatly increase the cell surface expression of olfactory receptors (ORs) when expressed in heterologous cells. We have generated RTP1 and RTP2 double knockout mice (RTP1,2-/-) to test the function of RTP1 and RTP2 *in vivo*. RTP1,2-/- mice are viable and show no gross morphological defects. Consistent with the role of RTP1 and RTP2 in OR trafficking, cilia localization of a specific OR is lost in RTP1,2-/- mice. OMP and ACIII expression indicate fewer mature OSNs in the RTP1,2-/- olfactory epithelium which can be explained by a four fold increase in apoptosis of the olfactory epithelium in these mice. Strikingly, expression of ATF5, an indicator of the unfolded protein response and ongoing OR gene choice is vastly expanded in the olfactory epithelium of the knock out mice suggesting that these neurons may be unable to stably express a single OR. This is further reinforced by the expanded expression of LSD1, a histone modifier responsible for the desilencing and initiation of the OR transcriptional machinery. Surprisingly, while expression of many ORs is diminished in RTP1,2 -/- mice, some ORs are overexpressed in the mutant, suggesting a biased OR choice in the absent of RTP1 and 2. Electroolfactogram recordings as well as odor-induced c-Fos induction in the olfactory bulb suggest that RTP1,2-/- mice show dramatically diminished responses to odors. Furthermore axons of OSN expressing OR-M71 do not converge in the olfactory bulb,, indicating that the axons are unable to target specific glomeruli. Together, these results show that RTP1 and RTP2 are crucial for development and function of the olfactory system.

Title: Identifying odor receptors in *C. elegans*

Authors: *J. J. YOUNG[1], S. APOSTOL[1], S. NATHAN[1], E. NEWMAN[1], A. COX-HARRIS[1], F. TAN[1,2], C. BRUEGGEMANN[2], N. L'ETOILE[2];

Abstracts: Although scientists have been studying olfaction in *C. elegans* for decades, olfactory receptor proteins remain largely uncharacterized. We are currently using two approaches to address this knowledge gap. A forward genetic screen was carried out to identify genes involved in odor signaling. Mutants were selected if they displayed repeated lack of attraction to benzaldehyde (which is sensed by the olfactory neuron AWC) after exposures to benzaldehyde and E. coli. 27 worm strains were isolated as potentially interesting mutants. We are currently analyzing these mutants for olfactory defects, and have identified two such lines. We are also pursuing localization of candidate proteins. Data generated by Yen-Ping Hsueh in the Sternberg lab identified a set of putative odor receptor genes that are expressed in AWC. We selected eight of these genes for localization analysis and obtained GFP-reporter constructs from the Transgenome Project. We are producing tagged lines and determining which of these proteins localize to the olfactory cilia.

Title: Odorant receptor activation patterns *in vivo*

Authors: *T. S. MCCLINTOCK[1], K. ADIPIETRO[2], P. BREHENY[3], A. WALZ[4], P. MOMBAERTS[5], H. MATSUNAMI[2];

Abstracts: Analogous to distinguishing colors by differential activation of opsins, the patterns of *in vivo* activation of receptor proteins by odorants must be fundamental to odor discrimination. However, these patterns are as yet undefined. We identified receptors activated by odorants *in vivo* by measuring the enrichment of all receptor mRNAs after activity-dependent capture of olfactory sensory neurons, an approach made possible by the fact that these neurons each express only one receptor. Receptors for the odorants muscone (a base note in perfumes) and eugenol (a flavoring) were identified first. These odorants activated similar, but nonoverlapping, patterns consisting of core sets of a few related odorant receptors, with weaker evidence of activation of additional receptors. For example, the receptors most strongly activated by muscone both *in vivo* and in heterologous expression assays belonged to the mOR214 and mOR215 families, with Olfr1440 (mOR215-1) and Olfr235 (mOR214-3) showing the strongest responses. These receptors were not activated by polycyclic musk odorants. The homologous human receptor, OR5AN1, was similarly selective for macrocyclic musk odorants over polycyclic musks. As expected, easily discriminated odorants showed distinct patterns of receptor activation. Some patterns were atypical, however, such as the activation of both odorant receptors and trace amine-associated receptors (TAARs) by 2-phenethylamine.

Title: Odor responses of *Drosophila* receptor neurons - Response profiles, mixtures and individual response dynamics

Authors: *D. MÜNCH, J. S. IGNATIOUS RAJA, T. LAUDES, A. NISSLER, C. G. GALIZIA; Biol., Univ. of Konstanz, Konstanz, Germany

Abstracts: Olfactory sensory systems usually consist of multiple classes of olfactory receptor neurons (ORNs) that are tuned to different but overlapping sets of odorants. Thus, when odors are presented, specific activation patterns consisting of all the activated, inhibited or non-activated ORNs arise. Tuning profiles of individual ORN classes differ in the number of odorants they respond to, ranging from generalist ORNs that are sensitive to hundreds or thousands of chemical compounds, to specialist ORNs that respond only to a handful or to single substances only. On a single cell level, ORN responses vary in strength as well as in their dynamics, e.g. response polarity or response duration. ORN responses become even more complex when one considers more natural odor-stimuli i.e. mixtures. Two substances might interfere when stimulating an ORN, generating a mixture response that is distinct in strength or dynamics from the components response. Here we describe response profiles of eight classes of *Drosophila* ORNs in response to a set of ~100 odorants. We also analyzed the response dynamics from the ~800 odorant-ORN combinations in detail. For a smaller set of ORNs and odorants we studied the responses elicited by binary mixtures compared to their single components. We found breadth of tuning to be widely distributed observing both, generalist- and specialist ORNs in our set. For Or56a neurons which are known to be specifically tuned to the single odorant geosmin, we found several ligands besides that single odorant, even though these responses were much weaker. The majority of responses we recorded from the eight ORNs were excitatory, fewer were inhibitory or showed initial excitation followed by a post-stimulus inhibitory phase. Dynamical response-features differed across odorant-ORN combinations: Some generated strong and prolonged responses that continued beyond stimulus offset, others were short-lived (phasic), still others were complex over time, including excitatory and inhibitory bouts. Most of the binary mixtures tested produced weak or no interactions, though a few combinations lead to suppressive (response weaker than the response elicited by the stronger component alone) or synergistic (response much stronger than the response elicited by the stronger component alone) mixture responses. Across ORNs, about half of the mixture responses followed one of the two odorant components, while the other half had distinct activity patterns. These measurements are relevant for understanding how odor information is coded in combinatorial activity patterns.

Title: Ancestral amphibian V2Rs are expressed in the main olfactory epithelium

Authors: ***A. S. SYED**, S. I. KORSCHING;
Inst. for Genetics, Univ. of Cologne, Cologne, Germany

Abstracts: The sense of smell helps animal species to evade predators, localize prey and recognize viable mates. In mammals olfactory receptor families are segregated into different olfactory organs, main olfactory epithelium (MOE) and vomeronasal organ (VNO). In contrast, teleost fish olfactory receptor families are intermingled in a single sensory surface. To what extent such differences influence the coding and discrimination abilities of the respective olfactory systems is unclear, and the evolutionary path toward such segregation is unknown. The analysis of amphibians, which are early diverging tetrapods compared with mammals, may shed light on this transition from shared sensory surface to segregated subsystems. For this study, we focused on the V2R (vomeronasal type 2 receptor) gene family, by thorough datamining we showed the Xenopus V2R family to encompass nearly 500 genes in total. A phylogenetic analysis led to the identification of three distinct subdivisions in the largest group of V2R genes (A1, A2, A3). We used this sequence information to clone several Xenopus laevis V2R gene representatives of above mentioned subdivisions. Xenopus laevis (African clawed frog), is the system of choice for physiological studies of the amphibian olfactory system and furthermore, a close relative of Xenopus tropicalis. We report here that to our surprise, several V2R genes were expressed exclusively in the MOE, and not in the VNO. These genes occupied basal positions in the phylogenetic tree, whereas late diverging V2R genes were exclusively expressed in the VNO. Moreover, within the MOE V2R genes are expressed in a basal zone, partially overlapping, but clearly distinct from an apical zone of OMP and odorant receptor-expressing cells. The unique bimodal V2R expression pattern in main and accessory olfactory system of amphibians presents an excellent opportunity to study the transition of V2R gene expression during evolution of higher vertebrates. Title: Compensatory plasticity in the olfactory periphery: Timing and reversibility

Authors: C. N. BARBER[1], *D. M. COPPOLA[2];
[1]Biol., [2]Randolph-Macon Col., Ashland, VA

Abstracts: Like other biological systems, olfaction responds homeostatically to perturbations, including chronic fluctuations in the stimulus milieu. This phenomenon, referred to as compensatory plasticity, appears to be implemented at multiple levels of the olfactory system; however, it has been most thoroughly studied at the periphery. In the olfactory epithelium, chronic stimulus deprivation or enrichment trigger opposite changes in the transcription/translation of proteins involved in odor transduction. These responses, at the molecular level, to odor environment manipulation are thought to underlie the modulation of receptor neuron gain observed physiologically and, at least in part, odor threshold modulation observed behaviorally. Until now, olfactory compensatory plasticity has been studied, almost exclusively, in developing animals. It is unknown whether, like in other sensory systems, this plasticity has a 'critical' period and is irreversible. Here we study unilateral odor deprivation in adult mice using nasal plugs to eliminate nasal airflow unilaterally. Plugs were placed in one nostril for two to six weeks after which electroolfactograms (EOGs) were recorded from the olfactory epithelium of the occluded and open sides of the nasal cavity. The stimuli were isoamy acetate, carvone, and eucalyptol, delivered at 1 part per thousand. Untreated animals served as negative controls and adult mice that had undergone standard unilateral naris cautery as neonates served as positive controls. Mean EOG amplitudes from plugged mice were significantly greater on the occluded side than the open side of the nasal cavity. The duration of plugging did not affect the results, suggesting that plasticity occurs within two weeks. Moreover, EOG differences between the open and occluded sides of the nasal cavity in plugged animals were comparable to those seen in positive controls. In another group of adult mice, plugs were allowed to stay in place for four weeks and were then removed for two weeks. After this recovery period, EOG mean amplitudes were not significantly different between the always-open and previously-plugged sides of the nasal cavity suggesting that compensatory plasticity in the olfactory mucosa is reversible.

Title: Novel protein Rook modulates olfactory transduction kinetics and contributes to proper olfactory behavior

Authors: *A. K. TALAGA[1], O. MAYBERRY, III[1], C. SIMBOLON[1], J. REISERT[2], H. ZHAO[1];
[1]Biol., The Johns Hopkins Univ., Baltimore, MD; [2]Monell Chem. Senses Ctr., Philadelphia, PA

Abstracts: The cilia of olfactory sensory neurons (OSNs) are specialized for transducing and encoding odor information. Various ciliary proteins mediate and/or modulate olfactory signal transduction. We detected a novel protein, which we named Rook (Regulator of olfactory kinetics), from a proteomic screen of murine OSN cilial membrane preparations. Rook is conserved among eukaryotes and is a unique protein, as no paralogs exist in the mouse genome. Bioinformatic analysis suggested that the majority of the Rook sequence is composed of ARM domains, which mediate protein-protein interactions. Knocking out Rook specifically in OSNs alters kinetics of the olfactory response, as assayed by the electroolfactogram. Mice that lack Rook show a faster and more transient electroolfactograph to brief odorant stimulation, with both a faster rising phase and a faster falling phase. In single cell recordings, OSNs that lack Rook display some of the same kinetic alterations, including reduced time to peak and faster termination, upon odorant stimulation. In these recordings, Rook mutant OSNs also recover the ability to fire action potentials to a second stimulus faster. Interestingly, Rook conditional mutants perform poorly in more demanding behavioral assays, demonstrating that proper kinetics of the OSN response are critical for olfactory behavior. Together, we identify a novel protein, Rook, that functions to modulate olfactory transduction kinetics by “slowing down” the olfactory response and contributes to proper olfactory behavior.

Title: Formyl peptide receptor expressing neurons in the mouse vomeronasal organ - a comparative biophysical characterization

Authors: *T. ACKELS[1], B. VON DER WEID[2], I. RODRIGUEZ[2], M. SPEHR[1];
[1]Dept. of Chemosensation, RWTH Aachen Univ., Aachen, Germany; [2]Dept. of Genet. and Evolution, Univ. of Geneva, Geneva, Switzerland

Abstracts: The mouse vomeronasal organ (VNO) is a chemosensory structure that detects both hetero- and conspecific social cues. Based on largely monogenic expression of either type 1 or 2 vomeronasal receptors (V1R / V2R) or members of the formyl peptide receptor (FPR) family, the vomeronasal sensory epithelium harbors at least three neuronal subpopulations. While various neurophysiological properties of both V1R- and V2R-expressing neurons have been described using genetically engineered mouse models, the basic biophysical characteristics of the more recently identified FPR-expressing vomeronasal neurons have not been studied. Here, we employ a transgenic mouse strain that expresses an enhanced variant of yellow fluorescent protein driven by the Fpr-rs3 promoter to identify and analyze FPR-rs3 expressing neurons in acute VNO tissue slices. Single neuron electrophysiological recordings thus allow comparative characterization of the biophysical properties inherent to a prototypical member of the FPR-expressing subpopulation of VNO neurons. In this study, we provide an in-depth analysis of (a) passive membrane properties, (b) several types of voltage-activated ionic currents, and (c) action potential discharge patterns in fluorescently labeled versus unmarked vomeronasal neurons. Our results reveal striking similarities in the basic (electro)physiological architecture of transgene-expressing and nonexpressing neurons, confirming the suitability of this transgenic mouse model for future studies addressing more specialized issues in vomeronasal FPR neurobiology.

Title: Stimulus-dependent lateral interactions between olfactory glomeruli revealed via *in vivo* optogenetic analysis

Authors: Y. CHOI[1], T. TOMBAZ[1,2], R. HOMMA[2], T. BOZZA[3,4], *L. B. COHEN[1,2], O. BRAUBACH[1,2];
[1]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [2]Yale Univ., New Haven, CT; [3]Northwestern Univ., Evanston, IL; [4]Visiting Scientist Program, HHMI Janelia Farm Res. Campus, Ashburn, VA

Abstracts: Olfactory glomeruli serve as functional units of the olfactory bulb which organize and process the olfactory signals that are transduced by the olfactory receptor neurons. Multiple mechanisms of interglomerular lateral interaction have been proposed to play roles in olfactory processing, but these have not been established *in vivo*. We used optogenetics combined with calcium imaging in mice that express channelrhodopsin-2 in a single olfactory sensory neuron type. Low power laser stimulation of the olfactory epithelium activated a single target glomerulus, several hundred juxtaglomerular neurons, and, rarely, non-target glomeruli. We next examined if an increase in laser intensity to the epithelium could cause a spread of the ON responses from the target glomerulus to neighboring cells and glomeruli. Increasing the laser intensity indeed increased the numbers of ON non-target glomeruli and juxtaglomerlar cells. The new ON response cells were close to newly recruited ON glomeruli, and 70 % of these cells were GABAergic, suggesting that non-target glomeruli receive an inhibitory input from the nearby GABAergic ON cells. These data demonstrate that *in vivo* processing of olfactory information involves interglomerular lateral inhibition.

Title: The role of a single olfactory receptor in odor perception

Authors: *C. TRIMMER[1], J. R. WILLER[2], A. KELLER[3], L. B. VOSSHALL[3], N. KATSANIS[2], H. MATSUNAMI[2], J. D. MAINLAND[1];
[1]Monell Chem. Senses Ctr., Philadelphia, PA; [2]Duke Univ., Durham, NC; [3]The Rockefeller Univ., New York, NY

Abstracts: In color vision, genetic variation in a single type of vision receptor leads to a perceptual deficit termed red-green colorblindness. Humans have a large amount of genetic variation in odorant receptors (ORs), suggesting that there may be olfactory phenomena analogous to color vision, but it is unclear how the absence of a single odorant receptor alters perception. Only 10% of human ORs have even one published ligand, and we know of only five cases that specifically link genetic variation in an OR with alterations in perception, making it difficult to generalize to the entire 400-member OR family. The objective of this study was to determine how loss-of-function in a single odorant receptor alters an odor's perceived intensity and valence. To this end, we asked 321 human subjects to rate the intensity and valence of 68 odors. We then developed a protocol to sequence each subject's OR subgenome with high coverage. In a genotype/phenotype association analysis, we identified 31 polymorphisms significantly associated with the perception of 24 different odors ($p < 0.05$ with false discovery rate correction). These polymorphisms are found in 15 distinct gene clusters, but extensive linkage disequilibrium in these clusters precludes the identification of a single causal receptor. To address this issue, we cloned major receptor variants found in several OR gene clusters. We then tested these OR variants for their response to odors via a heterologous luciferase assay. Our results show that, under certain circumstances, receptor function *in vitro* corresponds with human intensity perception *in vivo*. For example, human subjects with genetic variants of OR411 that reduce response to 2-ethylfenchol *in vitro* rated the intensity of the odor to be lower ($F(3,325) = 13.08$, $p < 0.001$) in comparison to subjects with a functional allele. However, we find that the affinity of the OR for the odor determines the relevance of our assay to human behavior and

define a functional allele that will increase intensity perception as one that responds to odor with high affinity. For 5 ORs with segregating functional and non-functional variants, human subjects with a functional variant rate the intensity of the corresponding odor to be significantly higher than those subjects with a nonfunctional variant. These results provide a potential approach for identifying behaviorally relevant OR/odor interactions via a heterologous assay and demonstrate that, despite the combinatorial nature of the olfactory code, alterations in a single odorant receptor can have a significant effect on odor perception.

Title: Determining the molecular basis of olfactory adaptation: An EOG analysis of double mutant mice that lack CNG channel desensitization and PDE1C

Authors: *C. FERGUSON, H. ZHAO;
Biol. Sci., Johns Hopkins Univ., Baltimore, MD

Abstracts: Olfactory sensory neurons (OSNs) exhibit reduced sensitivity upon prolonged or repeated odor exposure--a phenomenon known as adaptation. This physiological plasticity is thought to underlie, at least in part, the perceptual desensitization to an odor over time. The precise molecular basis underlying olfactory adaptation remains unclear. Here we report investigations on mutant mice that lack multiple negative regulatory mechanisms of olfactory transduction. Specifically, we have performed electroolfactogram (EOG) analysis on mice that lack both the calcium-dependent desensitization of the olfactory cyclic nucleotide-gated (CNG) channel and the activity of phosphodiesterase 1C (PDE1C). We used two adaptation stimulation paradigms, a paired pulse paradigm and a sustained pulse paradigm, and found that these mice display deficits in both stimulation paradigms. In contrast, the lack of CNG channel desensitization or PDE1C alone resulted in a less severe deficit and in only one of the two

paradigms. These results support the notion that olfactory adaptation is derived from an integration of multiple regulatory mechanisms.

Title: CNGA4 and TRPC2, two proteins involved in the detection of mice pheromones

Authors: D. BOVARD[1], J. BRECHBÜHL[1], M. NENNIGER TOSATO[1], I. RODRIGUEZ[2], *M.-C. BROILLET[1];
[1]Univ. Lausanne Dep. Pharmacol & Toxicol, CH-1005 Lausanne, Switzerland; [2]Univ. Geneva Dep. Genet. & Evolution, Geneva, Switzerland

Abstracts: Mammalian pheromones are key chemical signals in the regulation of intraspecies social behaviors. Detection of these pheromones, which takes place in sensory neurons of the vomeronasal organ (VNO), implies the activation of the transient receptor potential canonical channel 2 (TRPC2) as the final effector. Interestingly, discrepancies between TRPC2-/- mice and mice lacking a VNO suggest the implication of another protein in the pheromone signaling pathway. This protein could either form a heteromeric channel with TRPC2 or a separate homomeric ion channel. The cyclic nucleotide-gated channel subunit CNGA4 is also expressed in the rodent VNO but its role and properties in this organ remain unknown. CNGA4 belongs to the CNG channel family which is playing an important role in different sensory pathways such as in light and odorant detection. We thus decided to study the role of the CNGA4 protein in the mouse VNO. We found CNGA4 to be expressed in axons, dendrites and, together with TRPC2, on the microvilli of the vomeronasal sensory neurons. We then performed *in vitro* experiments using HEK cells as an expression system. We transfected these cells with both CNGA4 and TRPC2. We could verify that CNGA4 directly interacted with TRPC2 functioning either as a chaperon translocating TRPC2 at the plasma membrane or as a subunit of a heteromeric channel. To further investigate the vomeronasal function of CNGA4 we generated CNGA4-/- mice. We observed that these mice were impaired in some pheromone dependent behaviors such as

aggressivity or mating. Interestingly these modified behaviors were similar to the behaviors of TRPC2-/- mice and, given the in-vitro results, we looked at the expression of CNGA4 in the VNO of TRPC2-/- mice. We observed that even if the neuronal microvilli were still present in TRPC2-/- mice, CNGA4 was not expressed anymore in this cellular region. Conversely, the expression of TRPC2 in CNGA4-/- mice was observed. These results might suggest a modulatory role for CNGA4 in a heteromeric TRPC2+CNGA4 ion channel. Further experiments will give more insights on the combined role of these transduction ion channels in pheromone detection.

Title: An RNA-Seq screen of the *Drosophila* antenna identifies a non-neuronal gene required for olfactory response to ammonia

Authors: K. MENUZ, N. K. LARTER, J. PARK, *J. R. CARLSON;
Yale Univ., New Haven, CT

Abstracts: Many insect vectors of disease detect their hosts through olfactory cues, making it imperative to better understand how odors are encoded. In insects, olfactory receptor neurons (ORNs) are compartmentalized with non-neuronal auxiliary cells in sensilla. In *Drosophila*, there are three morphological classes of olfactory sensilla, but few genes have been identified that distinguish them, other than the olfactory receptors themselves. In particular, little is known about the function of coeloconic sensilla, an evolutionarily ancient class of sensilla that detect amines and acids, including components of human odor that are cues for many insect vectors. Here, we undertook a high-throughput RNA profiling screen to identify genes that are highly enriched in coeloconic sensilla and may contribute to their unique function. The analysis revealed unanticipated chemosensory receptors in the wild type antenna, and the screen identified 250 genes whose transcripts are depleted in a mutant that lacks coeloconic sensilla.

Many of these 250 genes are predicted to function as ion channels, transporters and biotransformation enzymes; few were previously implicated in olfaction. We further investigated one of them, an ammonium transporter, to validate the utility of the screen. Electrophysiological and genetic analysis revealed that this transporter is essential for ammonia responses in a class of coeloconic ORNs, but is not required for responses to other odorants. The transporter is not expressed in ORNs, but rather in neighboring auxiliary cells. Thus, our data support the notion that auxiliary cells make an essential contribution to the coding of specific odors, and illustrate why comprehensive studies of sensory signaling must consider neural circuits in the context of their environment.

Title: Development of an automated method for analysis of mouth movements and orofacial reactions in restrained rats

Authors: *M. P. GARDNER[1], L. HOU[2], C. SAMUELSEN[1], A. FONTANINI[1], D. SAMARAS[2];
[1]Neurobio. and Behavior, [2]Computer Sci., SUNY At Stony Brook, Stony Brook, NY

Abstracts: Animals respond to gustatory stimuli with well-defined facial expressions. Orofacial responses, such as licking and gaping, have been shown to reflect the palatability and aversiveness of tastes. These behaviors are used to measure the perceived hedonic value of different taste solutions (Grill and Norgren, 1978). The standard method used to assess orofacial responses relies on visual inspection and manual labeling of videos of rats' mouth movements. This procedure is both dependent on the reviewer and is a very time consuming process. In order to increase the efficiency and reduce the subjectivity of scoring these behaviors, we developed a method for automatic scoring of rats' orofacial behaviors using a support vector machine for classification. To optimize the classifier, different combinations of 9 independent features (such as eigenfaces, fisherfaces, optical-flow, local binary patterns, etc.) were tested to determine the

most accurate and efficient method. This classifier can detect particular orofacial movements (licks, gapes, tongue protrusions, lateral tongue protrusions, mouth openings) based on few samples defined and cross-validated by multiple users. Electromyographic recordings of the digastric muscle were also included to complement information provided by the videos. Altogether, the classifier was able to correctly predict 82.0% of user-labeled frames (chance level was 21.2%) with 93.4% of lateral tongue protrusions and 84.1% of gapes being correctly labeled (chance levels were 16.6% and 4.40% respectively). We also trained a similar classifier to detect and disambiguate conditioned mouth movements evoked by cues predicting different tastes in rats trained on a classical conditioning paradigm. By implementing features extracted during and after the predictive cue (CS), but prior to the taste (US), the classifier was able to identify the trial-type with an accuracy of 41.4% (the chance level being 20.0% for five cues). The classification of the tastes themselves reached an accuracy of 65.6%. Finally, using this automated method we were able to compare the numbers of palatable and aversive mouth movements across expected and unexpected taste deliveries within single sessions of the classical conditioning paradigm. Overall our method improves the current efficiency of labeling orofacial behaviors and also provides a novel procedure for detecting subtle distinctions between conditioned responses in a multi-cue classical paradigm.

Title: Layer-specific amygdalar activation of excitatory and inhibitory circuits in gustatory cortex

Authors: ***A. MAFFEI**, M. S. HALEY, A. FONTANINI;
Neurobio. and Behavior, SUNY-Stony Brook, STONY BROOK, NY

Abstracts: Projections from the basolateral amygdala (BLA) to gustatory cortex (GC) have been shown to underlie firing activity that carries information on the palatability of a taste stimulus as

well as sensory cues that predict the availability of a taste. While the behavioral and functional aspects of this projection have been the focus of many studies, the synaptic mechanisms that underlie the effects of BLA activation on GC are poorly understood. In order to study the BLA to GC synapse in greater detail, we employed an optogenetic approach to activate BLA terminal fields in an acute slice preparation of GC. Using a combination of whole-cell patch-clamp recordings and pharmacological methods, we tested the hypotheses that 1) BLA directly targets excitatory (EXC) and inhibitory (INH) neurons in GC; 2) BLA engages GC circuits in a layer-specific manner. Our results demonstrate that BLA does in fact provide monosynaptic, excitatory input to both EXC and INH neurons across GC laminae. Furthermore, we show that this input has layer-specific properties. BLA directly targets a larger percentage of EXC (64%) and INH (57%) neurons in supragranular GC, with significantly larger BLA-evoked currents than in infragranular GC. We also find that BLA input is sufficient to drive a similar fraction of EXC and INH neurons to fire action potentials in all layers. Using a brief (5ms) pulses of LED stimulation we observe a fast monosynaptic EPSC in EXC neurons, followed by a short-latency polysynaptic IPSC. Despite differences in current amplitudes, the ratio of excitation to inhibition is not significantly different between layers. Given the ability of BLA projections to drive feedforward excitation and inhibition in GC more strongly in the superficial layers, we next sought to determine how sustained BLA activation might differentially engage circuit dynamics across laminae. Ramp stimuli were used to activate terminal fields with increasing intensity over 6s, and BLA-evoked spontaneous EPSCs and IPSCs were recorded. Sustained BLA activation increased the frequency of spontaneous EPSCs and IPSCs in both supragranular and infragranular layers, however activation of supragranular GC was more robust and longer-lasting. This increase in spontaneous activity outlasted the duration of the ramp. Increases in spontaneous event frequency could also be recorded in neurons that did not receive direct BLA input, suggesting that these neurons were driven by BLA-dependent recruitment of GC recurrent circuits. Together these data indicate that BLA can persistently alter network dynamics in GC by recruiting both excitatory and inhibitory circuits in a layer-specific manner.

Title: Integration of gustatory and anticipatory signals in the gustatory thalamus (VPMpc) of behaving rats

Authors: *H. LIU[1,2], A. FONTANINI[1,2];
[1]The Dept. of Neurobio. & Behavior, SUNY, Stony Brook, Stony Brook, NY; [2]Program in Neuroscience, SUNY Stony Brook, Stony Brook, NY

Abstracts: Recent reports on the gustatory cortex (GC) have emphasized its involvement in coding both the physiochemical and the psychological aspects of gustatory experience. The chemosensory and psychological dimensions of taste are hypothesized to originate from thalamic and amygdalar (AMY) pathways, respectively. Studies focusing on AMY-GC pathway have shown its contribution to hedonic, attentional, and anticipatory signals and have emphasized the temporal dynamics of its neural coding. However, less attention has been paid to the thalamic route, which involves the parvicellular portion of the ventral posteromedial nucleus of the thalamus (VPMpc). The VPMpc has been shown to encode gustatory stimuli and to be responsible for taste responses and network states in GC. Behavioral studies with VPMpc lesion have challenged the traditional view of sensory thalamus as just an information relay station and have suggested its roles in higher-order functions, such as anticipation. Despite the importance of VPMpc in taste processing and taste-guided behavior, little is known about taste coding in VPMpc of behaving animals. Here, we present results from multielectrode recordings in VPMpc of alert rats, which were engaged in a task involving cued, self-administrations (Self) and passive, unexpected (Pass) deliveries of taste solutions. 128 single units were recorded from 11 rats. Almost half of the neurons (43.75%, 56/128) had significantly different responses across tastants with fast onsets and rich temporal dynamics. Further analyses revealed the encoding of both taste quality and palatability. Comparison of responses to expected and unexpected tastes showed a strong state-dependency, with faster (average taste-quality coding onset: 669.5 ms Pass vs 502.5 ms Self) and better (average decoding performance: 0.4 Pass vs 0.48 Self) coding in the case of cued, self-administered taste. Improvements in coding were related to a reduction of neural response variability (Fano factor mean: 0.81 Pass vs 0.58 Self) and an increase of coding density (taste number decoded/unit: 3.13 vs 2.46). Surprisingly, we found a considerable proportion of thalamic neurons (64.06%, 82/128) responding to the anticipatory cue and whose activity was correlated with the animal's decision to self-administer. Altogether our data provide the first description of how the VPMpc of behaving rats encodes gustatory and anticipatory information according to the state of the animal. The results suggest that the role of VPMpc goes beyond encoding the physiochemical properties of taste stimuli and extends to the coding of palatability and expectation.

Title: Multimodal integration of taste and odor signals in the gustatory cortex of alert rats

Authors: *C. L. SAMUELSEN, A. FONTANINI;
Neurobio. and Behavior, Stony Brook Univ., Stony Brook, NY

Abstracts: Gustatory and olfactory signals are naturally coupled during food consumption. The simultaneous activation of taste and olfactory receptors results in robust multisensory associations. The gustatory cortex (GC) receives multiple inputs conveying gustatory and olfactory signals. Neuroimaging experiments point to GC as an integrative locus for these chemosensory signals. However, GC single neuron responses to olfactory stimulation have not been studied in alert animals. Using multielectrode recordings in behaving rats, multimodal chemosensory responses in GC were examined after intra-oral deliveries of single tastants and tasteless odorants in water. We recorded 272 single units in GC, of which 33% (89/272) responded to taste-only, 6% (16/272) to odor-only, with a substantial multimodal group of 12% (33/272) responding to both taste and odor. To determine whether odor responses in GC depend on the activation of olfactory receptors in the nasal epithelium, a nasal deciliation protocol was used. A mild detergent was applied directly into each nostril rendering the subjects anosmic. Preliminary results (49 single units) show that detergent application does not affect taste-responsive GC neurons (Pre: 122/272, 45% vs. Post: 21/49, 43%), but significantly reduces the number of odor-responsive GC neurons (Pre: 49/272, 18% vs. Post: 2/49, 4%). Additional analyses were performed to examine taste coding in the three groups of neurons recorded. Multisensory neurons, those which respond to both taste and odor, appeared to be strongly tuned to encode taste palatability. This group of neurons showed increased activity to the palatable tastes, sucrose and salt, while showing suppressed responses to aversive stimuli (citric acid and quinine). Interestingly, the response dynamics to intraoral odors were similar to those evoked by palatable tastes. Using a palatability index, we found a significantly greater number of multisensory neurons coding palatability (29/33, 88%) compared to taste-only neurons (58/89, 65%). This difference was temporally represented 2.5 to 3 seconds after stimulus onset. To

determine whether the response dynamics of multisensory neurons paralleled the behavioral consumption of chemosensory stimuli, a brief access task was employed. We found that rats avoid sampling the aversive taste stimuli, while equally sample palatable tastes and odors, supporting the suggestion that multisensory neurons represent palatability. Altogether these results provide novel evidence for GC as an area of multimodal integration of intra-oral chemosensory signals.

Title: Pre-exposure to a diverse array of tastes enhances later conditioned taste aversion to novel sucrose

Authors: *V. FLORES[1,2], A. MORAN[2,3], D. B. KATZ[2,3];
[2]Psychology, [3]Volen Ctr. for Complex Systems, [1]Brandeis Univ., Waltham, MA

Abstracts: In conditioned taste aversion (CTA), an animal learns to avoid a particular taste that has been paired with malaise. Many factors influence the strength of aversion learning; notable among these is taste novelty - the animal's familiarity (or lack thereof) with the taste used as a conditioned stimulus (CS). The effect of familiarization with tastes other than the CS has received less investigation, however. The present studies examine the impact that exposure to a range of fluid stimuli (including distilled water, sodium chloride and citric acid) before or during conditioning has on an aversion learned to novel sucrose. Rats were exposed to tastes via both a bottle and intra oral cannula (the latter method facilitated exposure of diverse tastants, while the former ensured strong conditioning). Presentation of the entire taste array within the conditioning session reduced the resultant sucrose aversion, as expected. Pre- training exposure to a taste array that excluded sucrose, however, strengthened CTA, an effect that scaled with the number of tastes in the pre-exposure array and with the amount of pre-exposure; this phenomenon was observable regardless of the diversity of tastes presented during the conditioning session. These results reveal that experience with the realm of tastes changes an animal's future handling of

even novel tastes. Since CTA protocols using animals often lack stimulus exposure prior to conditioning training, these results have implications for the interpretation and development of CTA protocols investigating the complex underpinnings of learning and behavior.

Title: Pharyngeal sense organs drive robust sugar consumption in *Drosophila*

Authors: *E. E. LEDUE[1], Y.-C. CHEN[2], A. Y. JUNG[1], A. M. LOMELI[2], A. DAHANUKAR[2], M. D. GORDON[1];
[1]Zoology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Univ. of California, Riverside, CA

Abstracts: The fly pharyngeal sense organs lie at the transition between external and internal nutrient sensing mechanisms. Inaccessible to electrophysiology, their function has remained largely unexplored. Here, we investigate the physiology and behavioural role of pharyngeal sense organ gustatory neurons expressing sweet receptors. Using calcium imaging, we find these neurons to be broadly responsive to sweet compounds. Selective rescue of Gr64e and Gr5a mutants in just two labral sense organ (lso) neurons is sufficient to restore preference for glycerol and trehalose, respectively. We also demonstrate that pox-neuro mutants lacking peripheral taste function have intact pharyngeal sweet taste, which is both necessary and sufficient to drive robust consumption of sweet compounds. Moreover, in the absence of sweet taste, flies prefer some, but not all, nutritional sugars. Together, our data demonstrate that pharyngeal sense organs play an important role in directing consumption of sweet compounds, and that their function must be considered when distinguishing between taste and postingestive sensory inputs.

Title: The ventral tegmental area modulates gustatory responses of the neurons in the parabrachial nuclei

Authors: *C.-S. LI[1], Y. K. CHO[2];
[1]Anat., Southern Illinois Univ. Sch. Med., CARBONDALE, IL; [2]Physiol. & Neurosci., Kangnung Natl. Univ. Col. of Dent., Kangnung, Korea, Republic of

Abstracts: The nucleus of the solitary tract (NST) and the parabrachial nuclei (PbN) are the first and second central relays in the central taste pathway of the rodent, respectively. Taste information is further transmitted to the various forebrain nuclei from the PbN, including the thalamus, the lateral hypothalamus, the central nucleus of the amygdala, the bed nucleus of the stria terminalis, the nucleus of accumbens, and to the insular cortex. These forebrain gustatory nuclei not only influence activity of gustatory cells in both the NST and PbN but are also known to modulate gustatory responses of the cells in the NST and PbN. The ventral tegmental area (VTA) in the midbrain is the site of the origin of dopaminergic cells bodies of the mesolimbic reward circuitry. Although there is no anatomical data to support the direct neuronal connectivity between the gustatory pathway and the mesolimbic reward pathway, recent behavioral and electrophysiological studies provided strong evidence that indicate the interaction between these two pathways. It has been reported that alcohol taste selectively activates sucrose cells in both the NST and PbN. Furthermore, ethanol increases firing activity of dopamine cells in the VTA, and sham feeding of sucrose increases dopamine concentration in the nucleus acumens which is a component of the mesolimbic reward circuitry. In the present study, we investigated whether activity of gustatory neurons in the PbN is influenced by activation of the VTA, and that whether activation of the VTA modulates taste responses of the PbN cells. Extracellular single-unit activity was recorded from the urethane anaesthetized hamster PbN and taste responses were confirmed by delivery of 32 mM sucrose, NaCl, quinine hydrochloride, and 3.2 mM citric acid to the anterior tongue. After confirming the responsiveness of a PbN cell to taste stimulation, the VTA was stimulated (0.5 ms, ≤ 100 μA, 1/3 Hz) using a concentric bipolar stimulating electrode. We recorded a total of 32 taste-responsive cells from the PbN; 11 being NaCl-best, 7 being sucrose-best, 6-being citric acid-best, and 8 being quinine hydrochloride (QHCl)-best neurons. Electrical stimulation of the VTA activated 20 of 32 PbN neurons (62.5%) orthodromically (15

cells were inhibited and 5 cells were excited). We further examined whether electrical stimulation of the VTA alters taste responses of the PbN cells. High frequency stimulation (100 Hz, 0.2 ms) of the VTA activated or suppressed taste responses in 6 cells tested which is parallel to the type of the input of the PbN cells receive from the VTA. These results suggest that the mesolimbic reward pathway influences taste information processing in the PbN.

Title: Toll-like receptor 4 is involved in spontaneous fat and sugar preference

Authors: *S. CAMANDOLA, R. G. CUTLER, M. P. MATTSON;
Lab. Neurosciences, NIA, BALTIMORE, MD

Abstracts: The gustatory system allows animals to discriminate among foods in order to select nutritious diets and maintain energy balance. Although a broad range of economic, social and behavioral factors influences food choices, the immediate pleasantness generated by taste is still for most individuals the driving force behind food consumption. Most animals, including humans, display an innate attraction for lipid-rich foods. In a typical Western diet fats account for almost 40% of the daily energy content. The hedonic response to palatable macronutrients, and consequent over-consumption of tasty high calorie foods, has been suggested to play a role in the increasing prevalence of obesity world wide. However, the mechanisms underlying such eating behavior are largely unclear. Toll-like receptor 4 (TLR4) is a transmembrane protein involved in the detection of lipopolysaccharide in gram negative bacteria. In addition to its well characterized role in innate immune responses, it was recently shown that TLR4 plays a role in central nervous system plasticity, learning and memory, and cognition. Since the discovery that obese, type 2 diabetic, and metabolic syndrome subjects have increased levels of TLR4 expression in various tissues, many studies have been conducted to elucidate its function in the metabolic consequences of diet-induced obesity. In the present study we provide evidence that TLR4 is involved in orosensory detection of fat and sugar. TLR4 knock mice displayed decreased spontaneous preference for a high fat, high sugar diet, resulting in reduced food consumption and caloric intake, and less weight gain. Compared to wild type animals TLR4

deficient mice showed reduced preference for lipids (i.e. linoleic acid), as well as sugars (i.e. sucrose, fructose, saccharin) and umami (i.e. inosine-5'-monophosphate) in two bottle preference tests. The altered gustatory preferences of TLR4 knock mice were associated with decreased expression of key regulatory molecules for the detection of sweet, umami and fat taste in the tongue epithelium. Experiments are currently under way to determine the cellular and molecular mechanism by which TLR4 impacts taste perception and eating behavior.

Title: Decision making in *C. elegans* chemotaxis to alkaline pH

Authors: *I. MARUYAMA, T. MURAYAMA;
Okinawa Inst. of Sci. & Technol. Grad. Univ., Okinawa, Japan

Abstracts: Monitoring of environmental and tissue pH is crucial for the survival of animals. The nematode *C. elegans* is a model organism suitable for the analysis of neural circuits that regulate animal behaviors. The animal is attracted to mildly alkaline pH, and avoids strongly alkaline pH. Our genetic dissection and Ca2+ imaging demonstrate that ASEL and ASH are the major sensory neurons responsible for the attraction to mildly alkaline pH and repulsion from strongly alkaline pH, respectively. In ASEL, a transmembrane guanylyl cyclase, GCY-14, is activated by environmental alkalinization, and in turn, a cGMP-gated channel serves for Ca2+ influx into the sensory neuron. In ASH, TRPV channels are found to be required for the neural activation upon stimulation with strongly alkaline pH. To understand the animal's behavioral switch at molecular and cellular levels, we have also analyzed behaviors of mutants defective in ASEL and/or ASH under various alkaline pH, and have found that activities of ASEL and ASH compete each other for the behavioral switch. While mildly alkaline pH preferentially activates ASEL, strongly alkaline pH activates both ASEL and ASH, and ASH activity overrides the activity of ASEL. Neural circuits responsible for this decision making will be discussed.

Abstracts: Introduction: A case study with vivid and perceptually correct aftertaste in the absence of taste is described. Case Study: A 55 y/o male two years prior to presentation was exposed to Scott's Crabgrass Preventer herbicide. Within one week there was a gradual decline in sweet and salt taste perception and dysgeusia where potato chips taste like potatoes, apple pie tastes like apples, Pepsi tastes like chemicals, chocolate tastes bitter and corn flakes have a salty taste. For the last one year, he has intermittent salty phantageusia of his entire mouth, whereby regular water tastes like seawater. Six months ago he noted onset of palinageusia, a strong aftertaste of food that was consumed earlier in the day, the way it should taste, but of 50% intensity. Cheese, has no taste, but 8 hours later he can taste cheese flavor. Cinnamon bun is flavorless, but half-hour after eating, the taste appears and lasts for 5 minutes. Sausage has a slight taste at the time of consumption, but two hours later he experiences a much more flavorful and savory taste of sausage, which lasts for half an hour. The aftertaste is always of the last food he has eaten. Rather than being repulsed by these aftertastes, he "savors them" because it provides he only taste experience. Since onset, he has lost of pleasure in eating and has lost 60 pounds. He complains of mild dysphagia, halitosis and omeprazole responsive reflux. Neuropsychiatric exam: decreased short-term memory, sadness, and irrational fears of others out to do him harm. Beck Depression Inventory and Zung Anxiety Scale: normal. Neurologic exam: decreased blink frequency, bilateral palmar erythema and 1+ bilateral pedal edema. Motor: R pronator drift. Reflexes: absent. Candidiasis cultures - negative. Chemosensory tests: see table. Discussion: Potential causes for his condition include: Zenker's diverticulum, esophageal dysmotility, Gastroesophageal Reflux, herbicide (Pendimethalin) toxicity with phantom aftertaste, prolonged chemosensory deprivation phantageusia and palinageusia (chemosensory equivalent of Phantom Eye Syndrome), illusion of taste due to autosuggestion, somatoform

delusion or somatic manifestation of depression or psychosis. Aftertaste warrants exploration in those with chemosensory dysfunction.

Olfactory Functions

Title: Temporal coding of foods in the parabrachial nucleus of the awake, freely licking rat

Authors: *M. S. WEISS[1], P. M. DI LORENZO[1], J. D. VICTOR[2];
[1]Psychology, Binghamton Univ., Binghamton, NY; [2]Weill Cornell Med. Col., New York, NY

Abstracts: The parabrachial nucleus of the pons (PbN) is the obligatory second synapse in the central gustatory pathway of the rodent. Analyses of taste-evoked spike trains in single neurons in the PbN of awake animals have shown that these neurons can use temporal coding to convey information about taste qualities (Weiss et al., J. Neurophysiol., 111(8):1655-70, 2013). However, the amount of information that these cells convey about taste qualities is far less than they convey when recorded from anesthetized rats. We hypothesized that the PbN, as part of the feeding system, might convey more information about actual foods than prototypical taste stimuli often tested in gustatory research. To test this idea, temporal coding of PbN responses to real foods (Clam juice [0.12M NaCl], 25% cream, grape juice [0.12M sucrose], lemon juice [0.016M citric acid], and coffee [0.019M caffeine]) vs. prototypical tastants (0.1M NaCl, 0.1M MSG, 0.1M sucrose, 0.01M citric acid, 0.0001M quinine-HCl) was assessed in freely licking rats. An 8-channel tungsten microwire assembly was implanted into the PbN of Sprague-Dawley rats. Following recovery, animals were water-deprived (22 hours/day) and placed into a testing chamber with free access to a lick-spout that delivered 12±1 µl of fluid per lick. Taste stimuli were presented as a 5-lick stimulus block, and five artificial saliva licks were each presented on a VR5 schedule as a rinse between stimulus blocks. An information theoretic metric was used to determine the amount of information conveyed by firing rate and spike timing. Preliminary results show that PbN neurons can respond to all of the food stimuli. Of particular interest, a subgroup of neurons (n = 4 of 10) responded to cream (representing a “fat taste”) within 100ms of a lick. Additionally, ~30% of neurons that responded to a food stimuli do not respond to their prototypical counterparts or vice versa. Finally, in neurons where temporal coding contributes significantly to the amount of taste quality information, PbN cells convey more information about food stimuli than prototypical tastants. These results underscore the idea that the PbN is a node in the feeding circuit, as well as the taste pathway.

Title: L-amino acid taste: Receptor system and transduction mechanisms

Authors: *S. PAL CHOUDHURI, R. J. DELAY, E. R. DELAY;
Biol., The Univ. of Vermont, Burlington, VT

Abstracts: Receptor heterodimer T1R1+T1R3 has been shown to be involved in detection of prototypical umami compound L-glutamate. Research with L-glutamate also suggests two other G-protein coupled receptors, taste-mGluR4 and taste-mGluR1, are important in umami taste. Umami taste transduction is mediated by PLC-β2 dependent rise of IP3 followed by release of intracellular calcium. Umami research also suggests a Gα-dependent pathway that down-regulates cAMP. 5' inosine monophosphate (IMP) is another umami taste stimulus and a potent flavor enhancer that synergistically enhances umami taste of L-glutamate. HEK cell expression data show that IMP can also potentiate the response to other L-amino acids (Nelson et al., 2002). However, the transduction mechanism for IMP and its synergy mechanisms are largely unknown. Further, while T1R1+T1R3 receptors appear to detect L- amino acids, contribution of other receptors have just begun to be studied. We used calcium imaging of isolated taste sensory cells (TSCs) and taste buds of mice to determine if: (1) receptors other than T1R1+T1R3 detect L-amino acids detection with or without synergistic responses, (2) transduction of L-amino acids other than glutamate also utilize the PLC-β2pathway, and (3) L-amino acids also use a cAMP-dependent pathway. Our calcium imaging data show that response patterns elicited by L-amino acids and IMP vary across TSCs. Further, TSCs also show synergy for different L-amino acids when mixed with IMP. We also found that TSCs from T1R3-/- mice can respond to various L-amino acids and IMP. Our data suggest that receptors or possibly receptor complex other than T1R1+T1R3 may be involved in detection of L-amino acids. Currently we are using pharmacological approach to elucidate the downstream signaling pathways for L-amino acids transduction.

Title: Anion effect and osmotic sensitivity of salt-responsive taste bud cells isolated from mouse circumvallate papillae

Authors: *B. C. LEWANDOWSKI, S. K. SUKUMARAN, R. F. MARGOLSKEE, A. A. BACHMANOV;
Monell Chem. Senses Ctr., Philadelphia, PA

Abstracts: At least two distinct pathways transduce salty taste in rodents: a low threshold, amiloride-sensitive, Na+ (and Li+) selective pathway mediated by epithelial sodium channels, and a high threshold, amiloride-insensitive (AI), cation non-selective pathway whose mechanism is currently unknown. In both pathways, a salt's cation appears to be the proximal stimulus necessary to initiate cellular responses. In the AI pathway, however, responses are significantly modulated by a salt's anion, with gustatory nerve responses growing smaller as anion size increases. One popular model to explain this 'anion effect' phenomenon is built upon evidence that tight junctions at the taste pore are differentially permeable to cations vs anions. As cations diffuse through these tight junctions, larger and less permeable anions accumulate at the taste pore resulting in a negative transepithelial potential (TP) that, among other effects, inhibits diffusion of cations to the basolateral surface of taste cells where AI salt sensitive channels may exist. We tested the importance of TPs for the anion effect by measuring Fura2 calcium responses to Na+ salts in isolated taste cells from mouse circumvallate taste papillae. Using isolated taste cells removes any potential influence of TPs on salt responses. AI salt-sensitive type III taste cells were identified by responses to NaCl, NaCl + amiloride, and KCl. The anion effect was measured in physiologically identified AI type III taste cells by comparing responses to 250 mM NaCl and 250 mM NaGluconate. A cell was defined as exhibiting an anion effect if its response to NaGluconate was <70% of its response to NaCl. Of 44 AI type III cells, 30 exhibited an anion effect (average normalized (to 250 mM NaCl) response = 0.43 +/- 0.13) and 14 did not (1.05 +/- 0.26). To ensure that responses were salt related and not purely osmotic

effects, cells were tested with cellobiose stimuli osmotically matched to 250 mM NaCl. Osmotic responses were strongly dependent on the presence of Na+ (norm. resp. = 0.20 +/- 0.08 with 30 mM NaCl + 110 mM NMDG.Cl vs 0.61 +/- 0.36 with 140 mM NaCl; $p<0.05$). Furthermore, cells exhibiting the anion effect had significantly smaller osmotic responses than cells without an anion effect (0.43 +/- 0.29 vs 0.80 +/- 0.34; $p<0.05$). These data suggest that the lack of an anion effect in some putative AI taste cells may be attributed to the presence of osmotically sensitive channels permeable to Na+ but not larger cations (NMDG+). Current models of the anion effect may need revision because the observation of an anion effect in isolated taste cells indicates that larger anions can directly inhibit the AI salt transduction pathway in taste cells.

Title: Altered brain response to sweet taste in older adults with metabolic syndrome: An fMRI study

Authors: *C. MURPHY[1], A. JACOBSON[2], E. GREEN[3], L. HAASE[3], A. BUNCIC[2], E. MCINTOSH[2];
[1]San Diego State Univ/Univ of California, San Diego, San Diego, CA; [2]San Diego State Univ., San Diego, CA; [3]SDSU/UCSD Joint Doctoral Program, San Diego, CA

Abstracts: Metabolic syndrome involves a constellation of risk factors (obesity, large waist circumference, high blood pressure, elevated triglycerides, low HDL) for cardiac and vascular disease that are also associated with obesity, diabetes and dementia in later life. Obesity has increased to epidemic proportions, with significant health consequences. The abundance of highly palatable food may contribute to obesity, yet not everyone becomes obese. Physiological state (i.e., hunger and satiety) has been shown to affect the processing of appetitive stimuli in young adults, and age differences in hormones that influence hunger and satiety suggest differences in brain response to nutrients. We investigated brain activation with fMRI, recorded

at 3T, in older adults (65+ yrs), with and without metabolic syndrome, and compared their activation to those of young adults (18-26), while they rated the pleasantness of sweet taste, under the conditions of hunger and satiety. Results in the hunger condition are reported here. We conducted both whole brain activity and region of interest analyses, focusing on regions involved in taste and reward processing. FMRI revealed that older adults showed effects of metabolic syndrome, with group differences in activation in the hunger condition in brain areas involved in both gustatory and reward processing (e.g., OFC, Nucleus Accumbens). Reduced activation may reflect reduced dopaminergic function and a blunted response to appetitive, rewarding taste stimuli in older adults with metabolic syndrome. Further research with neuroimaging of human response and in animal models is needed to understand the mechanisms that drive brain response in those with metabolic syndrome. We hypothesize that altered brain response to chemosensory stimuli is one underlying mechanism that contributes to the development and maintenance of obesity in metabolic syndrome. Title: Effects of selective gastric vagotomy on sucrose consumption in obese and lean rats

Authors: *A. DENMAN-BRICE[1], P. DI LORENZO[1], K. CZAJA[2];
[1]Psychology, Binghamton Univ., Vestal, NY; [2]Washington State Univ., Pullman, WA

Abstracts: Obese humans exhibit differences from lean humans in taste preference for sucrose, which may play a role in sustaining disordered eating behavior. Roux-en-Y gastric bypass surgery (a weight loss surgery which damages the vagus nerve) has been reported to cause changes in sucrose taste perception in both humans and rats. Additionally, evidence suggests that the gut contains taste-receptive cells which may project to taste areas of the brain (particularly

the nucleus of the solitary tract, or NTS) via the vagus nerve. We hypothesize that taste changes in obesity are mediated by changes in vagal post-ingestive feedback. In the present experiment we tested sucrose preference and sucrose reward value in diet induced obese (DIO, induced by feeding a high-fat chow for at least 4 wks) and lean rats before and after selective gastric vagotomy (Vx) or sham surgery. Sucrose preference was examined by presenting food-deprived rats with brief access (10 sec, signaled by a house light and counted from the first lick) via a computer-controlled lick spout to 6 sucrose solutions of different concentrations (0.005M, 0.015M, 0.05, 0.15M, 0.5M, 1.5M) presented in random order. The number of licks to each sucrose solution as well as the proportion of total licks for each concentration was calculated. Sucrose reward value was tested with a progressive ratio (PR) schedule with licks as the operant response. This procedure begins at 1 dry (unreinforced) lick between "reinforcement blocks" consisting of 5 consecutive licks, each reinforced with 12 µl of 0.1M sucrose. The number of dry licks required for each subsequent reinforcement block increments by 1 dry lick. Subjects remain in the apparatus until at least 5 min have passed without licking. The breakpoint is the number of dry licks that the rat emits to get its last reinforcement. Results showed that prior to surgery, obese rats exhibited a steeper preference curve for varying concentrations of sucrose and a lower PR breakpoint compared to lean rats. After surgery, lean Vx rats exhibited lower PR breakpoints, resembling the performance of DIO subjects. These results imply that altered sucrose taste preferences in obese animals may be mediated by hypoactivity of vagal post-ingestive feedback signals.

Title: *In vivo* confocal Ca2+ imaging to study salt taste in the geniculate ganglion

Authors: ***A. WU**[1], G. DVORIANTCHIKOV[2], E. PEREIRA[2], N. CHAUDHARI[1], S. ROPER[1]; [1]Dept. of Neurosci., [2]Dept. of Physiol. and Biophysics, Univ. of Miami, Miller Sch. of Med., MIAMI, FL

Abstracts: NaCl elicits contrasting gustatory responses in mammals: dilute NaCl solutions (<~100 mM) are preferred over water while high concentrations (>~150 mM) are aversive. Evidence exists for two taste transduction pathways for sodium salts. One, an amiloride-sensitive pathway, is dependent on epithelial sodium channels (ENaC) expressed in a subset of taste bud cells. An alternative, amiloride-insensitive pathway may be specialized for aversive salt taste. This latter pathway is ENaC-independent and appears to be mediated by a different population of taste bud cells. We are interested in identifying salt-sensing gustatory neurons in the geniculate ganglion. These neurons innervate taste buds in the anterior tongue, a region that is highly sensitive to salt taste. To study how individual neurons respond to oral stimulation with salty stimuli, we have used confocal Ca^{2+} imaging of geniculate ganglion neurons from *Pirt*-GCaMP3 mice (Kim *et al. Neuron* 2014). We first confirmed that the genetically-encoded Ca^{2+} reporter in these mice is expressed in all geniculate ganglion neurons and that in acutely isolated ganglia, all neurons respond with a robust increase in fluorescence ($\Delta F/F_0$) when depolarized with 50 mM KCl. We developed an *in vivo* preparation with a surgically exposed geniculate ganglion, imaged confocally while the tongue and palate were stimulated with NaCl (30 to 250 mM). The preparation permits us to e visualize individual neurons with good resolution and obtain highly reproducible responses ($\Delta F/F_0$) simultaneously from many neurons. Individual geniculate ganglion neurons varied widely in their sensitivity to NaCl, with EC_{50} ranging from 50 to 500 mM. We have not observed discrete classes of low- *vs.* high Na-sensitive cells. In one series, responses in ≈ half the geniculate neurons were completely blocked by adding benzyl amiloride (benzamil, 1 μM) to the NaCl stimuli. In the remaining half, NaCl-evoked responses were insensitive to benzyl amiloride. Our investigations of salt taste are designed to extract a new and more precise view of how salt taste is represented in the peripheral gustatory system.

Title: Design of voltage sensitive dye imaging for analysis of taste-recognition neural network in *Aplysia* buccal ganglion

Authors: *Y. MIYAKE[1], Y. YOSHIMI[1], T. NAGAHAMA[2];
[1]Dept. Appl. Chem., Shibaura Inst. Technol., Koto-Ku, Japan; [2]Dept. Biophysics, Fac. Phar. Sci., Toho Univ., Funabashi, Japan

Abstracts: Taste is sensed by small number of chemoreceptor types but identified by a sophisticated neural network. Analysis of the neural network concerning taste will contribute to further understanding of informational processing in the central nervous system. A marine gastropod *Aplysia* shows clear food preferences. We attempted to analyze the neural network which generates ingestive or rejective response by using voltage sensitive dye (VSD) imaging. Buccal mass and buccal ganglia of *Aplysia* californica were isolated with keeping their connection by buccal nerves. The neurons in the ganglia were stained with VSD (Di-4-ANEPPS) in the presence of tetraethylammonium (TEA) chloride. Then the responses of the stained neurons were explored after administration of 1 mM solution of L-asparagine (L-Asn) or L-aspartic acid (L-Asp) to radula inside the buccal mass. L-Asn induces ingestive response of the jaws and radula, while L-Asp induces rejective response of them. The administration of L-Asp induced the firing in S1 and S2 clusters with shorter time lag than that of L-Asn as shown in Table 1. This tendency was also observed by electrophysiological experiments using a glass microelectrode. Therefore, the staining and TEA treatment of neurons which are necessary to VSD imaging would not affect seriously neural response because the time lag of firing from the administration of amino acids were almost same whether these treatments were performed or not. The results suggest that VSD imaging is useful for an analysis of neural network for taste recognition because this method can detect neural signals in response to taste stimulation in large numbers of neurons simultaneously. A clarification of the neural network for taste will be achieved by the further analysis of spike activity in these clusters using VSD imaging.

The time lag of firing from administration of amino acids in S clusters neurons (n=6)

	S1 cluster	S2 cluster
L-Asn	4.52 ± 1.40 s (4.57 s)	4.47 ± 1.37 s
L-Asp	2.16 ± 0.31 s (2.02 s)	2.15 ± 0.31 s

Values in parenthesis are the time lags measured electrophysiologically. (n=1)
