Abstracts: Intravital microscopic imaging of the sensory system could be a powerful experimental tool, but this has been unprecedented for the taste sensory organ due to the anatomical barrier. Here, we report cellular imaging of the dorsal surface of the tongue in live mice. This was made possible by developing a suction holder that externalizes the tongue from the oral cavity noninvasively and a tongue stabilizer that suppresses the tissue motion while allowing optical and chemical access simultaneously. Using the tongue imaging window in combination with a video-rate two-photon microscope, we visualized the three-dimensional microanatomy and physiological dynamics, such as blood perfusion, molecular diffusion, and functional activity of taste cells. Moreover, we revealed that the so-called intravascular taste sensing takes place in the taste cells, presumably at the microvilli, by small tastant molecules diffused out from pericellular blood vessels and permeated through tight junctions. Intravital tongue imaging would open a new avenue towards comprehensive understanding of peripheral taste sensation.

Title: Effects of temporal inactivation of gustatory insular cortex and gustatory thalamus on taste neophobia

Authors: J. ARTHURS, S. REILLY, *J.-Y. LIN;
UIC PSYCHOLOGY, CHICAGO, IL

Abstracts: Permanent lesions of the gustatory insular cortex (GIC) or gustatory thalamus (GT) attenuate taste neophobia (TN). That is, rats with either type of lesion consume more of a novel, fear-inducing taste than neurologically intact subjects; with repeated benign exposures all rats recover from neophobia and reach the same intake asymptote. In the present study we attempted to dissect the temporal aspects of the permanent lesion effect by inactivating the GIC (Experiment 1) or GT (Experiment 2) before or after the first taste neophobia trial. In Experiment 1a, water deprived male Sprague Dawley rats received 15-min access to 0.5% saccharin once every third day for a total of 5 trials. Twenty min before Trial 1, rats in the control group were handled or given intra-GIC infusions of the saline vehicle; the experimental rats were infused with a baclofen/muscimol (BM) cocktail; all rats were allowed to freely consume saccharin without handling or infusions on Trials 2-5. The results show that GIC inactivation elevated intake on Trial 1, decreased intake on Trial 2, and that saccharin intake was not different from control subjects on Trials 3-5. In Experiment 1b, GIC inactivation occurred after the first exposure to a novel 0.0001 M quinine solution, in a procedure that was otherwise identical to that of Experiment 1a. The results reveal no influence of GIC inactivation on the recovery from TN. In a second series of experiments, the same procedures were used to investigate the involvement of the GT in TN. In Experiment 2a, GT inactivation had no influence on Trial 1 intake. However, whereas control subjects increased intake on Trial 2 relative to Trial 1, the GT rats showed no such between-trial change, an effect that served to delay their recovery from TN over the remaining taste trials. In Experiment 2b, post-Trial 1 GT inactivation significantly suppressed intake on Trial 2, which delayed the across-trial recovery from TN relative to the control subjects. This series of experiments has benefitted understanding of the roles of the GIC and GT in TN. We propose that the GIC is critically involved in the perception of taste novelty and that a disruption of this process results in a genuinely novel taste being treated as if it were familiar and safe (which explains why lesions of the GIC retard but do not eliminate conditioned taste aversion learning). Importantly, the absence of a Trial 1 disruption clearly indicates that the GT has a different role in TN than the GIC. We propose that the GT is involved in processing "safety" feedback from a novel taste stimulus, the nature of which is under investigation.

Title: Candidate second-order gustatory neurons that connect the primary gustatory center to other regions in the gnathal (subesophageal) ganglia in the *Drosophila* brain

Authors: ***T. MIYAZAKI**[1], T.-Y. LIN[1], K. ITO[2], C.-H. LEE[1], M. STOPFER[1];
[1]Natl. Inst. of Child Hlth. and Human Develop., NIH, Bethesda, MD; [2]Inst. of Mol. and Cell. Biosci., The Univ. of Tokyo, Bunkyo-ku, Tokyo, Japan

Abstracts: With a relatively simple nervous system and a plethora of genetic tools, *Drosophila* affords an excellent model for mapping neural circuits and testing their functions. Previous studies identified various classes of gustatory sensory neurons (GSNs) which respond to different tastants and relay information to distinct subregions of the primary gustatory center (PGC) in the gnathal (subesophageal) ganglia. However, little is known about the identities of the neurons that receive synaptic inputs in the PGC, or how these follower neurons process taste information. Here we used a combination of anatomical and functional methods to identify candidate second-order gustatory neurons from a pool of genetically-defined subsets of cells. After screening ~5,000 GAL4 lines, we identified 32 lines that label neurons whose dendrites innervate the PGC. As a secondary screen, we used the GRASP (GFP reconstitution across synaptic partners) technique to visualize potential contacts between the candidate neuron dendrites and axonal terminals of Gr5a-expressing GSNs, which have been shown to respond to sucrose. To differentiate simple membrane contacts from true synapses, we incorporated an active zone marker (Brp-mCherry) to label presynaptic sites of Gr5a-expressing GSNs and checked whether it was co-localized with GRASP. Finally, by expressing a genetically-encoded calcium indicator (G-CaMP6m) in candidate neurons and by using a novel tastant-delivery system we determined whether the neurons increased their activity when sucrose solution was delivered to the

proboscis. Two types of candidate second-order neurons met these criteria and showed stimulus-elicited increases in fluorescence. Together, our results suggest these neurons receive excitatory input from sucrose-responsive Gr5a-expressing GSNs. In addition, we analyzed distributions of input and output sites of one of the candidate neurons using GFP/RFP-tagged acetylcholine receptor subunit (Dα7) and active-zone marker (Brp), respectively. Whereas postsynaptic sites were almost coincident with the synaptic contacts to Gr5a-expressing neurons, presynaptic sites were distributed in distinct regions, suggesting that the labeled neurons transmit information from the PGC to distinct third-order neurons. Further, we are using our tastant delivery apparatus to present multiple taste solutions to animals to analyze responses of the labeled neurons. Our results will provide new information about how the gustatory system encodes tastants.

Title: Chemical neural processing and behaviour in zebrafish larvae

Authors: *R. CANDELIER[1], M. S. MURMU[2], G. SUMBRE[2], G. DEBREGEAS[1];
[1]Lab. Jean Perrin (UMR 8237), CNRS / UPMC, Paris, France; [2]Inst. de Biologie de l'École Normale Supérieure, Paris, France

Abstracts: Vertebrates use two chemosensory systems, taste and olfaction to detect and distinguish chemicals from their surroundings. How these chemical sensory stimulus are detected by the brain, processed and transformed into adequate motor pattern remains a central question. However, experimental investigation of the precise mechanisms underlying this sensory modality is extremely difficult since the delivered stimuli have very often poor spatial and temporal resolution, owing to the complex nature of molecule transport and diffusion in fluids. To study the neural responses and motor behaviour associated with chemical stimulation, we have developed an innovative microfluidic chip that enables the presentation of different chemical stimuli (e.g. gustatory, olfactory or nocioceptive) with unprecedented spatio-temporal accuracy. We combined this microfluidic chip with a two-photon microscope to monitor with single-cell resolution the dynamics of neural circuits induced by gustatory stimuli in intact,

optionally behaving, transgenic zebrafish larva expressing a genetically encoded calcium indicator (GCaMP). Optical imaging of neural responses reveals that sour (aversive) and umami (appetitive) stimuli activate non-overlapping neural circuits in the primary gustatory centre, the vagal lobe. The spatial segregation of sour and umami tastes is also maintained in the upstream taste processing centre, the telencephalon where both tastes activate non-overlapping neural circuits in Dm (dorsomedial), Vi (area ventralis pars intermedia) and Dp (area dorsalis pars posterior) telencephalic nuclei. This segregation between aversive and appetitive stimuli evoked responses may play a role in the generation of gustatory-induce motor behaviours, where aversive stimuli evokes a startle response away from the source while appetitive stimuli induces forward swim (towards the source) or no behaviour at all. The effect of stimulus duration has also been investigated: for an increasing presentation time, the number of responding neurons in the vagal lobe and in the telencephalon increase but the average activity of the responding neurons remains constant. Altogether, this evokes a spatial coding scheme in both the primary gustatory center and the telencephalon.

Title: The neural processing of gustatory information in the mouse

Authors: ***S. M. TYREE**, J. TÖLE, W. MEYERHOF;
Mol. Genet., German Inst. of Human Nutr. (dife) Potsdam, Nuthetal, Germany

Abstracts: Taste receptors mediate the detection of tens of thousands of bitter compounds. Research in our group has revealed bitter receptor cell populations on the tongue expressing different subsets of receptors. Results from the Nucleus of the Solitary Tract (NTS) indicate that different bitter stimuli activate distinct, yet overlapping neuron populations. These results

suggest possible discrimination between bitter tastants occurring at the level of the taste receptors and the brain stem. The NTS projects to the Parabrachial Nucleus (PbN), a crucial structure for learned taste aversion, which projects via the Thalamus to the Gustatory Cortex. Integration with other sensory information produces the complex sensation of flavour. Being crucial for avoidance behaviour, the PbN is an interesting structure in which to study the neural response to bitter taste stimulation. We aim to characterise the cellular processing of gustatory information in the PbN to investigate mechanisms underlying discrimination between bitter substances. The Arc catFISH method (cellular compartment analysis of temporal activity by fluorescent *in situ* hybridization) relies on the immediate early gene Arc (activity-regulated cytoskeleton-associated protein) as a neuronal activity marker. Arc expression is induced by neuronal activity and its mRNA follows a strict temporal pattern of intracellular distribution. A protocol was designed in which animals were stimulated twice, allowing the intracellular localization of the Arc mRNA to provide information about which stimulation activated which neurons. C57BL/6 mice were stimulated orally with bitter tastants. Animals showed an increase in Arc expression in the PbN compared to controls, in a similar ratio to results from the NTS, however, the number of PbN cells activated by both stimulations was lower.

Title: Expression profile of ecto-nucleotidases and equilibrative nucleoside transporter in the rat circumvallate papillae

Authors: *K. NISHIDA, A. OHISHI, K. NAGASAWA;
Kyoto Pharmaceut. Univ., Kyoto, Japan

Abstracts: Taste cells in taste buds have been classified into four cell types on the basis of their cytological and ultrastructural characteristics, and their communication plays crucial roles in gustatory function. ATP is one of the intercellular signaling molecules in taste buds, and

extracellular ATP fate is tightly regulated by its cellular clearance. As for ATP metabolism, ectonucleoside triphosphate diphosphohydrolase 2 is expressed by type I glial-like cells, but little is known about expression of other ecto-nucleotidases, such as ecto-5'-nucleotidase (NT5E), ecto-nucleotide pyrophosphatase/phosphodiesterase (ENPP) 1, 2 and 3. Equilibrative nucleoside transporters (ENTs) are major molecules that regulate extracellular levels of adenosine as a metabolite of ATP and adenosine also works as a signaling molecule in taste buds. However, there is no information on their expression in taste cells. Therefore, we examined expression profiles of ecto-nucleotidases and ENTs in rat circumvallate by real-time PCR and immunohistochemistry. mRNAs for Nt5e and Enpp1, 2 and 3 were detected in the rat circumvallate papillae, and NT5E immunoreactivity was detected in a region of non-taste bud cells of the circumvallate papillae, while neither PLC-β2-positive type II, chromogranine-A-positive type III nor SNAP25-positive type III cells were immunoreactive for NT5E. ENT1 immunoreactivity was detected in the PLC-β2-positive type II, chromogranine-A-positive type III and SNAP25-positive type III cells, but not in the non-taste bud cells. These results indicate that there is an ATP clearance system mediated by ecto-nucleotidases and ENTs, their coordination being considered to be important for gustatory function.

Title: A neuropod in enteroendocrine cells is nurtured by enteric glia

Authors: *D. V. BOHORQUEZ, R. A. LIDDLE;
Medicine/GI, Duke Univ. Med. Ctr., Durham, NC

Abstracts: Enteroendocrine cells are epithelial biosensors of the gastrointestinal tract. They sense nutrients, tastants, and bacterial byproducts in the lumen of the gut and when stimulated, they respond by secreting neuropeptides, like peptide YY or cholecystokinin, to modulate appetite and food intake. Although enteroendocrine cells in the intestine are largely regarded as flask-shaped, we recently developed transgenic Pyy-GFP and Cck-GFP mice and found in these cells a prominent axon-like process of unknown function. We call this process a neuropod. Here, we combined confocal microscopy with serial block face scanning electron microscopy to study the three-dimensional ultrastructure of a specific enteroendocrine cell and its neuropod. This approach consists of the following three steps: First, tissue blocks 300 microns wide by 50 microns thick are obtained from a transgenic mouse model in which a specific subset of enteroendocrine cells expresses green fluorescent protein. Second, laser scanning confocal microscopy is used to identify and obtain z-stack images of tissue blocks with cells of interest. Third, selected tissue blocks are processed for 3D Electron Microscopy by using a Serial-Block Face Scanning Electron Microscope. We cut through an entire tissue block containing an enteroendocrine cell to generate a stack of 700 micrographs spaced every 70 nm at a resolution of 7 nm per pixel. Manual 3D rendering of the micrographs series revealed that the neuropod is tightly packed with secretory vesicles of various sizes, contains numerous mitochondria clustered at its tip, and has visible filaments, which we confirmed to be neurofilaments medium and light. The neuropod is also escorted by enteric glia, which are the cells that nurture enteric axons. And, using an *in vitro* minigut organoid model, we found that neurotrophins like NGF-B, artemin or S100B, augment the number and length of neuropods in enteroendocrine cells. These findings open a new field of exploration in the mechanisms of gastrointestinal chemosensation by revealing an unforeseen enteroendocrine cell-entric glia connection.

Title: Cortical responses to monosodium glutamate suggest umami is a combination of sweet and salty tastes

Authors: E. E. REID[1], M. A. BAEZ- SANTIAGO[1], J. X. MAIER[1], *D. B. KATZ[2];
[1]Brandeis Univ., Waltham, MA; [2]Dept Psychol, Brandeis Univ., WALTHAM, MA

Abstracts: Gustatory cortex, GC, has been shown to process sweet, salty, sour, and bitter tastes in a dynamic manner, with select epochs of responses containing specific types of taste information (i.e. their presence, identity, and palatability). However, responses to monosodium glutamate, MSG, an exemplar of the umami taste, have not been studied in this way. Here, GC responses were analyzed to better understand the relationship between MSG and the other basic tastes, as well as to further assess the nature of taste dynamics. We recorded single-unit gustatory cortical (GC) responses from awake behaving female Long Evans rats to a battery of five tastants: 0.2 M sucrose, 0.2 M NaCl, 0.1 M MSG, a mixture of 0.2 M sucrose and 0.2 M NaCl, and 0.0001 M quinine, all delivered in 40 uL aliquots through intraoral cannulae. Midway through tasting sessions, tastants were mixed with amiloride (40 uM), a selective sodium channel blocker, which aided in parsing the possible sodium contribution to the MSG responses. GC responses to MSG showed similar temporal structures found in responses to other basic tastes. Earlier periods of the MSG responses (corresponding to the previously mentioned "identity" epoch) were most similar to the sucrose and NaCl mixture responses, while later periods of the MSG responses were more similar to those of NaCl. After adding amiloride, NaCl responses not only became more similar to water responses, but MSG responses became more similar to sucrose responses. These findings are consistent with behavioral tests suggesting that MSG is a combination of sweet and salty tastes. Further analysis of these taste responses should reveal more specific information regarding the dynamics of the MSG response in GC, as well as the relationship between umami and sweet and salty tastes.

Title: Expression of taste signaling molecules in immune organs

Authors: *P. FENG, H. WANG;
Monell Chem. Senses Ctr., Philadelphia, PA

Abstracts: Interactions between the immune and chemosensory systems and, especially, the roles of taste receptors in immune defenses have been increasingly appreciated. Recent research has found high levels of expression of multiple key immune-related molecules in specific types of taste cells in taste buds and the expression of bitter and sweet taste receptors in various "extra-oral" tissues. Bitter receptors expressed in the airway epithelial cells can detect and respond to bacterial products, and regulate innate immunity. These studies greatly support the hypothesis that taste receptors and their downstream signaling components play an important role in innate immunity. However, the cellular and molecular connections between taste and immune signaling pathways are unclear. Here, we investigated the expression of α-gustducin in immune cells of spleen, thymus and GI tract using immunohistochemistry and RT-PCR. Differential α-gustducin immunoreactivities were found in these immune tissues. The presence of α-gustducin mRNA was further verified by real-time RT-PCR analysis. Specific antibodies against α-gustducin and immune cell-type markers (CD3 for T cells, B220 for B cells, and CD11b for macrophages) revealed that the α-gustducin immunoreactivity is primarily in T cells, less extensively in macrophages, and few in B cells.. These preliminary results indicate that taste signaling pathways may engage in some innate immune processes and GI tract homeostasis.

Title: A wearable vibrotactile sensory substitution device for the deaf and severely hearing impaired

Authors: *S. D. NOVICH[1,2], D. M. EAGLEMAN[1,2];
[1]Neurosci., Baylor Col. of Med., Houston, TX; [2]Electrical & Computer Engin., Rice Univ., Houston, TX

Abstracts: There are at least 2 million functionally deaf individuals in the United States alone and an estimated 53 million worldwide. The cochlear implant is an effective solution for regaining hearing; however, such implants are expensive, require invasive surgery, and have low efficacy in early-onset deaf adults. Given this, many deaf individuals would benefit from a hearing replacement that is low cost, does not involve an invasive procedure, and may have a higher efficacy for early-onset deaf adults. To this end, we have developed a "vibratory vest" by which auditory information is captured, digitally processed, and delivered to the skin of the torso via an array of small vibratory motors. Such sensory substitution approaches have previously been shown to allow congenitally blind individuals to have visual experience through the tongue or skin. We here present the current development status of our device and results of a speech perception experiments. Participants trained on the Vest by engaging in an identification task: on each trial, the participant was presented with a vibration-mapped stimulus of a spoken word from a training set of 50 phonetically balanced words. The participant was then presented with a set of options displayed on a screen from which they selected the word thought to have been felt, and they were given feedback on their choice. After 12 days of training, participants then ran the same procedure on a novel set of 50 words. Performance reached proficiency in 8 days, on average, from participants running the training task once per day (30-minutes to 1-hour). We performed this experiment across several different candidate audio-processing algorithms, based on (1) linear predictive coding, (2) cosine transforms, or (3) cepstral analysis. Our results demonstrate evidence of learning and transfer of knowledge: participants perform significantly better on their first day with the novel test set than their first day on the training set. Further, participants perform at or near chance the first time identifying a word from the training set, and significantly above chance the first time identifying a word from the test set. Funding for this research is supported by the Renz foundation and a training fellowship from the Keck Center of Interdisciplinary Bioscience Training of the Gulf Coast Consortia (NIBIB Grant No. 5T32EB006350-05).

Title: Deconstructing the sensory and cognitive components of hearing loss

Authors: K. GRODNER, B. VIPARINA, W. M. COLLINS, *L. BOUCHER;
Nova Southeastern Univ., Davie, FL

Abstracts: Hearing loss is commonly thought of as a sensory problem; not a cognitive one. According to the effortfulness effect, working memory in elderly adults with hearing loss is impaired due to the increased cognitive effort hearing loss places on the central executive. This increased need for attentional control makes it difficult to properly encode to-be-remembered information. We replicated hearing loss in the lab by presenting college-aged, normal hearing participants with white noise concurrent with to-be-remembered words. Specifically, participants were instructed to complete an auditory working memory load task in which they heard five to-be-remembered words, followed by a distractor task before they had to free recall the list of words. White noise was presented either during encoding of the words, during retrieval of the words, during both encoding and retrieval, or not at all. We also measured working memory capacity. We hypothesized that when white noise is presented during encoding, participants would recall significantly fewer words. We also hypothesized that if cognitive load is increased when white noise is present during encoding, then working memory capacity should predict performance in this task. We found support for both of these hypotheses strengthening the idea that white noise (as a proxy for hearing loss) adds strain to working memory. It is clear then that hearing loss should be thought of as not just as a sensory issue, but a cognitive one as well.

London, Dept of Speech, hearing and phonetic sciences, United Kingdom; [3]Ctr. for Psychology, Univ. of Porto, Porto, Portugal; [4]Dept of Psychology, Royal Holloway, Egham, United Kingdom; [5]Dept of Otolaryngology, Univ. of California, San Francisco, San Francisco, CA

Abstracts: Adults often report that they find listening to speech in the presence of background noise more effortful as they get older. Indeed, studies have shown that older listeners sometimes perform more poorly in speech in noise tasks than would be predicted by their pure-tone thresholds. Whilst a small number of studies have examined the neural basis of perception in noise in older adults, these studies have tended to examine neural responses to a single type of noise background. However, in our everyday life we encounter many different kinds of background noise, for example noise from machinery and the speech of others, and these different kinds of masking sounds have been shown to draw upon different cognitive and neural mechanisms. Here we compared neural responses between younger and older adults with normal hearing using functional Magnetic Resonance Imaging. In the scanner participants listened passively to short spoken narratives presented either without noise or in the presence of different masking sounds that had been equated for intelligibility but differed “parametrically” in their similarity to speech: speech modulated noise (SMN), rotated speech (Rot) and intelligible speech (Sp). Whilst the groups performed similarly on speech in noise tasks in post-scanner testing, their neural responses were shown to differ within the scanner. Older individuals exhibited reduced responses in the thalamus, putamen and left superior temporal gyrus, regions associated with the encoding of masking sounds. Whilst they showed a compensatory increase in activation in in the bilateral middle frontal gyrus, a region associated with cognitive control. Furthermore, the response in a number of frontal and parietal regions indicated that older adults processed non-speech maskers in a manner that was associated with responding to speech maskers in the younger group.

Title: Multiple deficits impact auditory stream segregation in aging

Authors: *E. DINCES, E. SUSSMAN;
Otorhinolaryngology, Albert Einstein Col. Of Med., Bronx, NY

Abstracts: Aging adults often have difficulty communicating in everyday situations when there are multiple competing sound sources. However, for aging individuals without sensorineural hearing loss, it is not well understood what type of impairments contribute to the inability to listen to one sound stream amongst many. This study investigated the level (e.g., automatic or attention-based processes) of difficulty for hearing a single sound stream amongst competing sounds in aging individuals (ages 61-79 years) with normal hearing. Electrophysiological and behavioral measures were obtained to assess the ability to segregate sounds, and to compare passive and active listening situations. Results were also compared with those from normal hearing young adults to assess the level of impairment and determine differences that contributed to identification of targets within a sound stream embedded in background noise. Overall, the results indicate that multiple levels of processing impairments, those associated with automatic and attention-related auditory processing, contribute to difficulty in segregating sounds in aging individuals.

Title: Neural entrainment is less responsive to attentional demands in older listeners

Authors: ***M. J. HENRY**[1], B. HERRMANN[2], J. OBLESER[2];
[1]Max Planck Res. Group Auditory Cognition, Max Planck Inst. For Human Cognitive and Brain Sci., Leipzig, Germany; [2]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany

Abstracts: Increasing age is accompanied by decreasing speech comprehension performance in the presence of background noise that cannot be fully explained by peripheral hearing loss. For young, normal hearing listeners, separating speakers in a "cocktail party" capitalizes on neural synchronization with (i.e., entrainment by) attended speech. Thus, an intriguing but as of yet untested possibility is that age-related speech-comprehension deficits might be attributable to changes in the fidelity or flexibility of neural entrainment. The current electroencephalography study characterized differences in entrainment capacities between younger and older adults under varying attentional demands. Younger (age 18-35 years) and older (age 65+ years) participant groups listened to 10-s narrow-band frequency-modulated sounds (FM = 2.8 Hz). Participants completed two sessions in counterbalanced order; in one session they passively listened to the sounds while fixating (passive), while in the other they detected the presence of near-threshold gaps (active); gaps were present in both stimulation blocks, although their presence was only relevant during active task performance. In order to characterize differences between onset-evoked neural responses between age groups, the same participants also completed a passive-listening block in which they were presented with an 8-minute tone sequence in which each tone randomly took on one of five frequencies. This block of stimulation was presented between the active and passive blocks of the frequency-modulated stimuli. Overall, entrained neural responses were larger when participants attended to the stimuli compared to during passive stimulation. However, the difference between entrainment strength for active versus passive stimulation was more pronounced in young than in older participants. This suggests that older participants' entrained neural responses are less flexible under changing attentional demands. With respect to evoked responses, older adults exhibited a larger N1 component than older adults during passive tone stimulation, but a significantly smaller P2. Gap-detection hit rates were modulated by FM stimulus phase, but the degree of performance modulation was similar across age groups. These results reveal critical age-related changes in the way that entrained neural responses adapt to changing attentional demands. Behavioral performance did not differ between groups in the current paradigm. However, we suggest that age-related deficits in perceiving speech against a noisy background might stem from decreasing flexibility to modulate entrainment strength based on top-down attention.

Title: Low-delta phase coherence reflects implicit temporal anticipation for supra-threshold stimuli

Authors: ***A. WILSCH**, M. J. HENRY, B. HERRMANN, B. MAESS, J. OBLESER;
Max Planck Inst. For Human Cognitive and Brain Sci., Leipzig, Germany

Abstracts: Temporal anticipation enhances encoding precision and facilitates subsequent processing of near-threshold stimuli. With respect to neural oscillations, anticipation is thought to affect the organization of phase in the delta (0.5-4 Hz) frequency band, presumably representing the alignment of an optimized brain state with the expected time of occurrence of an upcoming stimulus. For a situation in which an event is certain to occur, but the exact time of occurrence is not known, temporal anticipation of the event increases with passage of time. Thus, we expected to observe delta phase organization to be sensitive to temporal anticipation of supra-threshold stimuli in the context of variable event occurrence times. In a magnetoencephalography experiment using an auditory delayed-matching-to-sample task on clear speech tokens (N = 10), we serially presented two syllables (S1 and S2) following a temporal cue (analogous to Wilsch et al., 2014). Critically, the interval between cue offset and S1-onset ("foreperiod") was varied parametrically (0.5-1.8 s). Data were analyzed by means of time-frequency analyses (0.5-20 Hz; -4-7 s, time-locked to S1-onset) and event related fields (ERFs). With respect to S1, there were no differences in power, ITPC, and ERFs between cueing conditions for these supra-threshold stimuli. Next, in order to examine the neural correlates of temporal anticipation, single trials from all cueing conditions were binned (7 bins) according to pre-S1 interval (i.e., foreperiod), and inter-trial phase coherence (ITPC), power, and ERFs (-1-1 s time-locked to S1) were calculated for each bin. The relation between foreperiod and each dependent measure was assessed using a cluster-based permutation approach on correlations calculated across bins. Low-delta (i.e., 0.5-0.8 Hz) ITCP correlated positively with foreperiod at right-frontal sensors centered on S1-onset. Longest foreperiods yielded strongest phase concentration. Additionally, longer foreperiods were associated with lower alpha power (8-13 Hz) during the ensuing memory retention (i.e., post-S1) period. Higher-frequency ITCP, delta power, and ERFs were insensitive to foreperiod. Increasing low-delta ITCP with foreperiod most

likely reflects the alignment of an optimized brain state with the occurrence of a temporally anticipated stimulus. In turn, decreased alpha power during memory retention is a marker of reduced cognitive load due to longer foreperiods. Altogether, these results indicate that the neural system relies on temporal anticipation to optimize stimulus processing.

Title: Human sensing inaudible infrasound

Authors: ***T. IIJIMA**, Y. NAKASHIMA, Y. SUGITA;
Dept Psychol. Waseda Univ., Tokyo, Japan

Abstracts: We seldom notice the existence of infrasound, although infrasound is generated by air turbulence, ocean waves, traffic and other machinery and is also produced by our own respiration and heartbeat. We can perceive only infrasound of sufficiently high intensity, since our hearing sensitivity drops off markedly in the low frequencies. Here we show human subjects with normal hearing are sensing infrasound and able to learn appropriate response to the sound, even though the intensity of the infrasound is far below the hearing threshold. Human subjects received differential eyelid conditioning for two auditory conditioned stimuli (CSs): a 523.25 Hz tone and a complex tone consisted of the same 523.25 Hz tone and a 16 Hz inaudible tone, one of which was always followed by an airpuff (CS+), whereas the other was not (CS-). After the conditioning trials, the subjects began to respond to CS+ but not to CS-. However, the subjects could not discriminate these two tones at all. We also tested whether the infrasound alone can elicit the eye blink response in a single cue paradigm where the infrasound was presented alone and followed by the airpuff. However, the response was not observed even after extensive training. These results indicate that, when presented in conjunction with the other audible sounds, our brain detects the existence of inaudible infrasound and learns to respond appropriately.

Title: Neural oscillatory correlates of detected concurrent spectrotemporal regularities in acoustic stimuli

Authors: *A. M. GIFFORD[1], M. J. KAHANA[2], Y. E. COHEN[3];
[2]Psychology, [3]Otorhinolaryngology, [1]Univ. of Pennsylvania, Philadelphia, PA

Abstracts: A fundamental goal of the auditory system is to transform acoustic waveforms from low-level sensory representations into perceptual representations. These perceptual representations are the computational result of the auditory system's ability to detect, segregate, and group spectrotemporal regularities in the acoustic environment. Therefore, our perception of a sound is dependent on the regularities that exist in an acoustic stimulus. To understand the neural computations that transform sensations into perceptions, it is fundamentally important to determine how neural activity reflects both sensory- and perceptual-related representations. In addition to the functions of spiking activity in mediating auditory perception, several findings suggest that neural oscillations, which reflect large-scale, coherent activity in neural populations, may also contribute to sensory and perceptual representations. However, whereas the contribution of spiking activity to auditory perception has been extensively studied, the potential roles of neural oscillations have not. Thus, there are critical gaps in our knowledge of the relations between neural oscillations and auditory perception. For instance, it is unknown whether or if neural oscillations are modulated by (1) auditory stimuli that have spectrotemporal regularities occurring concurrently over multiple timescales and (2) a listener's perceptual judgments of these stimuli. Thus, the goal of this study was to test these relationships by analyzing neural oscillations in human subjects while they participate in an auditory deviance-detection task. Stimuli were sequences of tone bursts that contained regularities over different timescales. Each sequence consisted of 3 tone-burst triplets. In this sequence, a local regularity governed the frequency of the tone bursts in a triplet and a more global regularity governed the frequency change across each triplet. A sequence could maintain this pattern throughout its duration or deviate from either regularity with a frequency increase. Subjects listened to the

stimuli and reported whether or not they detected a deviation in one of the regularities by pressing one of two buttons. We found that the sequences elicited significant power and phase modulations in the oscillatory frequencies that corresponded to the timescales of the spectrotemporal regularities in the stimulus. These modulations occurred in auditory-related cortical regions including non-primary auditory, prefrontal, and parietal cortices. These findings support a potential role for neural oscillations in tracking spectrotemporal regularity and organizing the auditory scene.

Title: The role of attention in the buildup to stream segregation

Authors: *J. SUSSMAN-FORT, E. SUSSMAN;
Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstracts: The ability to process an auditory scene is impacted by both the dynamics of the environment and focused attention. The auditory system separates out the mixture of sounds that enters our ears into distinct sound sources and groups them together across time via a process termed stream segregation. The time required to perceive this mixture as segregated is known as the “buildup” period. The goal of this study was to examine the effect of focused attention on the timing of the buildup under different conditions of stimulus context to determine whether attention can speed up the buildup period. To do this we presented a pattern of repeating low and high frequency tones (L-L-H) in trains of stimuli separated by silence and recorded event-related potentials (ERPs). The stimulus context was manipulated by presenting two conditions in which frequencies roved or did not rove across stimulus trains. Subjects were instructed to press a button to identify higher intensity target tones randomly positioned at the end of each stimulus train, past what would be defined as the buildup period. Non-target higher intensity tones were randomly embedded in the early part of the stimulus train that would be defined as within the buildup period. ERP responses to the non-target tones indicated when the sounds were

segregated. This allowed us to observe the timing of the buildup. No responses were obtained to the non-target tones when the stimulus trains roved in frequency indicating attention did not impact the timing of the buildup. In contrast, responses were obtained to the non-target tones when the stimulus trains did not rove in frequency, providing evidence that in addition to effects of stimulus context on the buildup period, attention influenced how quickly sounds were segregated.

Title: The mismatched negativity as a marker for acoustic and phonological distinctions between vowel sounds

Authors: J. BURNISON[1], *J. S. BRUMBERG[2,1];
[1]Neurosci. Grad. Program, [2]Speech-Language-Hearing, Univ. of Kansas, Lawrence, KS

Abstracts: Speech perception of similarly sounding vowels is difficult despite clear phonological differences between perceptual neighbors. This effect can be characterized by the perceptual magnet effect, which states that discrimination of vowels similar to a good example of a referent vowel is more difficult than to a poor referent. In this study, we examine the neural processes that underlie perception of neighboring vowels, focusing on the influence of acoustic and phonological factors. We explore these effects in a mismatch negativity (MMN) event-related potential protocol using an auditory oddball paradigm. Prior MMN studies investigating auditory and phonological neural processing of vowels have lead to inconclusive results, with some studies indicating an auditory-only mechanism while others suggest linguistic factors enhance the neural response. Some of the ambiguity may be due to individual differences in vowel identification; therefore, the present studies used vowel sounds tailored to each participant. Methods: One standard and four deviant vowels were presented acoustically in a traditional MMN oddball paradigm. All five stimuli were synthesized according to prototypical and vowel transition boundary examples obtained from participants' perceptual identification

task results. We compare two experiments, one in which the standard stimulus is a prototypical vowel sound and deviants occur on the boundary transition with a neighboring vowel. Specifically, the four deviants are: within category, transition midpoint, across boundary and the prototypical neighboring vowel. The first three deviants are all poor examples of the standard stimulus. The second experiment utilizes the boundary midpoint condition as the standard to eliminate priming asymmetries. Results: In our first experiment, an MMN was elicited generally for each of the deviant stimuli relative to a good example of a referent vowel sound. We found linear trends indicating an increase in MMN peak amplitude and area under the curve and a decrease in peak amplitude latency as a function of perceptual distance from the standard, but there are no statistical differences between the four deviant stimuli. We therefore infer that preattentive neural processing is neither sensitive to acoustic nor phonological differences between vowels along the border transition from one vowel to its neighbor. This result is somewhat predicted the perceptual magnet effect; therefore, our second experiment will clarify whether differences in MMN amplitudes and latencies are found when discriminating border transition vowels relative to a poor referent, specifically the transition midpoint vowel.

Title: Relative magnitude of loudness determines pitch accents in sequencially presented noise-vocoded Japanese vowels

Authors: *M. TAKABAYASHI[1], K. I. KOBAYASI[2,3], H. RIQUIMAROUX[1,2,3];
[1]Grad. Sch. of Life and Med. Sci., [2]Dept. of Biomed. Information, Fac. of Life and Med. Sci., [3]Neurosensing and Bionavigation Res. Ctr., Doshisha Univ., Kyotanabe, Japan

Abstracts: We often perceive pitch changes created by temporal change in the fundamental frequency when we listen to somebody talks or sings. Noise-vocoded speech sound (NVSS) is a synthesized sound whose frequency information is greatly reduced while the amplitude envelope information remains preserved. In NVSS the fundamental frequency does not exist. However, changes in amplitude envelope, intensity cause changes in pitch. The “intensity” is physical characteristic and variations of intensity and loudness are not identical. The purpose of this study

is to investigate whether loudness of each vowel and that of noise- vocoded vowel are identical or not, and to examine whether loudness creates pitch change in NVSS. Japanese language has 5 vowels. Therefore, 25 combinations can be made when two vowels are paired. Noise-vocoded vowel pairs were also prepared. They were used for stimuli in this experiment. Intensity of the first sound was fixed at 60 dB SPL (re: 20μPa), while intensity of the second sound was varied between -9 and 9 dB SPL. Subjects listened to stimuli 4 times in random order. They evaluated whether loudness of the second sound was louder or softer than the first one. Loudness of each vowel in original speech was similar to that in NVSS. Results suggest that sequences of vowels act on whether the second sound was perceived louder or softer. On the other hand, differences between the first and the second sound when subjects evaluated two magnitudes of loudness as identical were measured. The extremely negative difference was shown in [a-e] pair, while extremely positive difference was shown in [u-u]. The smallest difference was found in [i-o] pair. There 3 noise-vocoded vowel pairs were used in the experiment where pitch change in NVSS was investigated. Subjects listened to these 3 combinations whose sound pressure level of the second sound was varied in a similar way used in the first experiment. Subjects evaluated the second sound whether pitch rises or falls from the first sound. Then results showed that pitch changes in NVSS were affected by spectral information of each noise-vocoded vowel. However, as 3 combinations, change in pitch could be perceived easier as rising as loudness of the second sound increased. In conclusion, loudness change creates pitch change in NVSS. However, it does not appear to be the only factor. Hence, vowels that tend to be overestimated or underestimated in loudness and its reason were investigated. Relationships between loudness and pitch change in NVSS were discussed.

Title: Differential neural adaptation of spectral transition and steady-state features in speech and non-speech

Authors: *M. SABRI, K. LEWIS, C. J. HUMPHRIES, E. LIEBENTHAL;
Neurol., Med. Col. of Wisconsin, MILWAUKEE, WI

Abstracts: We investigated feature-specific adaptation of speech and non-speech sounds during a repetition-suppression paradigm using auditory event-related potentials (ERPs). Stimuli were synthesized CV syllables consisting of two formants (F1, F2) representing an initial spectral transition (T) period followed by a spectral flat steady-state (SS) period. Three sets of stimuli were compared. Speech stimuli were generated with F1 and F2 in their canonical form. Non-speech stimuli were generated by spectrally rotating the F1 formant. Single-formant stimuli included only either the F1 or F2 formant. ERPs were recorded while subjects (n=15, 2 sessions) listened to trains of six sounds (inter-stimulus interval=200 ms), in which the last two sounds either: (1) matched the first four (i.e., full adaptation), (2) differed in the T period, (3) differed in the SS period, or (4) differed in both the T and SS periods. Subjects were instructed to identify catch trials (p=.1) that were missing one of the six sounds. These trials were discarded from the analysis. A moving window analysis based on an average of frontal electrodes was performed on the evoked response of sound 5 in the train (when a change from the adapting sound occurs). Differences between adaptation conditions were observed in the N1-P2 complex, showing a larger amplitude for SS and TSS compared to T ($p<.05$). Within the speech and non-speech conditions, N1 was greater for SS than T. Further, there was no difference within the speech condition between TSS and SS. Taken together these results demonstrate greater release from adaptation of steady-state (important for vowel identity) compared to transition (important for consonant identity) features of speech and acoustically-matched non-speech analogs, possibly reflecting the greater vulnerability to repetition of the longer and steady-state spectral segment. Differential neural adaptation may be a mechanism by which phonemic brain regions attain finer tuning to spectral transition information coding consonant identity relative to spectral steady-state information coding vowel identity, possibly resulting in more categorical perception of consonants relative to vowels.

Title: Neural correlates of acoustic and linguistic contributions to listening effort during speech comprehension

Authors: *Y. .-S. LEE[1], J. E. PEELLE[2], C. ROGERS[3], N. E. MIN[1], A. WINGFIELD[1], M. GROSSMAN[1];
[1]Dept. of Neurol., Univ. of Pennsylvania, Philadelphia, PA; [2]Dept. of Otolaryngology,, Washington Univ. in St. Louis, St. Louis, MO; [3]Volen Natl. Ctr. for Complex Systems, Brandeis Univ., Waltham, MA

Abstracts: Understanding connected speech requires coordination between sensory and cognitive processes within a core speech system centered in bilateral temporal cortex and left inferior frontal gyrus. Although it has been shown that additional resources are recruited when dealing with syntactically complex speech, less is known about how the brain can successfully cope with acoustically challenging speech. We hypothesized that similar compensation mechanisms may be at play when processing degraded speech signals. Here we used interleaved silent steady-state (ISSS) functional magnetic resonance imaging (fMRI) to examine compensatory neural mechanisms that support processing of acoustically-degraded sentences that vary in their syntactic demands. Twelve healthy young adults (mean age=24 yrs) were presented with a series of spoken sentences. Each sentence comprised of six words (e.g., “Boys that kiss girls are happy”); subjects indicated the gender of the character performing the action via button press. Sentences were presented in the absence of acoustic scanner noise, after which we collected 10 seconds of data. The sentences were constructed in a 2 (subject-relative vs. object-relative embedded clause) x 2 (clear vs. degraded speech) factorial design. To degrade the speech we used a noise-vocoding algorithm with 24 channels that reduced spectral detail but preserved the overall amplitude envelope of the signal. Behavioral testing in a separate group of 20 young adults confirmed that this manipulation preserved intelligibility, but reduced perceptual clarity, $t(19) = 5.84$, $p<.001$. In the fMRI study, accuracy was high (mean > 94%) and did not differ as a function of acoustic clarity. Our results revealed that the left frontotemporal areas were more activated by increasing the syntactic demand. Importantly, this network also showed increased activity to successfully process acoustically degraded speech. Lastly, a part of the left inferior frontal area yielded activity when processing sentences requiring most listening effort (e.g., degraded speech with object-relative embedded clause). Together, our data suggest that compensation mechanisms are required when processing spoken language signals for both linguistic and acoustic challenges along the frontotemporal speech network.

Title: Neural mechanisms for the recognition of the noise-vocoded speech sounds: An fMRI study based on individual differences

Authors: *S. MURAI[1], K. I. KOBAYASI[2,3], H. RIQUIMAROUX[1,2,3];
[1]Grad. Sch. of Life and Med. Sci., [2]Dept. of Biomed. Information, Fac. of Life and Med. Sci., [3]Neurosensing and Bionavigation Res. Ctr., Doshisha Univ., Kyoto, Japan

Abstracts: Human speech perception is robust. Even when frequency information of sounds is greatly reduced, a listener uses amplitude envelope information to comprehend speech. The neural basis for individual differences in the robustness, however, is still largely unknown. In the present experiment, the noise-vocoded speech sounds (NVSS), where frequency information was greatly reduced, were used to reveal neural circuits for speech perception. We tried to identify brain regions for contributing to individual differences in NVSS comprehension by using the functional magnetic resonance imaging (fMRI) with a sparse sampling paradigm. The original speech sounds were Japanese sentences consisted of 13-16 morae (2-3 s) recorded at 8 kHz sampling rate with 16 bits and reduced noise below 60 Hz using high-pass filter. NVSS was created by dividing the original speech sounds into 3 bands (60-600, 600-1500, 1500-4000 Hz). The amplitude envelope for each band was extracted by half-wave rectification after low-pass filtering at 32 Hz. In addition, the amplitude envelope in each frequency band was multiplied with a band noise of the same frequency bandwidth. In test sessions, comprehension of NVSS was behaviorally evaluated before the MRI session. Adult native Japanese speakers listened to NVSS sentences and reported how they perceived NVSS without feedback in a soundproof chamber. Answers were written down on paper. In the MRI session, participants listened to new sets of NVSS sentences through headphones. Then, the same NVSS sentence was repeated while the original sentence was shown on a screen in text. As a result, average percentage of correct morae was 15.0%, and standard deviation of correct percentage was 16.9%. The individual differences were quite variable. To identify regions contributing to the NVSS comprehension, a multiple regression analysis for the individual scores from pre-scanning test (percent of correct morae) was performed on individual contrast images while listening to NVSS in each subject. The individual variation in the NVSS comprehension score was significantly correlated to BOLD

signal of the left inferior frontal gyrus (IFG). Data showed that brain activities in the left IFG were reflected subjects' ability to comprehend NVSS sentences, and the region may be related to the individual variation in robustness of speech perception.

Title: Network analysis of human speech perception: An intracranial recording perspective

Authors: *M. STEINSCHNEIDER[1], K. NOURSKI[2], A. RHONE[2], H. OYA[2], H. KAWASAKI[2], M. HOWARD, III[2];
[1]Albert Einstein Med. Col., BRONX, NY; [2]Univ. of Iowa Med. Ctr., Iowa City, IA

Abstracts: Speech perception engages a large network of cortical regions that begins in Heschl's gyrus (HG) and later activates many areas, including the temporal and frontal lobes. In order to clarify the sequence and roles of these regions, we recorded the electrocorticogram of subjects who were neurosurgical patients undergoing chronic invasive monitoring for medically refractory epilepsy. All research protocols were approved by the NIH and The University of Iowa IRB, and subjects could rescind consent at any time without detriment to their surgical evaluation. Stimuli were words and non-words from TIMIT or LibriVox or complex tones. Each word/non-word was spoken by different speakers (14 male, 6 female) and edited to be 300 ms in duration. There were three categories of words: animals (cat, dog), colors (red, white), numbers (five, ten) and two sets of non-words (res, tem). Subjects were instructed to press a button

whenever they heard a target (e.g., female voices, animals) embedded in a stream of all other stimuli. Locations of recording sites were confirmed by co-registration of pre- and post-implantation structural imaging. Event-related band power in the high gamma frequency range (70-150 Hz) was examined. Responses recorded directly from posteromedial HG (i.e., core auditory cortex) primarily reflected the acoustic attributes of the sounds (e.g., male vs. female voice, voice onset time) and were not strongly modulated by the behavioral tasks. A similar pattern was observed in the early activity recorded from posterolateral superior temporal gyrus (PLST). In contrast, later activity on PLST was strongly modulated by task requirements and was enhanced to targets and, to a lesser degree, non-targets whose perception was relevant for the task. Later activity elicited by targets, however, was not modulated by behavioral performance. Activity overlying the inferior frontal gyrus (IFG) was also enhanced to targets and relevant non-targets, but the activity was strongly modulated by behavioral performance. Finally, activity overlying the middle frontal gyrus (MFG) was only elicited by targets. We conclude that differential patterns of responses to speech are distributed across HG, PLST, IFG, and MFG. HG and early activity on PLST primarily reflect acoustic attributes of speech, whereas later activity on PLST and that elicited in all other regions studied are strongly modulated by task requirements. The finding that later activity on PLST is not modulated by behavioral performance, contrasting with activity on IFG, suggests that object formation of speech (e.g., semantic meaning) only begins to emerge on PLST and becomes complete in regions of frontal cortex.

Title: EEG oscillations entrain their phase to high-level features of speech sound

Authors: *B. ZOEFEL, R. VANRULLEN;
Ctr. De Recherche Cerveau Et Cognition (cerco), Toulouse, France

Abstracts: Neural oscillations adjust to rhythmic patterns in the environment, a mechanism called phase entrainment. Phase entrainment has encountered wide interest in speech research, as aligning neural oscillations and speech sound can improve speech intelligibility. However, the precise nature of phase entrainment is still debated, as, in everyday speech sound, low-level (e.g., fluctuations in sound amplitude) and high-level features (e.g., fluctuations in speech information) co-vary. Thus, on the one hand, brain oscillations could merely passively follow the rhythmic changes in amplitude or spectral content of speech sound. On the other hand, phase entrainment might also include a high-level process: an active adjustment to the co-varying speech information. Obviously, these alternatives could not be disentangled by the use of common speech sound as experimental stimuli. Thus, we constructed novel speech/noise stimuli without systematic fluctuations in sound amplitude or spectral content, while keeping both fluctuations in speech information and intelligibility. This construction made it possible to disentangle, for the first time, passive (low-level) and active (high-level) components of phase entrainment. Recently, by using those stimuli in a psychophysical experiment, we showed that perception indeed entrains to high-level features of speech sound (Zoefel and VanRullen, Society for Neuroscience Abstract 2013). Here, we ask whether this perceptual entrainment to high-level features of speech goes along with neural entrainment as well. We presented subjects (N = 12) with our constructed speech/noise stimuli while recording electroencephalography (EEG). Indeed, we found that neural oscillations entrain to speech rhythm (as assessed by speech-EEG phase-locking) even when speech information is not accompanied by changes in sound amplitude or spectral content. This effect was abolished when intelligibility was disrupted by presenting snippets in reverse, indicating that entrainment was indeed due to rhythmic changes in speech information. Additionally, by comparing original (without noise) and constructed (with noise) speech snippets, we were able to dissociate sensory (low-level) and high-level components of phase entrainment: Cross-correlation revealed two prominent time lags of coherence between original speech and neural signal at ~110 ms and 190 ms, whereas only the later component was present for constructed speech/noise snippets. The latter effect was abolished as well when constructed snippets were time-reversed, indicating again a high-level component that reflects entrainment to rhythmic changes in speech information.

Title: Alpha oscillations index differential distractor-speech interference

Authors: *M. WÖSTMANN, B. HERRMANN, B. MAESS, J. OBLESER;
Max Planck Inst. For Human Cognitive and Brain, 04103, Germany

Abstracts: Speech processing can be demanding *in situ*ations where listening to a particular speaker is obstructed by distracting speech from other speakers. When confusion between target speech and distractors is high, listening success depends on selective attention to the speech signal at the expense of distractors. Cortical alpha (~10 Hz) oscillations are argued to play a role in attention by inhibiting task-irrelevant processing. However, the role of alpha oscillations in selective attention during effortful listening to auditory stimuli, for example speech, is less well investigated. In a combined magneto-/electroencephalography (MEEG) study, we tested the hypothesis that alpha oscillations contribute to auditory selective attention and that alpha oscillations allow predicting the participant's degree of distractor-speech interference during selective listening. In a dichotic listening paradigm, human participants were cued to attend to and maintain a stream of four spoken digits presented to one ear, while ignoring a distracting (same-talker) stream of digits presented to the other ear. Following acoustic stimulation, participants selected the digits in the to-be-attended stream from a visually presented array of twelve digits. Behaviorally, participants correctly recalled the majority of digits (~80 %) from the to-be-attended stream. Critically, participants also showed specific interference by the distractor stream. That is, they showed confusions between the two streams as indicated by reports of digits from the to-be-ignored stream. Furthermore, stream confusions occurred more frequently than reports of digits that were not presented in any of the two streams (false alarms). On the neural level, alpha power showed significant modulations and generally decreased during the time course of the trial. These findings suggest an important role of alpha oscillations during on-line speech processing in effortful multi-talker listening situations. In particular, fluctuations in alpha power might indicate the differential inhibition of distracting information to support auditory selective attention to the task-relevant speech signal.

Title: Neural amplitude fluctuations in multiple frequency bands predict auditory perception in a rhythmically variable context

Authors: *B. HERRMANN, M. J. HENRY, J. OBLESER;
MPI For Human Cognitive and Brain Sci., Leipzig, Germany

Abstracts: Neural oscillations are thought to provide listeners with a mechanism for making and evaluating temporal predictions. When acoustic stimulation is temporally regular, low-frequency neural oscillations become aligned with (i.e., entrained by) the event structure. In turn, listening behavior is optimized, as expected events coincide with the "excitable" phase of the entrained neural oscillation. However, it is less clear how amplitude-envelope fluctuations influence listening behavior, in particular in contexts with variable degrees of temporal regularity in which listeners might use either a "rhythmic" or a "continuous" attentional processing mode. To that end, the current magnetoencephalography study investigated the relation between neural amplitude-envelope fluctuations in auditory cortex and human listening behavior in a rhythmically-variable listening situation. Tone sequences varied in temporal regularity (i.e., mean rate 2 Hz ± 0.14 Hz standard deviation), and participants (N=20) indicated the presence of difficult-to-detect intensity changes. An oscillator model was used to estimate the degree to which each target tone was expected based on the preceding temporal context. Time-frequency analyses quantified the degree to which the amplitude of pre-target neural oscillations predicted behavioral performance. First, we confirmed that intensity changes were better detected when their occurrence was more predictable based on the timing of the preceding sequence. With respect to neural oscillations, we observed interactive effects of pre-target neural amplitude at three distinct frequencies on perception. First, amplitude of the 2-Hz neural oscillation differentially predicted target-detection performance - expected targets were best detected when 2-Hz neural amplitude was high, whereas unexpected targets were best detected when amplitude was low. Second, we observed modulations of target-detection performance by alpha-frequency amplitude (~8 Hz and ~13 Hz, respectively), which, third, depended on low-frequency (2 Hz) amplitude. In detail, hit rates increased linearly with increasing 8-Hz amplitude, but this effect was strongest when 2-Hz amplitude took on intermediate values. Hit rates were further increased for either high or low 13-Hz alpha amplitude, but this quadratic trend was strongest for high and low, but not intermediate, 2-Hz amplitude values. The current results demonstrate that, in temporally-variable contexts, auditory perception depends on complex interactions of neural amplitude fluctuations that might reflect an instable neural state between "rhythmic" and "continuous" processing modes.

Title: Training induced change in categorical boundaries of speech sounds

Authors: E. STIPES[1], P. MASON[2], M. PIERCE[1], *C.-L. TENG[3];
[1]Biol., [2]Cognitive Sci., [3]Univ. of Virginia, CHARLOTTESVLE, VA

Abstracts: Humans and animals perceive the world categorically. Our abilities to categorize, simplify and streamline information are fundamental to the development of cognition. Take color perception for example: although the changing wavelengths are continuous, color perception is categorical. Another example is speech sound perception: /ba/-/da/-/ga/ varies in a continuous dimension but human perception separates the physical attributes into perceptual categories. The phenomenon categorical perception (CP) is found in many sensory and cognitive dimensions. However, to what degree it is learned rather than innate remains unclear. We hypothesize that a categorical boundary is a by-product in optimizing discrimination and that its location varies with the training stimuli. Using a linear decoding model, we show that optimal weights assigned to neurons tuned between the training stimuli changes sign. Assuming a perceptual decision is based on the weighted sum of the sensory inputs, an optimized discriminator has the same characteristics as in categorical perception. They are (1) stimuli appear similarly within a category, (2) stimuli appear dissimilarly between categories, and (3) of the same change of physical attributes, stimuli appear most differently at the categorical boundary. We developed an awake-behaving animal experiment, instructing a rat to either initiate and sustain or withhold from licking to indicate a perceptual decision. We found that by training an rat to discriminate two speech sounds /ba/-/pa/, a categorical boundary emerged naturally in between. There was a sigmoidal but not a linear change in percent licking as voice-onset-time varies. Further, discrimination was the highest at the boundary. The location of the boundary, however, was not in the middle of the training stimuli, suggesting an interaction with innate neuronal processing.

Title: The influence of hearing acuity and perceptual effort on recall for word-lists

Authors: *K. COUSINS, A. WINGFIELD;
Brandeis Univ., Waltham, MA

Abstracts: Everyday listening conditions are rarely ideal, as ambient noise or hearing loss can interfere with the auditory signal, and can make speech difficult to hear. Studies of noise-masking have shown that even when the distracting noise is mild, and auditory stimuli are identifiable, memory for the auditory information suffers. In previous studies, we have demonstrated that this negative effect of noise-masking extends beyond the masked material, and recall for nearby non-masked words suffers as well. It is assumed that this adverse effect of masking on recall is due to the perceptual effort expended to correctly identify the masked word. Here, we test if this recall deficit for masked and non-masked words is a unique effect of background noise, or also extends to other situations of strained perception. Participants were older adults (aged 65 or older) who ranged in hearing acuity, measured by their speech reception threshold (SRT). Word-lists were 6 words long. Instead of using noise-masking, all words in the list are presented in quiet. To test the effect of difficult perception, one word in the list was made challenging to perceive by presenting it just above listening threshold, adjusted according to each individual's SRT (7dB sensation level; SL). All other words in the list, and words in the control list, were played at 15dB SL. Participants showed a depressed recall for the critical-quiet word, as well for neighboring, appreciably louder words. These results indicate that straining to hear a soft word can impoverish the ability to also encode other words presented, even when they are clearly audible.

Title: The Oxford Vocal (OxVoc) Sounds Database: A validated set of non-acted affective sounds from human infants, adults and domestic animals

Authors: *C. PARSONS[1], K. YOUNG[1,3], M. CRASKE[4], A. STEIN[1], M. KRINGELBACH[2]; [1]Univ. of Oxford, Oxford, United Kingdom; [2]Univ. of Oxford, oxford, United Kingdom; [3]UCLA, La, CA; [4]UCLA, LA, CA

Abstracts: Sound moves us. Nowhere is this more apparent than in our responses to genuine emotional vocalisations, be they heartfelt distress cries or raucous laughter. Here, we present perceptual ratings and a description of a freely available, large database of natural affective vocal sounds from human infants, adults and domestic animals, the Oxford Vocal (OxVoc) Sounds database. This database consists of 173 non-verbal sounds expressing a range of happy, sad and neutral emotional states. Ratings are presented for the sounds on a range of dimensions from a number of independent participant samples. Perceptions related to valence, including distress, vocaliser mood, and listener mood are presented in Study 1. Perceptions of the arousal of the sound, listener motivation to respond and valence (positive, negative) are presented in Study 2. Perceptions of the emotional content of the stimuli in both Study 1 and Study 2 were consistent with the predefined categories (e.g., laugh stimuli perceived as positive). While the adult vocalisations received more extreme valence ratings, rated motivation to respond to the sounds was highest for the infant sounds. The major advantages of this database are the inclusion of vocalisations from naturalistic situations, which represent genuine expressions of emotion, and the inclusion of vocalisations from animals and infants, providing comparison stimuli for use in cross-species and developmental studies. The associated website provides a detailed description of the physical properties of the each sound stimulus along with cross-category descriptions.

Title: Neural substrates representing temporal and motor sequences of rhythm

Authors: *N. KONOIKE[1], Y. KOTOZAKI[2], J. HYEONJEONG[2], A. MIYAZAKI[2], K. SAKAKI[2], T. SHINADA[2], M. SUGIURA[2], R. KAWASHIMA[2], K. NAKAMURA[1];
[1]Primate Res. Institute, Kyoto Univ., Inuyama, Japan; [2]Inst. of Development, Aging and Cancer, Tohoku Univ., Sendai, Japan

Abstracts: When separate sounds occur with temporally structured patterns, we can feel a 'rhythm'. Perception of rhythm often makes us move involuntarily or intentionally. We have previously reported that the fronto-parieto-cerebellar system showed a dynamic change in activity during the encoding and retrieving of rhythm information. Most of these regions have been thought to play an important role in motor control. Based on our results and those of previous studies, we hypothesized that rhythm information is represented in two different domains; temporal and motor sequences. The motor sequences should depend on effectors, such as, finger, foot, or mouth. On the other hands, the temporal sequence would be effector-independent. So far, little is known about neuronal substrates representing temporal or motor sequences of rhythm. To address this issue, we measured brain activity by functional magnetic resonance imaging while 29 healthy right-handed subjects memorized auditory rhythm and reproduced it by tapping using a right index finger, a left index finger, or a right foot, or by articulation. Conjunction analysis revealed that the right inferior frontal gyrus (IFG) and inferior parietal lobule (IPL) exhibited significant effector-independent activations during both encoding and retrieving of rhythm information. On the other hand, the left IFG exhibited effector-dependent activation during encoding, and the left IPL and supplementary motor area (SMA) showed effector-dependent activations during the retrieving of rhythm information. These results suggest that temporal sequences of rhythm may be represented in the right fronto-parietal

system, whereas the motor sequences of rhythm may be represented in the left fronto-parietal system.

Title: Dynamic affective and neural responses to expressive timing fluctuations in music

Authors: ***N. K. FLAIG**[1], T. P. ZANTO[2], H. L. CHAPIN[3], E. W. LARGE[1];
[1]Complex Systems and Brain Sci., Univ. of Connecticut, Storrs, CT; [2]Univ. of California San Francisco, San Francisco, CA; [3]Educ. & Training Systems Intl. (ETSI), Chapel Hill, SC

Abstracts: Research has shown that the brain synchronizes to musical events. The perception of rhythm involves entrainment of endogenous cortical oscillations to low frequency periodicities in many spatially distinct neural regions, and rhythmic entrainment is thought to underlie temporal expectancy. In expressive musical performances tempo varies, creating violations of temporal expectancy. A recent study has shown activation of motor-related areas, emotion-related limbic and paralimbic structures, and reward centers when listening to expressive, but not mechanical, music. However, it is not known whether expectancy violations themselves are responsible for increased limbic and paralimbic activations. We asked whether the fluctuations in tempo and intensity of an expressive musical performance would lead to emotion and reward related neural activations, and whether musical experience would modulate these responses. Musicians and non-musicians listened to a skilled music performance that included the natural expressive variations that musicians use to evoke emotional responses. We compared the time derivative of performed tempo and performed intensity to both real-time ratings of arousal and valence and to BOLD signal changes. Results showed that fluctuations of expressive timing (changes in tempo) are correlated with listener ratings of affect as well as BOLD signal changes in cortical and subcortical motor areas. Our findings provide evidence that expressive timing fluctuations and resulting expectancy violations are integral to affective musical responses.

Abstracts: Melodies are regarded as pitch sequences integrated over time, thus pitch direction is a main feature of melodic information. Contemporary western music is usually organized as a melodic stream with rhythmic/ harmonic background accompaniment. In this case the melodic stream carries the main musical interest. Conversely, in chorales 4 simultaneous melodic streams are interwoven into a complex musical score. Pitch processing is felt to take place in the primary and secondary right hemispheric auditory cortices. However, the spatial distribution and temporal dynamics of melodic pitch processing within a complex musical piece, like a choral, are largely unknown. Utilizing the temporal and spectral resolution of direct cortical recordings from subdural electrodes (electrocorticography; ECoG), we examined cortical representations of pitch direction and melodies of complex auditory stimuli. Two subjects with right temporo-parietal grids listened to a piano version of a J. S. Bach choral (BWV 406). Each of the 4 melodic lines consisted of 28 single events, appearing in a regular beat (600 msec.). Melodies occur simultaneously but in different pitches (top, upper middle, lower middle, low). For each melodic stream we identified the pitch direction of each event and categorized these events in pitch direction 'up' and 'down'. We then computed the amplitude of the recorded local field potentials by bandpass filtering in the 'delta (1-4 Hz)', 'theta (4-8 Hz)', 'alpha (8-12 Hz)', 'beta (12-30 Hz)', and 'high gamma (80-150 Hz)' frequency range for categories 'up' and 'down' were computed for each melodic stream. An ANOVA was performed comparing 'up' and 'down' in each melodic stream. F values were corrected via permutation testing. We found a significant difference in theta power between 'up' and 'down' only in the top melodic stream (mean $F = 20$, $p < .0001$). We identified differences between 150 and 450 msec. after each event. Those differences were most prominent over auditory areas. Pitch direction 'up' showed a significant increase in theta power as compared to pitch direction 'down' ($p=.005$). There were no significant results for the other frequency bands. In summary, our ongoing study provides initial evidence that theta power tracks pitch direction in auditory areas and similar to modern Western music the top melodic stream in classical choral music captures the main musical attention.

Title: Hemodynamic phase synchronization analysis reveals functional network dynamics with novel and familiar musical sequences

Authors: *B. M. GREEN[1], E. GLEREAN[2], M. SAMS[2], J. P. RAUSCHECKER[1], I. P. JÄÄSKELÄINEN[2];
[1]Dept. of Neurosci., Georgetown Univ. Med. Ctr., Washington, DC; [2]Biomed. Engin. and Computat. Sci., Aalto Univ. Sch. of Sci., Espoo, Finland

Abstracts: We have previously demonstrated that dorsal auditory stream areas are implicated in the processing of novel musical sequences, with both dorsal and ventral stream areas associated with the processing of familiar ones (Green et al., SFN Annual Meeting, 2012; 2013). This segregation is consistent with the current understanding of the functions of the dorsal stream (Rauschecker, HearRes, 2011) and the close relationship between the auditory and motor systems in the perception of music and speech (Zatorre, et al, NRneuroscience, 2007). However, how these areas are interconnected is not well known. In the present study we used a phase synchronization analysis (http://becs.aalto.fi/bml/software.html) with functional magnetic imaging to investigate how novel and familiar musical sequences modulate inter-subject hemodynamic similarity and dynamic functional connectivity. We computed voxel-wise time-varying inter-subject phase-synchronization and time-varying functional connectivity to identify regions and putative connections influenced by i) novel sequences, ii) familiar sequences, iii) novel sequences preceded by short familiar sequences, iv) novel sequences preceded by long familiar sequences. Increased PS across subjects during novel sequences was seen in bilateral posterior superior temporal gyrus (pSTG), Heschl's gyrus, Planum Temporale (PT), insula and operculum; left hippocampus, parahippocampal gyrus, precuneus, superior parietal lobule (SPL), and supramarginal gyrus (SMG); posterior and anterior cingulate gyrus; frontal pole, primary visual cortex, and cerebellum. Familiar sequences showed a negative effect within the same areas. Novel sequences preceded by short familiar sequences resulted in increased inter-subject synchronization and functional connectivity between bilateral pSTG, HG, PT; left SMG, SPL, insula, operculum, and inferior frontal gyrus pars triangularis. Novel sequences preceded by long familiar sequences showed increased functional similarity between right caudate, putamen, nucleus accumbens, and cerebellum; and bilateral primary visual cortex. These results are

consistent with our previous findings showing increased activity in dorsal stream, basal ganglia, and premotor areas during the processing of novel sequences. We have hypothesized that the recruitment of these areas during the perception of sound sequences reflects a broadening of their function from simply motor areas to domain-general sequencing areas. The current results show an increase in synchronization and functional connectivity in these areas during novel sequence processing in support of this hypothesized function.

Title: Mismatch negativity (MMN) used for analyzing the recognition of sounds in professional musicians using hearing protectors

Authors: E. EMMERICH[1], J. GÜNTHER[1], *A. LEHMENKUHLER[2], F. RICHTER[1]; [1]Inst. of Physiol. I, Univ. Hosp. Jena, Jena, Germany; [2]Ctr. for Med. Educ., Pain Inst., Dusseldorf, Germany

Abstracts: Use of hearing protectors in professional musicians performing classical music is a controversial issue. These musicians often claim that hearing protectors impair their ability to perform or hamper the recognition of errors. In order to provide objective evidence, we compared tune recognition and elicited MMN's. We investigated 10 normal hearing professional musicians (age 25-38 yrs.) Stimuli were presented as series of in-tune synthetic C-major chords intermitted by either slightly or markedly mistuned chords (altered note G). Stimuli were presented in a free field mode, in each series we randomly presented 200 stimuli according to the oddball paradigm (in-tune to mistuned = 4:1). Intensities were 65 dB SPL, 45 dB SPL, and 65 dB SPL but wearing a custom-made hearing protector (attenuation 18-43 dB). The musicians were asked to push a button when recognizing a mistuned chord. The EEG was recorded from 31 electrodes with the BrainVision™ system. We analyzed the error recognition rates by counting hits, and comparing the components of the auditory evoked potentials (AEP), focusing on MMN.

In the slightly distorted condition, the musicians recognized at average correctly 88.6 % of the chords as being whether in-tune or out-of-tune, when using hearing protectors 86.2 %. The AEPs in these series had clearly distinguishable P50, N100, and P200 components, however, no MMN or P300 was observed. In the markedly distorted condition, 98.2 % of all chords were recognized correctly, regardless whether sound intensity was reduced or hearing protectors were worn, AEPs showed clearly elicited MMN and P300 components. The onset of the MMN was slightly delayed and area under the curve was reduced by 19.3 % or 21.4 %, respectively, when the presentation intensity was reduced or hearing protectors were worn. In the latter series, we observed also significantly increased amplitudes of the N2b component which may indicate unintended increased attention or overlap with MMN component. Our results show that the use of these hearing protectors worsens error recognition significantly but not more than lowering the sound intensity by 20 dB SPL. The MMN provides objective evidence for recognition of distinctions, however, subtle distinctions between stimuli not necessarily induce the MMN.

Title: The disctinction between stimulus strength manipulations and volitional control in bistable perception

Authors: *J. A. RANKIN[1], J. RINZEL[1,2];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Courant Inst. of Mathematical Sci., New York, NY

Abstracts: Bistable perception has been widely studied in the visual system where ambiguity in sensory information coming from, for example, binocular, depth or motion cues leads to spontaneous shifts in perception. Indeed, Moreno-Bote et al. (2010) investigated rivalrous

dynamics induced by ambiguity in these sensory cues and generalized Levelt's proposition II (Levelt, 1968) that describes the effect of stimulus strength manipulations around equidominance: ``the mean dominance duration of the stronger percept changes more than that of the weaker percept''. Bistability also occurs in auditory streaming experiments for stimuli with alternating high- A and low-frequency tones B appearing in a repeating ABA- pattern. Pressnitzer and Hupé (2006) showed that auditory and visual bistability share the common traits of perceptual bistability using such ABA- sequences and visual motion plaids. In each modality there are alternations between a grouped percept (a galloping ABA-ABA- stream; coherent pattern motion) and a split percept (segregated streams A-A-A-A- and -B---B--; drifting transpent motion). They further investigated the effect of volitional control at equidominance and found that attending to one percept (grouped or split) reduced mean dominance durations of the unattended (weaker) percept. These findings are incompatible with the generalized Levelt's Proposition II if one assumes that volition increases the strength of the targeted percept. Starting with a canonical rivalry model we propose a new volitional mechanism with state-dependent inputs that resolves this apparent conflict by accounting for differences between direct input strength manipulations and top-down attention. We further present a new three-population model with periodic inputs for the auditory case to which our general result extends. Our modeling results can explain important differences between input strength and attention that generalize across sensory modalities.

Title: Dichotic listening while walking: Age effects on auditory control and spatio-temporal parameters of gait

Authors: *C. RODRIGUEZ-ARANDA[1], K. WATERLOO[1,2], M. M. GORECKA[1];
[1]Dept. of Psychology, Univ. of Tromsø, Tromsø, Norway; [2]Dept. of Neurol., Univ. Hosp. North Norway, Tromsø, Norway

Abstracts: Dual-task paradigms are experimental procedures to study the simultaneous performance of two different tasks. Recently, dual-tasks involving motor and cognitive execution

have been used to understand how cognitive demands, especially those related to attention, affect gait in elderly populations. However, cognitive tests so far employed rely upon simple tasks like counting or standardized tests lacking ecological validity. In this study, we use a task concomitant to walking that resembles a daily situation and assesses divided attention and hemispheric lateralization (i.e. dichotic listening (DL)). **Objectives.** a) Determine degree of cognitive-motor interference of the dual-task paradigm in young and older adults. b) Evaluate possible lateralized effects on gait. **Method.** 32 young adults (19 males; age: *M* =24.9 years) and 36 healthy elderly over 65 years of age (17 males; M =68.5 years,) participated in the study. All participants were right-handed. Audiometry test was applied. The Bergen DL test was used concomitant to walking. The dual-task situation followed the 3 standard conditions of DL: Non-forced, Forced-Right and Forced-Left. Correct answers, laterality indexes, and errors were registered. Gait was evaluated over ground with the GaitRITE system. Speed, step length, and swing were quantified. The mean (*M*), standard deviation (*SD*) and the coefficient of variation (CV) were used for group comparisons. Factorial analyses of variance with repeated measures were conducted. **Results** DL: Significant main effects of condition and ear were observed for correct responses. Significant interactions DL x group and DL x ear x group were found. Followed-up tests showed significant group differences on FR condition for both ears ($p < .01$) and on FL on left ear ($p < .0001$). Gait: Speed decreased in all DL conditions ($p<.0001$) from 1.2 m/s to 1.17 m/s for young and to 1.13 m/s for elderly. Step length decreased from 67.9±1.05 cm to 63.9±1.05 cm for young and 66.5±0.9cm to 62.6±1.06 cm for elderly. Also *SD* and CV for step length changed in all conditions. Analyses of step length on each separate foot showed significantly decrements all along conditions and interactions were found CVs x group. Further analyses revealed increased CV for the elderly group on the right foot during NF condition and on left foot on FR condition. Similar results were also found for swing in older adults. **Conclusion**. Execution of DL while walking impairs particularly the control of focus of auditory attention on left ear and increases gait variability asymmetrically in the elderly. Use of DL in dual-task methods is a convenient approach to understand modulation of attention during walking in older adults.

Title: Audiovisual associations alter low-level motion perception

Authors: *H. KAFALIGONUL[1], C. OLUK[2];
[1]Natl. Magnetic Resonance Res. Ctr. (UMRAM), Bilkent Univ., Ankara, Turkey; [2]Dept. of Psychology, Bilkent Univ., Ankara, Turkey

Abstracts: Perception is affected by immediate pattern of sensory inputs and prior experiences acquired through multisensory associations. Recently, several studies reported that a quick association can be formed between directions of visual motion and static sounds with distinct frequencies (Hidaka et al., 2011; Teramoto et al., 2010). After the association is formed, sounds are able to change the perceived direction of visual motion. In these studies, the moving stimulus was localizable in space. Such stimuli can activate both low-level motion energy mechanisms (Anstis, 1980; Braddick, 1980) and high-level positional tracking mechanisms (Cavanagh, 1992; Lu & Sperling, 1995). To determine whether this rapid audiovisual association and its influence on visual motion perception are dependent on the involvement of higher-order attentive tracking mechanisms, we designed psychophysical experiments using regular and reverse-phi random dot motions that isolated low-level pre-attentive visual motion processing (Anstis, 1970). In our experiments, either regular random dot or reverse-phi random dot motion was used during each association phase lasting around 8 minutes. Human observers viewed these random dot displays moving either clockwise (CW) or counterclockwise (CCW) direction with 100% coherency. CW and CCW motion directions were synchronized with a static tone of either high (2000 Hz) or low (500 Hz) frequency. To assess the influence of audiovisual associations, before and after each association phase, we measured direction discrimination thresholds by varying the coherency of regular and reverse-phi motion presented with static tones. After the regular random dot association phase, the static tones significantly biased the perceived direction of both regular and reverse-phi motion in favor of the exposed audiovisual association. However, reverse-phi motion direction and static tone association only changed the perceived direction of reverse-phi motion. Overall, our results show that an association between the directions of low-level visual motion and static sounds can be formed and this association alters the subsequent perception of low-level visual motion. Based on these findings, we conclude that multisensory associations are not restricted to high-level attention based motion system and early level visual motion processing has some role.

Title: The development of audiovisual crossmodal attentional cueing

Authors: *K. SCHMITTGEN, C. VILTER, L. D. KWAKYE;
Neurosci., Oberlin Col., Oberlin, OH

Abstracts: Many studies have examined the interaction between attention and multisensory integration in adults; however, little is known about how this complex relationship develops during childhood. In the current study, we investigated the development of multisensory attention using a crossmodal orthogonal attentional cueing paradigm. Adult studies of this task have shown that a stimulus in one modality can shift the spatial attention of another modality. For example, an auditory cue presented in the left periphery will speed the detection of a visual target presented on the left but slow the detection of the target on the right. We first adapted and verified an audiovisual child-themed version of the attentional cuing task. Visual targets were jellyfish presented in one of the four corners of a monitor. Exogenous auditory cues were buzzes which were presented from the left, right, or both speakers. Endogenous cues were the words “left,” “right,” or “jelly” spoken in a cartoon voice presented from both speakers. Cues could be valid (correctly identifying the location of the upcoming target), invalid (incorrectly identifying the location of an upcoming target), or neutral (giving no spatial information). Additionally, the stimulus onset asynchrony (SOA) was varied between the cues and targets in 150ms increments from 150ms to 900s for the endogenous and in 200ms increments from 200ms to 1200ms for the endogenous. The age range included in the study spanned from 4-17 years old for the child participants and from 18-40 years old for the adult participants. Preliminary results showed that global response times (RT’s) decreased with age until approximately age ten. All age ranges showed the expected “U-Shaped” relationship between SOA and RT, indicating an optimal delay between cue and target. Interestingly, the youngest children exhibited the greatest improvements in RT’s for valid cues as compared to invalid cues. In fact, the maximum difference (largest difference in RT between valid and invalid cues regardless of SOA) decreased with age until approximately age 15. Additionally, developmental changes in crossmodal attentional cueing did not differ by cue type (i.e. endogenous versus exogenous). The preliminary results of this study indicate that in children as young as four, stimuli presented in one modality may be able to shift the spatial attention of another modality, indicating an early development of this aspect of

multisensory attention. Given the complex relationship between attention and multisensory integration, many additional studies are needed to further characterize the developmental trajectory of other aspects of multisensory attention.

Title: The neural correlates of multisensory temporal processing in an audiovisual steady-state electroencephalogram task

Authors: *S. RUSS, E. ALIGBE, L. D. KWAKYE;
Neurosci., Oberlin Col., Oberlin, OH

Abstracts: Many studies have investigated the behavioral consequences and neural correlates of temporal multisensory processing in humans as well as animal models. Collectively, these studies demonstrate the necessity of the precise temporal alignment of multisensory stimuli for multisensory integration. These studies have also revealed a fundamental network for assessing the relative timing of audiovisual stimuli that includes the visual cortex, auditory cortex, and superior temporal sulcus. One caveat is that almost all of these studies have utilized discreet auditory and visual stimuli. Many naturalistic audiovisual objects produce somewhat continuous stimuli in the auditory and visual modalities that feature regularly repeating elements. The synchrony of these stimuli may not be judged by differences in onset as is the case with discrete audiovisual stimuli. Instead, individuals may rely on the overall temporal pattern produced in each modality. In the current study, we took advantage of the ability of sensory neurons to entrain to regularly repeating elements of external stimuli to produce steady state visual and auditory potentials. Visual stimuli consisted of a white square that flickered at a rate of either 10Hz or 30Hz. Auditory stimuli consisted of amplitude-modulated white noise at frequencies between 4Hz and 48Hz. The audiovisual stimuli were synchronous (both visual and auditory frequencies at 10Hz or 30Hz), or asynchronous, with the auditory being faster or slower (20% or 60% increase/decrease). Auditory and visual-only stimuli were presented with static stimuli in the other modality. Participants were asked to report whether the visual and auditory stimuli were synchronous while continuous electroencephalograms were recorded using a 64-channel

ActiChamp system. Preliminary behavioral data indicate that participants were generally more accurate at identifying the synchrony of audiovisual stimuli centered at 10Hz as compared to 30Hz. Additionally, participants were more accurate at correctly identifying asynchronous audiovisual presentations when the auditory stimulus was presented at a slower rate than the visual. Future analyses will investigate changes in oscillatory amplitude and coherence for trials in which participants reported the audiovisual stimuli to be synchronous as compared to asynchronous. Additionally, we will investigate individual differences in the mechanism for multisensory pattern discrimination that may be applicable to the study of individuals with known alterations of multisensory temporal processing (e.g. in autism spectrum disorders or in musicians).

Title: Auditory-visual interactions in brain and behaviour using modulated stimuli

Authors: Q. VUONG, M. LAING, *A. REES;
Inst. of Neurosci., Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstracts: Outside the laboratory natural acoustic events are often accompanied by information from other modalities such as vision or touch. Compared with our understanding of individual senses we know much less about the mechanisms and brain areas that underpin such interactions. To address this, we developed a paradigm that uses sinusoidally amplitude-modulated tones and visual shapes (a cuboid which expanded and contracted at the modulation rate) that enabled us to manipulate the extent to which listeners fuse the auditory and visual components of our stimuli. Listeners heard pairs of modulated tones (1.5 s duration, 250 Hz carrier frequency, 2 Hz modulation rate) and judged whether their modulation depth (range 20-52% in 8% steps) was the same or different (Audio Only). On bimodal trials, we paired the shape (modulation depth 70%) with the tone with the greatest (AV >) or least (AV <) modulation depth. We found that the modulated shape influenced how listeners perceived the modulation depth of the tones. We found that this auditory-visual interaction was nearly eliminated when the tone and shape differed in their modulation frequency (e.g., 1 Hz shape modulation and 2 Hz tone modulation).

Furthermore the listeners report that when the modulation frequency in both modalities was the same, they perceive the shape to be the source of the tone (i.e., bimodal integration) whereas this merged percept is strongly weakened or non-existent when the frequency did not match. In a preliminary functional magnetic resonance imaging study using sparse imaging data acquisition, we found that superior-temporal, intraparietal and frontal areas responded more when the tone and shape had the same rather than different modulation frequencies. Our findings are important because they provide evidence (1) that auditory-visual interactions observed with speech and faces generalise to simpler stimuli occurring over a similar time scale to speech; and (2) that temporal information, such as modulation frequency, is important for fusing sight and sound in both brain and behaviour.

Title: Association between concurrently recorded fNIRS and EEG signals for low-level visual and auditory stimuli

Authors: *L.-C. CHEN[1], P. SANDMANN[2], J. D. THORNE[1], S. DEBENER[1,3];
[1]Dept. of Psychology, Carl Von Ossietzky Univ. Oldenburg, Oldenburg, Germany; [2]Dept. of Neurol., Hannover Med. Sch., Hannover, Germany; [3]Res. Ctr. Neurosensory Sci., Univ. of Oldenburg, Oldenburg, Germany

Abstracts: Unlike other functional neuroimaging techniques functional near-infrared spectroscopy (fNIRS) does not interfere with concurrently recorded electroencephalogram (EEG) data, enabling the investigation of neuronal activity and hemodynamic responses without artifact contamination. Here we tested the feasibility of fNIRS to image sensory modality-specific cortical activation and explored the relationship between hemoglobin concentration changes and sensory-specific neuronal activity. fNIRS was recorded over visual and auditory brain areas with an 8 (sources) by 12 (detectors) system and combined with concurrent EEG

recordings from 96 scalp sites. Visual and auditory stimuli were presented in a block design for the complementary analysis of evoked EEG activity. Data from 24 normal hearing participants were collected. The fNIRS results showed a clear distinction between visual and auditory sensory modalities. Specifically, the results demonstrated significant area specificity, that is, maximal fNIRS responses in visual and auditory areas for the visual and auditory stimuli respectively, and significant stimulus selectivity, whereby the visual and auditory areas responded mainly toward their respective stimuli. In addition, a stimulus-dependent modulation of the fNIRS signal was observed in visual areas, confirming that fNIRS is sensitive to physical properties of visual stimuli. To investigate the relationship between fNIRS and EEG, features from the EEG were correlated with fNIRS data. This included sensory-related features from visual-evoked potentials (VEPs) and auditory-evoked potentials (AEPs), and components extracted from principal component analysis performed on time-frequency transformed evoked EEG signals. Both block-by-block correlation and across-subject correlation analyses were performed. Significant correlations between simultaneously recorded VEPs and deoxygenated hemoglobin (DxyHb) concentration, and between AEPs and oxygenated hemoglobin (OxyHb) concentration were found. In sum, these results suggest good sensitivity of fNIRS to basic sensory processing in both the visual and the auditory domain. The data provide further evidence for the neurovascular coupling between hemoglobin concentration changes and neuronal activities.

Title: Phase tracking of visual speech in the human auditory cortex revealed by intracranial EEG

Authors: *P. MEGEVAND[1,2], D. M. GROPPE[1,2], A. D. MEHTA[1,2], C. E. SCHROEDER[3,4]; [1]Neurosurg., Hofstra North Shore LIJ Sch. of Med., Manhasset, NY; [2]Feinstein Inst. for Med. Res., Manhasset, NY; [3]Cognitive Neurosci. and Schizophrenia Program, Nathan S Kline Inst., Orangeburg, NY; [4]Dept. of Psychiatry, Columbia Univ., New York, NY

Abstracts: People comprehend speech better when they watch the face of their speaker. Previous studies showed that speech-reading activates hierarchically early auditory cortex with short latencies, consistent with a feed-forward influence of visual cortex on auditory processing. Recent intracortical recordings in monkeys established that the phase of ongoing oscillations in sensory cortices determines their excitability, and that cross-modal sensory stimulation resets the phase of these ongoing oscillations. Based on these findings, it has been proposed that visual speech cues facilitate the comprehension of auditory speech by resetting the phase of oscillations in auditory cortex, thus placing it in a state of optimal excitability (Schroeder et al., Trends Cogn Sci 2008). To test this hypothesis, we recorded the responses of human auditory cortex to continuous auditory and visual speech using stereo-EEG electrodes in patients with drug-resistant epilepsy considered for surgery. Electrodes were localized by co-registering pre- and post-implantation high-resolution MRI and CT scans. The video stimuli consisted of 8 short stories (8-12 s) told by 2 narrators whose whole face was visible. The last word of each story was cut off, and patients had to decide whether a written word provided an adequate ending. Each video was shown 8 times in each of 3 modalities: audiovisual, auditory and visual. Time-frequency analysis of the intracranial EEG was performed on bipolar channels using wavelet transform. We focused on changes in high-gamma power (HGP; 70-170 Hz), thought to index neuronal firing, and in inter-trial coherence (ITC) in lower frequencies (1-50 Hz). Auditory-responsive channels were identified by their expected strong HGP and ITC increases to auditory speech signals as well as their anatomical location in or bordering the transverse temporal gyrus. Phase tracking of auditory speech was significant for all frequencies examined, most prominently in the delta and theta bands (1-8 Hz). Crucially, we found that the auditory cortex also displayed significant phase tracking of visual-only speech, in the delta to alpha bands (1-13 Hz). Additionally, we observed small HGP increases in response to visual speech signals in those sites where ITC increases were the strongest. Our results support the notion that visual speech cues are able to impact the early cortical processing of auditory speech through phase reset of ongoing cortical oscillations. More generally, they refine our understanding of the neural underpinnings of multisensory integration in the human brain.

Title: Electrocorticographic responses to synchronous and asynchronous audiovisual speech

Authors: *D. MOHANTY[1], M. OZKER[2], D. YOSHOR[3], M. S. BEAUCHAMP[2];
[1]DEPT OF NEUROSCIENCE, BAYLOR COLLEGE OF MEDICINE, HOUSTON, TX; [2]Dept. of Neurobio. and Anat., Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX; [3]Dept. of Neurosurg., Baylor Col. of Med., Houston, TX

Abstracts: Humans readily integrate auditory and visual speech information (talker's voice and face) even when there is a substantial temporal offset (asynchrony) between the modalities. Tolerance for asynchrony is asymmetric: we more readily integrate speech in which the talker's voice begins after the talker's face moves than when the talker's face moves after the voice is heard is (Conrey and Pisoni, 2006). This asymmetry corresponds to the physical properties of naturalistic speech: talkers prepare their facial musculature before emitting a vocalization, resulting in a natural visual-before-auditory order. For optimal multisensory integration, the brain should only integrate auditory and visual speech information according to the likelihood that they have the same cause (Magnotti, Ma, and Beauchamp 2013). Activity in the human left superior temporal gyrus and sulcus (STG/S) is a neural measure of audiovisual integration during speech perception (Nath and Beauchamp, 2011). Therefore, we hypothesized that neural responses in the STG/S to asynchronous speech should reflect the propensity to integrate observed behaviorally. We examined 264 subdural electrodes implanted in 3 patients with intractable epilepsy and selected 24 electrodes that were nearest the STS, lying directly over the sulcus or closely adjacent to it. The stimuli consisted of 4 audiovisual words spoken by a native English talker (Conrey and Pisoni, 2004). For each word, the auditory and visual components were either unchanged from the original recording (Sync) or manipulated so that the auditory component either preceded the video component by 300 ms (A before V, A−>V) or followed it by 300 ms (V−>A). Subject accurately judged synchronous stimuli to be synchronous (mean synchrony reports 97% ± 3% SEM). Consistent with the behavioral literature, shifting the auditory component of the stimulus in different directions produced asymmetric results. A−>V stimuli were rarely perceived as synchronous (4% ± 3%), but V−>A stimuli often were (74% ± 17%). Next, we examined the response to these stimuli in the STG/S electrodes. A time-frequency analysis was used to compare responses in the high gamma band (70-110 Hz) to the words (analysis window from auditory onset to one second after onset) to baseline (one second before onset to half-second before onset.) The mean response to Sync was 57% ± 7% (SEM)

above baseline. The response to A−>V was significantly less than the response to V−>A (35% ± 7% vs. 48% ± 6%, t = 2.7, p = 0.01); the effect was observed in 18 of 24 electrodes. These results suggest a link between STS/G activity and synchrony perception, as observed with fMRI (Stevenson, James, et al., 2009).

Title: Processing of audiovisual speech and non-speech stimuli within and beyond human auditory cortex: An intracranial electrophysiology study

Authors: *A. E. RHONE[1], B. MCMURRAY[2], K. V. NOURSKI[1], H. OYA[1], H. KAWASAKI[1], M. A. HOWARD, III[1];
[1]NEUROSURGERY, [2]PSYCHOLOGY, Univ. of Iowa, Iowa City, IA

Abstracts: Audiovisual (AV) speech provides neurophysiological facilitation and behavioral advantages relative to audio-alone (A) speech. A large network of cortical areas has been implicated in AV processing; the visual-alone (V) responsiveness and speech-selectivity of these areas was the focus of this study. Areas of interest included Heschl's gyrus (HG), posterolateral superior temporal gyrus (PLST), middle temporal gyrus (MTG), inferior frontal gyrus (IFG), and precentral gyrus. The high temporal and spatial resolution of electrocorticography (ECoG) allowed us to test whether visual information activates auditory areas prior to the onset of speech, and whether responses to auditory stimuli were differentially modulated by visual speech vs. nonspeech content. We measured ECoG activity in neurosurgical patients undergoing chronic

monitoring for medically refractory epilepsy. Stimuli were A or V speech syllable /da/ combined with nonspeech stimuli /da/-shaped noise or gurning. Unimodal A and V /da/ were also presented. Subjects monitored for A, V, or AV /tu/ (button press response; all subjects > 95% correct; ECoG responses to response trials not analyzed). Trials were averaged to the onset of the talker's static face, approximately 700 ms prior to visible articulation. All sound tokens had the same onset (1168 ms). Event related band power in the high gamma band (70 -150 Hz) was measured in two time windows, 300 ms following the onset of mouth motion (PreA) and 400 ms following the onset of sound (PostA). Unimodal V stimuli activated PLST, IFG, MTG, and precentral gyrus; no high gamma activation was observed on HG. Comparisons of responses by modality and speech content revealed increased activity for visual speech stimuli in PreA time window for MTG only. Responses on IFG were not modulated by speech content in either window. In the PostA window, PLST, MTG and precentral gyrus showed increase for V speech relative to V nonspeech. On PLST, speech elicited larger high gamma power than nonspeech in both modalities, and showed the highest response when both modalities contained speech. A large network of cortical structures was activated by V alone stimuli; however, primary auditory area HG was not. Speech vs. nonspeech comparisons revealed distinct patterns of activation in different cortical regions. These effects occurred prior to acoustic onset in select sites on MTG. Following acoustic onset, the earliest auditory cortical area that was modulated by speech content was PLST, with no evidence for sensitivity to visual speech content on HG. Responses in other areas (IFG, precentral) were consistent with their hypothesized involvement in multisensory perception.

Title: The modality-specific spatial attention control between vision and audition under same stimulation background: A simultaneous EEG-fMRI study

Authors: *W. WANG, S. VISWANATHAN, S. T. GRAFTON;
Psychology, UCSB, Santa Barbara, CA

Abstracts: In natural settings, people are flooded by sensory inputs from multiple, concurrently occurring events in the immediate environment. These events can each occur at different spatial locations, generating information that is potentially detectable by distinct sensory modalities. People are able to bias their attention to both the sensory modality as well as the spatial location to localize events. In the current study, we identified brain states associated with sustained attending under modality- and location-dependent demands as well as switches between these states. Participants monitored a spatially localized stream of naturalistic stimuli for infrequent target objects in the presence of a complex multisensory (auditory-visual) background. We used distinctive images/sounds of common objects and domestic animals. Stimulus duration was 250ms for both the visual and auditory stimuli. Brain responses induced were measured simultaneously using electroencephalography (EEG) and functional magnetic resonance imaging (fMRI). Although behavioral accuracies were matched between modalities, the response times (RT) to detect auditory targets (~1000ms) showed a latency compared to visual targets (~600ms). The fMRI BOLD activity lateralized to sensory cortices. Monitoring the auditory stream produced a larger activation in superior temporal gyrus; while monitoring the visual stream evoked a larger activation in the occipital and superior parietal and inferior temporal gyrus, establishing that the task successfully modulated the allocation of attention. Unlike the block-level fMRI analysis, the EEG data were analyzed at the trial-level. The event related potentials (ERP) showed the earliest and the most significant difference between monitoring vision or audition, occurring at ~100ms on Pz electrode (bottom-up) and during 250ms to 600ms on Fz electrode (top-down) after stimulus onset. In the "late" phase the auditory ERPs over central-parietal cortex were significantly more negative than the corresponding visual ERPs (around ~600ms) ipsilateral with stimuli. Strikingly, in the electrodes over the frontal cortex from ~350ms to 600ms, the visual ERPs were more negative than the corresponding auditory ERPs when stimuli were displayed to the right side of fixation. The former could be related to suppress contralateral irrelevant auditory stimuli, and the latter may reflect a spatial-specific inhibition to irrelevant auditory stream. Our results identify timing and brain systems involved in both modality- and location-dependent mechanisms engaged in monitoring sensory stimuli coming from separable visual and auditory events.

Title: The effect of early visual deprivation on the neural bases of multisensory processing

Authors: *M. J. GUERREIRO, L. PUTZAR, B. ROEDER;
Biol. Psychology and Neuropsychology, Univ. of Hamburg, Hamburg, Germany

Abstracts: Visual deprivation has long been known to affect processing in the remaining sensory modalities (e.g., Bavelier & Neville, 2002). Only recently, however, the recovery of visual and multisensory processing after visual restoration has been started to be investigated in humans, revealing deficits in higher-order visual and multisensory processes (e.g., Putzar et al., 2007, 2010) despite intact lower-level multisensory processing skills (Putzar et al., 2012). The goal of the present study was to investigate the effect of early visual deprivation on the neural bases of multisensory processing. A group of 9 cataract-reversal individuals (aged 18-51 years, M = 34, 7 female) and 9 normally sighted controls (aged 19-56 years, M = 35, 8 women) were tested in a series of 1-back tasks involving the presentation of visual, auditory and audiovisual speech stimuli, while underdoing functional magnetic resonance imaging. We performed a region of interest analysis, focusing on visual (i.e., BA 17 and BA 18/19), auditory (i.e., BA 41/42) and multisensory areas (BA 22). The results revealed no evidence for multisensory integration in visual areas. Interestingly, however, although there was no difference in visual cortex activation between cataract patients and sighted controls during unisensory stimulation, there were differences between groups during multisensory stimulation, such that activation in visual areas during audiovisual stimulation was lower in cataract patients than in sighted controls. In addition, there was evidence for multisensory integration in auditory and multisensory areas in sighted controls, but not in cataract patients. The present results suggest reduced multisensory integration in auditory and multisensory areas in cataract patients. In addition, the present results reveal reduced visual cortex activation during multisensory processing in cataract patients, despite equivalent levels of visual cortex activation during unisensory processing, suggesting that during multisensory processing, cataract patients process bimodal audiovisual stimuli as if they were unimodal (auditory) stimuli.

Title: Enhanced functional connectivity between V1 and multimodal cortex in congenitally, profoundly deaf adults revealed by time-lagged cross-correlation of the "fast" optical signal

Authors: *J. L. SEYMOUR[1], A. CHIARELLI[1], M. FABIANI[1], G. GRATTON[1], M. A. FLETCHER[1], K. LOW[1], E. MACLIN[1], K. MATHEWSON[2], M. W. G. DYE[1];

Abstracts: Research has shown that early deafness positively impacts peripheral visual attention. The useful field of view (UFOV) task has previously been used to show that deaf subjects have lower presentation duration thresholds for determining the location of a peripheral target among distractors while performing a concurrent central discrimination task. These appear to be effects of deafness and not using sign language, as deaf non-signers show the effect and hearing signers do not. Here we combined structural MR with diffusive optical imaging techniques to explore how deafness alters functional connectivity between visual and auditory cortices. By combining functional optical data with co-registered structural MR data, it is possible to examine functional connectivity between cortical regions with excellent spatial and temporal resolution. This permits both functional connectivity analyses alongside an analysis of processing pathways with excellent temporal precision (c. 39 Hz). Results show that activity in BA17, primary visual cortex, predicts activity 50 ms later in the posterior STG of the right hemisphere in congenitally, profoundly deaf adults but not in hearing adults. Whilst enhanced recruitment of the posterior STG in the right hemisphere of deaf adults is well known, this is the first demonstration of enhanced functional connectivity between that region and primary visual cortex. The short time lag suggests either (a) direct functional connectivity between these regions rather than a mediated connection, or (b) a common precursor region that routes neural activity to V1 more rapidly than to the posterior STG (possibly the thalamus). Title: Cortical coupling between occipital cortex and intraparietal sulcus predicts auditory abilities in early blind individuals

Authors: *P. VOSS, R. J. ZATORRE;
Cognitive Neurosci. Unit, Montreal Neurolog. Inst., McGill Univ., Montreal, QC, Canada

Abstracts: Early blind individuals have been shown to possess thicker occipital cortex compared to sighted ones. This increase in occipital cortical thickness is also predictive of performance on several auditory discrimination tasks in the early blind, which suggests that the increase in thickness reflects crossmodal plasticity mechanisms. In light of this atypical relationship between occipital thickness and auditory function, we sought to investigate here the covariation of occipital cortical morphology in occipital areas with that of all other areas across the cortical surface, to assess whether the anatomical coupling with the occipital cortex is altered following visual deprivation. Measures of anatomical coupling were obtained by performing vertex-wise covariance analyses on cortical thickness measures derived from standard magnetic resonance imaging (3T) anatomical T1 images. We observed a reduction in anatomical coupling in a group of early blind individuals (n=14) relative to sighted controls (n=19) between the right occipital cortex and several frontal areas of the visual dorsal stream involved in oculomotor control. In a separate analysis, we asked the question whether better auditory abilities in the early blind could be linked to greater cross-cortical covariance between the occipital cortex and task-relevant brain areas. We show that the performance of the early blind in a transposed melody discrimination task was strongly predicted by the strength of the cortical coupling between the occipital cortex and intraparietal sulcus, a region for which cortical thickness in the sighted was previously shown to predict performance in the same task. These findings therefore constitute the first evidence linking altered anatomical coupling to early sensory deprivation, and also provide compelling evidence that investigating anatomical coupling can be an effective way to characterize individual (behavioral) differences and crossmodal plasticity.

Title: An fmri study of a visual-auditory paired associate task

Authors: ***P. T. CORBITT**[1], J. F. SMITH[2], B. HORWITZ[2];
[1]NIH, MD; [2]Brain Imaging & Modeling Section, NIDCD-NIH, Bethesda, MD

Abstracts: Visual-auditory associations play an important role in many human cognitive functions, including naming and reading. To understand the neural basis for such associations, we performed an fMRI visual-auditory paired associate task. We collected fMRI data from eleven subjects. An initial abstract visual stimulus had an abstract visual (VV) or auditory (VA) target paired associate presented 9 s after the cue stimulus. The data were acquired after the subjects were trained and tested three times over a period of 4 weeks; the paired associates were well-learned. Three scanning sessions consisted of twenty trials equally divided between VA and VV (50% matching trials). A slow event-related paradigm was used to separate the BOLD signals associated with different task components. This design used a TR of 1.8 s, and each trial was 23.4 s long. Our finite impulse response (FIR) model used 11 time bins each 1.8 s in width. The FIR time bins can be considered as belonging to the cue, delay, and response periods. A prior MEG study (Pillai et al. 2013), using a similar design, detected power differences when comparing the VA to VV task in the right superior temporal gyrus (STG) during the equivalent cue/delay period. MEG, compared to fMRI, lacks the spatial resolution for pinpointing regions involved in the paired associate task. Due to the exploratory nature of this investigation, we used a voxelwise significance criterion of $p < 0.001$ (uncorrected) in the group level analysis. Comparing VA to baseline, we detected BOLD responses in the right STG during the late cue and early delay periods. We then directly contrasted the VA and VV conditions. Two regions that showed showed larger relative BOLD responses in VA compared to VV were putative Brodmann areas 44 and 45 in the cue, delay, and response periods. During the delay period, the relative BOLD response was greater in the insula, parietal lobe, and thalamus for VA compared to VV, and in the fusiform gyrus, hippocampus, and occipital lobe for VV compared to VA. In

the response period, relative BOLD signals for VA compared to VV were greater in the frontal lobe, whereas they were greater in the occipital lobe for VV relative to VA. Our results suggests that inferior frontal areas are differentially more involved in VA compared to VV. Moreover, consistent with the prior MEG study, we found activation in right STG occurred before onset of the auditory paired associate. Based on these and other results from the literature, we suggest that prefrontal areas are playing a central role in the retrieval of the paired associate of the initially presented stimulus.

Title: An unbiased approach to analyzing the effect of numerosity and other visual features of dot arrays on neural and behavioral variables

Authors: ***N. K. DEWIND**, J. PARK, G. K. ADAMS, M. L. PLATT, E. M. BRANNON; Ctr. for Cognitive Neurosci., Duke Univ., Durham, NC

Abstracts: The approximate number system (ANS) subserves estimation of the number of items in a set. Typically, ANS function is assessed using dot arrays that differ in numerosity. Controlling these numerical stimuli is a well-known and difficult problem. In particular, when numerosity is varied, other visual stimulus features also necessarily vary. Here we present a novel mathematical description of dot array stimuli that specifies the three degrees of freedom available to researchers when designing these stimuli. As a result, dot array stimuli can be described by their position within a three-dimensional “stimulus space”. These dimensions are numerosity and two novel terms that describe the size and spacing of the items in the array. Numerosity, item surface area, item perimeter, total surface area, total perimeter, area encompassing the entire stimulus, array density, overall scaling, and foreground to background ratio can all be described algebraically as linear combinations of these three dimensions. Thus, this new stimulus space provides a very rich, but also parsimonious description of dot array stimuli. Because the three degrees of freedom are independent, we can design a generalized

linear model to estimate the effect of each stimulus dimension on a dependent variable. By virtue of the algebraic relationships between the three dimensions of the stimulus space and the other visual features, we can use the coefficients of the linear model to estimate which visual features of a stimulus drive changes in the dependent variable. A critical advantage of this approach over previous paradigms for controlling visual features is that the linear models are as sensitive to changes caused by other visual features as to those caused by numerosity, allowing an unbiased estimation of the parameters that affect the dependent variable. The most important advantage of the stimulus space, however, is its versatility. With minor changes we have adapted our linear models to estimate the effect of numerosity and other visual features on behavior in a discrimination task, scalp voltage from electroencephalograms, blood-oxygen-level-dependent signals from functional magnetic resonance imaging, and firing rate from single neurons. This approach allows us to demonstrate that human numerical discrimination is primarily reliant on number with some biasing effects of other features; that EEG event-related potentials triggered by dot arrays show sensitivity to number at very early time windows; and that single neurons in monkey intraparietal sulcus encode many stimulus features across a population distinguished by its heterogeneity.

Title: Dissecting the neural network of duration perception with fMRI

Authors: ***M. CAI**, D. M. EAGLEMAN;
Neurosci., Baylor Col. of Med., Houston, TX

Abstracts: Neural models of time perception often assume a dedicated amodal brain system for encoding time. In contrast, some recent models suggest that time may be intrinsically encoded in sensory cortices that also code for other aspects of stimuli. To date, few studies have attempted to decode temporal features of sensory stimuli with fMRI. To this end, we examined both intrinsic and dedicated models of time perception by evaluating whether we could decode subjective duration from activity in both sensory and other brain regions. A block-design

functional localizer contrasting a duration discrimination task against a color discrimination task identified higher activity for duration discrimination in early visual cortex, right inferior parietal sulcus, and right middle frontal gyrus. Participants next performed a duration bisection task in which they judged if the duration of a stimulus was longer or shorter than a remembered, intermediate duration. The stimuli were concentric sinusoidal gratings that were either static or expanding at different speeds (2, 6, or 18 Hz)_a manipulation that is known to bias subjective duration. We then used partial least square regression to decode subjective duration based on the pattern of local hemodynamic response amplitudes. We find that all three regions contribute to encoding subjective duration, allowing the decoding of subjective duration simply from observing neural activity.

Title: Overlapping topographic representations of numerosity and item size in the human parietal cortex

Authors: *B. M. HARVEY[1], A. FRACASSO[2], N. PETRIDOU[3], S. O. DUMOULIN[2]; [1]Exptl. Psychology, Helmholtz Inst., [2]Helmholtz Institute, Exptl. Psychology, Utrecht Univ., Utrecht, Netherlands; [3]Radiology, Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

Abstracts: Introduction: Perception of numerosity, the set size of a group of visually presented items, is affected by the sizes of these items, particularly during development. We recently demonstrated neural population tuning for numerosity within a topographic map in human parietal cortex (Harvey et al, 2013). But we also showed that this numerosity tuning is affected by item size and speculated an interaction between the representation of numerosity and item size. Here we ask whether item size is also topographically represented in the human parietal cortex, and whether the representations of these two quantities coincide on the cortical surface?

Methods: Using high-field fMRI (7T), we acquired 2D-EPI volumes with 1.8mm isotropic resolution while showing visual stimuli varying systematically either in numerosity or the size of a single item. We developed a custom-built model-based analysis that captures numerosity or item size tuning following a population receptive field design (Dumoulin and Wandell, 2008). Using a forward model, we predict the fMRI response amplitude at each time point based on a model of neural response selectivity for numerosity or item size. This model describes population neural response selectivity at each recording site as a Gaussian function in logarithmic space, with parameters describing the preferred numerosity/item size and tuning width. Results: We describe neural populations tuned to small item sizes (up to 1.5°) in human posterior parietal cortex. These neural populations are organized topographically, forming a map of item sizes where preferred size item increases from posterior to anterior cortex. The location of this item size map coincides with that of reported numerosity maps, but its direction of response preference change differs. As with population numerosity tuning, tuning width increases with preferred item size. Conclusion: The topographic organization of both item size and numerosity tuning demonstrates that this fine scale organization of quantities is not limited to numerosity. As with numerosity tuning, the cortical organization of item size tuning shares similarities to the maps found in the primary sensory cortices. Overlapping representations of these two quantities may explain why their perceptions interact. These overlapping and interacting representations of item size and numerosity may arise because these quantities are estimated by similar neural mechanisms.

Title: High-level expertise for mathematical concepts recycles lateral occipito-temporal and parietal regions for number processing

Authors: *S. DEHAENE[1,2], M. AMALRIC[1], M. PIAZZA[1], B. THIRION[3];
[1]Cognitive Neuroimaging Unit, INSERM-CEA, GIF/YVETTE, France; [2]Collège de France, Paris, France; [3]Parietal team, INRIA, Gif sur Yvette, France

Abstracts: How does the brain represent and manipulate advanced mathematical concepts? Mathematics can be considered as a cultural construction process whose foundations lie in basic intuitions of space, time and number provided by innate "core knowledge" systems. Many studies have dissected the role of the intraparietal sulcus in basic number sense, its cross-talk with nearby areas for spatial coding, and its foundational role in school-based arithmetic. We hypothesized that mathematical expertise for abstract non-numerical concepts would rely on a "neuronal recycling" of this evolutionarily ancient system. We also predicted that the acquisition of expertise for mathematical expressions, much like the acquisition of literacy, would lead to a reorganization of ventral visual cortex, perhaps encroaching and expanding upon the recently discovered "number form area". High-resolution functional magnetic resonance images (fMRI) were acquired in 15 professional mathematicians and 15 researchers in humanities without mathematical training. Subjects listened to 90 high-level mathematical statements and non-mathematical sentences and decided whether they were true, false or meaningless. Statements, devoid of any numbers, covered algebra, analysis, topology and geometry (for instance "any square matrix is equivalent to a permutation matrix" is a false algebraic statement). Control sentences concerned general knowledge. In distinct blocks, we measured visual responses to mathematical expressions, words, numbers, faces, houses, tools, bodies and checkers, and also localized calculation and language areas. All meaningful mathematical statements, in mathematicians only, mainly evoked activations around the intraparietal sulcus, at a site also activated during numerical calculation. On the contrary, meaningful non-mathematical sentences only evoked classical language-related activations in the superior temporal sulcus. Listening to mathematical statements also induced top-down activations in the left fusiform gyrus, at a site activated by mathematical expressions and whose activation was highly enhanced for mathematicians compared to non-mathematicians. We also observed enhanced activation of the "visual number form area" in the lateral inferior temporal gyrus, a region previously reported only using intracranial electrophysiological recordings. Thus, the acquisition of mathematical expertise transforms both parietal and ventral visual areas to support abstract domain-general mathematical processing and the manipulation of mathematical expressions.

Title: Monkey math beyond addition

Authors: *M. S. LIVINGSTONE[1], D. LEE[2];
[1]Harvard Med. Sch., BOSTON, MA; [2]Neurobio., Yale Univ. Sch. of Med., New Haven, CT

Abstracts: We previously showed that monkeys can combine pairs of symbolically represented magnitudes to arrive at a value approximately equal to their sum. This result addresses the question of whether magnitudes are represented internally as a compressed scale, or as a linear scale with signal-dependent noise. Because, if the internal scale is compressed, we would expect supra-additive behavior, since the internal representation of, say, 3 would be more than half the internal representation of 6, leading the animal to estimate 3+3 as larger than 6. Therefore, our failure to find such supra-additive behavior contradicts the idea of a compressed scale. However, it is possible that our monkeys showed behaviors consistent with addition, because that is what we taught them. Namely, in our previous study, the animal always received reward proportional to the sum of the quantities represented by two symbols, so even if they had a compressed internal representation, their natural tendency to combine quantities supra-additively might have been overcome, allowing them to estimate the sum of two quantities more accurately. Instead, if we had rewarded them according to the the product of the quantities represented by two symbols, they might have learned to estimate the product, rather than, the sum of two quantities more easily. To test this, we presented symbol-literate monkeys with a singleton symbol on one side of a touchscreen and two symbols inside an oval on the other side, and rewarded them with the value represented by whichever side they chose: the singleton value, or the product of the two symbols presented in the oval. Results so far indicate that the monkeys value the two symbols additively, not multiplicatively, despite being rewarded multiplicatively. This argues against the idea of compressive internal representation of quantities.

Title: Changes in cerebellar-parietal connectivity contribute to differential anterior parietal activity for complex and simple mental calculation

Authors: *C. KATZ, A. KNOPS;
Humboldt Univ. of Berlin, Berlin, Germany

Abstracts: BACKGROUND: Animals are thought to have an innate "number sense" which supports numerical cognition (Dehaene and Cohen 1995). In addition to well-described parietal regions, numerical tasks have also been found to activate the cerebellum and it was suggested as an addition to the "triple-code model" of numerical cognition (Arsalidou and Taylor 2011). Despite extensive evidence of the cerebellum's non-motor cognitive role (Buckner 2013), little is known about its role in number processing. It remains to be seen how cerebellar and parietal regions are involved in functional networks underlying symbolic calculation. To this end, we examined the contribution of inferior parietal (IPL) and superior cerebellar regions to whole-brain activity in symbolic multiplication. METHODS: fMRI data (TR=2s, 3x3x3 mm) was collected from 17 right-handed adults performing simple (e.g. 6x3) and complex (e.g. 12x6) symbolic multiplication and analyzed using standard GLM analysis for functional localization and Psycho-physiological interactions (PPI) for connectivity. PPI seed regions were defined from cytoarchitectonically distinct IPL and superior cerebellar subdivisions. RESULTS: Consistent with previous research, complex multiplication (complex > simple) was associated with bilateral parietal as well as superior cerebellar activation. For cerebellar seed regions, connectivity was decreased to bilateral parietal regions in complex multiplication (cluster FDR $p < .05$). Bilateral cerebellar lobule VI hemisphere (h) and vermis (v) regions all increased connectivity to overlapping L anterior parietal clusters. Bilateral VI v regions increased connectivity to overlapping R anterior IPL clusters with R VI v connecting to a larger intra-parietal sulcus/SPL cluster. For IPL seed regions, connectivity to R middle frontal and R superior parietal (SPL) regions was increased in complex multiplication. Thus, while IPL regions increased coupling with R SPL and R middle frontal regions during complex calculation, cerebellum VI regions decoupled with larger bilateral parietal regions. Parts of these decoupled regions showed positive activation in GLM analysis. CONCLUSION: Changes in cerebellar-parietal connectivity

contribute to complexity related anterior parietal activity. Given the role of lobule VI in salience (Habas et al. 2009) and spatial attention shifts (Townsend et al. 1999); functional cerebellar-parietal decoupling in complex calculation might relate to increased spatial and attentional demands.

Title: Limitations of abstract number perception: An fMRI study on the temporal integration of auditory and visual number information

Authors: *S. CAVDAROGLU, A. KNOPS;
Humboldt Univ. zu Berlin, Berlin, Germany

Abstracts: The ability to perceive and manipulate numbers is thought to exist even in human infants and other animals which led to the idea of 'abstract number sense'. This notion refers to an innate mechanism that enables us to comprehend numerical values independent of the modality and format they are presented in. Previous studies point to the intraparietal suclus (IPS) as a key region for an abstract number representation. Yet, the modality independence of abtract number sense has not been studied exstensively in humans. The current study aimed at investigating the neural underpinnings of auditory and visual number perception. We presented participants with sequences of auditory (beeps) or visual (flicker) numerosities (5,7,11,16) while measuring brain activity with a 3T MR-system. Our slow event-related design allowed us to obtain numerosity-related BOLD signals that were not contaminated with interfering signal from adjacent stimuli or response-related processes. To maintain and control participants' attention in interspersed catch trials participants were required to numerically compare two subsequent numerosities. This way, we were able to keep subjects attentive during the experiment, assess the performance of subjects in comprehending numbers and disentangle number processing from comparison, which were mostly intermingled in previous studies. Localizer tasks were applied to independently define parietal sub-regions of interest (hAIP, hVIP, hLIP) for multivariate

analyses. Contrary to previous findings we observed no activation of IPS upon mere number perception. Rather, IPS was only activated during comparison trials. To further investigate the idea that IPS represents numbers independent of modality, we used multivariate pattern analyses to distinguish between numerosities in auditory and visual modalities, separately. In no-response trials classifier performance in IPS was at chance level, even when adopting a grid search approach for classifier parameter optimization or different classification algorithms (i.e. support vector regression). In contrast, we were able to classify numerosity during response trials in a task-based ROI in bilateral parietal cortex in both modalities. Our results suggest that integrating over time non-symbolic auditory or visual number information does not automatically activate the IPS in the absence of response preparation. We conclude that number-dependent IPS activity may be limited to task-regimes involving response preparation and/or numerical information that do not require integration over time.

Title: Value-based attentional capture induces automatic normalization during binary-choice decisions

Authors: *S. ITTHIPURIPAT, J. T. SERENCES;
UCSD, San Diego, CA

Abstracts: Traditional decision-making theories postulate that choice behavior is unaffected by the value associated with irrelevant stimuli (i.e., distractors), and it is therefore context-independent. However, cross-species studies have shown that choice behavior is context-dependent, as when more than two options are available the value of the lowest-valued option will influence decisions between the highest-valued and the second-highest-valued options. Recently, a computational model based on the divisive normalization of neural responses during decision stages has been proposed to account for this phenomenon. However, the model does not account for the possibility that contextual normalization effects during decision-making could be a result of automatic and early value-driven attentional capture. To test this account, we developed a novel probabilistic binary-choice paradigm, where human observers freely choose between one of two targets that were presented in the left and the right lower visual fields. Simultaneously, a single distractor that could never be chosen was presented between the two targets. All three stimuli were rendered in a unique color. The colors assigned to targets and to the distractor varied across trials. Over blocks of trials, the value associated with targets rendered in each color was also varied. We found that the value associated with the color stimulus presented at the distractor location, as was learned when it was a rewarded target in previous trials, reduced decision biases between the two target stimuli and also increased decision times. These data suggest that binary-choice decisions are context-dependent and that the recently proposed value normalization model for decision-making can be at least partially accounted for by value-based attentional capture.

Title: Neurophysiologic correlates of the speed-accuracy trade-off in humans: Setting thresholds in time and in amplitude

Authors: *N. A. STEINEMANN[1], R. G. O'CONNELL[2], S. P. KELLY[1];
[1]Biomed. Engin., Neural Systems Lab, City Col. of New York, New York, NY; [2]Trinity Col. Inst. of Neurosci., Trinity Col. Dublin, Dublin, Ireland

Abstracts: The trade-off between speed and accuracy in decision-making has been studied through human and animal behavior as well as electrophysiology. The prevalent view from mathematical psychology has long been that speed-emphasis in decision-making tasks leads to decreased decision thresholds, but there has been little direct neurophysiological evidence for this. In the present study, behavioral and electrophysiological changes induced by the emphasis of speed or accuracy are studied in humans. We employ a novel two alternative forced-choice contrast discrimination paradigm designed to give independent, neural read-outs of the sensory evidence via steady state visually evoked potentials (SSVEP), a centro-parietal potential (CPP) previously connected to decision formation, and lateralized readiness potentials (LRP) quantifying motor preparation. Within this experimental set-up we evoke behavioral changes through the implementation of time-dependent reward functions under three distinct conditions 1) An accuracy condition in which subjects earned response time-independent rewards for correct responses and lost points for incorrect answers. 2) A deadline speed emphasis condition in which subjects received constant rewards up to a short temporal deadline and finally 3) A 'faster the better' speed-emphasis condition in which rewards decreased linearly over time. We reasoned that the two distinct types of speed emphasis (deadline vs. 'faster the better') may be accounted for differently in the decision process, with thresholds more likely being set in time in the deadline condition than in amplitude. Behavioral results indicate that subjects show similar mean reaction times in both speed conditions, but distributions are comparatively symmetric and narrower in the deadline condition while they were right-skewed in the condition of decreasing-rewards. The centro-parietal positivity, which has previously been linked to decision formation shows increased amplitudes for decisions made under either kind of speed pressure, while correlates of motor preparation, and sensory evidence traces remain unaffected by experimental condition. Recent intracranial recordings in frontal eye field showing a similar tendency of increased firing rates at a higher rate when fast reactions are stressed over accuracy. These findings contradict the prevailing assumption that decision thresholds are lowered if decisions need to be made quickly, pointing towards potential changes in overall gain in the accumulation process.

Abstracts: Non invasive rhythmic neurostimulation techniques such as Transcranial Magnetic Stimulation (TMS) have emerged as unique approaches to explore causal relations between brain rhythms and cognitive processes in the human brain. Prior studies from our group (Chanes et al. J Neurosci 2013) have shown that 30 Hz TMS bursts delivered pre-target onset to the right frontal eye field (FEF), an area involved in spatial attentional orienting, increased perceptual visual sensitivity for near threshold lateralized visual targets. We here aim to further elucidate the neurophysiological mechanisms subtending such effects, and by using combined TMS-EEG recordings, we tested the hypothesis that rhythmic TMS patterns might increase the activity of neural oscillators and/or align their phases, hence entraining rhythmic activity at this frequency band, causally responsible for the ensuing visual performance modulations. To that end, a group of healthy human participants performed a visual task in which they were requested to signal whether or not they had seen a near-threshold target and if yes, if it had appeared to the left or right of a fixation cross. Prior to target onset, either frequency-specific sham or real 4 pulse 30 Hz TMS bursts, or random patterns of equal duration and pulse number were delivered to the right FEF. Behavioral results confirmed a previously reported facilitatory effect of the former, but not the latter activity patterns, increasing conscious visual detection performance. Moreover, during the stimulation, coupled TMS-EEG analysis revealed an entrainment of 30 Hz oscillatory activity, with increases of power and phase alignment, building-up during the course of the burst. In contrast, random TMS induced non frequency-selective power increases in several oscillation bands, un-modulated across the patterns. Our results provide preliminary evidence of local high-beta oscillation entrainment under rhythmic TMS delivered at this same frequency, as causally

related to conscious visual performance ameliorations, whereas, characterize random patterns as the injection of white noise with broadband oscillatory influences yielding no influences on visual perception.

Abstracts: A fundamental principle of vertebrate visual system relies on the functional separation of neuronal signaling into the ON and OFF pathways that generate visual contrast. These two pathways originate in depolarizing ON bipolar cells and hyperpolarizing OFF bipolar cells. Critical flicker frequency (CFF) is one of the useful ways to evaluate visual temporal resolution based on functional separation of ON and OFF visual pathways. CFF threshold is defined as the frequency at which a flickering light is indistinguishable from a steady one. CFF is also informative for clinical diagnostic criteria of retinal disease. Temporal vision is related to the ON and OFF pathways which are involved in parallel processing in the visual system. However, there is little understanding of the molecular mechanisms about temporal vision we perceive. Genetic manipulation of mouse model is an effective and widely used strategy for investigating how specific molecule influence physiological processes. Methods that analyze temporal vision of mouse model have provided fundamental information about molecular mechanism of human retinal function and visual perception. The aim of the present study was to establish a method to evaluate visual temporal perception of mice. C57BL/6 mice responded to two stimuli by making nose poke toward a light emitting diode (LED) screen that was equipped

with a touchscreen attachment for detecting responses. Illumination was provided by green (508 nm) LED. Mice were trained to distinguish stationary illumination (correct response) from flickering illumination (incorrect response). We continued to the task until mice could discriminate the differences between correct and incorrect choice. Once mice recognized stationary illumination as correct stimuli, we changed temporal frequency until mice could discriminate flickering stimulation as stationary stimulation, which defined as CFF. We established the method to evaluate visual temporal perception of mice to characterize critical temporal frequencies of ON and OFF pathway-mediated vision. This behavioral assay of mouse model could contribute to development of diagnosis of human retinal disease.

Title: Perceptual decision related activity in the ON and OFF pathways of the lateral geniculate nucleus (LGN)

Authors: *Y. JIANG[1], D. YAMPOLSKY[2], G. PURUSHOTHAMAN[2], V. CASAGRANDE[1,2,3]; [1]Psychology, [2]Cell and Developmental Biol., [3]Ophthalmology and Visual Sci., Vanderbilt Univ., Nashville, TN

Abstracts: Previous psychophysical evidence indicated a clear functional asymmetry between the perception of light (i.e. contrast increment) and dark (i.e. contrast decrement) (Blackwell 1946; Short 1966; Krauskopf 1980; Bowen et al. 1989, 1992; Chan and Tyler 1992; Kontsevich

and Tyler 1999; but see Komban et al. 2011). Physiological recordings in the early visual system also revealed various asymmetries between the ON and OFF pathways (for example see Chichilnisky and Kalmar 2002; Armstrong-Gold and Rieke 2003; Zaghloul et al. 2003; Jin et al. 2008, 2011; Yeh et al. 2009; Pandarinath et al. 2010; Xing et al. 2010; Kremkow et al. 2014). How do ON and OFF neurons contribute to the perception of light and dark? How can the physiological asymmetry of the ON/OFF pathways be linked to the psychophysical asymmetry of light and dark perception? To answer these questions, we recorded from LGN Parvocellular (P) ON-Center and OFF-Center neurons in awake monkeys while they passively viewed (i.e. simple fixation) and actively detected (i.e. two-alternative, forced-choice detection) contrast increment and decrement changes. We found that: 1) OFF neurons were more sensitive in detecting contrast decrements than ON neurons were in detecting contrast increments during both tasks, 2) OFF neurons had lower choice probabilities than ON neurons during detection, 3) Interneuronal correlations of ON-ON, ON-OFF, and OFF-OFF neural pairs were not significantly different from 0 during detection, but they were all significantly above 0 during fixation, 4) OFF neurons also differed from ON neurons in their spontaneous firing rate, peak response amplitude, and response transiency, and these differences were consistent across the detection and the fixation tasks, and finally 5) OFF neurons had lower Fano factors (variance/mean) than ON neurons during detection, whereas ON neurons had lower Fano factors than OFF neurons during fixation. Across ON and OFF cell classes, we observed a breakdown of the previously established correlation between the neurometric sensitivity of a neuron and its choice probability (Britten et al. 1996; Purushothaman and Bradley 2005; Gu et al. 2007; Price and Born 2010; Liu et al. 2013), as in our experiments the neurons that exhibited lower thresholds, higher firing rates, and overall more robust contrast responses (i.e. OFF neurons) were less correlated with the behavioral choice of the animal. A causal, bottom-up pooling model linking fluctuations in LGN ON and OFF neural responses to the monkey's choices in the absence of interneuronal correlations accounted for these results.

Title: Neurons that fire together select together: Reduced variability of visual search target selection times for simultaneously as compared to sequentially recorded neurons

Authors: *W. ZINKE, R. P. HEITZ, B. A. PURCELL, J. D. SCHALL;
Dept. of Psychology, Vanderbilt Univ., Nashville, TN

Abstracts: Previous research by our and other laboratories has described the neural process of saccade target selection during visual search in the frontal eye field (FEF), posterior parietal cortex, and superior colliculus. After an initial visual response, neurons distinguish whether the target or a distractor is in the receptive field at a time that can be determined statistically, referred to as the target selection time (TST). If this selection process is a result of local interactions between neurons, then a reasonable implication would be that the TST of neurons recorded simultaneously will differ less than the TST of neurons recorded sequentially (hence impossible to interact). Multiple neurons were recorded simultaneously from FEF in two macaque monkeys (Macaca radiata) that earned fluid rewards for shifting their gaze to the singleton target during visual search tasks. We compared the absolute differences of TSTs (dTST) for pairs of neurons recorded simultaneously with a null distribution of dTST for all pairs recorded sequentially. Less variability in dTST, as indicated by a reduced mean dTST, was observed among simultaneously recorded neurons (mean dTST: 38.3 ms) as compared to sequentially recorded neurons (mean dTST: 50.2 ms). This result adds to our previous findings of neural coordination of saccade target selection in the FEF circuit (Cohen et al. 2010 J Neurosci). The reduced variance of dTST for simultaneously recorded neurons implies that accumulator models that pool data from neurons across sessions (Purcell et al. 2010 Psych Rev; Purcell et al. 2012 J Neurosci) overestimate the variability of the input. Instead, a group of neurons participating in the decision process select the target in a much more synchronized manner. Further work is needed to understand how this coordination happens between brain regions that exhibit measurably different TST values within search conditions (Buschman & Miller 2007 Nature; Cohen et al. 2007 J Neurophysiol; Zhou & Desimone 2011 Neuron; Katsuki & Constantinidis 2012 Nature Neuro; Purcell et al. 2012 J Neurophysiol).

Title: Psychophysical measurement of visual behavior in the ferret

Authors: S. U. NUMMELA[1], J. LEDLEY[2], *K. J. NIELSEN[1];
[1]Neurosci., [2]Johns Hopkins Univ., Baltimore, MD

Abstracts: The domestic ferret (Mustela putorius furo) is one of the main animal models for research of brain development, in particular the development of visual cortex. Due to a short gestation period, much of neocortical development occurs postnatally, and is thus accessible to experimental investigation and manipulation. The functional properties of neurons in primary visual cortex of the adult ferret are well characterized, including detailed measurements of orientation, direction, and spatial frequency tuning. The developmental time courses of these tuning properties have also been described. However, despite our knowledge of these neuronal response properties, relatively little is known about the ferret's visual behavioral capabilities. We set out to systematically measure ferret visual capabilities by training 5 adult female ferrets on a variety of visual tasks, including the detection and discrimination of sine-wave gratings. All ferrets trained on two-alternative forced choice visual detection and discrimination tasks learned these tasks with an average performance of 90% correct on the easiest conditions. We used both tasks to measure contrast sensitivities over a range of spatial frequencies. Psychometric curves could reliably be determined for all ferrets. Our data show highest contrast sensitivities for spatial frequencies between 0.18 and 0.25 cycles per degree of visual arc (cpd). Contrast sensitivity rapidly declined for spatial frequencies larger than 0.7 cpd, with no ferrets capable of reaching discrimination thresholds at even the highest contrasts for stimuli with spatial frequencies larger than 1.4 cpd. These measurements match published data of spatial frequency tuning in the central visual field locations in ferret primary visual area 17. These data report optimal spatial frequencies up to 0.5 cpd, with a geometric mean of 0.25 cpd (Baker et al, Eur J Neurosci 10, 1998). Our results demonstrate the feasibility of visual psychophysical measurements in the ferret. They also provide a benchmark for comparison for visual studies of developing ferrets.

Title: Temporal evolution of information in neural networks with feedback

Authors: A. GIAHI SARAVANI[1,3], *X. S. PITKOW[2,3];
[2]Neurosci., [1]Baylor Col. of Med., Houston, TX; [3]Electrical and Computer Engin., Rice Univ., Houston, TX

Abstracts: Recurrent neural networks are pivotal for information processing in the brain. Here we analyze how the information content of a neural population is altered by dynamic feedback of a stimulus estimate decoded from the network activity. We quantify information using the Fisher information which is directly related to discriminability between stimuli. We find that the temporal evolution of the Fisher information in the model with feedback is bounded by the Fisher information in a network of pure integrators. The available information in the feedback model saturates with a time constant and to a final level both determined by the match between the estimator weights and the feedback weights. This network then encodes signals specifically from either the beginning or the end of the stimulus presentation, depending on this match. These results offer an interpretation of recent experimental measurements of psychophysical kernels. These kernels indicate that earlier stimuli have a stronger influence on perceptual discrimination than later stimuli. In the context of our model, that finding constrains the nature of the feedback signals that are capable of generating such an effect. We also discuss consequences of this network model for choice correlations, which measure how individual neuronal responses relate to perceptual estimates.

Title: Non-invasive measurement of population dynamics during computation of choice

Authors: *M. C. KLEIN-FLÜGGE[1], G. R. BARNES[1], M. W. WOOLRICH[2], T. E. J. BEHRENS[1];
[1]UCL, London, United Kingdom; [2]OHBA and FMRIB, Oxford Univ., Oxford, United Kingdom

Abstracts: One key advance in the way neuroscientists study neuronal computations was caused by a recent shift from studying individual neuronal responses towards studying neuronal population dynamics. Changes in firing rates of a neural population can be thought of as a trajectory through a high-dimensional state space, and this state space can often be reduced to a few meaningful dimensions that carry most of the variance for a particular task. For example, when monkeys are asked to decide about the motion direction or dominant colour of a noisy random-dot stimulus, the state space contains three orthogonal axes relating to the two inputs, colour and motion, and the choice (Mante et al., Nature, 2013). Movement along trajectories in state space can reveal the neural computations this population of neurons is performing. We developed a novel approach for similarly examining ongoing computations of neural populations using non-invasive neuroimaging in humans. The task was an adapted version of Mante et al., where decisions were made about the colour or motion of a random-dot stimulus. We used magnetoencephalography (MEG) which records the magnetic fields produced by the summed neural activity of large populations of neurons with a high temporal precision. Because these measurements do not allow us to identify the dimensions of the relevant subspace, we selectively manipulated the neural populations of interest using repetition suppression. Each random dot stimulus ('test stimulus') was preceded by another random dot stimulus ('adaptation stimulus'), which determined the population of neurons that would be 'primed' and thus the feature of the choice - colour, motion, or response - that was selectively suppressed in the neuronal population. By comparing situations where adaptation and test stimuli were the same versus different in either their inputs or their responses, we could then examine rapid transitions in neuronal representations during the decision computation. This revealed that responses in premotor cortex first suppressed to the relevant input and only later to the response. Plotting this input suppression directly against the response suppression revealed a 'suppression' trajectory that first deflected in the direction ('axis') of decision input and later response. This trajectory closely resembled the state-space population trajectories obtained from direct recordings in the frontal eye fields of monkeys performing the same task (Mante et al.). Thus, our combined repetition suppression and MEG approach allows a time-resolved study of the computations of populations of neurons using non-invasive measurements obtained in humans.

Title: Suppression of enhanced physiological tremor via stochastic noise: Initial observations

Authors: C. TRENADO[1], F. AMTAGE[1], F. HUETHE[1], J. SCHULTE-MÖNTING[2], I. MENDEZ-BALBUENA[3], M.-C. HEPP-REYMOND[5], *E. MANJARREZ[4], R. KRISTEVA[1]; [1]Dept. of Neurol., [2]Inst. for Med. Biometry and Med. Informatics, Univ. of Freiburg, Freiburg, Germany; [3]Facultad de Psicologia, [4]Inst. of Physiol., Benemerita Univ. Autonoma de Puebla, Puebla, Mexico; [5]Inst. of Neuroinformatics, Univ. of Zürich and ETH Zürich, Zürich, Switzerland

Abstracts: Enhanced physiological tremor is a disabling condition elicited by a central tremor generator in combination with a finger mechanical component of the spinal stretch reflex. Under the light of the hypothesis “boosting the strength of the peripheral input pushes the tremor-related spinal and cortical systems closer to anti-phase firing and hence reduces tremor (Baker, personal communication)”, the present study aims at investigating whether Gaussian stochastic noise enables reduction of enhanced physiological tremor accompanied with performance improvement during a visuomotor task. Specifically, eight subjects with enhanced physiological tremor performed a visuomotor task requiring to compensate isometrically with the right index finger a static force generated by a manipulandum on which Gaussian noise (3-35 Hz) was applied. The finger position was displayed on-line on a monitor as a small white dot which the subjects had to maintain in the center of a green circle defined as the reference. EMG from the active hand muscles and finger position were recorded. The performance was measured by the mean absolute deviation of the white dot from the zero position. The tremor was identified by the acceleration in the frequency range 7-12 Hz. Two different conditions were compared: with and without optimum noise. We found that application of optimum noise reduces tremor (accelerometric amplitude and EMG activity) and improved the behavioral performance as

reflected by the improved mean absolute deviation from zero, although no significant correlation between both variables was found. Thus, we provide the first evidence of a significant reduction of enhanced physiological tremor in the human sensorimotor system due to application of external stochastic noise.

Title: Relationship between neural latencies in area MT and behaviora latencies of smooth pursuit eye movements in monkeys

Authors: *J. LEE, J. YANG, S. G. LISBERGER;
Neurobio., Duke Med. Ctr., Durham, NC

Abstracts: Sensory motor reaction times of human and non-human primates depend on many factors, including internal factors such as arousal and attention and external factors such as the intensity of the sensory stimulus. In smooth pursuit eye movements, they tend to have longer latencies when the contrast of the visual target is low versus high. Our goal was to ask whether the effect of stimulus contrast on response latency depends on shifts in neural response latencies versus effects of contrast on response amplitudes. We have recorded the responses of MT neurons and smooth pursuit eye movements for moving targets with different forms and contrasts. We used three different forms of tracking targets: random dot patches, sine wave gratings, and bi-kinetic plaids, each at three levels of contrast (100, 36, and 12%). We used objective procedures to estimate the effect of stimulus form and contrast on neural and behavioral latencies, in independent sessions. For each neuron, we then plotted the latency of the neural response for each stimulus as a function of the latency of pursuit for the same stimulus

and performed regression analysis. For 31 MT neurons, the regression slopes ranged from -1 to 3 and formed a distribution that was centered at 0.92. On average, the behavioral latency for different stimulus forms and contrasts had almost a one-to-one relationship with the neural latency. We conclude that behavioral latency follows sensory neural latency loyally, at least for changes in the form and contrast of visual motion targets.

Title: Whole brain cellular resolution mapping of circuits underlying goal-directed behavior in zebrafish

Authors: *C. A. HARRIS, K. L. BRIGGMAN;
NIH, Bethesda, MD

Abstracts: Goal-directed behaviors such as predation depend on multiple interacting brain regions and involve several neural processes including perception, recognition, motivation, action selection and motor control. To better understand the neural basis of goal-directed behavior we are developing a set of techniques that integrate information about behavior, neural circuit dynamics and synaptic connectivity from a whole-brain preparation. We have developed a virtual reality assay to elicit prey-tracking behavior in larval zebrafish. We carefully restrained one week-old zebrafish by the neck in agarose, leaving the eyes and tail free to move. The semi-restrained fish were presented with a prey-like target moving on the left or right side of the visual field. Prey-tracking behavior in the form of target-directed tail movements and a characteristic pattern of sustained eye convergence was detected in real-time and used to update the movement of the virtual prey in a way that simulates approach. Using this closed-loop behavioral assay we were able to evoke sequences of up to five target-directed swims with sustained eye convergence. We are now beginning to monitor the brain during these episodes of predation by means of light-sheet microscopy in fish expressing calcium indicators in the brain. In preliminary experiments we have imaged the brains of agarose-embedded live fish at cellular resolution and

with a frame rate of about 1 Hz. Once we have gathered detailed information about the activity and location of neurons whose activity is associated with prey-tracking we will use electron microscopy (EM) to study the synaptic connectivity of those neurons. We are particularly interested to see how known features of the behavior, such as the fine tuning of motor output to target trajectory, is reflected in the underlying circuit structure. In combination with modern methods for EM serial sectioning and dense circuit reconstruction, this work will help answer fundamental questions about the neural circuit basis of goal-directed behavior in the vertebrate brain.

Title: Behavioral training for oculomotor tasks in head-free non-human primates

Authors: *J. WANG[1], S. W. EGGER[1], E. D. REMINGTON[1], M. JAZAYERI[1,2];
[1]McGovern Inst. for Brain Res., [2]Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstracts: The oculomotor system of the non-human primate (NHP) has advanced from a premier motor system to one of the most informative platforms for studying the neural correlates of cognitive and sensorimotor processing. In a typical experiment, an animal might be trained to respond through specific eye movements. Conventionally, to measure eye movements, the animal's head is fixed via a mechanical coupling between the chair and a headpost that is surgically attached to the skull. This procedure imposes several limitations. First, the post-surgical healing time required for the proper adherence of the headpost to the bone delays the start of training. Second, maintenance of the implant is time consuming for the experimenter. Third, the process of restraint can be stressful and may result in a negative association with the primate chair, which would further delay progress. Fourth, acclimatization of an untrained animal to head restraint could compromise the stability and reliability of the headpost. Here, we

report that NHPs can be straightforwardly trained to maintain approximate head position and perform sophisticated oculomotor tasks involving gaze control, smooth pursuit and targeted saccades without head fixation. Our approach is based on adapting a commercially available video eye tracker (Eyelink 1000, Desktop Mount, SR Research Ltd.), which is commonly used for monitoring eye movements in human psychophysics. Using simple forms of instrumental conditioning, we have successfully trained three head-free NHPs to perform multiple tasks that require eye fixation and targeted saccadic eye movements. Our analyses show that head-free NHPs can be trained to maintain fixation on a central spot within a 4-degree eye fixation window throughout several-second long trails, and that they can perform tasks that require the animal to make a saccade either reactively or proactively to visually or memory guided locations. We show that the accuracy and precision of head-free and head-fixed eye tracking is comparable and no additional training is required during the transfer from the head-free to the head-fixed system (for subsequent electrophysiology). This procedure expedites behavioral training, reduces post-surgery care, and facilitates the acclimation of headpost-mediated stabilization, which in turn increases stability and longevity of the headpost. This training method is advantageous both as an intermediate step to head fixation for traditional electrophysiology, and also for studies using tethered and wireless multi-electrode array systems. We aim to adapt this approach to train animals to perform sensorimotor tasks in their home cages.

Title: Action value modulates mirror neuron activity

Authors: *D. ARNSTEIN, J. K. POMPER, P. THIER;
Hertie Inst. For Clin. Brain Res., Tuebingen, Germany

Abstracts: Mirror neurons discharge while a monkey performs a goal-directed action and when the monkey observes another human or monkey performing a similar action. Since their discovery, mirror neurons have been suggested to play a role in social interactions; for instance, helping observers choose appropriate responses to others' actions. Supporting a role of mirror neurons in response selection, a recent study found that mirror neuron activity depends on the ability of the observer to interfere with the observed action (Caggiano et al., 2009, Science, Vol. 324). In order to select an appropriate response to someone else's action, it is necessary to consider its egocentric value; namely, whether it is god, bad, or neutral for the observer. Experiments have shown that mirror neuron activity is modulated by the size of the reward associated with the observed action (Caggiano et al., 2012, PNAS, Vol. 109). However, manipulating reward size not only modifies value but also attention and arousal. In order to disambiguate potential influences of value and attention, we performed experiments in which we associated observed actions not only with rewards (=positive value) but also with punishments (=negative value) of varying size because both large rewards and large punishments capture attention (Leathers & Olson, 2012, Science, Vol. 338). We recorded from mirror neurons in premotor area F5 of two monkeys while they observed filmed actions. After observing the action, the monkey received a large reward (~0.6 mL water), small reward (~0.2 mL water), small punishment (0.5 s unrewarded eccentric fixation), or large punishment (5 s unrewarded eccentric fixation). At the beginning of each trial, a visual cue indicated which outcome the monkey would receive after the action. Many mirror neurons responded to the action differently depending on which outcome was expected. To rule out that this modulation was driven by differences in attention or alertness, we compared the spike rate associated with small vs. large outcomes. The large rewards and punishments raised the monkey's heart rate in comparison to the small rewards and punishments, but this effect was not reflected in mirror neuron activity. On the contrary, mirror neuron spike rates were a monotonic function of action value. These results clearly suggest that mirror neurons encode the egocentric value of an observed action. Encoding of egocentric value may facilitate selecting an appropriate response to the action.

Abstracts: Anterior cingulate cortex (ACC) has long been implicated in processing cognitive conflicts. However, whether ACC primarily contributes to conflict detection, conflict resolution, error monitoring, learning or any combinations of the above, with or without the interaction from other brain areas, remains a topic of debate. We investigated the response properties of neurons in ACC, supplementary motor areas (SMA), amygdala with a speeded version of color/word Stroop task. While patients performed this task we simultaneously recorded single neurons in 11 epilepsy surgery candidates with implanted intracranial depth electrodes. Specifically, we investigated i) whether there is single-neuron signature of cognitive conflict during the stimulus-response interim period , and ii) whether ACC/amygdala neurons signals after or before the commission of errors. For incongruent trials, subjects responded slower (Stroop effect on average 87ms) and made more errors (26% and 5% of incongruent and incongruent trials, respectively). We identified a subset of neurons in ACC, SMA and amygdala that significantly changed firing rate after subjects made errors. In ACC, 21% (29/137) neurons signal errors with a significant rate increase. In amygdala 19% (23/122) neurons and in SMA 14.2% (6/42) neurons signaled errors with rate decrease. Responsive neurons were selected using a 1s window starting at button press with a bootstrap procedure and only sessions with 8 or more errors were considered. Notably, these neurons responded immediately after button press before feedback was provided. They thus represent an internally generated error signal. In contrast, out data seem to suggest an absence of conflict modulation at the single unit level due to cognitive conflict following stimulus onset. Our results support the theory of a tripartite error detection and correction system consisting of ACC SMA and amygdala.

Title: Behaviorally relevant efficient cortical coding of visual motion signals in the pursuit system of monkeys

Authors: *B. LIU[1], L. OSBORNE[2];
[1]Neurobio., [2]Neurobio. Dept., Univ. of Chicago, Chicago, IL

Abstracts: Performance in sensorimotor behaviors guides our understanding of many of the key computational functions of the brain: the representation of sensory information, the translation of sensory signals to commands for movement, and the production of behavior. Eye movement behaviors have become a valuable testing ground for theories of neural computation because the circuitry has been well characterized and eye movements can be tightly coupled to cortical activity. Here we show that pursuit eye movements, and the cortical sensory signals that mediate them, demonstrate the hallmarks of efficient coding. Barlow proposed that neurons should adapt their sensitivity as stimulus conditions change in order to maintain efficient representation of sensory inputs. Evidence for efficient coding of temporal fluctuations in visual contrast has been observed in the retina. We asked whether adaptation to stimulus variance generalizes to higher cortical areas whose neurons respond to features of visual signals that do not drive adaptation in the periphery and whether such adaptation impacts performance of visually-driven behavior. Specifically, we studied the impact of cortical adaptation to fluctuations in motion direction on pursuit. We recorded eye movements of monkeys pursuing moving targets with an added stochastic perturbation. Using the same perturbation stimuli, we also recorded the responses of neurons in the middle temporal cortical area that provides visual motion inputs for pursuit. We find that both neural and behavioral gain -- the relationship between firing rate or eye movement and target movement -- rescales in inverse proportion to the standard deviation in target direction fluctuations, consistent with the efficient coding hypothesis. Step changes in target motion variance created a transient decrease in the information capacity of pursuit and in MT. Rescaling of the stimulus-response distributions can be detected as early as 20ms after a change in motion variance, but the detection of a step on single trials takes substantially longer. Furthermore, these

gain changes cannot be accounted for by saturation - they occur when the highest observed firing rate is below the peak firing rate of the neuron (or eye velocity), however this work does not identify a mechanism. These data suggest that feature selective cortical areas are themselves capable of efficient sensory coding and that efficiencies in cortical coding can be relevant to behavioral performance.

Title: Neurons in the primate central thalamus predicting the timing of periodic stimulus

Authors: ***K. MATSUYAMA**, M. TANAKA;
Dept. of Physiol., Hokkaido University, Sch. of Med., Sapporo, Japan

Abstracts: We recently found that neurons in the cerebellar dentate nucleus carry temporally-specific signals when monkeys predicted the timing of periodic stimulus (J Neurosci 33: 15432, 2013). To understand how these signals are processed further in the downstream thalamocortical pathways, we examined neuronal activity in the anterior intralaminar and paralaminar nuclei of the thalamus. In the missing oddball task, a brief (35 ms) audiovisual stimulus was presented repeatedly at a fixed interstimulus interval (ISI, 100-600 ms). Monkeys were trained to make an immediate saccade to a visible target when one stimulus in series was omitted, so that they predicted next stimulus timing throughout the trial. So far, we have recorded from 53 task-related thalamic neurons which were classified into 3 groups; 1) Entrainment-type neurons (38%) exhibited a gradual elevation of inhibitory response to each stimulus as the repetition progressed, similarly to neurons in the cerebellum. 2) Sensory-type neurons (28%) regularly responded to each stimulus but reduced the response gain for the repeated stimuli. 3) Switch-type neurons (34%) initially showed excitatory response to each stimulus, but in trials with long ISIs, the direction of firing modulation gradually reversed, resulting in a shift of the timing of peak activity that eventually synchronized with the stimulus onset. To examine the properties of these signals, two additional trials were presented. Firstly, in the non-target trials, the saccade target

never appeared and the animals maintained fixation throughout the trial so that they did not need to predict the timing of each stimulus. Like neurons in the cerebellum, both the Entrainment-type and Switch-type neurons decreased the firing modulation in the non-target trials compared to the missing oddball trials. For the Switch-type neurons, the response reversal and synchronization of peak activity to stimulus onset disappeared in the non-target trials. Secondly, to distinguish these signals from motor preparation, we devised the explicit deviant oddball trial, in which monkeys were required to detect the deviation in color and pitch of the repetitive audiovisual stimuli. In this trial, color of the fixation point differed from the other tasks in order to inform monkeys of the trial type. The firing modulation was reduced in the deviant oddball trials compared to the missing oddball trials while both tasks required saccades. These results suggest that neurons in the central thalamus might integrate signals from sensory areas and the cerebellum, thereby generating a predictive code for the next stimulus timing that can be separated from motor preparation.

Title: Alpha neural activity in the somatosensory and visual cortices when drawing under conflicting proprioceptive and visual inputs

Authors: *N. LEBAR, J. DANNA, S. MORE, L. MOUCHNINO, J. BLOUIN;
LNC, Marseille, France

Abstracts: There is increasing evidence that the brain can dynamically change the weight of sensory inputs as a function of their relevance during the planning and control of movements. For instance, EEG event related desynchronisation (ERD) around 10Hz in the somatosensory and visual areas have been linked to the use of proprioceptive and visual feedback during movement planning and execution, as well as during motor imagery. The literature suggests that *in situ*ation where vision and somatosensory information is incongruent (mirror task), somatosensory input becomes a misleading information, degrading movement accuracy. Experimental evidence argues that in such a case, inhibiting somatosensory input could be a way for the brain to overcome the discrepancy. Here we examined neural activities (time-frequency

domain of EEG recordings) in the somatosensory and visual regions in tasks with and without visuo-somatosensory incongruency. To do so, participants (n=12) had to control a cursor on a horizontal screen with a digital pen, while their controlling hand was visually hidden. After a resting period (baseline), they had to follow accurately the outline of irregular shapes with a congruent relation between the cursor and the pen movements. After a variable period of time (between 8 and 12s), participants were submitted to either a strong (120°), weak (13°, not perceived) or absent (0°) incongruence between the cursor and the pen movements. Free non-visually guided hand movements (cursor feedback only) were also executed as control trials. We assessed drawing accuracy and performed EEG time-frequency decomposition of each condition compared to baseline. We found that participants' performance was markedly impaired in strong incongruent condition, and with no impairment in trials with the weak or absent incongruence. EEG preliminary analyses showed the known 10Hz ERD linked to movement initiation in somatosensory areas, as well as in occipital areas. However, we found a supplementary 10Hz ERD in strong incongruent condition, over both the somatosensory and occipital areas. We interpret these results in term of task-relevant weighting sensory inputs.

Title: How specific is non-specificity? Early motor facilitation during action observation is specific to the viewed effector

Authors: ***K. R. NAISH**, S. S. OBHI;
Dept. of Psychology, Wilfrid Laurier Univ., Waterloo, ON, Canada

Abstracts: It is well established that activity in the human motor system is modulated by action observation; however, the level of muscle-specificity of these motor responses is unclear. Recently, Cavallo et al. (2013) found evidence of an early non-specific facilitation of motor excitability, followed by facilitation that was specific to the muscle involved in the action.

Specifically, motor-evoked potentials (MEPs) were facilitated similarly in two hand muscles (first dorsal interroseous, FDI; abductor digiti minimi, ADM) at an early phase of index finger observation, while only the FDI (involved in the movement) was modulated after 200ms. The current study sought to determine how 'non-specific' this initial modulation is, by investigating MEP modulation in a forearm muscle (the flexor digitorum superficialis, FDS), in addition to two hand muscles (FDI, ADM). MEPs were elicited in these three muscles as healthy adult participants watched index finger and little finger abductions. The timing of effects was tracked by eliciting MEPs at five time points (100, 150, 200, 250, 300ms). During index finger observation, MEPs were facilitated (relative to static hand viewing) in both the ADM and FDI at 150ms. Muscle-specific modulation - facilitation of the FDI only - was demonstrated at 300ms. Little finger observation evoked a similar pattern of modulation: facilitation in the ADM and FDI at 150ms, and facilitation of the ADM only (i.e., muscle-specific) at 300ms. This pattern of modulation found in the hand muscles is consistent with previous findings in terms of the early non-specific and later muscle-specific modulation, although it is not clear why MEPs were not modulated at 100ms. Interestingly, data from the forearm (FDS) showed facilitation of MEPs at one time point - 200ms - during observation of both index and little finger abductions. Although the FDS is not involved in either movement, it does control finger flexion. Therefore, one possible explanation of this facilitation is that this muscle is activated in order to maintain the posture of the hand when the index or little finger moves. In addition, MEP modulation was found to be smaller overall than modulation in either the ADM or FDI, showing that activity in this muscle was influenced to a much lesser extent during finger movement observation. Importantly, our data indicate that non-specific facilitation occurring pre-200ms is specific to the effector being viewed, rather than being a more general motor priming. Such an effector-specific response might be analogous to the 'broadly-congruent' mirror responses recorded in monkeys, and their significance for behaviour should not be dismissed.

Title: The role of pretectal microcircuitry in the control of visual motor responses

Authors: *L. CAPANTINI, A. KARDAMAKIS, B. ROBERTSON, S. GRILLNER; Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstracts: A behaviourally relevant motor action has to be spatially oriented and directed toward or away from a target, such as a prey or an obstacle. During a goal-directed behaviour, visual stimuli are responsible for driving the movements and the visuo-motor coordination is essential to guarantee the success of the action. The pretectum mediates short latency motor responses, such as escape reactions and visual reflexive behaviour (Ullén et al., 1993, 1997). The knowledge of the pretectum in lamprey, as well as in other vertebrates, is however still limited. The present study aims to investigate the role of the pretectal microciruitry in visual motor responses, using the lamprey, one of the first vertebrates to emerge, as experimental model. Anatomical tracing and immunohistochemistry defined the pretectal connectivity. Afferents from the retina and optic tectum, the superior colliculus in mammals, represent the two main excitatory inputs. An additional sensory input derives from the lateral line (electro- and mechanoreception) via the octavolateral area. Projections from the lateral pallium, the homologue of cortex, indicate that pretectum may be involved in motor control, as electrical stimulation of lateral pallium elicits eye, orienting, and body movements (Suryanarayana et al., SfN Abstract 2014). The dorsal pallidum, the basal ganglia output layer, instead provides a tonic inhibition. The main pretectal outputs are direct projections to reticulospinal neurons and the optic tectum. In particular, a subpopulation of pretecto-reticular cells have large somata and a dendritic arbour that extends into the optic tract, indicating that these cells receive direct retinal input and could thus play a role in the fast motor response. Patch clamp recordings were performed to examine the basic electrophysiological characteristics and synaptic interactions of pretectal cells. Analysis of membrane and firing properties revealed different subpopulations of neurons. Electrical stimulation of the posterior commissure gave a robust inhibition in a subpopulation of pretectal cells. This inhibition most likely derives from contralateral GABAergic neurons as combined tracing and GABA-immunohistochemistry showed that GABAergic pretectal cells cross in the commissure. We believe in the critical role of pretectum in the visuo-motor coordination, and the present findings confirm the assumptions and shed light on the role of pretectum.

Title: Activating medullary neurons through optogenetics in the locust optic lobe

Authors: *H. WANG[1], R. B. DEWELL[1], M. U. EHRENGRUBER[2], F. GABBIANI[1,3]; [1]Neurosci., Baylor Col. of Med., Houston, TX; [2]Biol., Kantonsschule Hohe Promenade, Zurich, Switzerland; [3]Computat. and applied mathematics, Rice Univ., Houston, TX

Abstracts: Locusts are widely used as a neuroethological model for *in vivo* electrophysiological recordings. Previously, we had successfully expressed Channelrhodopsin (ChR) -Venus in neurons of the locust optic lobe by injection of a temperature-sensitive Semliki Forest virus variant [SFV(A774nsp)-ChR-Venus]. The Lobula Giant Movement Detector (LGMD) is an identified, looming-sensitive neuron in the lobula of the locust optic lobe, processing and relaying information on the impending collision of approaching objects to a postsynaptic neuron, the Descending Contralateral Movement Detector (DCMD). Our previous two-photon imaging demonstrated that ChR-Venus labeled medullary (MED) neuronal terminals overlapped with the dendritic arbor of the LGMD labeled with Alexa 594. These medullary neurons are thought to be presynaptic to the LGMD. However, up to now, there is no direct electrophysiological evidence. Using paired-tungsten metal electrodes, we extracellularly recorded the spontaneous spiking and ChR-mediated spiking of medullary neurons in response to 488 nm laser illumination. In contrast to spontaneous spiking, laser illumination increased the firing rate of MED neurons. Correspondingly, intracellular recordings from the postsynaptic LGMD exhibited constant spiking due to the firing of MED neurons. Spike sorting of the laser-evoked MED neuronal spiking and comparison with the spiking of the LGMD allowed us to analyze the correlation between the activity of MED neurons and the LGMD. These data suggest that SFV-based ChR-optogenetics is effective in activating the LGMD through the firing of the MED neurons, which may help identify the local neural circuitry involved in the processing of looming stimuli and understand neuronal information processing in the locust optic lobe.

Title: Development of functional connections between the superficial and intermediate layers of the rodent superior colliculus revealed by optical imaging

Authors: *M. NANA[1], R. P. HASEGAWA[2,1], K. MURASE[1], H. IKEDA[1];
[1]Grad. Sch. of Engin., Univ. of Fukui, Fukui City, Japan; [2]Natl. Inst. of Advanced Industrial Sci. and Technol. (AIST), Tsukuba, Japan

Abstracts: The mammalian superior colliculus (SC) is important for visual orientation behaviors. The SC includes two layers; the superficial layer (SGS) receives visual inputs and the intermediate layer (SGI) sends motor outputs, both of which have mutual connections. Although it is generally understood that the pathway from the SGS to SGI is involved in visuomotor transformation, there are little evidence in support of the role of this pathway. Recently interlaminar excitation was reported in the pathway from SGS to SGI as well as that form SGI to SGS using optical imaging. It is, however, still unclear how these pathways develop. We focused on the development of the functional properties of the mutual connections between SGS and SGI in mice. In this study, we examined excitability of the pathways in the SC slices by the optical imaging at two different developmental stages: “infant” (7-9 days old) and “young” (25-35 days old). We applied single-pulse electrical stimulation (500μA) to either the SGS or SGI, and observed whether the evoked response was propagated. In infant mice, whose eyes had not opened yet, the stimulation in the SGS or SGI elicited the near-by response. The response, however, remained within the stimulated layer and was not propagated to the other layers. In young mice, whose eyes have already opened, we observed the propagation by single-pulse stimulation to SGI. The SGI stimulation initially evoked the response within the SGI, and then the response tended to be propagated to the SGS. The peak response in the SGI was not changed by non-NMDA-glutamate receptor antagonist CNQX, but the peak in the SGS was almost completely abolished by CNQX, indicating that the propagation from SGI to SGS was not the artifact caused by antidromic excitation of the pathway from SGS to SGI. On the other hand, by SGS stimulation, the optical response was evoked only within the SGS, but was not propagated to the SGI although the level of the near-by SGS response was stronger than that of the near-by SGI response. These results suggest that the mutual connections between the SGS and SGI in the

SC might develop in an asymmetric fashion. It is thought that not only the pathway from SGI to SGS but also the pathway from SGS to SGI physically exists and could be activated in a similar fashion. It was, however, difficult to evoke it even with the stimulation, which elicited the response at the near-by SGS site as well as the propagation from SGI to SGS. It is possible that the excitatory pathway from SGS to SGI is normally suppressed probably because the SC can control generation of too much reflexive action, giving chance of involvement of higher cognitive areas in visual orientation behaviors.

Title: Unilateral strength training while mirror viewing the exercising hand, augments cross-education and reduces cortical inhibition and corticospinal excitability

Authors: ***T. ZULT**[1], S. GOODALL[2], K. THOMAS[2], T. HORTOBÁGYI[1], G. HOWATSON[2]; [1]Ctr. for Human Movement Sci., Univ. of Groningen, Groningen, Netherlands; [2]Dept. of Sport, Exercise and Rehabil., Northumbria Univ., Newcastle-upon-Tyne, United Kingdom

Abstracts: Introduction: Unilateral strength training not only strengthens muscles of the trained side, but also the contralateral homologous muscles of the non-trained side. This phenomenon (cross-education) is a promising therapeutic strategy to strengthen muscles of the affected side by training the non-affected side for patients who suffer from unilateral orthopaedic and neurological conditions. The magnitude of cross-education is modest; however it has been hypothesized that heightened sensory feedback by viewing the exercising hand in a mirror could augment cross-education by modulating intracortical, intercortical and corticospinal pathways. Consequently, we examined the hypothesis that mirror training augments the cross-education of strength by modifying motor cortical excitability and short interval intracortical inhibition (SICI) of the primary motor cortex (M1) and interhemispheric inhibition (IHI) from the left to right M1. **Methods:** Healthy, young right-handed adults, were allocated to a mirror ($N = 11$) and no-mirror training group ($N = 12$) and performed 640 shortening muscle contractions of the right wrist flexors at 80% maximal voluntary contraction (MVC) during 15 sessions over three weeks. **Results:** MVC of the trained wrist flexors improved similarly in the mirror group (75 ± 39%)

and no-mirror group (76 ± 39%; $P = 0.961$). MVC of the non-trained wrist flexors increased more in the mirror (62 ± 36%) than no-mirror training group (42 ± 33%; $P = 0.044$). The augmented strength transfer of the mirror training group was accompanied by a decrease in corticospinal excitability (19%) and SICI (9%) of the left ("trained") M1, while the no-mirror training group increased corticospinal excitability (38%) and SICI (15%) (interaction, $P \leq 0.047$). Corticospinal excitability and SICI of the right ("non-trained") M1 and IHI from left to right M1 were not different between groups ($P \geq 0.093$). **Discussion:** Augmented sensory feedback by viewing the exercising hand in the mirror augments the cross-education of strength by modulating corticospinal excitability and SICI of the trained M1. Remarkably, corticospinal excitability and SICI of the non-trained M1 and IHI from trained to non-trained M1 did not show between group differences. Previous studies showed that these pathways play a key role in evoking cross-education of strength but we found that these pathways are not additionally modified when unilateral strength training is performed with a mirror. Regardless of the underlying mechanisms, this study demonstrates that mirror-aided unilateral strength training could be an adjuvant tool for accelerating functional recovery from unilateral impairment.

Title: Two-photon imaging of lateral interaction in the superficial layer of the superior colliculus

Authors: ***M. KASAI**[1], T. ISA[1,2];
[1]Natl. Inst. For Physiological Sci., Okazaki, Aichi, Japan; [2]Life Sci., The Graduated Univ. for Advanced Studies (SOKENDAI), Hayama, Japan

Abstracts: The superior colliculus (SC) is a brainstem center which plays a key role in sensory-motor translation and attention. The superficial layer of the SC (sSC) is directly innervated by the optic tract and visual space is represented in the retinotopic coordinates. In the early stage of visual processing, firing activity of neuronal population in response to the stimuli presented in

their response field is often inhibited by stimuli presented outside of their receptive field. This effect is known as “lateral inhibition” or “surround suppression”. To date, neural implementation of the “lateral inhibition” remains unclear, especially at the neuronal population level. In this study, we applied *in vivo* two-photon calcium imaging to reveal visually evoked neuronal population activities. We tested two-point stimulus, in which spatially separated two stimuli were presented simultaneously. When the two stimuli were close as respective excitatory response fields were overlapped, neuronal responses were increased. On the other hand, when the two stimuli were presented with larger separation, resulted neuronal responses were significantly decreased. These results indicated there was inhibitory interconnection from the outside of their excitatory response filed. More than half of neurons in the sSC are GABAergic inhibitory neurons and it has been debated whether horizontal inhibitory connection is responsible for such lateral inhibition. To understand the relationship between the inhibitory interconnection and underlying neural circuits, we used GAD67-GFP knock-in mice, in which GABAergic neurons are specifically labelled with GFP and examined differences between stimulus size tuning properties, another form of lateral inhibition, of the excitatory and inhibitory neurons. We found both non-GABAergic and GABAergic neurons showed similar center-suppression profiles when a large stimulus was presented. These results suggested that long-range GABAergic neurons mediate the lateral inhibition in the sSC.

Title: Distinct roles for alpha- and beta-band oscillations during construction of goal-directed action plans

Authors: ***L. BRINKMAN**[1], F. P. DE LANGE[1], A. STOLK[1], H. C. DIJKERMAN[2], F. S. S. LEIJTEN[3], I. TONI[1];
[1]Radboud Univ. Nijmegen, Donders Inst. For Brain, Cognition & Behaviour, Nijmegen, Netherlands; [2]Helmholz Inst., Utrecht Univ., Utrecht, Netherlands; [3]Rudolf Magnus Inst. for Neurosci., Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

Abstracts: Action plans can be regarded as simulations of movements which are used to issue motor commands to the muscles and predict the sensory consequences of our actions. In order to construct an action plan, specific neuronal populations controlling particular features of that movement need to be selected, while other neuronal populations need to be suppressed. Neuronal oscillations in the alpha (8 - 12 Hz) and beta (15 - 25 Hz) band frequency range provide a possible mechanism for implementing these processes of activation and suppression in the sensorimotor system. However, their relevance and specificity for selecting neuronal ensembles remain unclear. Here we use magnetoencephalography (MEG, n = 24) and electrocorticography (ECoG, n = 9) to investigate the relative contribution of these rhythms to the construction of action plans. Changes in oscillatory power were measured while participants imagined grasping a cylinder whose orientation changed from trial to trial. This paradigm allowed us to study the neuronal processes that underlie the construction of an action plan in the absence of signals related to motor execution and sensory reafference. Given human biomechanical constraints, some object orientations evoke consistent over-hand or under-hand grasping movements, whereas other orientations are compatible with both movements. These task features allowed us to experimentally manipulate movement selection demands and to behaviourally validate motor imagery performance. Source-reconstructed MEG data revealed a dissociation between the alpha and beta band activity evoked during the imagery process. Alpha-band oscillatory power increased in the ipsilateral sensorimotor cortex, whereas beta-band power concurrently decreased in the contralateral sensorimotor cortex. These findings emerged both when movement selection demands were modulated within the imagery condition and when imagery trials were compared to trials of a control condition. These observations indicate that neural oscillations in the alpha-band mediate the allocation of computational resources, disengaging task-irrelevant cortical regions. In contrast, a reduction of neural oscillations in the beta-band may be directly related to the computations of movement parameters. We are currently analyzing ECoG data of patients implanted with subdural electrodes performing the same motor imagery task, to validate and spatially define these observations.

Title: Sensory gating by the delta phase determines network and behavioral response to weak visual input in freely behaving ferrets

Authors: *F. FROHLICH, J. LU, K. K. SELLERS, C. YU, S. L. SCHMIDT;
Psychiatry, Univ. of North Carolina, Chapel Hill, NC

Abstracts: Brain networks identify and selectively process behaviorally relevant sensory input. Oscillatory activity in neuronal networks has been implicated as a mechanism for such information selection and routing. In particular, both the power and the phase of alpha oscillations (8-12 Hz) modulate perceptual responses in trained cognitive tasks that require attention [e.g. 1]. Yet, it has remained unknown how neuronal networks process and filter sensory input during untrained, naturalistic behavior. We hypothesized that the phase of ongoing cortical oscillations in primary visual cortex (V1) gates neuronal and behavioral responses to weak visual stimuli that lack behavioral consequences. To test this hypothesis, we performed wireless electrophysiological recordings of multiunit activity (MUA) and local field potential (LFP) in V1 of freely behaving ferrets. The animals were acclimated to a large recording arena that included species-appropriate toys. Behavioral monitoring by infrared videography revealed a broad set of behavioral states, including play, exploration, rest, and sleep. At random intervals, we presented brief (200 ms), dim (1-3 lumen) house-light flashes and investigated MUA, LFP, and behavioral responses. We found that during naturalistic behavior, V1 represents weak, neutral sensory input with substantial trial-to-trial variability that was explained by the instantaneous phase of the delta oscillation (< 4 Hz). Synergistic interaction between MUA and LFP network dynamics mediated this gating mechanism. We found subtle changes in the behavior of the animal in response to the stimuli as measured by the velocity of the animal. Stronger representation of the stimulus in V1 was associated with more pronounced acceleration of the animal in response to the stimulus. However, acceleration of the animal was not associated with an increase in MUA representation of the stimulus. Therefore, these data suggest that the strength of representation in V1 guided overall behavioral response. In turn, the amplitude of the MUA response was shaped by the phase of the delta oscillation in the awake, behaving animal. Such a role of the delta oscillation as the key mediator of sensory gating and information routing in V1 suggests a new mechanistic role of the delta oscillation in the awake behaving animal and highlights the benefits of studying the brain-behavior relationship in the context of naturalistic

behaviors. 1. Palva, S., and Palva, J.M. (2007). New vistas for alpha-frequency band oscillations. Trends in neurosciences 30, 150-158.

Title: Tackling the sensitivity of FEFsem neurons during smooth pursuit: Microstimulation of the superior colliculus and multiple linear regression

Authors: *L. R. BAKST[1], J. FLEURIET[2], S. ONO[2], M. J. MUSTARI[2];
[1]Neurobio. and Behavior, [2]Ophthalmology, Univ. of Washington, Seattle, WA

Abstracts: Accurate smooth pursuit (SP) requires the integration of retinal and extra-retinal signals to keep the fovea on a moving target. Identifying the weight of these signals during SP through visuomotor pathways is crucial to understanding the sensorimotor transformation. Here, saccades evoked by electrical microstimulation (MS) of the deep superior colliculus (SC) are used to perturb the trajectories of eye movements during a step-ramp paradigm. This technique separates the influence of eye velocity and position by causing an offset in position while eye velocity is maintained. Recently, we showed that perturbing SP reveals two types of responses in the smooth eye movement subregion of the frontal eye field (FEFsem) (Fleuriet et al. 2013). After perturbation, some FEFsem neurons show no change in their firing rate (FR) compared to control, as long as SP eye velocity is maintained. Other neurons exhibit a decrease in FR even with maintained eye velocity, presumably due to the position offset. We recorded from 10 FEFsem neurons in 1 monkey while MS (20-40 μA, 30-50 ms, 400 Hz) was applied to the SC 100-500ms after the step. Neuronal response was measured in the 100 ms following the evoked saccade. We estimated the contribution of visual motion and eye motion to the neuronal response

using multiple linear regression modeling. Neuronal latency was estimated, and neuronal dependence on visual input was tested by extinguishing the target for 150 ms, 100-500 ms after the target step. Of 10 neurons, 5 show a decrease of 10-72% in FR after perturbation compared to control trials. Qualitative analysis shows some neurons with a decreased FR after perturbation resume their response when the eyes return to the target and active tracking continues. Multiple linear regression modeling revealed 4 neurons whose FR variance was best explained by eye velocity, 1 by eye acceleration, 1 by retinal position error, and 4 by retinal velocity error. Neuronal latencies for FEFsem neurons ranged from 64-184 ms after target step. FEFsem neurons that showed a decreased FR after perturbation did not differ from the general population as defined by multiple linear regression modeling or neuronal latency. Also, the decrease in FR after perturbation was not due to visual signals, as the neurons with the largest decreases showed only a small decrease due to the target blink (FR was 75- 120% of control trials). There is also a trend suggesting those neurons that show no decrease after perturbation are more caudal in the FEFsem. These preliminary results suggest there may be a subpopulation of FEFsem neurons whose activity is dependent on accurate SP: eye velocity must be maintained and retinal error must be minimal.

Title: Decomposition of visual vs. auditory representations of gaze target location into 3-D eye and head movement commands: A neural network study

Authors: *M. DAEMI[1], D. CRAWFORD[2,3];
[1]Ctr. For Vision Res., Toronto, ON, Canada; [2]Biol., York Univ., Toronto, ON, Canada; [3]Ctr. for Vision Res., Toronto, ON, Canada

Abstracts: Coordinated gaze shifts can be aimed at both visual and auditory targets (Frens and Van Opstal, 1998). Visual and auditory responses in the gaze control system show different frames of reference (Maier and Groh, 2009), but there is no clear theoretical framework for

understanding how these signals are differentially transformed and decomposed into separate 3-D eye and head commands. To investigate this question, we have designed three feedforward neural networks and trained them by kinematically correct and physiologically inspired computational algorithms. All the networks have the initial eye-in-head and head-on-shoulder 3-D orientation signals as the input and the desired eye-in-head and head-on-shoulder 3-D displacement signals as the output. Orientation and movement signals of eye and head are represented in hybrid canal/Listing's coordinates and hybrid canal/Fick coordinates respectively. The difference between the networks is in their driving input signals. The first network has the retinal error, retinotopically encoded 2-D position of the target relative to the eye, as the input. The second network has the so-called cranial error, 2-D position of the target relative to head encoded in a manner similar to auditory representation of space in SC (or bird's optic tectum), as the input. The third network has access to both of the retinal error and cranial error although with potentially different reliabilities. We trained all the networks by a resilient backpropagation algorithm. After training, all networks produced the right, biologically comparable, behavior at the output, including eye-head coordination rules, head-free version of Listing's law, and Fick constraint for head. A preliminary analysis of the activities of the units in the hidden layer of the networks shows highly nonlinear receptive fields. Hidden layer receptive fields are all eye-centered in the first network and are all head-centered in the second network. Gain field modulation of these response fields by the initial gaze orientation have been observed for first and second networks. Our further aims are to 1) analyze the 3rd version of the network as a model of sensory integration, 2) work out the details of the eye-head decomposition process in these networks, and 3) compare our results with single unit recordings from SC and FEF collected in our lab. Title: Sensory recalibration in the ventriloquism aftereffect integrates local and global stimulus history

Authors: *P. BRUNS, B. RÖDER;
Biol. Psychology and Neuropsychology, Univ. of Hamburg, Hamburg, Germany

Abstracts: Vision usually provides the most accurate and reliable information about the location of objects in our environment, and thus serves as a reference for recalibrating auditory spatial maps. This can be exemplified by exposing participants to consistently misaligned audiovisual stimuli for several minutes. After such an adaptation phase, a shift in unimodal sound localization is observed that corrects for the cross-modal spatial mismatch. This so-called ventriloquism aftereffect has been associated with changes in spatial representations early in the auditory cortical processing stream. In line with an involvement of early, tonotopically organized regions of auditory cortex, some studies reported that the ventriloquism aftereffect did not occur when the sound frequency of the auditory stimuli used during adaptation differed from the sound frequency of the test stimuli. The initiation of auditory space recalibration does, however, not necessarily require accumulated evidence of cross-modal mismatch to be triggered, but occurs immediately after a single exposure to discrepant audiovisual input. By measuring the ventriloquism aftereffect on a trial-by-trial basis, we show that such an immediate recalibration is mediated by different mechanisms than recalibration to sustained cross-modal discrepancy. Participants performed a sound localization task in which they indicated the perceived location of 750 Hz and 3000 Hz tones that were presented from six different locations spanning ±22.5°. The tones were either presented alone, or together with synchronous visual stimuli displaced 13.5° to the left or to the right. Importantly, the two different sound frequencies were paired with opposite directions of audiovisual spatial mismatch: For half of the participants, the 750 Hz tone was always presented with visual stimuli to the left and the 3000 Hz tone with visual stimuli to the right, and vice versa for the other half of the participants. In accordance with this global stimulus history, localization in unimodal auditory trials was shifted in opposite directions for the two sound frequencies. This frequency-specific recalibration was, however, modulated depending on whether the directly preceding audiovisual trial featured the same sound frequency (and thus direction of spatial mismatch) or not. Thus, the local stimulus history led to an immediate recalibration of sound localization in a frequency-unspecific manner, in addition to the frequency-specific adaptation to the global stimulus history. This finding suggests that separate recalibration mechanisms operating at different timescales jointly determine sound localization behavior.

Title: Use of multisensory information by flying bats

Authors: *A. KRISHNAN, W.-J. LEE, C. F. MOSS;
Univ. of Maryland, College Park, MD

Abstracts: Animals gather sensory information about their environment in support of diverse behavioral tasks such as navigation, foraging, and mating. Integrating information from multiple sensory modalities can facilitate the performance of these behavioral tasks by improving the detectability of a stimulus. Flying bats emit ultrasonic echolocation calls, and use spatial information obtained from echoes in order to navigate. When approaching a target, they adaptively alter the temporal, spectral, and directional parameters of their echolocation calls to enable accurate target localization. The use of visual cues by flying bats has received relatively little attention, although vision may serve as a relatively long-range orientation cue guiding navigation. This study is aimed at understanding the influence of visual cues on flight and echolocation parameters. We obtained high-speed video and audio recordings of different species of bats as they flew to a hanging food source, both in darkness (where they relied largely on acoustic cues) and in lit conditions (where multisensory information was available). Preliminary analyses indicate differences in flight and adaptive vocal parameters between lit and dark conditions. This suggests that flying bats are capable of utilizing available visual information to guide their flight.

Title: Characterization of parietal spike train spectra during multimodal limb position estimation

Authors: *P. VANGILDER, JR, Y. SHI, G. APKER, C. A. BUNEO;
SBHSE, Arizona State Univ., Tempe, AZ

Abstracts: Limb position sense is crucial for the maintenance of body schema and for performing volitional movements. Visual and somatic information, such as efference copy and proprioception, are the primary cues for computing limb position estimates. In order to improve neural prosthetic design, as well as fully understand the sensory basis of limb movement, it is imperative that we understand how visual and somatosensory information interact in multimodal regions of the brain. The posterior parietal cortex has been implicated as a possible location for multisensory integration and for limb position sense. As a result we recently examined the integration of visual and proprioceptive information in area 5 as monkeys reached to and actively maintained their limb positions at multiple frontal plane locations presented in a virtual reality environment. Positions were maintained with vision (V condition) or without vision (NV condition) of the arm. A 2-factor ANOVA ($P<0.05$) identified populations of neurons that were modulated by limb position, limb vision, and/or the interaction of these factors. Both the firing rate and neural variability, the latter measured by the Fano Factor and coefficient of variation, were found to be reduced in the V condition. These changes indicated the presence of both trial-by-trial and intra-trial spiking variability. To determine whether reductions in intra-trial variability were associated with greater temporal structure of the spike trains in the V condition, rate-normalized spike train spectra were computed for each neuron in both the vision and non-vision conditions, as well as for each population of neurons. We found there to be significant differences in the gamma band power (25-100 Hz) between the V and NV conditions in all three subpopulations as well as the in the overall cell population. However, these differences in spectral power did not appear to arise from a marked increase in temporal structure of the spike trains in the presence of vision. Thus, reductions in spiking variability in area 5 appear to arise from a mechanism other than enhanced temporal structure. Future analyses will be directed at exploring alternative mechanisms that may underlie this phenomenon.

Title: Alpha activity indexes task-related neuronal populations on large and small scales: Evidence from ECoG in a multimodal study in humans and a non-human primate

Authors: *A. DE PESTERS[1,2], P. BRUNNER[1,3], A. GUNDUZ[4], A. L. RITACCIO[3], P. DE WEERD[5,6], M. ROBERTS[6], N. BRUNET[6], R. OOSTENVELD[6], P. FRIES[6,7], G. SCHALK[1,2,3]; [1]Neural Injury and Repair, Wadsworth Ctr., Albany, NY; [2]State Univ. of New York at Albany, Albany, NY; [3]Dept. of Neurol., Albany Med. Col., Albany, NY; [4]Univ. of Florida, Gainesville, FL; [5]Dept. of Cognitive Neuroscience, Fac. of Psychology and Neurosci., Maastricht Univ., Maastricht, Netherlands; [6]Donders Inst. for Brain, Cognition and Behaviour, Nijmegen, Netherlands; [7]Ernst Strüngmann Inst. for Neurosci., Frankfurt, Germany

Abstracts: Performing different tasks involves different neuronal populations. Previous studies suggested that variations in oscillatory activity in the alpha band (8-12 Hz) may implement the selection of task-specific populations by inhibiting cortical activity in task-irrelevant areas (Klimesch 2007, Jensen and Mazaheri 2010). However, the temporal and spatial relationships between modulatory alpha activity and population-level cortical activity in the gamma range (70-170 Hz) remain undefined. In addition, while there is evidence in different modalities that alpha may constitute a coarse selection mechanism, the evidence that it could contribute to fine

selection among interwoven, and spatially restricted networks is scarce. Here, we addressed these two questions by investigating the temporal and spatial dynamics of modulations in the gamma and alpha bands during auditory and motor tasks. We recorded electrocorticographic activity from subdural electrode grids in five human subjects and one macaque monkey during the presentation of natural auditory stimuli from 6 different categories. After each presentation, the human subjects were asked to press a button. Our results confirm that gamma power accurately tracks task-related behavior. Moreover, we found that alpha activity was suppressed in task-relevant areas and increased in task-irrelevant areas. Importantly, this facilitation/inhibition mechanism not only applied to the selection of neuronal populations associated with the auditory vs. the motor system, but also to subpopulations within the auditory system. Specifically, alpha activity was suppressed in the locations within the auditory system that responded to particular sound stimuli, and increased in the remaining locations. Interestingly, this pattern of facilitation/inhibition was predicted by the initial gamma response to the stimuli. Furthermore, alpha suppression trailed gamma activity in auditory areas during auditory stimulation, but preceded it in the motor areas during the motor task. This observation prompts the hypothesis that the central nervous system can regulate cortical excitability in response to sensory input and in preparation to motor output. Finally, ongoing work provides evidence for a link between this putative selection mechanism and the communication-through-coherence hypothesis (CTC). CTC suggests that cortical communication can only be accomplished during specific temporal windows. In sum, we expect that this work will contribute to our understanding of the mechanisms underlying the selection of the specific neuronal populations required for task execution.

Title: Auditory modulation of wind-elicited walking behavior in the cricket

Authors: *M. FUKUTOMI[1], M. SOMEYA[1], H. OGAWA[2];
[1]Grad. Sch. of Life Sci., [2]Dept. of Biol. Sciences, Fac. of Sci., Hokkaido Univ., Sapporo, Japan

Abstracts: To perceive environments adequately, animals combine various sensory information mediated by multiple sensory organs in different modalities. Neural process for the multisensory integration has been studied previously in mammals such as cat, macaque and human (Stein and Stanford, 2008). Multisensory integration has 'cross-modal effect' in which simultaneous presentation of two or more stimuli in different sensory modalities modulate animal behavioral performance. However, little is known about how neural circuit underlying multisensory integration modulates animal behavior. We developed a new behavioral paradigm to test cross-modal effect in the cricket, which has simple neural system consisted of much smaller number of neurons comparing to mammalian brain. Crickets have two different aero-detecting sensory organs, tympanal organ for auditory sense and cerci to detect air-flow surrounding the animal. Information of stimulus direction is extracted by both of these sensory systems to mediate distinct 'oriented behaviors'. The auditory system induces positive phonotaxis to approach a singing male, and the cercal system triggers quick walking considered as 'escape behavior' from a predator. Although local circuits and ascending interneurons involved in these behaviors have been investigated, little is unknown about the interaction between both sensory systems. To verify the cross-modal effect between the auditory and cercal sensory systems, we examined wind-elicited walking behavior combining with 10-kHz pure tone using a spherical treadmill. We found that tone sound preceding the air-current stimulus provided from lateral side alters walking direction of escape behavior backward, but does not modulate other locomotion parameter including turn angle, walking velocity, and reaction time. Auditory modulation of walking direction did not depend on the stimulus side of the preceding tone. These results demonstrated cross-modal effects between auditory and cercal sensory systems, but did not suggest multisensory integration of directional information.

Title: Crossmodal integration improves sensory detection thresholds in the ferret

Authors: *K. J. HOLLENSTEINER, F. PIEPER, G. ENGLER, A. K. ENGEL;
Dept. of Neurophysiol. and Pathophysiology, Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstracts: Sensory evidence about the environment can trigger changes in behavior or mental states. Distinct sensory systems (i.e. visual, auditory, etc.) have evolved to continuously pick up information from different modalities. Hence, perception is always based on combining and weighing inputs in all covered modalities. Information from different sensory systems can influence behavior in synergistic or competitive ways. In four ferrets (*Mustela putorius*) we have tested and quantified the effect of unimodal vs. congruent multi-modal audio/visual stimulation in a spatial detection task. In a 2-altenative-forced-choice task the water restricted animals had to detect the spatial position of a brief (100ms) auditory (white noise) and/or visual (moving circular grating; size 22,5°, 0.2 cycl/°, 5Hz) presented at random position and time (500-1500ms after trial start) either left or right from their midline. During the task the animals' body was slightly restrained in an acrylic tube, while the head remained freely movable to indicate the location of stimuli presented via speakers and/or on a LCD screen. Responses were detected using infrared light barriers on either side from center, coupled with a spout for rewarding correct answers. During the stimulus period, the maintenance of the central head-position was ensured through an additional, central light barrier. We evaluated the detection thresholds individually in both modalities, varying the stimulus-intensities between 10-60dB (auditory) and 0.01-0.38 Michelson contrast (visual) in a staircase manner. For the bimodal stimulation, intensity in one modality remained at threshold, while the intensity in the other modality was varied, again using the staircase procedure to obtain bimodal thresholds. We expected the animals to perform more accurate and faster in the bimodal cases, because congruent inputs from two modalities provide more reliable sensory evidence. As predicted, bimodal thresholds were reduced compared to both unimodal conditions. Additionally, all ferrets reacted faster and more precisely when the auditory stimulus was visually supported. In some subjects the multisensory response enhancement (MRE) was up to 35%. On the other hand, adding auditory information to the visual stimulation had no significant effect regarding the MRE, though all animals reached lower intensities in the visual-audio compare to the visual-only case, indicating a stronger behavioral relevance of vision compared to audition in ferrets. Taken together, the data demonstrate that principles of multisensory integration previously shown in other species also apply to crossmodal processing in the ferret brain.

Title: Behavioral evidence for opposing geotaxis by geomagnetic field and gravity in *Drosophila*

Authors: J.-E. BAE[1], S.-H. KWON[1], Y.-H. LEE[3], *K.-S. CHAE[2,1];
[2]Dept. of Biol. Education, Teachers' Col., [1]Kyungpook Natl. Univ., Daegu, Korea, Republic of;
[3]Korea Res. Inst. of Standards and Sci., Daejeon, Korea, Republic of

Abstracts: Geotaxis is the behavioral response of living organisms moving toward or away from the Earth and gravity is believed as the environmental cause to provoke geotaxis. However, the belief may be flawed because another physical factor surrounding Earth, the geomagnetic field (GMF), also varies in space like gravity. The GMF is regarded as a behavioral cue for the horizontal migration of magnetoreceptive animals such as birds and sea turtles and for body alignment of cattle, dear, and cockroach, etc. In contrast, it has never been considered a cue for vertical movement or altitudinal positioning of animal. Here using *Drosophila* model, we report hitherto unknown GMF-modulated positive geotaxis antagonizing negative geotaxis caused by gravity, and suggest the regulatory GMF parameters for the positive geotaxis. The various experimental GMF conditions including near-zero or strengthening, were generated using 3-axis Helmholtz coils. In several *Drosophila* strains, negative geotactic behavior under near-zero GMF condition was ascertained by several behavior assays such as tube-positioning, Y-maze, and free flight suggesting that GMF exerts positive geotaxis under ambient condition. The near-zero GMF-induced negative geotaxis was dependent on light intensity and necessitated 400-420 nm of light. Mutants deficient of geotaxis genes cry and Pdf, and gravity sensing gene pyx failed to show the geotaxis indicating that these genes are necessary for the geotaxis. In contrast, Z-axis strengthened GMF elicited significant positive geotaxis compared to control flies, confirming that ambient GMF opposes to gravity in modulating of geotaxis. In addition, a formula for relative strength of the GMF-modulated positive geotaxis is suggested based on the geotaxis data

from various GMF conditions, revealing that interplay of parameters such as vertical vector, total intensity, and declination is critical for the geotaxis. The results suggest crucial role of GMF-modulated magnetotaxis opposing to negative geotaxis by gravity to adjust vertical movement or altitudinal positioning of animal and a novel concept for GMF-based vertical coordinate for magnetotactic organisms.

Title: Decoding multisensory information from the parietal cortex: A comparison of maximum likelihood and artificial neural network decoders

Authors: H. MAO[1], Y. SHI[2], G. APKER[2], J. SI[1], *C. A. BUNEO[3];
[1]Electrical Engin., [2]Biomed. Engin., Arizona State Univ., Tempe, AZ; [3]Arizona State Univ., TEMPE, AZ

Abstracts: Multisensory integration is currently a topic of great interest due to its relevance for understanding perception, the control of action, and adaptation to neural prosthetic and sensory substitution devices. As a result we recently examined the integration of visual and proprioceptive signals in area 5 as monkeys reached to and actively maintained their arm position at multiple target locations in a frontal plane. On half of the trials both visual and non-visual feedback of the endpoint of the arm was available (V condition), while on the remaining trials visual feedback was withheld (NV condition). We previously reported that during the active maintenance of arm positions, vision of the arm decreased spiking activity and spiking variability in area 5. Using a maximum likelihood (ML) decoder, we also showed that such modulations were associated with improved decoding of arm position at the population level. Here we report additional decoding results using an ML decoder (Poisson spiking model) and

compare its performance with that of an artificial neural network (ANN), which makes no assumptions about spiking statistics. Performance of both decoders was validated with a leave-one-out procedure. When the ML decoder was applied to activity obtained from populations of position-modulated neurons (as determined by ANOVA), decoding accuracy increased with sample size, reaching a maximum decoding accuracy of ~85%. Decoding performance gain with vision reached a maximum of ~4% at a population size of ~10 neurons. When the decoder was applied to both tuned and untuned neurons, maximum decoding accuracy dropped to ~40% and peak performance gain with vision reached ~6% at a population size of ~150. When an ANN decoder was applied to position-modulated cells only, decoding accuracy also increased with sample size, reaching a maximum of ~80%, but peak performance gain with vision dropped to ~2% (at a population size of ~10). For the population of tuned and untuned neurons, maximum decoding performance reached ~35%. Peak performance gain with vision reached a maximum of ~1.25% at a population size of ~75 neurons, then decreased for larger populations. The results suggest that vision benefits decoding the most in smaller neural ensembles in area 5.

Abstracts: Many animals can sense infrared radiation; however, only pit vipers were assumed to be capable of infrared imaging based on the camera-like pit structure and the infrared receptive topology in the optic tectum resembling the visual one. Reconstruction of infrared images in the central nerve system of vipers was proposed by using an idealized linear formalism. It is still unclear, however, whether the neuronal response can reflect the infrared imaging in the optic

tectum. Using a peltier as the warming source, a programmable robotic arm carrying the peltier moving along four directions (up-down, left-right, left up-right down and left down-right up) and reversal was constructed by our lab to test spatial preferences of infrared neurons. A device with a programmable shutter in front of the peltier was made for testing temporal features of infrared neurons. Our primary results show that the tectal neurons processing the infrared signal have the responsive preferences for moving directions of stimuli with the broader curves of the responsive pulses (50 ms duration) compared with the sharp curves of pulses in visual system (10 ms duration) on short-tailed pit vipers.

Title: Retronasal odorants modulate responses of taste cells in the nucleus of the solitary tract of the awake, behaving rat

Authors: *O. D. ESCANILLA, P. DI LORENZO;
Binghamton Univ., Binghamton, NY

Abstracts: Gustatory and olfactory interaction is important in flavor perception. During food consumption, odors can be sampled orthonasally through the nose or retronasally through the mouth and the internal nares. In previous experiments, we found that olfactory and gustatory signals converge in the nucleus of the solitary tract (NTS) and that orthonasal odorants can modulate the responses of taste-responsive cells in this area. Here we studied whether odorants delivered retronasally will have the same effect on the initial stages of gustatory processing. Rats were implanted with an 8-micowire bundle electrode and allowed to recover for 7 days. Rats were then mildly water deprived and placed in an experimental chamber containing a lick spout for fluid delivery. Gustatory stimuli were 0.1M Sucrose, 0.1M NaCl, 0.01M Citric Acid, 0.0001M Quinine, and artificial saliva (AS). Odor and paired odor-taste stimuli were formulated by diluting each odorant, (0.01%) amyl acetate, (0.01%) acetic acid, (0.01%) phenylethyl alcohol and (0.01%) octanoic acid in either AS (for retronasal odor only presentations) or different

tastant solutions. Odor concentrations were below the detectable level for evoking gustatory or somatosensory responses in rats. Each odor, taste or taste-odor stimulus was presented for 5 consecutive licks separated by AS rinses that were on a variable ratio 5 schedule. A continuous stream of air flowed through an odor port located next to the lick spout to minimize odor contamination. Preliminary results show that retronasal odorants presented by themselves, can elicit a response from taste-responsive NTS cells while retronasal odorants paired with tastants can enhance or attenuate the taste responses in the NTS. These results suggest that retronasal and orthonasal odorants can affect taste responses in the NTS in similar ways. Further, data confirm that a subset of taste cells in NTS are multimodal implying that they may participate in the neural representation of a "food object," even at this early stage of processing.

Title: Oscillatory alpha activity reflects tactile spatial coordinates differently in sighted and blind individuals

Authors: *J. T. SCHUBERT[1], V. N. BUCHHOLZ[2], J. FÖCKER[3], A. K. ENGEL[2], B. RÖDER[1], T. HEED[1];
[1]Biol. Psychology and Neuropsychology, Univ. of Hamburg, Hamburg, Germany; [2]Dept. of Neurophysiol. and Pathophysiology, Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [3]Dept. of Psychology and Educational Sci., Univ. of Geneva, Geneva, Switzerland

Abstracts: Touch can be represented in skin-based and, when integrated with body posture, in space-based, external coordinates. Behavioral and ERP evidence suggests that sighted individuals automatically recode touch into external coordinates, whereas congenitally blind individuals rely on skin-based coordinates for touch representation, implying a crucial role of vision for external coding in touch. Oscillatory alpha (8-12 Hz) brain activity is thought to reflect

attention-related tactile processing. Therefore, we investigated how the reference frames involved in pre- and poststimulus attentional tactile processing are expressed in EEG alpha activity in sighted and blind humans. In each trial, an auditory cue instructed participants to direct attention to one hand, and a stimulus was presented 1000 ms later either to the attended or the other, unattended hand. A foot response was required to rare deviant stimuli at the attended location. To modulate the external coordinate of tactile stimuli, participants adopted an uncrossed or a crossed hand posture. Power modulations in the alpha band were analyzed in the 500 ms interval preceding stimulation, and 200-700 ms after stimulation onset. In the sighted, expectation of tactile stimulation following the auditory cue elicited a lateralization of alpha activity with uncrossed hands prior to stimulation, that was reduced in the crossed posture. Beamforming localized this posture-related effect in the intraparietal sulcus (IPS). In contrast, pre-stimulus alpha lateralization was unaffected by limb crossing for blind individuals.For sighted and blind groups, poststimulus alpha activity was reduced contralateral to tactile stimulation. In the sighted, hand crossing modulated alpha activity bilaterally, with a smaller alpha decrease for attended, but a larger decrease for unattended stimuli over centro-parietal regions. Blind participants, too, displayed these attention-related alpha band modulations, albeit to a lesser degree than the sighted. Susceptibility of alpha activity in the IPS of the sighted to hand posture suggests that the attentional processing reflected by this frequency band operates in external coordinates both prior to and following tactile stimulation. The stronger alpha decrease for unattended stimuli with crossed than with uncrossed hands may suggest that attention is directed on the basis of both skin-based and external coordinates in the sighted. In contrast, congenitally blind individuals seem to rely predominantly on skin-based coordinates for tactile attention.

Title: Foveal attention modulates saccade frequency during smooth pursuit

Authors: *S. J. HEINEN[1], E. POTAPCHUK[1], S. N. J. WATAMANIUK[2];
[1]Smith-Kettlewell Eye Res. Inst., SAN FRANCISCO, CA; [2]Wright State Univ., Dayton, OH

Abstracts: Previously, we showed that foveal stimuli increased the number of saccades during pursuit, presumably because a salient foveal spot activated a position correction mechanism (Heinen et al., SfN 2013). As attention is normally linked to foveating saccades, it might be that foveal targets attract attention during pursuit, causing saccades to occur. To investigate this, we attempted to move attention in and out of the fovea. Observers pursued a stimulus of 4 peripheral dots arranged symmetrically about a central one. At a random time, one of the dots dimmed briefly, and observers had to identify it with a keypress. In a block of trials, either the central dot or the 4 peripheral dots were potential targets, drawing attention into or out of the fovea, respectively. Saccade frequency was highest when attention was drawn foveally, and reduced when it was drawn peripherally, supporting the idea that foveal attention during pursuit was modulating saccades. However, removing the central dot altogether further reduced saccades, indicating that the central spot still attracted attention even though observers knew it was not a potential target. To test whether this was because the attention "window" required to attend to the 4 peripheral dots encompassed the central one, we attempted to move attention completely away from the foveal dot by having observers perform the identification task on a peripheral, miniature version of the 5-dot stimulus (.5 deg diameter). Here the foveal pursuit target remained and the peripheral stimulus moved with it. Saccades were indeed reduced compared to when the attention window encompassed the center, but not as much as when the central dot was removed. The results suggest that attention modulates a position-correcting system used during pursuit, and are consistent with the idea that pursuit of foveal stimuli requires attention.

Title: Physical causality guides saccades during visual pursuit initiation

Authors: K. WENDE[1], A. DROżDżEWSKA[3], B. FELTZ[3], *M. MISSAL[2];
[2]Lab. de Neurophysiologie, [1]Inst. of Neurosciences, IONS - COSY, Brussels, Belgium; [3]Inst. Supérieur de Philosophie, Univ. catholique de Louvain, Louvain-la-Neuve, Belgium

Abstracts: When a moving object collides with a stationary one that subsequently starts to move, humans 'perceive' a causal interaction. Causality cannot be sensed directly but must be inferred from the spatio-temporal characteristics of objects' trajectories. Albert Michotte (1946) hypothesized the existence of an automatic inference mechanism that could rapidly and implicitly recover the causal “Gestalt” of events. In the present study, we investigated how physical causality might influence catch-up saccade latency during visual pursuit initiation. We hypothesized that if causality is indeed processed implicitly in the visual system, then the initial catch-up saccade during pursuit initiation could have a shorter latency if the pursued target is moving in agreement with the laws of mechanics and a longer latency if the target is moving in a physically unlikely direction. Eye movements were recorded in 16 healthy humans while observing a launching display. The stimulus consisted of a large moving launcher entering the display from a masked periphery and moving toward the center of the screen where it collided with two smaller targets that subsequently started to move. One target moved in a direction that was in agreement with the laws of mechanics (oblique causal target, 'C') and the other target moved along a physically unlikely horizontal trajectory (non-causal target, 'NC'). Subjects were required to pursue the launcher and after the impact to continue to pursue one of the two smaller targets selected freely. Control conditions consisted in either pursuing a small cross instead of a large launcher or fixating a stationary cross prior to motion of the two smaller targets. In both control conditions, one target was moving obliquely and the other horizontally to exactly match the trajectories in the launching condition. We found that saccadic latencies were significantly shorter during launching when the causal target was selected (causal: 192±8ms, n=1758; non-causal: 208±6 ms, n=1629). In the control moving fixation cross condition there was also a significant difference between latencies of oblique and horizontal target motion (oblique: 184±5ms, n=1351; horizontal: 199±2ms, n=1400). However, no difference in latencies was found in the stationary fixation cross condition (189±4ms, n=1629 vs. 189±5ms, n=1572) suggesting that motion trajectory itself is not explaining differences of latencies measured. The effect of causality on catch-up saccade latency is consistent with the hypothesis that physical causality is an implicit prior that is automatically applied by the visual system to predict object motion.

Title: Saccadic reaction time distributions follow the matching law in a concurrent random interval reinforcement schedule

Authors: *L. MADELAIN[1,2];
[1]Psychology, Ureca - Univ. Lille 3, Villeneuve D'Ascq, France; [2]Inst. de neurosciences de la Timone, Marseille, France

Abstracts: Studies of decision-making process revealed that animals are sensitive to the sources and timing of rewards and use these variables to choose among alternatives. In particular experiments on foraging behavior indicate that the distribution of time among foraging sites is proportional to their relative value. These relations were expanded to a general principle of choice termed the matching law (Herrnstein, 1961) which states that the fraction of choices made to an option will match the fraction of total income earned from that option. Because saccadic reaction time distributions are known to be strongly affected by reinforcement schedules (Madelain et al, 2007) we now ask whether saccade latencies as well could match reinforcement proportions in a concurrent schedule. Our procedure was similar to the one used by Sugrue et al (2004) except that reinforcement depended on saccade latencies rather than on target choice. We had two subjects make saccades to a visual target stepping horizontally by 10 deg at a 0.6Hz rate. Fast and slow latencies (defined with respect to the first and last quartile of baseline RT distribution respectively) were reinforced in a concurrent Random Interval schedule with unsignaled changes of reinforcement ratios (9/1, 1/1 or 1/9) during extensive training. Using the generalized matching equation we found that saccade latencies were well controlled by the current schedule (sensitivity=0.704, bias=-0.004). A moving 30-trials temporal window revealed that local distributions of latencies were well correlated with the local ratios of obtained reward ($R2=0.79$, $P<0.05$). Interestingly, saccade peak velocities were higher in the “fast” than in the “slow” latencies. Simulations based on leaky integration of reward streams exhibit 80% agreement with human subjects demonstrating that a simple local choice rule may provide an adequate descriptive model of real matching behavior in this dynamic foraging task. These data indicate that saccade latency distributions follow the rules of other choice behavior and may depend on past behavior more than previously thought.

Title: Spatiotemporal distortions in visual scene reconstruction during and shortly after a saccade

Authors: *J. S. ATSMA[1], F. MAIJ[1], D. E. IRWIN[2], W. P. MEDENDORP[1];
[1]Donders Ctr. for Cognition, Donders Inst., Nijmegen, Netherlands; [2]Dept. of Psychology, Univ. of Illinois, Champaign, IL

Abstracts: Although we frequently make saccades, we seem to perceive a stable, continuous visual scene. However, the post-saccadic reconstruction of the pre-saccadically viewed visual scene is not always perfect. Small changes in object location during a saccade are often not detected, an observation classically known as saccadic suppression of displacement (SSD). So far, little is known about the impact of SSD on visual targets other than the saccade target (ST). If the region around the ST is most important for anchoring visual stability, as the saccade target theory entails (McConkie & Currie 1996), one could expect that ST displacements are more precisely detected than other targets. Here, we compared SSD of the ST with SSD of the initial fixation target (FT) and a peripheral non-target (NT). The FT, ST, and NT formed an equilateral triangle with 15 deg sides; the saccade was always directed horizontally between FT and ST. During the saccade, two of the targets disappeared while one was displaced (by -5 to 5 degrees) parallel and orthogonal to the saccade direction. The displaced target was presented for three different durations (50 ms, 300 ms, and ~1000ms). Participants (n=8) indicated the remembered pre-saccadic position of this target by using a mouse cursor. We examined the precision (1/SD) and the bias (mean) of the position judgments. Our results show that displacements orthogonal to the saccade are detected more precisely than parallel displacements for both ST and FT, but not for NT. Geometrically, the mean position judgment for each of the targets showed compression towards a point within the triangle of targets. This compression was modulated by the duration of the post-saccadic stimulus, with more compression during the shorter displaced-target durations. These results put limits on the realm of the saccade target theory, providing a signature of the spatiotemporal transformations that are involved in visual scene reconstruction during a saccade.

Title: Change of gaze by retinal movements during locomotion by jumping spiders

Authors: D. B. ZUREK[1], *C. GILBERT[2];
[1]Biol. Sci., Univ. of Pittsburg, Pittsburg, PA; [2]Cornell Univ., ITHACA, NY

Abstracts: Visual properties of eyes are not uniformly distributed across the field of view, thus animals with moveable eyes change their direction of gaze to view objects of interest with the high acuity region of the retina. In jumping spiders, the principal eyes perform high acuity inspection and spectral analysis of objects. Their retinas can move to change the gaze direction through the lens, which is fixed in the exoskeleton. We have filmed these retinal movements in the horizontal plane as transparent spiders walked freely in a blank arena, tracked a horizontally moving target with retinal and body movements, and inspected a scaffolding to select an escape route. Retinal scanning movements occur independently or synchronously in the two eyes. Retinal movements may occur while the spider walks, but occur more frequently when stopped. The angular range of gaze movement is greater in the ipsilateral direction. Consequently, when a moving target approaches in the spider's peripheral visual field, the ipsilateral retina begins tracking the target first. As it passes into the contralateral field of view the other retina begins to follow the target more closely. When this retina reaches the end of its movement range, a body turn occurs.

Title: Time-frequency analysis of the precue effects on saccade latency in behaving monkeys

Authors: *J. HUANG[1,5], K. SONG[6], Y. XU[1], I. SIMPSON[1], K. KOSEK[2], Y. ZHOU[5], H. ZHU[1], W. ZHOU[1,3,4], H. LUO[6];

Abstracts: It has been well documented that a cue preceding a target modifies the saccade latency to the target. This cue effect on saccade latency has served as an effective model to study immediate plasticity in sensorimotor transformations. A recent study performed time-frequency analysis on precue effects in a visual discrimination task (Song et al., 2014). A surprising finding was that the precue induced dynamic oscillations at α-band frequencies (8 - 20Hz) in reaction time measurements. In the present study, we employed the time-frequency approach to examine the temporal characteristics of precue effects on saccade latency in a monkey. The monkey was trained to fixate a central target while a cue was presented for 75ms at left or right 10 degree. After a varying interval of cue-to-target, i.e., stimulus onset asynchrony (SOA) (20ms to 1020ms at a step of 20ms), a target was presented at the same (valid condition, 50%) or opposite (invalid condition, 50%) location with respect to the cue. The monkey was trained to make a saccade to fixate the target for juice rewards. Saccade latency was measured for each condition and plotted as a function of SOA. Compared to the control condition, there is a reduction in saccade latency in both valid and invalid conditions, indicting a general alert effect of the cue. Interestingly, we found that the reduction of saccade latency in the invalid condition was larger than that in the valid condition, indicating the monkey's interpretation of 50% cue validity was biased toward the invalid condition. The time-frequency analysis (the short-time Fourier transform) revealed that precue induced oscillations in saccade latency at α-band frequency at SOAs of 100ms, 300ms and 800ms. In other words, the α-band oscillations are modulated at θ band frequencies (3 - 5Hz). These preliminary results suggest that time-frequency analysis is a powerful tool to elucidate the temporal structures of the precue effects on saccade generation. Ongoing studies will further characterize these structures and investigate the underlying neural mechanisms.

Title: Visual and auditory targets elicit a unidirectional prosaccade switch-cost

Authors: *M. D. HEATH, F. E. STARRS, E. A. MACPHERSON, J. WEILER;
Univ. of Western Ontario, London, ON, Canada

Abstracts: An antisaccade is a non-standard task that requires decoupling standard (i.e., direct) stimulus-response relations and executing a response to a target's mirror-symmetrical location. As well, the completion of a directionally correct antisaccade is linked with changes in neural activity within high- and low-level oculomotor networks ¬- a modulation that is thought to reflect a presetting that prevents the evocation of a stimulus-driven prosaccade. Recent work by our group (e.g., Weiler and Heath 2014: Acta Psychologica) has shown that antisaccade presetting elicits a lingering inhibition of oculomotor planning mechanisms. In particular, the execution of an antisaccade to a (visual) target selectively delays the reaction time (RT) of a subsequent prosaccade; however, the converse switch does not influence RT (i.e., the unidirectional prosaccade switch-cost). The goal of the present investigation was to determine whether the aforementioned switch-cost is: (1) selectively tied to decoupling the standard response mapping of a visual stimulus, or (2) relates to a persistent and sensory-independent activation of a non-standard task-set. To accomplish our objective, participants randomly alternated between pro- and antisaccades in separate conditions wherein targets were defined via visual or auditory stimuli. As in previous work, results elicited a reliable unidirectional prosaccade switch-cost; that is, prosaccades preceded by antisaccades were associated with an increase in RT. Most notably, the magnitude of the switch-cost was equivalent between the visual and auditory conditions. As well, it is important to note that the switch-cost could not be attributed to a speed-accuracy trade-off in movement planning as the endpoint accuracy and variability of prosaccade switch trials was comparable to their non-switch trial counterparts. Taken together, results show that a sensory-independent task-set associated with antisaccades persists inertially and delays the planning of a subsequent prosaccade.

Title: Blinking during torsional optokinetic eye movements partially resets eye torsion

Authors: ***M. F. KHAZALI**, A. SMILGIN, F. BUNJES, P. THIER;
Cognitive Neurol., Hertie Inst. For Clin. Brain Res., Tübingen, Germany

Abstracts: Torsional optokinetic nystagmus (tOKN) is a reflexive ocular motor response evoked by looking at a rotating stimulus. It consists of a slow phase in which the eye tries to follow the rotation of the visual stimulus in order to reduce the slip of its retinal image followed by a saccadic fast phase torsion (FP) in the opposite direction. The FP ensures that the eyes stay within the mechanicals limits of the plant. On the other hand, the FP inevitably impairs vision because it induces a "saccadic suppression" of the impact of the high velocity motion of the background image during the FP. Blinking, carried out at frequencies of 15 to 30/ min in order to keep the cornea moist, also causes a transient interruption of normal vision because of the co-occurrence of a blink related eye movement (EM) (Volkmann, Riggs et al. 1980). The raison d´etre of these EMs is not fully clear. They may help to hydrate the cornea. On the other hand, they may be a consequence of an important additional role of blinks, namely to protect the eyes against potentially harmful stimuli. Finally, blinking EMs may serve to exploit the EM related suppression of the visual distortions accompanying blinks. As EM related suppression decreases the time available for scrutinizing the visual world, we reasoned that coordinating blinks with FP might be a useful strategy. We tested this hypothesis in a group of 5 healthy human subjects in whom we evoked tOKN around the naso-occipital axis. We used video oculography to record blinks and eye position in 3D. We found that practically every blink was accompanied by a partial resetting of torsional eye position in the direction of the starting position, thereby partially compensating the deviation caused by the slow components of the tOKN. The amount of resetting depended linearly on the torsional eye deviation at blink onset. Surprisingly, the amount of resetting of eye position brought about by FP components independent of blinks was unrelated to eye deviation at FP onset. Blanking the optokinetic stimulus for a period corresponding to the duration of a blink did not cause a resetting of eye position. In accordance with this result, we also failed to find a correlation between blink duration and the amount of resetting. These

findings suggest that the oculomotor system shapes the eye movements required by blinks such as to at the same time serving the needs of the tOKN.

Title: An advanced real-time monocular/binocular eye tracking system using a high frame-rate digital camera

Authors: ***K. MATSUDA**[1], A. TAKEMURA[1], K. MIURA[2], T. OGAWA[2], K. KAWANO[2]; [1]AIST, Tsukuba, Japan; [2]Kyoto Univ., Kyoto, Japan

Abstracts: We developed a new eye tracking system by adopting an IEEE-1394b or an USB3.0 digital camera that provides high sensitivity, high resolution, and high frame rate. The system is non-invasive and inexpensive and can be used for mice, monkeys, and humans. An infrared light illuminates one eye, and its reflected image on the cornea and the black image of the pupil are captured by the camera. The center of the pupil is calculated by fitting an ellipse and tracked over time. The reflected image on the cornea is used to compensate head-movements. The system has two-steps of calibration. Step-1, "passive calibration": when the subject spontaneously moves its eye, the system calculates the rotation center of the pupil, the rotation radius of the pupil, and the cornea curvature center in camera-coordinates. Step-2, "active calibration": when the subject fixates on small targets (from 3 to 9) on a computer display successively, the system provides a transition matrix for eye position from camera-coordinates to target-coordinates. Thus, after the passive and active calibration, we are able to measure the eye position in target-coordinates. However, since the active calibration is not realistic on mice, the eye movements of mice are recorded only in camera-coordinates. The eye position and pupil size data are read out on-line via computer network to be stored for off-line analysis and/or outputted as analog voltage through a digital-analog converter. The adoption of the WINDOWS 7, 8, 8.1 x 64 as the operation system makes this eye tracking system user-friendly. The program is available at https://staff.aist.go.jp/k.matsuda/eye/. Recent advances in inexpensive high-quality

digital cameras make the system applicable in measuring human binocular eye movements. We adopted a wide-field, hi-resolution, and hi-frame-rate camera of 2048x2048 pixels resolution and captured the images of both eyes simultaneously and calculated positions of the two eyes at each frame. Because of the high frame rate of the digital camera, the sampling rate of the system can be as high as 700Hz. By using this system, we succeeded in characterizing vergence eye movements of humans when ocular fixation shifts between two targets placed at different distances in the 3-D space.

Title: Interspersing fixation trials better reduces anticipatory pursuit than randomizing target direction

Authors: *S. N. WATAMANIUK[1], S. J. HEINEN[2];
[1]Psychology, Wright State Univ., DAYTON, OH; [2]The Smith-Kettlewell Eye Res. Inst., San Francisco, CA

Abstracts: Typical pursuit latency for humans is approximately 130 msec. However, it can be difficult to accurately identify pursuit onset because anticipatory pursuit prior to stimulus motion obscures the onset of stimulus-driven pursuit. Anticipatory pursuit can also impact measurement of open-loop pursuit parameters. To mitigate anticipatory pursuit, it is common to randomize pursuit direction. While randomization reduces anticipatory pursuit, it does not eliminate it (Kowler & Steinman, 1979; Heinen et al., 2005). Here we show that interleaving fixation trials among pursuit trials virtually eliminates anticipatory pursuit. Observers pursued a small spot target that moved at a constant speed. The target either started at the center of the display, or at a display edge, a condition that specifies target direction uniquely. As a baseline, we alternated or randomized pursuit direction (left & right). Then, pursuit direction was held constant, and within a block, either fixation trials or blank trials (no stimulus) were interleaved. Anticipatory velocity

was measured at target motion onset. We found that anticipatory velocity was highest when target motion was repeated in the same direction, or when target direction alternated left and right and target motion began at an edge. As expected, randomly alternating pursuit direction from a central position reduced anticipatory pursuit. However, it was reduced even more if pursuit trials alternated with fixation trials, and longer fixation trials resulted in a greater reduction. Fixation trials randomly interspersed among pursuit trials were the most effective at reducing anticipatory pursuit. Interleaving blank trials did not reduce anticipatory pursuit, nor did simply extending the random fixation period prior to stimulus motion onset, suggesting that knowing fixation trials were possible actively suppressed anticipation. The results demonstrate a heretofore undocumented interaction between fixation and pursuit circuitry.

Title: Sensitivity of catch-up saccades kinematics to repeated unperceived changes of target velocity

Authors: C. KAYAL, B. GAYMARD, *P. M. DAYE;
Inst. du Cerveau et de la Moelle épinière, Paris, France

Abstracts: Saccades and smooth pursuit are combined to ensure a clear vision while tracking a moving object. Because the pursuit gain (ratio between eye velocity and target velocity) is normally inferior to one, the eyes frequently lag behind the target (Meyer et al., 1985). Accurate foveation therefore requires catch-up saccades that are triggered by the central nervous system to cancel this growing error and bring the eye closer to the target. Interestingly, as initially pointed out by Dodge (1903), visual acuity is markedly decreased during saccades. McLaughlin (1967) took advantage of this phenomenon to design a new paradigm in which target location is systematically altered during the saccade by a constant displacement. A key point of his protocol is that subjects do not perceive the change of target position during the saccade. In the first trials, saccades land near the initial target position, thus requiring a corrective saccade towards the new

target position. However, after a series of similar trials, saccades land progressively closer to the modified target position. This well known behavior, called saccadic adaptation, has been extensively studied since. Here, we investigate using a new paradigm the effect of a change of target velocity during catch-up saccades on their kinematics. Subjects sat in dark room and looked at a screen (refresh rate: 144 Hz) located 60 cm ahead of them. They were required to look at a moving target. After a central fixation, the target jumped diagonally (randomly upward or downward: amplitude [5..15] deg. Horizontal step: -0.1*horizontal target velocity) and started to move horizontally (either leftward or rightward randomly) with a random velocity (amplitude: [20..30] deg/s). Subjects had to trigger a saccade towards the moving target to initiate the movement. During this saccade, the amplitude of the target velocity was systematically increased by 20 deg/sec. A test block was composed of 800 trials with a change of velocity. Before the test block, a block of 200 trials without a modification of target velocity was done to build the baseline behavior of the subjects. Subjects did not do more than one test block per day. Subjects did not perceived the modification of target velocity during the saccade. We analyzed the saccade trajectory and found an effect of the target velocity step on the horizontal component of the saccade. We also found a modification of the pursuit velocity at the end of the saccade correlated with the change of target velocity. Our results suggest that the unperceived change of target velocity during the saccade is taken into account by the central nervous system to alter both the saccade trajectory and the pursuit behavior.

Title: Slow eye movements reflect human decision-making about visual motion direction

Authors: *S. B. KRISHNA[1], E. POLAND[1], S. GLIM[1], B. EICHELBERGER[1], S. TREUE[1,2,3]; [1]Cognitive Neurosci. Lab., German Primate Ctr., Goettingen, Germany; [2]Bernstein Ctr. for

Computat. Neurosci., Goettingen, Germany; [3]Fac. for Biol. and Psychology, Univ. of Goettingen, Goettingen, Germany

Abstracts: The random-dot-motion (RDM) task, which tests motion signal perception in noise, has proved extremely useful in the study of sensory decision-making. Neuronal recordings in monkeys have revealed how motion-direction information is accumulated between stimulus onset and a monkey's decision. However, a non-invasive and easily-measured variable that reflects the dynamics of decision-making in humans at a fine temporal scale remains to be found. Here, we evaluate whether slow eye movements (SEMs) in humans viewing a RDM pattern are correlated with their ongoing decision-making process, inspired by the known parallels between motion perception and SEMs (like smooth pursuit). Human subjects viewed a low-coherence RDM pattern containing signal dots moving to the left or right and indicated their decision about motion direction using either a keyboard press (Experiment 1), a horizontal saccade (Experiment 2) or a vertical saccade (Experiment 3). Independent of response modality, their eyes slowly moved ("drifted") on average in the direction of the impending decision in all three experiments. Trials with SEMs were associated with better performance. The average SEMs on error trials indicated the direction of the subject's incorrect response, rather than the direction of the coherently moving dots. SEMs in the direction of the subjects' response were also found in trials using zero-coherence stimuli. SEMs appear to show a pattern similar to that of the neural activity of single neurons in monkey parietal cortex reported in the literature. SEMs may thus provide a non-invasive window into decision-making and allow the testing of motion-processing models with high temporal resolution.

Title: Neural mechanisms of visuomotor updating within an illusory context

Authors: *A. J. DE BROUWER[1,2], J. B. J. SMEETS[1], T. GUTTELING[2], I. TONI[2], W. P. MEDENDORP[2];
[1]MOVE Res. Inst. Amsterdam, VU Univ. Amsterdam, Amsterdam, Netherlands; [2]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstracts: Performance of the double-step saccade task requires visuomotor updating: the spatial dimensions of the second saccade must be computed based on the initial retinal coordinates of the target and the metrics of the intervening first saccade. The posterior parietal cortex (PPC) has been implicated in this gaze-centered computation. What is the role of visuospatial contextual information in this updating process? We used 3T fMRI to examine how parietal representations during a double step saccade task are affected by a visual contextual illusion. While in the scanner, subjects briefly viewed a horizontal Brentano version of the Müller-Lyer illusion with a target at its middle vertex, while fixating at one of the two endpoints of the illusion. Next, the eyes' fixation point jumped to a position above or below the target, orthogonal to the orientation of the illusion. After a delay, subjects made a saccade to the remembered position of the target. Behavioral results showed that the visuomotor updating process is distorted by the Brentano illusion. The direction of the second saccade was not purely vertical, but had a small horizontal component in the direction of the illusion. Because the PPC has a gaze-centered organization, we expect a contralateral bias in BOLD response preceding the second saccade if the PPC contains an erroneous target representation due to the illusion. Our results suggest that target representations in the PPC are indeed affected by this contextual information.

Title: Micro-meter magnitude components of eye movement separated from miniature head motion revealing pro- and anti-correlation vectors

Authors: *Y. TANAKA[1], H. FUJIE[2], S. SHIMEGI[3];
[1]Vision Section, Neuromathematicslaboratory, Kobe, Japan; [2]R&D section, Paris-Miki Inc., Himegi, Japan; [3]Grad. school of medicine, Osaka Univ., Osaka, Japan

Abstracts: Study of miniature eye movements reveals that micro-saccades are important in visual perception and attention when we fixate our eyes to a specific spot. Details of miniature eye movements such as ocular drifts and tremors were yet to known due to various sources of noise and technical limitations. By developing a novel video occulography (VOG) using an ultra-high speed camera, micro-meter level images of eye and head were tracked by SURF method (Tanaka et al., 2014). As a result, we could extract pure components of miniature eye movements in tenths of micro-meter order, which is independent of head motion in a simple fixation task. Spatial, temporal, and frequency analyses reveal that two distinct types of miniature eye movements: one 10 to 50 micro-meter order, and the other smaller than this with higher temporal frequencies (60 to 100 Hz). Furthermore, we found two different types of miniature head motion, one which is comparatively large with the degree of 10 to 50 micro-meter order, and the other which is smaller with higher temporal frequencies. Correlation analysis between eye and head motion yielded in the both pro- and anti-correlation vector components of eye and head movements over seconds in both large and small scales, representing a miniature version of vestibular ocular reflex (VOR). These results illustrate a novel aspect of eye-head coordination of their micro meter magnitude.

Title: Seeing space through time: Visual consequences of eye movement transients

Authors: *M. RUCCI[1], M. POLETTI[2], J. D. VICTOR[3], M. BOI[2];
[1]Boston Univ., BOSTON, MA; [2]Boston Univ., Boston, MA; [3]Weill Cornell Med. Col., New York, NY

Abstracts: Humans acquire visual information by alternating fast relocations of gaze (saccades) with periods of "fixation", in which microscopic eye movements continually occur. Although it is well established that the visual system is highly sensitive to temporal transients, relatively little attention has been paid to how the modulations resulting from the continual alternation between macroscopic and microscopic eye movements affect spatial vision and its dynamics. To address this question, we report results from a combination of techniques, including spectral analysis of the spatiotemporal input signals to the retina, neural modeling of the responses of retinal ganglion cells, and psychophysical experiments with precise control of retinal stimulation. We first show that, during fixation on natural scenes, saccades and the smooth fixational motion of the eye (a movement commonly known as ocular drift) yield temporal modulations with highly different spatial distributions. Specifically, ocular drift equalizes temporal power over a broad range of spatial frequencies (Kuang et al., 2012), but saccadic transients leads to power at low spatial frequencies. In a model based on the responses of simulated retinal ganglion cells, the transition between these two spectral distributions yields specific predictions regarding the dynamics of contrast sensitivity: fixational eye movements enhance sensitivity to high spatial frequencies, while saccades mainly contribute to vision at low spatial frequencies. Finally, we validate these predictions by means of psychophysical tests of contrast sensitivity using high-resolution eye-tracking and a system for gaze-contingent display. We show that elimination of saccadic transients and fixational modulations selectively affects sensitivity at low and high spatial frequencies, respectively. These findings show that the interplay between saccadic and fixational eye movements results in a coarse-to-fine dynamics of visual perception in each intersaccadic interval.

Title: Eye movements during a transition between different non-constant target velocity profiles

Authors: *E. HAINQUE, E. APARTIS-BOURDIEU, P. M. DAYE;
CR-ICM, UMR 7225, UMRS 975. Cnrs-inserm-Université, Paris, France

Abstracts: Two types of eye movements are combined while tracking a moving object: smooth pursuit and saccade. Saccades are rapid redirections of the visual axis between two centers of interest. Smooth pursuit keeps the image of a moving target on the fovea. Because the pursuit gain is smaller than one (Meyer et al., 1985), the eye would increasingly lag behind the target without any correcting movements. Thus, "catch-up saccades" are triggered by the central nervous system (CNS) to cancel this growing position error between the eye and the target. Using a ramp-step-ramp paradigm, De Brouwer et al (2002) showed that a multiple regression using both position and velocity errors sampled 100 ms before saccade onset account for 96% of the variance of saccade amplitude. These authors suggested that this 100 ms delay represents the sensory delay of the visual system. Using a target with a non-constant velocity, Daye et al (2014) showed that catch-up saccades amplitude is better correlated with position and velocity errors sampled at saccade onset than with these parameters sampled 100 ms before saccade onset. Because of the inherent sensory delays, the authors suggested that the CNS uses an internal model of target movement to correct catch-up saccades amplitude. Daye et al. (2014) proposed that the same internal model could be used to control pursuit and to correct catch-up saccades amplitude. This study analyzes how the CNS controls eye movements (smooth pursuit and catch-up saccades) during the transition between two target trajectories with non-constant velocity profiles. After a 500 ms central fixation, subjects were required to track a horizontal moving target with a sinusoidal velocity (peak to peak displacement: 24°, frequency: 0.75 Hz). After either [2.375, 2.4375, 2.875, 2.9375] cycles of motion, the target jumped (amplitude randomly selected in [-1,0,1]°) and started to move with another non-constant velocity profile. The velocity could be either exponential, quadratic or sinusoidal (control condition without position step). Nine different target trajectories (4 exponentials, 4 quadratics and 1 control) were randomly intermixed during a block of 72 trials. Subjects did not do more than 4 blocks a day. After the pursuit initiation, eye velocity is correlated with target velocity during the first part of the protocol (sinusoidal velocity). Three hundred milliseconds after the change of target motion, eye velocity is better correlated with second target than with the sine if it has persisted. In between, our results suggest a smooth transition from one pursuit mode to the second. The analyses of catch-up saccades kinematics also show a transition.

Title: Prior experience biases the oculomotor response to a moving target

Authors: *N. DERAVET[1], J.-J. ORBAN DE XIVRY[1], G. BLOHM[2], P. LEFEVRE[1];
[1]ICTEAM / IoNS, Univ. catholique de Louvain, Louvain-la-Neuve, Belgium; [2]Ctr. for Neurosci. Studies, Canadian Action and Perception Network, Queen's Univ., Kingston, ON, Canada

Abstracts: The brain relies on prior experience to predict the trajectory of a moving target. This information is crucial when the target transiently disappears or when visual information is noisy. In a recent model, Orban de Xivry et al. (2013) suggested that the impact of visual and prior (predictive) information on smooth pursuit eye movements is weighted by their reliability. Here, we test this hypothesis. Thirteen subjects were asked to pursue a (visually noisy) moving target that consisted of a Gaussian spot with a standard deviation of 1.27 deg. In this experiment, a prior was built by presenting identical target motion (15 or 20 deg/s) for several trials in a row (training trials). After a series of training trials, the velocity of the target was either increased or decreased by 5 deg/s (catch trials). Catch trials (20 minus 5 deg/s or 15 plus 5 deg/s) were compared to training trials with (1) an identical number of preceding training trials and (2) matching target velocity (control trials). By selecting these trials, we made sure that visual information was identical between control and catch trials whereas prior information from training trials was different (20 vs. 15 deg/s or 15 vs. 20 deg/s). We compared the gain of the smooth pursuit response during steady-state pursuit and the features of catch-up saccades across catch and control trials. The eye velocity gain during catch trials was influenced by prior information. That is, when a catch trial with a 15 deg/s target followed a series of training trials with a 20 deg/s target, the observed velocity gain during the catch trials was higher than for 15 deg/s control trials (main effect of trial type: $p<0.001$). In other words, prior information about a 20 deg/s moving target influenced the visually-guided smooth pursuit response to a 15 deg/s target. The same pattern of response was observed when target velocity was reduced during the catch trial (from 20 deg/s to 15 deg/s). In this case, the steady-state eye velocity gain was higher during the catch trials than during control trials with identical target motion but different prior

(main effect of trial type: $p<0.001$). Furthermore, catch-up saccades were also influenced by prior information. Catch-up saccades made during catch trials with a 15 deg/s target (following training trials with 20 deg/s target) had higher amplitudes than saccades of corresponding 15 deg/s control trials ($p= 0.0175$). The opposite effect ($p<0.0001$) was found in catch trials (20 deg/s) following training trials with a slower target (15 deg/s). These observations suggest that prior information about target motion is readily incorporated in the motor commands that drive both smooth pursuit and catch-up saccades.

Title: Smooth pursuit eye movements in the common marmoset

Authors: J. F. MITCHELL[1], *N. J. PRIEBE[2], C. T. MILLER[3];
[1]The Salk Inst., La Jolla, CA; [2]Univ. Texas, Austin, AUSTIN, TX; [3]Psychology, UCSD, La Jolla, CA

Abstracts: Smooth pursuit eye movements have been extensively studied in Old World primates (macaques) and humans providing critical insight into visual processing, choice, motor planning and plasticity. Pursuit eye movements allow the stabilization of slow moving objects on the retina by matching eye velocity with target velocity. This behavior is associated with specific cortical circuits that includes areas MT, MST and the FPA. To date, considerable variation has been reported across different New and Old World primate species for other specialized movements, such as fine grasping, along with corresponding anatomical variation in cortical-motor circuitry (Bortoff and Strick, 1993). Here we investigated if the common marmoset, a small New World primate, exhibits smooth pursuit eye movements. Two critical components are

required to generate smooth pursuit: 1) a moving stimulus and 2) the primate's selection a target to pursue in order to engage the tracking system. If the marmoset were to exhibit this behavior, it could provide an ideal platform to study sensory-motor transformations, as both parietal and frontal cortical areas are accessible given its lissencephalic brain. We measured smooth pursuit in two marmosets, previously trained to perform fixation tasks, using the Rashbass step-ramp paradigm. Initial pursuit eye movements were in the direction of the target motion indicating that pursuit is driven by target movement rather than target displacement. To determine how motion signals drive smooth pursuit we measured the relationship between target speed and eye acceleration during the open-loop interval. Initial eye acceleration strongly depended on the speed of horizontal target motion with faster targets evoking larger eye accelerations (4 deg/s: 32 deg/s2, 8 deg/s: 52 deg/s2), in agreement with previous measurements in macaques (Lisberger & Westbrook, 1985). We displayed faster targets (12 deg/s), but both animals had difficulty pursuing these targets, suggesting that smooth eye movements in marmosets are constrained to slower speeds than in macaques. Smooth eye movements were evoked by motion along both horizontal and vertical axes, but vertical pursuit had both smaller initial eye accelerations and reduced gain during maintenance. In sum, we have demonstrated that smooth pursuit eye movements naturally occur in marmosets to moving targets and these eye movements have similar characteristics to the eye movements observed in other non-human primates.

Title: Characterization of the optokinetic and optomotor response in mice

Authors: *F. KRETSCHMER, T. C. BADEA;
NNRL, NEI/NIH, Bethesda, MD

Abstracts: The mouse is the most common biological model organism due to it's fast reproduction cycle, relatively small size and the vast amount of genetic strategies that were developed to manipulate this species. To study the visual system of this animal various methodologies exist to examine the anatomy and physiology of the various tissues involved in the visual pathway. A limitation of these methods is that crucial questions e.g. whether or not a

specific drug can recover a vision deficit caused by a specific disease can only be addressed very indirectly and reveal little information about the properties of the actual visual performance of the animal as a whole. Since mice are unable to directly communicate their perception, objective behavioral criteria are needed to determine visual thresholds. Unfortunately mice are hard to train to perform behavioral tasks. In this study we present a novel setup that can be used to automatically evoke optokinetic and optomotor responses in mice. The resulting head and eye-movements can be recorded and quantified to determine various properties of the visual system in a robust, fast, and entirely objective way. Stimuli are presented on four computer screens surrounding the animal covering the whole field of view as textures on the surface of a virtual sphere. The sphere is positioned in such a way that the animal is always located in the center. Hence the distance to all areas of the stimulus is held constant. This is an important aspect to measure parameters like spatial acuity that are dependent on the perceived size and therefore on the distance between the head and the presented stimulus. Head and body movements are measured without the need to restrain the animal while the measurement of eye movements requires a fixation of the animal to keep the eye in the focus of a camera. The former are recorded by video tracking the snout and body axis of the animal in real time. This data is also used to objectively quantify optokinetic responses. Our self-developed video tracking algorithm continuously determines the location of the animal head that is used to readjust the position of the virtual sphere. The building plans and software of this setup are going to be released under an open source license in near future. We are currently using the setup to determine the spatial acuity, contrast thresholds, the temporal resolution, the visual field and the directional tuning in wild type mice. This data will help us to design experiments in future, establishing a baseline that enables us to analyze the visual deficits caused by mutations and diseases. For this purpose we already recorded various known mouse models for retinal degeneration at multiple time points.

Title: Disconjugacy of eye movements in zebrafish larvae

Authors: C.-C. CHEN[1], C. J. BOCKISCH[1,2,3], G. BERTOLINI[1], *D. STRAUMANN[1], Y.-Y. M. HUANG[1];
[1]Univ. Hosp. Zurich, Dept. of Neurol., Zurich, Switzerland; [2]Univ. Hosp. Zurich, Dept. of Ophthalmology, Zurich, Switzerland; [3]Univ. Hosp. Zurich, Dept. of Otorhinolaryngology, Zurich, Switzerland

Abstracts: In zebrafish larvae, the two eyes mostly move in the same direction and their saccades occur at the same time. However, the eye movements appear to be disconjugate. First, the saccadic peak velocities and amplitudes during optokinetic stimulation and in the dark are significantly higher in the nasal-to-temporal (N-T) than the temporal-to-nasal (T-N) direction. Second, the time constant of centripetal eye drift in the dark is higher in the T-N direction than the N-T direction. Third, during optokinetic stimulation, the median eye velocity is lower in the N-T than in the T-N direction. Moreover, the beating field shifts more eccentrically when slow phases point in the N-T direction, although maximum slow-phase eye velocities are not significantly different between slow phases in the N-T and T-N directions. In this study, we investigated possible mechanisms of this horizontal disconjugacy using the top-down approach. A mathematic ocular motor model comprising an optokinetic system, an eye plant, burst neurons, and a velocity-to-position neural integrator (VPNI) was designed to simulate the larval eye movements. The model parameters were estimated based on the empirical data. A subsequent modeling-parameter analysis was performed to simulate how single subsystems affect the eye movements. The modeling results suggested that the ocular motor control signals in zebrafish larvae are separate for the two eyes and the two directions in the orbit (N-T vs. T-N), suggesting four distinct neural networks, i.e. two on both sides.

Title: Measuring ocular drifts for the study of natural images

Authors: *D. SNODDERLY[1], H.-K. KO[2], M. POLETTI[3], M. AYTEKIN[3];
[2]Neurosci., [1]Univ. Texas, AUSTIN, TX; [3]Boston Univ., Boston, MA

Abstracts: As we scan natural images, the eye encounters fine as well as coarse detail. The information about this detail is acquired primarily during intersaccadic drift periods. Mounting evidence indicates that the drift motions of the eye are a feature that enhances fine detail, but physiological studies have not analyzed the effects of these microscopic drifts. Responses of visual neurons to natural images have generally been studied as if the eye is stationary during fixation. One reason for this situation is the challenge of measuring ocular drift with high accuracy and precision. We have been evaluating methodology for the purpose of studying neural responses to natural images with high precision during drift periods. To characterize the accuracy and precision of an eyetracker for measuring ocular drift requires utilization of a model eye or eyecoil that can mimic the signal from a real eye but be rendered absolutely stationary. This requirement has not been met for the most popular video eyetrackers, which have known artifacts related to decentration of the pupil. For two systems that are not affected by this artifact, an eyecoil (Remmel labs EM6) and a dual-Purkinje image eyetracker, (DPI v.6) we have made measurements of gain, noise and drift with model systems to assess the eyetrackers' ability to measure ocular drift. At maximum gain, the optimized eyecoil system with a bandpass of 0-320 Hz had an RMS noise level of 0.08 minarc and slow drifts over a duration of 10 min that were less than 0.03 minarc. The RMS noise level of a DPI eyetracker, measured with a model eye, was approximately 0.35 minarc for both the horizontal and the vertical axes. These values represent the best performance that could be obtained, but they will be degraded by potential artifacts that will be discussed. One such factor is unwanted micro head movements. The head is often only partially immobilized by means of a chin-rest during recordings with video eyetrackers, and residual head motion may occur even when the head is restrained with a bitebar. We have examined the amount of head motion under these different conditions and its impact on the quality of the recordings. We also compared standard calibration procedures with a novel procedure based on a gaze-contingent display and we find the new procedure can improve the accuracy of gaze localization by more than a factor of two on both axes. These results should facilitate development of standard procedures for optimizing study of the dynamics of microscopic ocular drift. Examples of drift measurements in the presence of natural images will be presented, perhaps with some neural responses as well.

Title: Color cannot be used as a contextual cue during rhesus monkey saccadic adaptation

Authors: *A. L. CECALA[1], I. SMALIANCHUK[2], S. B. KHANNA[2], M. A. SMITH[2], N. J. GANDHI[2];
[1]Biol., Elizabethtown Col., Elizabethtown, PA; [2]Univ. of Pittsburgh, Pittsburgh, PA

Abstracts: When the head does not move, rapid movements of the eyes called saccades are used to redirect the line of sight. Saccades are defined by a series of metrical and kinematic (evolution of a movement as a function of time) relationships. For example, the amplitude of a saccade made from one visual target to another is roughly 90% of the distance between the initial fixation point (T0) and the peripheral target (T1). However, this stereotypical relationship between saccade amplitude and initial retinal error (|T1-T0|) may be altered, either increased or decreased, by surreptitiously displacing a visual target during an ongoing saccade. This form of saccadic adaptation has been described in both humans and monkeys. We tested the hypothesis that a contextual cue (target color) could be used to evoke differential gain (actual saccade/initial retinal error) states in rhesus monkeys. We did not observe differential gain states correlated with target color during horizontal adaptation regardless of whether these targets were displaced simultaneously, sequentially, along the same vector as the primary saccade or perpendicular to it. These results are consistent with hypotheses that state that color cannot be used as a contextual cue and are interpreted in the context of previous studies of contextual saccadic adaptation in both humans and monkeys.

Title: Phasic and tonic types of glycine-mediated inhibition dominate in parvalbumin positive dorsal horn interneurons

Authors: *R. J. CALLISTER[1], K. M. SMITH[1], D. I. HUGHES[2], B. A. GRAHAM[1];
[1]Biomed Sci. and Pharm., Univ. of Newcastle, Callaghan, Australia; [2]Inst. of Neurosci. and Psychology, Univ. of Glasgow, Glasgow, United Kingdom

Abstracts: The dorsal horn of the spinal cord is an important site for modality specific processing of sensory information related to nociception, touch, temperature and itch. Importantly, segregation of these modalities is essential for contextually relevant sensory experience. When modality segregation fails aberrant sensory experiences such as allodynia may emerge. We have recently described a population of inhibitory parvalbumin-positive interneurons (INs) with functional properties and connectivity that would enable them to segregate tactile and nociceptive information (Hughes et al, 2012 J Physiol 16:3927). These parvalbumin-positive INs receive weak excitatory synaptic input, which is surprising as the output of neural circuits is governed by the opposing action of excitatory and inhibitory inputs. Here we examine inhibitory drive to parvalbumin-positive INs using targeted patch-clamp recording in transgenic mice that express enhanced green fluorescent protein (eGFP) in parvalbumin-positive INs. Adult mice (2-3 months old, both sexes) were deeply anaesthetized with ketamine (100 mg/kg, i.p.) and decapitated. Transverse spinal cord slices (300 um thick) were prepared from the lumbar cord. Recordings were made with a CsCl-based internal at 34^{o}C (holding potential -70 mV). Phasic and tonic forms of inhibition were detected in all recordings from parvalbumin-positive INs (n = 9). Miniature inhibitory postsynaptic currents (mIPSCs) had large mean amplitudes (124 ± 23 pA), fast rise (0.78 ± 0.09 ms) and decay times (6.12 ± 0.54 ms), and occurred at a relatively high frequency (1.31 ± 0.25 Hz). Bath application of bicuculline (10 uM) had minimal effect on mIPSC properties, whereas addition of strychnine (1 uM) completely abolished all mIPSCs. This suggests glycine-mediated synaptic inputs provide most of the phasic inhibitory input to parvalbumin-positive INs. The holding current in all parvalbumin-positive IN recordings decreased (mean amplitude = 104.69 ± 52.18 pA) during the application of strychnine, indicating that a tonic glycine-mediated inhibitory current also

regulated the activity of parvalbumin-positive INs. Together these data suggest both phasic and tonic glycine-mediated inhibition can modify the output of parvalbumin-positive INs and thus alter the capacity of spinal circuits to process and segregate tactile and nociceptive signals.

Title: Multiunit recordings of superficial dorsal horn nocicepitive neurons in a longitudinal slice of mice spinal cord

Authors: E. CISNEROS, I. MAZO, *C. ROZA, I. RIVERA-ARCONADA, J. A. LOPEZ-GARCIA;
Univ. De Alcala, Alcala De Henares., Spain

Abstracts: Central sensitization underlying chronic pain is conceived as an increased excitability of neural circuits processing pain signals in the spinal cord. Although most of the evidence supporting spinal sensitization arises from studies of individual neurones, adjustments in the temporal correlation of neuronal discharges might also occur and these need to be addressed with techniques allowing the simultaneous recording of a number of discrete elements. The spinal cord was extracted from > 5 weeks old mice via a dorsal laminectomy under anaesthesia (i.p. urethane 2 g/ Kg). We obtained a single longitudinal slice (~500 μm thick) sectioned in a vibratome containing the superficial layers of the cord and dorsal roots of lumbar segments 1 to 5. The slice was maintained *in vitro* by continuous superfusion of ACSF at 22±1 ºC. NeuroNexus multiple electrode arrangement (MEA) mounted on a motorised micromanipulator were carefully lowered down into the preparation to record multiple neurons. Extracellular recordings were performed in a total of 107 units clearly identified by spike sorting obtained from a total of 20 experiments. Most of the units with spontaneous activity (68/105) presented irregular

spontaneous discharges, however 37 showed specific patterns as revealed by their autocorrelograms (burst n = 9; duplets, n = 14; clock-like, n= 10 and short trains, n = 4). Most neurons showed synaptic responses to the activation of Aβ- (n = 20), Aδ- (n = 35) or C fibres (n = 15) and a small proportion showed wind-up to repetitive stimulation at C-fibre intensity (n = 14). NBQX (5 μM) produced a significant decrease in spontaneous firing (16/18) and wind-up (n = 3/3) and increased the input intensity required to evoke a synaptic response (n = 8/8). DAP-5 (50 μM) had no effect on spontaneous activity (n = 0/5) or in the input intensity (n = 3/3), but was able to decrease the wind-up (n = 3/3). Application of CP9999 (10 μM), NK1R-antagonist, inhibited spontaneous activity in most of the neurons (11/14), decreased wind-up responses (n = 4/4) but had no effect on the synaptic responses evoked by single stimuli. Apparently, synaptic activity in superficial dorsal horn neurons is largely mediated via AMPA and NK1 receptors, whilst wind-up seems to be mediated by both AMPA and NMDA receptors together with NK1. MEAs constitute a valuable tool to record simultaneously from small populations of neurons allowing long term stable recordings, favouring pharmacological approaches and reducing the number of animals used. Furthermore, differential effects of compounds on individual neurons recorded simultaneously might help understanding nociceptive circuits in superficial layers of the spinal cord.

Title: Hyperexcitability of spinal neurons contributes to pain in a transgenic mouse model of sickle cell disease

Authors: *G. CATALDO[1], K. GUPTA[2], D. A. SIMONE[1];
[1]Diagnos. and Biol. Sci., [2]Med., Univ. of Minnesota, Minneapolis, MN

Abstracts: Pain is a major defining characteristic of sickle cell disease (SCD), is difficult to treat, and contributes significantly to a poor quality of life. Acute features of sickle pain and the development of chronic pain syndromes in many patients with SCD suggests that central neural mechanisms contribute to pain in this disease although the underlying mechanisms are poorly understood. Using a transgenic mouse model of SCD, electrophysiological approaches were used to determine whether nociceptive neurons in the spinal cord become sensitized during the disease process and contribute to hyperalgesia. Studies were carried out using Berkeley sickle mice (HbSS-BERK) homozygous for the expression of human sickle hemoglobin, which show severe hematologic phenotype, organ damage and characteristic features of pain observed in human sickle cell disease. Littermate controls (HbAA-BERK) expressing normal human hemoglobin on the same mixed genetic background we also used. This unique transgenic mouse provides an opportunity to investigate neural mechanisms that mediate pain in SCD. Mice were tested for mechanical hyperalgesia then anesthetized with isoflurane before a laminectomy exposed the lumbar spinal cord. Extracellular recordings were made from single dorsal horn neurons with receptive fields (RFs) located on the plantar surface of the hind paw. RFs were identified by stroking the skin and applying mild pressure and mapped using von Frey filaments. Neurons were classified functionally as WDR or HT using mechanical stimuli of graded intensities. The discharge rate of spontaneous activity was recorded for 3 minutes. Mechanical response thresholds and responses evoked by suprathreshold mechanical stimuli were also determined. Comparisons of discharge rates were made between control and sickle mice. Nociceptive dorsal horn neurons in sickle mice were sensitized as evidenced by enlarged RFs (HbAA 16.5mm^2 ± 2.2, HbSS 39.6mm^2 ± 3.1), increased rate of spontaneous activity (HbAA 0.23 ± 0.19, HbSS 8.7 ± 4.3), lower mechanical thresholds (HbAA 26.8mN ± 3.0, HbSS 15.6mN ± 3.2), enhanced responses to mechanical stimuli, and prolonged after-discharges following mechanical stimulation as compared to control mice (data combined for WDR and HT neurons). Direct recordings of enhanced action potential activity in dorsal horn neurons from sickle mice suggest that central sensitization may be a key factor contributing to chronic pain in patients with SCD. These findings are essential to elucidating the mechanisms that underlie central sensitization in SCD in order to identify novel targets for treating the debilitating pain associated with this disease.

Title: Intradermic capsaicin increases autogenic and heterogenic PAD in Aδ articular afferents as part of a control mechanism that regulates information flow in nociceptive afferents

Authors: *A. O. RAMIREZ[1], E. F. HERNÁNDEZ[2], P. RUDOMIN[2,3];
[1]Physiol., Biophysics and Neurosciences, Ctr. De Investigación Y Estudios Avanzados, México D.F., Mexico; [2]Physiol. , Biophysics and Neurosciences, Ctr. de Investigación y Estudios Avanzados del IPN, Mexico DF, Mexico; [3]Colegio Nacional, Mexico DF, Mexico

Abstracts: Previous studies in the anesthetized cat have indicated that, in contrast with tendon organ afferents, autogenic primary afferent depolarization (PAD) of single afferents in the posterior articular nerve (PAN) is relatively small, but can be increased by capsaicin-induced skin inflammation. Since at present there is limited information on the type of articular afferents that express the capsaicin-induced autogenic PAD, we have now extended these studies and examined PAD of single slow conducting PAN afferents. PAD was inferred from changes in the current required for single afferent fiber antidromic activation by stimuli applied within the region where the PAN evoked field potentials were largest (L6-L7 segments 0.6 to 2.2 mm depth). The examined fibers had conduction velocities and peripheral thresholds in the Aδ range (34.2 ± 1.2 m/s and 2.8 ± 0.3 xT, mean ± SE). Two hours after the intradermic injection of capsaicin, PAN nerve stimulation (3 pulses 1.2- 5xT, 700 Hz, applied 35 ms before the test pulse) reduced the intraspinal threshold of 8 PAN fibers from 94.6 ± 1.3%, relative to control threshold, to 87.2 ± 1.5%. That is, it produced PAD. In 7 fibers, before capsaicin, PAN stimulation increased the intraspinal threshold to 113.3 ± 2.5% (PAH). However, after capsaicin, these same stimuli produced PAD since they reduced the intraspinal threshold to 90.9 ± 4.4%. In 6 cases, after capsaicin, PAN stimuli below the peripheral threshold of the examined fiber produced PAD (from 105.8 ± 2.9% to 88.2 ± 3.6%). In 9 fibers, in addition to the facilitation of the autogenic PAD, the intraspinal threshold produced by stimulation of the cutaneous SP and SU nerves changed from 91.1 ± 2.3% to 84.6 ± 2.4% and from 93.6 ± 2.1% to 82.4 ± 9.9% respectively. These observations provide evidence that nociceptive stimulation induced by intradermic capsaicin increases transmission along the pathways producing autogenic and heterogenic PAD of Aδ, presumably nociceptive, PAN afferents. An increased autogenic PAD of these afferents would limit the activation induced by nociceptive stimulation of the skin and could function as part of a self-regulating control of nociceptive information in this pathway. The increased autogenic and heterogenic PAD could result from intrinsic changes in spinal neuronal connectivity as well as from changes in descending control.

Title: Stress induces pain transition by potentiation of AMPA receptor phosphorylation

Authors: S. LIU[1,2], Y. YANG[1], C. LI[1,2], H. FANG[1], O. FURMANSKI[1], J. SKINNER[1], R. JOHNS[1], R. HUGANIR[1], *F. TAO[1,3];
[1]John Hopkins Univ. Sch. Med., BALTIMORE, MD; [2]Zhengzhou Univ. Basic Med. Col., Zhengzhou, China; [3]Texas A&M Univ. Baylor Col. of Dent., Dallas, TX

Abstracts: Table of Contents **Aim of Investigation:** Chronic pain after surgery is a serious issue in clinical practice that has received increased interest in recent years. However, it is unclear how the transition from acute to chronic postsurgical pain occurs. Previous studies have shown that psychosocial and socio-environmental factors are involved in the development of chronic postsurgical pain. In the present study, we investigated the molecular mechanism underlying pain transition after surgery. **Methods:** Wild-type and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor phosphorylation mutant mice were used in this study. Social defeat stress and plantar incision were carried out as described previously. Western blotting was conducted to analyze AMPA receptor phosphorylation. Surface biotinylation, cross-linking, and pHluorin assays were conducted to detect AMPA receptor trafficking. Electrophysiological recording was performed for long-term potentiation (LTP) induction. **Results:** We found that social defeat stress markedly enhanced plantar incision-induced AMPA receptor phosphorylation in the spinal cord and greatly prolonged plantar incision-induced pain, but stress alone did not produce pain behaviors. We also found that targeted mutation of AMPA receptor GluA1 phosphorylation site Ser831 significantly inhibited stress-induced prolongation of incisional pain. In addition, we observed that stress significantly increased GluA1 membrane surface expression and GluA2 internalization in the spinal dorsal horn neurons, and that stress hormone corticosterone induced GluA1 membrane insertion and GluA2 internalization in

cultured spinal cord neurons. Our electrophysiological experiments showed that subthreshold 10-Hz stimulation induced LTP in AMPA receptor phosphomimetic mutant mice, suggesting that AMPA receptor phosphorylation can lower the threshold for LTP induction and increase the probability of synaptic plasticity. **Conclusion:** AMPA receptor phosphorylation may play an important role in stress-induced pain transition and the development of chronic postsurgical pain. *(Supported by the Blaustein Pain Research Fund and NIH R01 Grant DE022880)*

Title: Morphological and physiological characteristics of a subgroup of GABAergic spinal lamina II neurons in CCI mice

Authors: *H.-M. ZHANG[1], Y. LI[1], Q. YANG[2], P. M. DOUGHERTY[1];
[1]Anesthesiol., The Univ. of Texas MD Anderson Cancer Ctr., Houston, TX; [2]Dept. of Integrative &Pharmacology, The Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX

Abstracts: The processing of sensory, including nociceptive, information in spinal cord dorsal horn is critically modulated by spinal GABAergic neurons. GABAergic neurons in spinal dorsal horn have been classified morphologically and physiologically, but the morphological and physiological properties under the neuropathic pain condition had not been investigated. We used a transgenic mouse strain co-expressing enhanced green fluorescent protein (EGFP) and the GABA-synthesizing enzyme GAD67 to compare the morphological and physiological properties change of GABAergic neurons in sham control and CCI neuropathic pain mice. Whole-cell patch-clamp technique was used for intracellular labelling and physiologically characterize EGFP-expressing lamina II neurons in spinal cord slices. The EGFP labelled neurons in both sham and CCI mice morphologically exhibited islet, central and vertical cells but no radial cell was observed. The length of cell dendrities is significantly shorter in CCI mice (155.96 ± 18.29 μm) compared with sham control mice (334.93 ± 29.48 μm). The resting membrane potential of

the EGFP-expressing neurons in sham and CCI mice is no significant difference (-60.5 ± 3.2 verse -61.8 ± 3.5mV). When stimulated by rectangular current injection, the firing pattern of these EGFP-expressing neurons showed tonic, delayed, initial and irregular firing pattern, which also have been observed in CCI mice. These results suggest that GABAergic neurons are morphologically shrink with the excitability no change in neuropathic pain condition. The morphological changes may contribute to the neuropathic pain of CCI mice.

Title: Properties of recombinant isolectin B4 (IB4): Binding and immunostaining

Authors: M. D. KOHLS, *D. A. LAPPI, L. R. ANCHETA;
Advanced Targeting Systems, SAN DIEGO, CA

Abstracts: Isolectin B4 (IB4) is a protein found in the seeds of *Griffonia simplicifolia*, a woody climbing shrub native to western and central Africa. Although initially used as an identifier and agglutination agent for B-type red blood cells, it has since become widely used in the neurosciences as a neuronal tracer, for labeling specific populations in the spinal cord, and as a targeting moiety for delivering toxins to specific cells. Recent developments in response to competition from the nutritional supplement industry have reduced the available supply of seeds from which the native protein is purified. In order to create a consistent supply of pure and active IB4 we have determined the full nucleotide sequence of the IB4 gene, cloned it from *Griffonia* genomic DNA, and expressed recombinant IB4 in *E. coli*. The recombinant IB4 (rIB4) was purified and tested in several activity assays against the native protein. A fusion protein of rIB4 and GFP was created to demonstrate the use of this protein in immunostaining. *Griffonia* also contains isolectin A that agglutinates A-type red blood cells - the A and B lectins form tetramers with varying subunit combinations. These tetramers are potential sources of contamination in preparations of the native protein. rIB4 is completely free of any A lectin contamination. The rIB4 is highly pure, and has identical activity to the native protein.

Title: Modulation of nociceptive processing at the spinal cord level by PAR2 receptors

Authors: *P. MRÓZKOVÁ[1,3], J. PALECEK[2];
[1]Dept. of Functional Morphology, Inst. of Physiol. Acad. of Sci., Czech Republic; [2]Dept. of Functional Morphology, Inst. of Physiol. Acad. of Sci., Prague, Czech Republic; [3]Dept. of Physiol., Charles Univ. in Prague, Fac. of Sci., Prague, Czech Republic

Abstracts: Modulation of synaptic transmission in the spinal cord dorsal horn plays a key role in the development of pathological pain states. Protease-activated receptors (PARs) are a family of four G-protein-coupled receptors (PAR1-4) activated by proteases. The role of PAR2 receptors in pain perception is established in the peripheral tissues. However, the role of PAR2 receptors on the central branches of DRG neurons in the spinal cord is not fully understood. The present study aimed to study the role of PAR2 in nociceptive processing and modulation of synaptic transmission in the superficial dorsal horn (DH) neurons. Whole-cell patch clamp recordings of miniature - mEPSCs, spontaneous - sEPSCs and evoked - eEPSC currents (by dorsal root

stimulation) were made from superficial DH neurons in acute spinal cord slices prepared from Wistar rats 21 days old, with the presence of strychnine (5uM) and bicuculline (10uM), at -70mV holding potential. TTX (0.5uM) application was used for mEPSC detection. Application of PAR2 agonist SLIGKV-NH2 (PAR2 AP, 100μM) induced inhibition of mEPSC frequency. In a second set of experiments PAR2 AP application induced sEPSC frequency increase and also increased the amplitude of eEPSC recorded in the superficial DH neurons. Application of the inactive peptide VKGILS-NH2 (100uM) did not evoke any change in the mEPSCs, sEPSC frequency or eEPSC amplitude. The changes in the mEPSC, sEPSC and eEPSC induced by the PAR2 AP application were dependent on activation of protein kinase C. Application of PKC inhibitor (staurosporin 250nM) prevented all changes evoked by the SLIGKV-NH2 alone. Additionally, effect of PAR2 AP was also prevented by application of TRPV1 antagonist SB366791 (10uM). Our results suggest that presynaptic PAR2 receptors may play an important role in modulation of nociceptive synaptic transmission in the spinal cord dorsal horn. Further experiments are needed to fully evaluate the role of spinal cord PAR2 receptors in pain modulation under control and pathological conditions.

Title: Monosynaptic convergence of somatic and visceral C-fiber afferents onto spinal lamina I neurons: A mechanism of referred pain

Authors: E. FERNANDES[1], L. L. LUZ[1], E. KOKAI[2], M. SIVADO[2], P. SZUCS[2], *B. V. SAFRONOV[1];
[1]IBMC, Porto, Portugal; [2]Univ. of Debrecen, Dept. of Physiol., Debrecen, Hungary

Abstracts: Referred pain is a phenomenon of feeling pain at a site other than the site of its origin. Examples include myocardial ischemia during a heart attack where pain is often felt in the

neck, shoulders and back rather than in the chest, the site of the injury. One of the most widely accepted theories of referred pain suggests that inputs from somatic and visceral afferents can converge within the spinal cord. However, it is not known whether these afferents converge directly (monosynaptically) onto a specialized neuron, or, alternatively, a polysynaptic processing is required. Furthermore, little is known about the anatomical classes of neurons involved in somatovisceral integration. Here we used the isolated spinal cord preparation with preserved greater splanchnic and intercostal Th9 peripheral nerves, to show that nociceptive C-fibers of somatic and visceral origin converge monosynaptically onto a subgroup of lamina I neurons in the thoracic (Th9-Th8) spinal cord. Neurons receiving converging inputs were both anterolateral-tract projection neurons and local-circuit neurons. Two other subgroups of lamina I neurons were specialized in receiving monosynaptic either somatic or visceral inputs. Thus, our data show that different classes of lamina I neurons process somatic-specific, visceral-specific and converging somatovisceral inputs. The monosynaptic somatovisceral convergence of C-fiber afferents on lamina I neurons provides physiological mechanism of referred pain at the spinal cord level.

Title: Temporal dynamics of dorsal horn projection neuron responses to spinal cord stimulation depend on stimulation frequency and GABAergic inhibition

Authors: ***T. ZHANG**[1], J. J. JANIK[2], W. M. GRILL[1];
[1]Biomed. Engin., Duke Univ., Durham, NC; [2]Stryker Corp., Kalamazoo, MI

Abstracts: The putative mechanism underlying pain relief by spinal cord stimulation (SCS) is suppression of the activity of sensory dorsal horn projection neurons by segmental inhibition activated by SCS. However, SCS may also excite dorsal horn neurons, and in some cases, SCS excites and inhibits the same neuron. The interaction between the excitatory and inhibitory

influences of SCS may partially explain why the efficacy of clinical SCS depends on stimulation frequency, but the temporal dynamics of this relationship have not been characterized. We recorded the responses of antidromically identified low-threshold (LT), wide dynamic range (WDR), and nociceptive-specific (NS) projection neurons in the lumbar dorsal horn to different frequencies of SCS in acute experiments in healthy, urethane anesthesized (1.6 g/kg) male adult Sprague-Dawley rats. In subsets of experiments, we administered either bicuculline (3 μg i.t.), a GABAa antagonist (12/51), or CGP 35348 (100 μg i.t.), a GABAb antagonist (8/51), to assess the effects of modulating GABAergic inhibition on neuronal responses to SCS. 32/51 antidromically identified projection neurons exhibited significant responses to SCS versus baseline. Both the responder and non-responder groups included LT, WDR, and NS neurons, but non-responders were more likely to be NS neurons and responders were more likely to be LT neurons ($p<0.05$, Pearson's Chi-Squared). Individual projection neurons exhibited a variety of responses to SCS, including transient inhibition, transient excitation, and combinations of inhibition and excitation, and both the magnitude and type of the post-stimulus response varied with stimulation frequency, often within the same neuron. Bicuculline enhanced transient excitatory responses in 3/12 neurons and unmasked excitatory responses in 3/12 neurons; CGP 35348 did not significantly affect responses to SCS. The temporal dynamics of neuronal responses depend on the SCS frequency even for the same neuron, and these responses are modulated by GABAergic inhibition, suggesting that managing the interaction between excitatory and inhibitory influences from SCS may be a way to inform more optimal SCS parameter selection.

Title: Distributed spinal fmri responses to noxious cold and heat stimuli in anesthetized monkeys

Authors: *P.-F. YANG[1,2], F. WANG[1,2], L. CHEN[1,2];
[1]Radiology and Radiological Sci., [2]Inst. of Imaging Sci., Vanderbilt Univ., Nashville, TN

Abstracts: In this study we compared noxious cold and heat stimuli evoked functional MRI (fMRI) responses at the cervical spinal cord in anesthetized squirrel monkeys. Three monkeys were scanned in a 9.4 T Varian magnet using a saddle-shaped surface transmit-receive coil positioned over the neck of the animal. Axial high-resolution Magnetization Transfer contrast (MTC) images (0.25x0.25x3 mm3) were acquired to enhance the visualization of grey and white matter. FMRI images were obtained with a gradient-echo multi-slice sequence (TE=6.5 ms; TR=24 ms; flip angle = ~12°, volume acquisition time = 1.54 s, slice = 5, 0.5x0.5x3 mm3 resolution). Two distal finger pads were stimulated with blocks (in 21 s on and 30 s off circles) of single or multiple temperatures, ranging from innocuous cool and warm (15 and 40 °C) to noxious cold and heat (4 and 47.5 °C) via a Medoc ATS probe. After physiological noise, slice timing and motion corrections, functional MRI data were analyzed with AFNI software. We found that noxious cold and heat stimulation (4 and 47.5 °C) produced reproducible fMRI responses in bilateral dorsal and ventral horns in two (out of five) consecutive spinal segments (3 mm in thickness), indicating localized spinal stimulus-evoked fMRI responses. FMRI signal time courses obtained from the ipsilateral dorsal horn differed significantly from those observed in the white matter. The nociceptive cold and heat responses were reproducible across imaging runs and sessions within each animal and across animals (n=3). Expanding on previous observations of fMRI responses to innocuous thermal stimulation in human subjects(Stroman et al., 2012), here we report distributed nociceptive cold and heat responses in both the dorsal and ventral horns of cervical spinal cord in anesthetized monkeys. Our data indicate that high-resolution MRI with novel MT contrast permits improved visualization and segmentation of spinal grey matter, thereby allowing better localization of nociceptive responses in the dorsal and ventral horns.

Title: Spinal cord astrocytes release endocannabinoids due to the activation of their CB1 receptors

Authors: *M. ANTAL[1], Z. HEGYI[1], T. OLÁH[1], A. KISS[1], Á. KőSZEGHY[1], K. HOLLÓ[1], T. PATONAY[1], L. CSERNOCH[1], A. MINCIC[2];

Abstracts: Bidirectional communication between neurons and glial cells mediated by endocannabinoid signaling has recently been demonstrated. Endocannabinoids released by neurons can activate CB1-Rs on astrocytes, resulting in glutamate release from astrocytes and a consecutive glutamate-mediated modulation of neural functions. Endocannabinoid mediated neuron-glia-neuron communication can play a major role in the regulation of many brain functions including pain processing in the superficial spinal dorsal horn. Concerning neuron-glia-neuron regulatory mechanisms neural-glial ensembles of the superficial spinal dorsal horn underlying pain processing can be an interesting functional unit of the central nervous system, since here in addition to CB1-Rs, astrocytes also express DGLα and NAPE-PLD, synthesizing enzymes of the two major endocannabinoids, 2-AG and anandamide, respectively. Thus, in the present experiment we explored the effect of astrocytic CB1-R activation on changes in intracellular Ca2+ concentration, possible Ca2+-mediated activation of DGLα and/or NAPE-PLD and consecutive release of 2-AG and/or anandamide from astrocytes. We demonstrated that application of CB1-R agonists evokes transient increase in intracellular Ca2+ concentration in astrocytes within the superficial spinal dorsal horn. To investigate whether this Ca2+ transient can activate DGLα and/or NAPE PLD, we established a primary astrocyte culture from astrocytes isolated from the spinal dorsal horn. We showed that, similar to the *in vivo* findings, cultured astrocytes express CB1-Rs as well as DGLα and NAPE-PLD. We showed that application of CB1-R agonists evokes elevation of intracellular Ca2+ concentration also in the cultured astrocytes. Measuring the 2-AG and anandamide content of the culture medium, we showed that the elevation of intracellular Ca2+ concentration of astrocytes is accompanied with a robust elevation of both 2-AG and anandamide concentration in the culture medium. The results indicate that spinal cord astrocytes can release endocannabinoids due to the activation of their CB1-Rs. We hypothesize that similarly to the cell culture environment astrocytes can release endocannabinoids also in the superficial spinal dorsal horn. The released 2-AG and anandamide then can act on neural CB1-Rs, influencing both excitatory and inhibitory neurotransmission. Thus, the astrocytic endocannabinoid signaling apparatus may influence ongoing spontaneous

network activity and integrated activity of neuronal ensembles in the pain processing neural networks of the superficial spinal dorsal horn.

Title: α5GABA-A receptors in the superficial dorsal horn regulate central sensitization

Authors: *J. PÉREZ-SÁNCHEZ[1], R. P. BONIN[1], L.-E. LORENZO[1], C. LABRAKAKIS[2], E. M. BRIDGWATER[3], B. A. ORSER[3], Y. DE KONINCK[1];

Abstracts: The tonic activation of extrasynaptic α5 subunit-containing GABA-A (α5GABA-A) receptors is known to regulate neuronal excitability in the CNS. In the spinal cord, tonic inhibition may be important for the control of nociception and has been suggested to contribute to hyperalgesia. However, the role of α5GABA-A receptors in nociceptive information processing remains elusive. We therefore explored the distribution of α5GABA-A receptors in the dorsal horn of the spinal cord and their functional contribution to pain processing. Immunohistochemical analysis showed that α5GABA-A receptors are localized in superficial

layers in the dorsal horn of the spinal cord, consistent with a role for these receptors in pain processing. In behavioural tests, mice lacking the α5GABA-A receptors (Gabra5−/−) exhibited increased responses in phase 2 of the formalin test, which has been associated with central sensitization in the dorsal horn. In addition, mechanical hyperalgesia produced by intraplantar administration of capsaicin was larger in Gabra5−/− as compared to wild type (WT) mice. However, baseline acute nociception was similar between Gabra5−/− and WT mice. Taken together, our data suggest that α5GABA-A receptors contribute to central sensitization in the dorsal horn of the spinal cord. Whole-cell recordings from dorsal horn neurons from Gabra5−/− and WT mice will show the contribution of α5GABA-A receptors in tonic inhibition in the spinal cord.

Title: Electrical stimulation of low-threshold afferent fibers depresses synaptic transmission of high-threshold afferent inputs in lamina II dorsal horn neurons

Authors: Q. XU[1,2], A. D. SDRULLA[3], V. TIWARI[3], S.-Q. HE[3], F. YANG[3], S. N. RAJA[3], X. DONG[1], *Y. GUAN[3];

Abstracts: The pain “gate control” theory postulates that activity of low-threshold/large myelinated afferent fibers (Aβ-fibers) drives a feed-forward inhibition of spinal nociceptive transmission. However, it is unclear how electrical stimulation of Aβ-fibers (Aβ-ES) modulates neuronal excitability and synaptic transmission in substantia gelatinosa (SG, lamina II) neurons,

which are important for relaying, integrating, and modulating converging nociceptive inputs in superficial dorsal horn. Therefore, we examined synaptic mechanisms in SG neurons that may contribute to pain inhibition from electro-analgesia therapies that use Aβ-ES. By conducting *in vitro* patch-clamp recording in spinal cord slices from mice (4-5 weeks old), we examined whether Aβ-ES at the dorsal root inhibits the evoked excitatory postsynaptic current (eEPSC) to high-threshold afferent inputs (i.e., C-fiber) in SG neurons. We calibrated the stimulus strength for Aβ-ES (10 μA, 0.1 ms) to activate only low-threshold afferent fibers by recording compound action potentials at the proximal dorsal root in response to increasing intensities of stimulation applied at the distal site (0-1.0 mA, 0.1 ms). The paired-pulse test stimulation (500 μA, 0.1 ms, 400 ms apart) was applied at an intensity that activates C-fibers. Aβ-ES (50 Hz, 5 min) induced a gradual and prolonged decrease in C-fiber eEPSC amplitude in SG neurons from both naïve mice and mice at 1-2 weeks after an L5 spinal nerve ligation. The paired-pulse ratio (amplitude 2nd eEPSC / 1st eEPSC) increased after Aβ-ES in these cells, suggesting that the inhibition of eEPSC by Aβ-ES may partly involve presynaptic mechanisms. Further, Aβ-ES inhibited both monosynaptic and polysynaptic C-fiber eEPSC. This study suggests that Aβ-ES at 50 Hz may depress the synaptic transmission of high-threshold afferent inputs in SG neurons. Future studies may reveal whether this novel form of synaptic depression, which is induced by Aβ-fiber activity and mostly mediates non-noxious inputs, contributes to pain inhibition from Aβ-ES therapy.

Title: Optogenetic dissection of pain and itch circuitry in the spinal dorsal horn

Authors: *J. HACHISUKA, K. M. BAUMBAUER, L. M. SNYDER, H. R. KOERBER, S. E. ROSS;
Dept. of Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstracts: Skin sensations, such as pain, touch, hot, cold and itch are processed in the spinal dorsal horn and relayed to the brain. There are multiple types of excitatory and inhibitory interneurons, which form circuits that modulate skin sensation. Recently, many molecules that relate to pain and itch have been localized in specific subsets of these interneurons. However, little is known about the role of these neurons in the spinal circuitry. In order to address these questions, we used specific mouse cre lines (e.g. neurotensin cre) crossed with cre-responsive channelrhodopsin (Ai32). The roles of these interneurons were investigated by recording from retrogradely-labeled spinoparabrachial tract cells in an *ex vivo* preparation consisting of whole lumbosacral spinal cord/DRG/nerve and skin. We performed whole cell patch clamp recordings from labeled cells visualized first by fluorescent microscopy and then oblique infrared LED illumination for establishing whole cell recordings. We first recorded from the channelrhodopsin-expressing neurons to confirm that blue light stimulation evoked inward current in voltage clamp mode and action potentials in current clamp mode. We next recorded from the projection neurons that are identified by retrograde labeling and examined whether they receive input from the different populations of interneurons. Finally, we identified the cell's receptive field by applying mechanical and thermal stimulation to the skin, and used the combination of blue light stimulation of the spinal cord with natural stimulation of the skin. The results of these experiments are providing novel insights of the circuitry of pain and itch sensation in the spinal cord.

Title: Low-threshold mechanoreceptive Aδ- and C-afferent units contribute to the inhibition of nociceptive transmission via the spinal μ-opioid system

Authors: *N. WATANABE[1], M. PICHÉ[2], H. HOTTA[1];
[1]Tokyo Metropolitan Inst. of Gerontology, Tokyo, Japan; [2]Dept. of Chiropractic, Univ. du Québec à Trois-Rivières, Trois-Rivières, QC, Canada

Abstracts: Background and aim Pain may subside by touching the skin near the painful site. As an underlying mechanism of touch-induced analgesia, the most common belief is that afferent inputs conveyed by large-diameter afferent fibers modulate spinal activity induced by small-diameter afferent fibers. However, the details of this theory have not been confirmed. Recently, we found that gentle mechanical cutaneous stimulation (touch) with a soft disc covered with microcones (with texture is similar to that of a finger), but not with a flat disc, inhibits nociceptive somatocardiac reflexes in anesthetized rats and conscious humans. The aim of the present study is to identify the types of cutaneous afferent fibers and spinal opioid receptors that contribute to the anti-nociceptive effects of microcone touch. Methods & Results The present study consists of two experiments performed on deeply-anesthetized rats. Touch was applied to the inner thigh for 10 minutes. In the first experiment, unitary activity of skin afferents was recorded from the saphenous nerve using bipolar wire electrode, and responses to touch using a microcone disc and flat disc (control) were compared. In total, 38 low-threshold mechanoreceptive afferents with slowly adapting property were obtained. Based on conduction velocity, recorded units were classified into Aβ (n = 13), Aδ (n = 12) and C (n = 13) fibers. During microcone touch, greater increments of discharge rate were observed in the majority of low-threshold mechanoreceptive Aδ and C afferent units, whereas most Aβ afferents similarly responded to the two types of touch. In the second experiment, we examined the effect of an intrathecal injection of opioid receptor antagonists on the inhibitory effects of microcone touch on heart rate responses to noxious heat stimulation. Heat stimulation was applied to the lower back of rats using a Peltier thermode and altered heart rate by 10.9 ± 1.2 bpm. The magnitude of the heart rate response was suppressed by microcone touch in saline-injected rats by approximately 36 % and the suppression continued even 10-15 minutes after touch terminated. Such an inhibition was blocked in naloxone- (non-selective opioid receptor antagonist) or CTOP- (μ-opioid receptor antagonist) injected rats. Naltrindole (δ-opioid receptor antagonist) did not influence the effect of microcone touch. Conclusion The present study suggests that low-threshold mechanoreceptive Aδ and C afferents excited by touch activate the μ-opioid system in the spinal cord, leading to the inhibition of nociceptive transmission that contributes to somatocardiac reflexes.

Title: Impact of spinal interneuron disinhibition on somatosensory processing in neuropathic pain

Authors: *K. LEE[1,2], S. A. PRESCOTT[1,2];
[1]Neurosciences and Mental Health, Hosp. For Sick Children, Toronto, ON, Canada; [2]Dept. of Physiol., Univ. of Toronto, Toronto, ON, Canada

Abstracts: Neuropathic pain is a debilitating condition whose symptoms arise from the abnormal processing of somatosensory input. Reduction of synaptic inhibition in the spinal dorsal horn can account for many features of neuropathic pain including mechanical allodynia, a phenomenon in which innocuous tactile stimulation to be mistakenly perceived as painful. Disinhibition derives at least in part from chloride dysregulation caused by down¬regulation of the potassium-chloride co-transporter KCC2. But it remains unclear how different types of spinal neurons are affected and, in turn, how this impacts network-level processing of sensory input. Recording *in vivo* from anesthetized rats, we found that pharmacological blockade of either KCC2 or GABAA receptors caused spinal interneurons to become hyperresponsive to light tactile stimulation, but whereas blockade of carbonic anhydrase by acetazolamide significantly reversed the effects of KCC2 blockade, it had no effect after GABAA receptor blockade. Given that acetazolamide has antiallodynic effects in behavioural studies, our data confirm the importance of KCC2 downregulation as a disinhibitory mechanism contributing to neuropathic pain. We also found that cutaneous receptive fields (RFs) were dramatically expanded after KCC2 blockade, consistent with normally subliminal excitatory input being unmasked by the reduction of inhibition. Indeed, whereas stimulation around the RF normally reduced the response to concurrent stimulation inside the RF, such stimulation enhanced responses after KCC2 blockade. This effect - the switch from inhibition to excitation by stimulation outside the normal RF - was significantly greater in excitatory interneurons than in inhibitory interneurons. Cell types were distinguished *in vivo* on the basis of spike waveform, spiking pattern, spontaneous spike rate, and modulation by KCC2 blockade; their identities as excitatory and inhibitory neurons were established by comparison with *in vitro* recordings from identified cell types. Our data demonstrate that disinhibition arising from distinct molecular mechanisms is differentially susceptible to different therapeutic interventions. Furthermore, although excitatory

and inhibitory interneurons both experience disinhibition, we show that excitatory interneurons are disproportionately affected because of their synaptic connectivity. The resultant changes in network-level processing are important for how disinhibition manifests the clinical features of neuropathic pain.

Abstracts: The dorsal horn of the spinal cord is the first central region where somatosensory information is processed. A complex network of excitatory and inhibitory interneurons integrates peripheral inputs before transferring them to supraspinal sites. How the different elements of this network are interconnected is not well established. In this study, we propose a quantification method to analyze the synaptic appositions from identified inhibitory neurons to identified excitatory neurons. This method uses transgenic reporter mice, immunostainning, confocal imaging and image processing using the IMARIS software. Our method allows us to generate a 3-D reconstruction of neuronal processes and detect close synaptic appositions inferior to 100nm. This approach enabled us to establish the connectivity pattern of parvalbumin interneurons onto their excitatory interneurons target. Furthermore, our results indicate that a single inhibitory interneuron can perform appositions onto multiple target excitatory interneurons. By combining this approach with behavioral experiments, we will examine

whether interfering with this pattern of connectivity impacts the processing of sensory information in the dorsal horn, especially in the context of chronic neuropathic pain.

Title: Dopamine modulation of synaptic transmission in lamina I neurons of the dorsal horn spinal cord

Authors: *M. PUOPOLO;
Anesthesiol., Stony Brook Med., Stony Brook, NY

Abstracts: The dorsal horn spinal cord is the first relay station where sensory information from the periphery and deeper tissue are received, integrated, and relayed to higher brain structures. Descending fibers from the Central Nervous System play a critical role in the integration of the sensory information in the dorsal horn spinal cord. While the contribution of descending noradrenergic, serotonergic, and GABAergic fibers is well established, the contribution of descending dopaminergic fibers from area A11 of the hypothalamus is poorly understood. The aim of the present project was to investigate whether dopamine can modulate the synaptic transmission between primary afferent fibers and projecting neurons located in lamina I of the dorsal horn spinal cord. We used the patch clamp technique in an intact spinal cord preparation *in vitro* isolated from rats (P14-21). Excitatory post synaptic currents (EPSCs) were recorded in whole-cell voltage clamp configuration (Vhold= -70 mV) from lamina I neurons. The external solution was (in mM): 125 NaCl, 2.5 KCl, 1.25 $NaH_2PO_4.H_2O$, 26 $NaHCO_3$, 1 MgCl2, 2 CaCl2, 20 Glucose, 0.01 bicuculline, 0.005 strychnine, and continuously oxygenated with 95/5% O_2/CO_2. The internal solution was (in mM): 125 $CsMeSO_3$, 10 NaCl, 2 MgCl2, 10 HEPES, 10 EGTA, 4 MgATP, 0.3 NaGTP, 14 Phosphocreatine, 5 QX-314, pH adjusted to 7.2 with CsOH. The dorsal root was stimulated with a suction electrode (0.1 ms duration, 350-500 μA constant current output) at 0.01 Hz. Lamina I neurons included in the study had large size (cross-sectional soma area of 339.28 ± 123.67 μm^2), and cell capacitance of 70.57 ± 21.18 pF, n=22, consistent with projecting neurons. Experiments were carried out at 35 ± 1 ºC. 20 μM dopamine reduced

the EPSC (measured as the charge transfer) to 46.1 ± 29.2 % (n=14), with respect to control. The inhibitory effect of dopamine on the EPSC could be mimicked by both D1/D5 and D2 dopamine receptor agonists. 10 μM SKF 81297 reduced the EPSC to 59.1 ± 25.5 % (n=5), with respect to control. When 20 μM quinpirole were added on top of 10 μM SKF 81297, the EPSC was further reduced to 53.9 ± 36.2 % (n=5), with respect to control. When the afferent fibers were stimulated with paired stimuli (2s apart), the ratio between the second and the first EPSC was increased from 0.43 ± 0.19 in control to 0.76 ± 0.22 (n=7) in the presence of 20 μM dopamine, consistent with a presynaptic effect of dopamine. The data presented here suggest that dopamine can modulate the synaptic inputs from primary afferent fibers onto projecting lamina I neurons. The effect of dopamine is mediated by activation of both D1/D5 and D2 dopamine receptors. Increase in the PPD ratio suggests a presynaptic effect of dopamine.

Title: Reduced pain sensitivity in plasma membrane calcium atpase 2 (pmca2) heterozygous mice

Authors: *V. KHARIV[1,2], W. DONG[2], R. F. HEARY[2], S. ELKABES[2];
[1]Grad. Sch. of Biomed. Sciences, NJMS, Rutg, Newark, NJ; [2]Dept. of Neurolog. Surgery, The Reynolds Family Spine Lab., Newark, NJ

Abstracts: Plasma membrane calcium ATPase 2 (PMCA2) is a calcium extrusion pump expressed in excitable cells. In the spinal cord, it is primarily localized to neurons in both the dorsal and ventral horns. Our earlier investigations indicated that PMCA2 is essential for the survival of spinal cord neurons, as silencing of PMCA2 expression causes neuronal death *in vitro*. Moreover, we reported that PMCA2 deficiency is associated with motor abnormalities and a reduction in motor neuron number, *in vivo*. It is not yet known whether PMCA2 plays a role in sensory function. To address this issue we assessed thermal and mechanical sensitivity in the $PMCA2^{+/-}$ mice and wild type littermates.The hotplate paw withdrawal and Von Frey filament

tests indicated that naïve, female PMCA2$^{+/-}$ mice are significantly less sensitive to thermal or mechanical stimuli than wild-type controls. This difference was not observed in male mice, demonstrating sex specificity. Following spinal cord injury, a condition that can elicit neuropathic pain, female PMCA2$^{+/-}$ mice continued to exhibit significantly less thermal sensitivity. To investigate the mechanisms underlying the sensory alterations in the PMCA2$^{+/-}$ mice, we initiated studies on the dorsal root ganglia (DRG) and the dorsal horn (DH). As we did not find expression of PMCA2 in the DRG, we focused on molecular changes in the DH. There was a significant, 40% reduction in the levels of NeuN, a general neuronal marker, in the DH of PMCA2$^{+/-}$ mice compared to the wild type. Since GABAergic interneurons, NMDA receptor-expressing neurons and metabotropic glutamate receptor (mGluR)-expressing neuronal and non-neuronal cells contribute to central pain mechanisms, we quantified NMDAR2B, mGluR1, mGluR5, and glutamic acid decarboxylase (GAD; the rate limiting enzyme in the synthesis of GABA) protein levels in the DH. mGluR5 levels were significantly decreased by 62% in the DH of the PMCA2$^{+/-}$ mice compared to the wild type. In contrast, mGluR1 levels were significantly increased by 2-fold. No significant differences were observed in NMDAR2B or GAD levels in the DH of PMCA2$^{+/-}$ and WT mice.These findings suggest that PMCA2 plays a role in mechanisms implicated in nociceptive processing. It remains to be determined how a reduction in PMCA2 affects mGluR1 and mGluR5-expressing cells in the DH and whether these alterations contribute to PMCA2-dependent changes in sensory function.

Title: A role for the transcription factor Lmx1b in pain modality discrimination

Authors: *A. KANIA[1], N. SZABO[1], R. V. DA SILVA[1], S. SOTOCINAL[2], J. MOGIL[2];
[1](IRCM) Inst. de recherches cliniques de Montreal, Montreal, QC, Canada; [2]McGill Univ., Montréal, QC, Canada

Abstracts: One important aspect of nociception is the ability to discriminate between modalities such as noxious heat versus mechanical stimulation. Electrophysiological studies suggest that neuronal circuits devoted to specific pain modalities are organised into “labeled lines”, such that pain sensation is processed by neurons primarily devoted to the sensation of a particular pain modality. While molecular correlates of such sorting in vertebrates are evident at the level of primary sensory neurons, few molecular markers of modality discrimination have been found in the dorsal horn of the spinal cord. Using a candidate gene approach we focussed on the transcription factor Lmx1b, which is expressed in dorsal horn neurons and essential for their normal development, but its role in nociception has not been characterised in postnatal animals. To assess the behavioral consequences of deleting Lmx1b in the spinal cord, we generated a conditional Lmx1b knockout mouse line using a spinal cord-specific Cre recombinase driver. Such mice show robustly lowered sensitivity to mechanical noxious stimulation but have normal thermal nociception. We are currently exploring the possibility that Lmx1b defines a population of dorsal horn neurons devoted to mechanical pain sensation, in line with the observation that human LMX1B mutations result in modality-specific nociception defects.

Abstracts: [Background and aims]Inflammatory bowel disease (IBD) is associated with chronic abdominal pain. Recent studies indicate that reactive oxygen species such as hydrogen peroxide (H_2O_2) may activate transient receptor potential ankyrin 1 (TRPA1). In this study, we investigated the role of H_2O_2 and TRPA1 in visceral hyperalgesia in rats following trinitrobenzene sulphate (TNBS)-induced colitis. [Methods]Adult male Sprague-Dawley rats (200-250 g) were used. Colonic inflammation was induced by intra-colonic administration of TNBS. Visceromotor response (VMR) against colorectal distention (CRD) was recorded to evaluate the painful response at 1, 3, 7 and 14 days after TNBS treatment. An antioxidant, N-acetyl-L-cysteine (NAC) or a TRPA1 antagonist, HC-030031 was intravenously administrated to the TNBS-(or vehicle-) treated rats. A group of rats were killed one day after TNBS treatment, 0.5-1 cm length of colonic tissue from the inflamed region was removed and then processed for assessment of its H_2O_2 contents. In a parallel experiment, intra-colonic H_2O_2-induced painful response in naïve rats and the effect of intravenous HC-030031 were measured by the VMR. [Results]TNBS treatment resulted in a significant increase in the VMR that maintained to at least 14 days. The H_2O_2 contents in the inflamed region of the colon in TNBS-treated rats were significantly higher than that in vehicle-treated rats. Intravenous administration of NAC or HC-030031 significantly suppressed the enhanced VMR in TNBS-treated rats without any effect on vehicle-treated rats. Moreover, we found that blockade of TRPA1 by HC-030031 significantly reversed the H_2O_2-induced visceral hyperalgesia in naïve rats. [Conclusion]These results suggest that H_2O_2 contents of the colonic tissue increase in the early stage of TNBS-induced colitis. The increased H_2O_2 may contribute to the visceral hyperalgesia by activating TRPA1. *This work was supported by the KAKENHI #25893280 (S.W.).

Title: TRPA1, but not TRPV1 contributes to the colonic motility-dependent visceral pain in rats

Authors: Y. HAO[1,2], S. WANG[1,4], Y. KOGURE[1,3], S. YAMAMOTO[1], H. MIWA[2], K. NOGUCHI[3,4], *Y. DAI[1,3,4];
[1]Dept pharmacy, Sch. pharmacy, Hyogo Univ. of Hlth. Sci., Kobe, Hyogo, Japan; [2]Intrnl. Med. (Gastroenterology), [3]Anat. & Neurosci., Hyogo Col. of Med., Nishinomiya, Japan; [4]Traditional Med. Res. Ctr., Chinese Med. Confucius Inst. at Hyogo Col. of Med., Kobe, Japan

Abstracts: Aims: The transient receptor potential vanilloid 1 and ankyrin 1 (TRPV1 and TRPA1, respectively) channels as a pain sensor are well recognized. Visceral pain is a major sign or symptom of many gastrointestinal diseases. Colonic dilatation, ischemia and inflammation are believed to cause visceral pain. The present study was conducted to investigate the role of these two TRP channels on colonic motility-dependent visceral pain. Methods: Adult male Sprague-Dawley rats (200-250 g) were used. Experimental colitis was induced by intrarectal administration of 2,4,6-trinitrobenzene sulfonic acid (TNBS), or oral administration of 4% (w/v) dextran sodium sulfate (DSS) added in drinking water. The colonic motility was evaluated by the intracolonic pressure, which was assessed by a pressure sensor connected with an end-closed, water-filled balloon inserting into rats' colon. Visceral pain was measured by electromyography what presented by visceromotor response (VMR) of the external oblique. Both pressure and VMR were recorded by the PowerLab data acquisition device. Capsaicin, allyl-isothiocyanate (AITC), serotonin and other chemical reagents were administrated intrarectally or intraperitoneally. Results: Substantial increases of both colonic motility and VMR were induced by intra-peritoneal administration of serotonin or bethanechol to naïve rats. The serotonin- or bethanechol-induced VMR was inhibited by their receptor's antagonist ondansetron or 4-diphenylacetoxy-N-methyl-piperidine methiodide (4-DAMP), respectively. It is of interest that intrarectal injection of AITC, but not capsaicin significant potentiated both colonic motility and VMR, which were completely blocked by 4-DAMP. Moreover, a clearly increase of VMR with an enhanced basal colonic motility was observed in rats with DSS- or TNBS-induced colitis when compared to naïve rats. The DSS- or TNBS-induced increase of VMR was blocked by 4-DAMP. Conclusion: Intensive colonic motility may induce visceral pain in naïve rats. This colonic motility-dependent visceral pain is related to the activity of TRPA1, but not TRPV1. Moreover, the colitis-induced visceral pain is accompanied with the increase of colonic motility.

Title: Exercise ameliorates urinary bladder hypersensitivity and dysfunction in maternally-separated female mice

Authors: *A. N. PIERCE, R. WANG, J. M. RYALS, J. A. CHRISTIANSON;
Anat. and Cell Biol., Univ. of Kansas Med. Ctr., Kansas City, KS

Abstracts: Exposure to early life stress serves as a risk factor for developing chronic pelvic pain disorders and comorbid mood disturbances. Urogenital pain patients often suffer from depression and/or anxiety, which has been attributed to altered functioning of specific brain regions that express corticotropin-releasing factor (CRF) including the hypothalamic-pituitary-adrenal (HPA) axis that regulates stress response and influences the perception of pain. Voluntary exercise has been shown to attenuate molecular and behavioral changes associated with a dysfunctional HPA axis; however, the therapeutic potential of exercise to ameliorate visceral hypersensitivity arising from early life stress has not been determined. To address this issue, we examined the effect of voluntary wheel running on bladder sensitivity and function in female mice that underwent neonatal maternal separation (NMS), a well-established model of early life stress. C57Bl/6 mice were born in-house and either were separated as litters from their dams for 3 hours/day from postnatal day 1-21 (NMS) or remained undisturbed (naïve). At 4 weeks of age, naïve and NMS mice were pair-housed with free access to running wheels (Exercised group [Ex]) or remained in standard caging without wheels (Sedentary group [Sed]). At 8 weeks of age, mice were assayed for bladder sensitivity, micturition analysis, and evidence of altered HPA axis output. NMS-Sed mice displayed significantly increased visceromotor response (VMR) during urinary bladder distension (UBD) compared to naïve-Sed mice. NMS-Ex mice had significantly diminished VMR compared to NMS-Sed mice and were not different from either naïve-Sed or naïve-Ex. Exercise also prevented significant increases in both micturition frequency and total urine output resulting from NMS. Both serum corticosterone and urinary bladder mast cell degranulation were significantly increased in NMS-Sed mice, compared to naïve-Sed mice, indicating

increased HPA axis activation. Voluntary exercise significantly reduced mast cell degranulation in urinary bladder from NMS mice, compared to sedentary counterparts. Taken together, these findings provide novel insight on the efficacy of exercise, an easily translatable clinical intervention, as a potential treatment strategy for chronic visceral hypersensitivity and neuroimmune dysfunction associated with early life stress.

Title: The impact of early life stress and voluntary exercise intervention on comorbid mood and urogenital pain disorders in male mice

Authors: *I. FUENTES, A. N. PIERCE, R. WANG, J. A. CHRISTIANSON;
Univ. of Kansas Med. Ctr., Kansas City, KS

Abstracts: Exposure to early life stress, such as childhood neglect or abuse, low socioeconomic status, or witnessing violence or parental discord in the home, has been shown to permanently alter the functioning of the hypothalamic-pituitary-adrenal (HPA) axis, which regulates the response to stress and influences pain perception. Disruption within the HPA axis has been shown to contribute to both mood and functional pelvic pain disorders, including interstitial cystitis, irritable bowel syndrome and prostatitis. We have investigated the impact of neonatal maternal separation (NMS), a commonly used rodent model of early life stress, on behavioral indicators of depression, pelvic organ sensitivity, and micturition in male mice, as well as the therapeutic potential of a voluntary exercise intervention. C57Bl/6 mice were born in house and

either separated as litters for 3 hours per day from postnatal day 1-21 (NMS) or received no handling outside of normal husbandry care (naïve). At 4 weeks, mice were pair housed in cages equipped with free running wheels (exercised groups [Ex]) or remained in standard caging (sedentary groups [Sed]). Adult NMS-Sed mice displayed depressive-like behavior measured as significantly lower sucrose intake during a two-choice preference assay; however, sucrose intake was not significantly altered in NMS-Ex mice, compared to naïve-Sed or naïve-Ex. NMS-Sed mice exhibited significantly lower withdrawal thresholds to von Frey monofilament application to the perigenital region than naïve-Sed mice. Voluntary exercise prevented this phenotype as the perigenital mechanical sensitivity of NMS-Ex mice was not significantly different from either naïve-Sed or naïve-Ex mice. Furthermore, NMS-Sed mice displayed increased micturition frequency and total urine output over a 1h testing period, compared to naïve-Sed mice; however, no significant differences were observed between NMS and naïve groups that were exercised. Toluidine blue staining revealed a significant increase in mast cell degranulation in both the bladder and prostate in NMS-Sed mice compared to naïve-Sed; and preliminary protein and mRNA expression studies suggest an improper negative regulation of the HPA axis, both within the hypothalamus and from higher limbic structures. Taken together, these results suggest that alterations within, and downstream of, the HPA axis are likely contributing toward our observed behavioral changes resulting from early life stress. We have also provided evidence that voluntary exercise may be a potent therapeutic option for patients suffering from comorbid mood and pelvic pain disorders.

Abstracts: Although bladder pain afflicts 3-6% of women in the United States, its pathophysiology is poorly understood. Moreover, these pain conditions are resistant to many analgesics that alleviate somatic pain, suggesting that there are distinct mechanisms of bladder pain. To advance our understanding about peripheral nerve fibers that innervate the bladder and their role in development of bladder pain, we characterized three transgenic mouse lines expressing the light-activated channel, channelrhodopsin (ChR2), fused to EYFP in Advillin, TRPV1 and Nav1.8-Cre expressingdorsal root ganglion (DRG) neurons. Prior reports suggest the possibility that TRPV1 is expressed in the urothelium, in TRPV1-ChR2 mice no fluorescence could be detected in the urothelium, indicating that the TRPV1 promoter drives no (or very little) expression in these cells. In Nav1.8-ChR2 mice, the parasympathetic postganglionic neurons found at the base of the bladder in the pelvic ganglion also expressed ChR2-EYFP. TRPV1-ChR2 expression was seen in dense projections to lamina I and II of the superficial dorsal horn, consistent with expression of TRPV1 in all unmyelinated sensory fibers during development. In the Nav1.8-ChR2 mice, projections are also seen in lamina III, a layer thought to receive both myelinated and unmyelinated input. Illumination of DRG neurons expressing ChR2 under control of the TRPV1 promoter led to robust action potential generation, even at very low light levels. In order to assess bladder nociception, we determined the visceromotor response (VMR) during graded bladder distension (20-60 mmHg), both prior to and during 473nm blue laser stimulation of the bladder. We observed robust sensitization bladder responses after activation of ChR2 expressing TRPV1 and Nav1.8 neurons in the bladder. We are currently exploring the physiological consequences of ChR2 activation in a range of fiber types directly innervating the bladder, to elucidate the cellular basis of bladder sensitivity via the use of optogenetics in mice.

Title: Prostatitis induces bladder hypersensitivity via neural cross-talk

Authors: *E. S. SCHWARTZ, E. E. YOUNG, B. FENG, G. F. GEBHART;
Dept of Anesthesiol., Univ. of Pittsburgh, PITTSBURGH, PA

Abstracts: Background: Chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) is a condition that involves the prostate, bladder, and pelvic floor, and causes symptoms that include frequent and urgent need to urinate, pain or burning when urinating, and pain radiating to the back, abdomen, and/or colorectum. The purpose of the study is to provide evidence of existing pathways in the development of organ cross-sensitization by demonstrating that bladder hypersensitivity develops following the induction of chronic prostatitis. Furthermore, we demonstrate sensory (afferent) co-innervation of the mouse prostate and bladder, changes in putative mediators in both prostate and bladder, and bladder afferent sensitization. **Methods**: Retrograde tracers were injected into the bladder (DiI) and/or prostate (fast blue, FB). Prostatitis was produced by injecting 0.1 mg zymosan in 1% FB into the dorsal lobe of the mouse prostate; sham mice received 1% FB. After zymosan/sham injection, DRG were collected and examined for innervation density, somata size, and content/expression (via single cell PCR) of putative nociceptive markers. Prostate and bladder histology, immunohistochemistry, and RNA were examined weekly. Cystometry, urinary bladder distension and bladder afferents were also assessed at these times. **Results:** We found that > 50 % of DRG afferent somata are shared by both the urinary bladder and prostate. Evaluation of mRNA content following prostate inflammation showed a significant upregulation in pro- and anti- inflammatory cytokines (i.e., TNF-α and IL-10) and growth factor NGF as well as changes in mRNA content in FB-labeled DRG somata which showed TRPV1, TRPA1, and ASIC-3 to be relatively abundant; expression was significantly increased during prostatitis. Significantly, bladder function, responses to distension, and bladder afferents were sensitized during prostatitis. **Conclusions:** These experiments revealed that prostate and bladder share afferent innervation via convergent DRGs. Experimental prostatitis significantly increased urinary bladder voiding frequency and decreased volume per void compared to controls and induced hypersensitivity to bladder distension. These observations provide mechanistic support for CPPS and prostate to bladder cross-organ sensitization.

Title: Estrogen receptor alpha and beta differentially mediate MAPK signaling pathway activation in the female rat spinal cord

Authors: *Y. JI, J. KARPOWICZ, S. PANDYA, D.-Y. CAO, R. TRAUB;
Univ. of Maryland, Baltimore, BALTIMORE, MD

Abstracts: We previously reported that the visceromotor response to colorectal distention fluctuates across the estrous cycle, sensitivity peaking as the plasma estrogen level reaches its apex during proestrus. Ovariectomy (OVx) decreases visceral sensitivity which is restored by subcutaneous (s.c.) or spinal (intrathecal) estradiol replacement, suggesting estrogen facilitation of visceral nociceptive processing occurs at the level of the spinal cord. Furthermore, s.c. and intrathecal administration of the estrogen receptor alpha (ERα) agonist PPT reversed the inhibitory effect of OVx similar to E2, suggesting ERα in the spinal cord may mediate cyclic changes in visceral sensitivity. Consistent with an increase in visceral sensitivity, s.c. E2 or PPT increases pERK1/2 expression in the spinal cord. In contrast, s.c. administration of the ERβ agonist, DPN, was antinociceptive, decreasing the visceromotor response. In the present study, we used an *in vitro* spinal cord slice preparation to further investigate the mechanisms underlying estrogen receptor mediated spinal signal transduction. OVx rats were injected with Oil, E2 (50μg), PPT (1mg/kg) or DPN (10mg/kg) and spinal cord slices were obtained 4h later. Incubation of spinal slices from E2 and PPT rats with L-glutamic acid (100 μM) for 5 to 30 min induced an increase in pERK expression compared with adjacent vehicle treated slices. In contrast, slices from Oil or DPN treated rats did not show any change of ERK phosphorylation after 5 min incubation. Longer term incubation (15 or 30 min) with L-glutamic acid decreased pERK expression. In a separate study, ER agonists were bath-applied to spinal cord slices from OVx rats to further explore the mechanisms underlying ER agonist mediated changes in response to glutamate. Bath application of E2 (1nM) and DPN (10nM) did not change the pERK/ERK level at 5 min, but increased ERK phosphorylation at 15min-1h. Bath application of PPT (10nM), on the other hand, had no effect on ERK phosphorylation at 5-15min, but caused a small increase in pERK2/ERK2 at 1h. Taken together, these data suggest activation of ERα and ERβ

differentially modulate MAPK signaling pathways at the level of the spinal cord which may contribute to differing effects on behavioral responses to visceral stimuli.

Title: Adrenergic signaling mediates pancreatic hyperalgesia through activation of purinergic receptors in primary sensory neurons in rats with chronic pancreatitis

Authors: S. F. HU[1], H.-Y. ZHU[1], Y. ZHOU[1], Y. ZHOU[1], *G.-Y. XU[2];
[1]Inst. of Neurosci., Soochow Univ., Suzhou, China; [2]Inst. of Neurosci., Soochow Univ., Jiangsu, China

Abstracts: Objective: The mechanism of pain in chronic pancreatitis (CP) is poorly understood and its treatment remains difficult, in large part due to our lack of knowledge about the neurobiological mechanisms in nociception. The aim of this study was designed to investigate roles of norepinephrine (NE) and P2X receptor signaling pathway in the pathogenesis of pancreatic pain in a rat model of CP. Methods: CP was induced in male adult rats by intraductal injection of trinitrobenzene sulfonic acid (TNBS). Pancreatic hyperalgesia was assessed by referred somatic behaviors to mechanical stimulation of rat abdomen. DiI dye injected into pancreas was used to label pancreas innervating dorsal root ganglion (DRG) neurons. P2X receptor (P2XR)-mediated responses in pancreas DRG neurons were measured using calcium-imaging and whole cell patch clamp recording techniques. Western blot analysis was performed to examine protein expression. Results: Administration of purinergic receptor antagonist suramine or A317491 attenuated pancreatic pain in CP rats. Expression of P2X3Rs and ATP-induced current density of pancreas DRG neurons were markedly enhanced after TNBS

injection. The sensitization of P2X3Rs was reversed by β adrenergic receptor antagonist propranolol but not by α adrenergic receptor antagonist phentolamine. CP was associated with an upregulation of expression of β2 adrenergic receptors in DRGs. The NE concentration in DRGs and pancreas was significantly enhanced in TNBS-treated rats. TNBS injection also produced a 2-fold increase in ATP-induced calcium signals and amplified the NE-induced potentiation of ATP responses when compared with controls. Using triple labeling techniques, we showed that β2 adrenergic receptors were colocalized with P2X3Rs in pancreatic DRG neurons. Furthermore, incubation of DRG neurons with NE significantly enhanced ATP-induced intracellular calcium signals, which was abolished by propranolol but not by phentolamine, and partially blocked by protein kinase A inhibitor H-89. Forskolin, an adenylyl cyclase activator, markedly enhanced ATP-induced responses of DRG neurons. Importantly, the pancreatic referred somatic hyperalgesia in CP rats was markedly attenuated by systemic administration of propranolol but not by phentolamine. Conclusions: Sensitization of P2X3Rs, which was likely mediated by adrenergic signaling in primary sensory neurons, contributes to pancreatic pain, thus identifying a potential target for treating pancreatic pain caused by inflammation.

Title: RvD1 and Chemerin alleviated inflammatory signs associated with endometriosis in rats

Authors: ***N. DMITRIEVA**[1], C. M. GARCIA PASCUAL[2], G. SUESS[2], R. SHIRLEY[2];
[2]Psychology, [1]Florida State Univ., TALLAHASSEE, FL

Abstracts: Endometriosis (ENDO) is a chronic estrogen-dependent painful condition that is characterized by the presence of endometrial growths outside the uterus. Inflammatory processes associated with ENDO such as increased local production of inflammatory mediators, increased permeability of the vascular bed within the growths to blood proteins and infiltrating leukocytes, suggest that chronic pain associated with ENDO has inflammatory origin. RvD1, 17(R)-RvD1 and RvE1 are pro-resolving lipid mediators (Resolvins) that are locally biosynthesized during the

resolution phase of acute inflammation. Chemerin is an endogenous peptide ligand for Chem23R, a receptor that can also become activated by RvE1. Recent findings indicate that these Resolvins can alleviate inflammatory signs including pain in some chronic conditions. We studied the effects of RvD1, 17(R)-RvD1 and Chemerin on increased vascular permeability of ectopic endometrial growths assessed by Evans Blue extravasation in rats with surgically-induced ENDO. In another group of ENDO rats, we studied the effect of i.p. injections these molecules on vaginal hyperalgesia, which was monitored telemetrically. Both Resolvins and Chemerin, but not vehicle, significantly decreased vascular permeability in ectopic endometrial tissue. 17(R)-RvD1 and Chemerin also significantly alleviated severity of vaginal hyperalgesia. Our results suggest that Resolvins and Chemerin can be effective in reducing inflammatory signs including visceral pain in women with ENDO.

Title: Colonic inflammatory molecules do not underlie inflammatory, post-, and non-inflammatory colorectal hypersensitivity in the mouse

Authors: *J.-H. LA, G. F. GEBHART;
Dept. Anesthesiol., Ctr. For Pain Research, Univ. Pittsburgh, PITTSBURGH, PA

Abstracts: BACKGROUND & AIMS: Colorectal hypersensitivity develops during, after and even in the absence of colorectal inflammation. In the absence of colonic inflammation, a low-level inflammatory milieu has been hypothesized to underlie the hypersensitivity. We tested this hypothesis by examining [1] the effect of dexamethasone in three mouse models of colorectal hypersensitivity and [2] colonic inflammatory molecules/mediators quantified by qRT-PCR. METHODS: Visceromotor responses to colorectal distension were quantified as a measure of sensitivity. On day 1, mice received intracolonic saline (control), TNBS (inflammatory on day 3; post-inflammatory on day 15), or acidified hypertonic saline (non-inflammatory).

Dexamethasone was administered once daily for two (TNBS day 3) or four days (days 11-14 in other models). RESULTS: Dexamethasone did not attenuate colorectal hypersensitivity in any model, but did inhibit gene expression of inflammatory molecules. Principal component analysis revealed six correlated groups of molecules: 1 (COX-2, IL-1β, Follistatin, IL-6, and Inhibin βA); 2 (Activin R2B, COX-1, substance P, and CGRPα and β; 3(TGF-β1, TGF-β2, POMC, and BAMBI); 4 (MCPT-1, IL-10RA, and TNF-α); 5 (IL-10 and TGF-βR1); and 6 (CGRPα and PGE2 synthase). No group was correlated with colorectal hypersensitivity. Gene expression of molecules in Groups 1 and 2 were up- and down-regulated, respectively, only in the inflammatory model. Group 3 distinguished non- from post- and inflammatory models, and Group 5, post- from the inflammatory model. CONCLUSIONS: Accordingly, a low-level colonic inflammatory milieu of candidate inflammatory molecules is neither sufficient nor necessary for development of colorectal hypersensitivity.

Title: Attenuation of visceral and somatic nociception by peripheral administration of ghrelin agonists

Authors: E. MOHAMMADI[1], *C. PIETRA[2], K. TYLER[1], R. NORTHRUP[3], B. GREENWOOD[1];
[1]Dept. of Physiol., VA Med. Ctr., University of Oklahoma Health Sciences Center, OK; [2]Helsinn Healthcare SA, Lugano- Pazzallo, Switzerland; [3]Helsinn Therapeut. Inc, Bridgewater, NJ

Abstracts: Background: Previous studies suggest that ghrelin inhibits nerve injury associated neuropathic pain though an inhibition of proinflammatory cytokines. Whether ghrelin-receptor mediated mechanism attenuate visceral or somatic pain in the absence of inflammation remains to be determined. This study investigated the effects of two potent and selective ghrelin agonists, one peripherally restricted, ipamorelin (IPA) and one peripheral and centrally acting , namely HM01. The efficacy of both compounds was investigated in experimental models of non-

inflammatory visceral hypersensitivity and somatic mechanical allodynia. **Methods**: Acute visceral hypersensitivity was induced experimentally in rats by infusing acetic acid into the colon at a concentration (0.6%) known to sensitize visceral afferents in the absence of mucosal inflammation. Colonic sensitivity was assessed via a visceromotor behavioral response (VMR) quantified as the number of abdominal contractions in response to graded isobaric pressures (0-60 mmHg) of colorectal distension (CRD). Somatic mechanical allodynia was quantified by the number of ipsilateral paw withdrawals in response to a calibrated von Frey filament. IPA was administered intravenously at 0.01, 0.1, and 1 mg/kg whereas HM01 was administered orally at 1, 3, 10, or 30 mg/kg. **Results**: Compared to vehicle controls, both IPA and HM01 caused a significant attenuation of visceral hypersensitivity and somatic allodynia. While HM01 was effective at all doses tested only the highest dose of IPA (1 mg/kg i.v.) showed efficacy. A comparison between the minimal effective doses is shown in the table below:

Groups	**Visceral Hypersensitivity(60mmHg) # of contractions**	**Somatic Allodynia Force (g)**
Vehicle Control	32± 1.6	51± 2.4
IPA (1 mg/kg i.v.)	18± 1.0**	117± 2.9****
HM01 (1 mg/kg p.o.)	24± 0.7**	98± 2.8****

** $p<0.01$, **** $p<0.0001$ compared to VEH **Conclusion**: We have shown for the first time that ghrelin-mediated mechanisms are involved in visceral and somatic nociception in the absence of an overt inflammatory nerve injury. Furthermore, a ghrelin agonist with both central and peripheral activity showed superior efficacy over a peripherally restricted agonist.

Title: Increased glutaminase and aspartate aminotransferase in rat sacral dorsal root ganglion neurons during acute colonic inflammation

Authors: *K. E. MILLER[1], R. JOHN[1], M. B. ANDERSON[1], C. KIM[1], K. TYLER[2], B. GREENWOOD-VAN MEERVELD[2];
[1]Dept Anat. & Cell Biol, Oklahoma State Univ. Ctr. Hlth. Sci., TULSA, OK; [2]Univ. Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK

Abstracts: At the onset of inflammation, nociceptive sensory neurons respond by altering their profile of protein expression. In somatic inflammatory pain models, the amounts of glutaminase (GLS) and aspartate aminotransferase (AST), enzymes for glutamate production, are increased in dorsal root ganglion (DRG) neurons within 24 hrs following the onset of inflammation. Our previous findings using a trinitrobenzene sulphonic acid (TNBS) model of inflammatory bowel syndrome (IBS) showed that sacral DRG neurons have elevated GLS and AST in sacral DRG neurons at 30 days post-inflammation. The current study was to determine if GLS and AST are elevated early in the DRG after the onset of visceral inflammation. **Methods**: In Sprague Dawley rats, an acute colonic inflammation was induced by intracolonic infusion of TNBS (50 mg/kg, 25% ethanol, 0.5 ml enema). Saline-enema and naïve rats were used as controls. A disease activity index (DAI) assessed the level of colitis. On days 1 & 2, sacral 1 DRG were isolated and processed for glutaminase (GLS) and aspartate aminotransferase (AST) immunohistochemistry and image analysis. **Results**: Compared to saline-enema treated or naive controls (n = 4/group), TNBS-induced rats had an increase in both AST and GLS-immunoreactivity (ir) in DRG neurons. AST-ir was elevated 23% over controls at day 1 and 37% at day 2 of inflammation. No change was detected in GLS-ir at day 1, but GLS-ir was elevated 55% at day 2. **Summary**: An inflammatory insult to the colon significantly increases GLS- and AST-ir within sacral DRG neuronal cell bodies within 24-48 hr. **Conclusion**: Our results suggest that elevated glutamate metabolism in primary sensory neurons may lead to increased glutamate production in and release from spinal or colonic primary afferent terminals. This may lead to visceral hypersensitivity by glutamate-mediated central and/or peripheral sensitization.

Title: Altered stress-induced visceral nociception in adult female rats previously exposed to unpredictable early life adversity

Authors: *S. KENNEDY[1], B. GREENWOOD-VAN MEERVELD[2];
[2]Oklahoma Ctr. for Neuroscience, Dept. of Physiology, VA Med. Ctr., [1]Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK

Abstracts: Early life adversity (ELA), such as neglect or abuse, has been indicated as a risk factor for the development of stress axis dysfunction in adulthood, specifically in females. Our laboratory has previously shown that unpredictable, but not predictable, ELA induces visceral hypersensitivity in adult female rats, and this effect is estrogen-dependent. However, it remains to be determined whether ELA has long lasting effects on visceral nociceptive responses to stress axis activation in adulthood. It is our hypothesis that following ELA, adult stress exposure induces allodynia and hyperalgesia in a sexually dimorphic manner. Neonatal rats underwent classical conditioning using unpredictable or predictable odor-shock pairing or an odor only control. In adulthood, visceral sensitivity was assessed via visceromotor behavioral response (VMR) quantified as the number of abdominal contraction in response to graded pressures (0-60 mmHg) of isobaric colorectal distension (CRD). Adult stress was induced using *acute* (1-day) or *chronic* (7-day) exposure to a 1-hr water avoidance stressor (WAS). In adulthood *acute* WAS increased the VMR to CRD in all female rats, however rats that experienced unpredictable ELA exhibited significantly ($P<0.001$) more pain behaviors (60 mmHg: 43.5±1.2 abdominal contractions in 10 min) compared to predictable ELA (33.1±2.5) or odor only controls (31.7±0.8). In adult female rats, *chronic* WAS increased the VMR to CRD, however the number of abdominal contractions in response to 60 mmHg CRD was significantly ($P<0.001$) greater in rats exposed to either unpredictable ELA (44.0±0.6 abdominal contractions in 10 min) or predictable ELA (43.0±1.7) compared to controls rats (32.3±0.5). In male rats, exposure to WAS increased colonic sensitivity to luminal distension, however prior exposure to neonatal ELA did

not correlate with increased magnitude of the WAS-induced VMR to CRD in adult life. In summary, this study suggests a novel consequence of ELA on visceral nociception in adulthood that is sex-specific. We demonstrated that ELA unmasks an exaggerated nociceptive response to an adult stressor in female rats. However, ELA does not serve as a risk factor for enhanced visceral nociception following adulthood stress in male rats. Taken together, these data indicate that ELA may interact with the female sex hormone estrogen to disrupt negative feedback mechanisms underlying stress axis homeostasis and responsivity to adulthood stressors. This dysregulation may ultimately predispose females to stress-induced visceral pain in adult life.

Title: Neurological differences between female irritable bowel syndrome patients and healthy controls during expectation of safety from abdominal threat

Authors: Z. GILL[1], J. LABUS[1], J. HONG[1], C. LIU[1], B. NALIBOFF[1], *E. A. MAYER[2], K. TILLISCH[1];
[1]Ctr. for Neurobio. of Stress UCLA, Los Angeles, CA; [2]Med., Oppenheimer Family Ctr. For Neurobio. of Stress, LOS ANGELES, CA

Abstracts: Background: IBS is a common gastrointestinal disorder characterized by chronic abdominal pain, alteration in bowel habits, and symptom-related anxiety. Previous studies have shown that IBS patients have abnormal brain responses to the expectation of visceral pain in regions associated with emotional arousal and visceral sensation. It is unknown whether individuals with IBS exhibit normal responses to 1) the expectation of a non-visceral threating stimulus or 2) the presence of a safety condition within the context of a threat paradigm. **Aims**: To identify differences in functional neural activity between IBS patients and healthy controls during the expectation of a threatening abdominal shock and during a designated safe period. **Methods**: 23 female IBS patients and 10 female healthy controls (ages 18-50) were recruited by advertisement. We recorded the blood oxygen level-dependent (BOLD) response to an

abdominal threat paradigm using a 3 Tesla Siemens Trio scanner. The paradigm was a jittered block design which included the following conditions: safe (no shock will be delivered), threat (shock may be delivered), and a neutral cross hair condition during which patients were told that no shock would occur. A two sample t-test was performed within SPM8 and regions of interest in the emotional arousal and sensory circuitry were evaluated. **Results**: We identified significant BOLD differences between the IBS group (31.4 years, SD=9.53) and the healthy control group (26.1 years, SD=5.38). Region of interest analysis using small volume correction in SPM8 showed significance in bilateral dorsomedial nuclei of the thalamus (left:-2, -16, 6 (XYZ), Z=4.59, p=0.002, family-wise error (FWE) corrected, and the right: 2, -14, 8, Z=4.03, p=0.015, FWE corrected). Brain activity in these regions were correlated with patient self-report of abdominal pain on a 10 point numeric rating scale and revealed significant positive correlations in both the left [r(23)=23, p=0.007] and right [r(23)=23, p=.012] thalamus. No differences were identified between groups in the threat period of the paradigm. **Conclusions**: The thalamus is associated with expectation-related neural activity consistent with increased afferent sensitivity. IBS patients' exhibiting a significantly greater level of activity in this region during expectation of safety suggests that those with IBS may have abnormalities in the deactivation of the afferent processing network. It is possible that this central alterations plays a role in the increased sensitivity of IBS patients to visceral sensations, and cardinal IBS symptoms such as bloating and abdominal pain.

Title: Behavioral and physiological characterization of the molecules involved in menstrual pain

Authors: *K. M. HELLMAN[1,2], F. F. TU[2];
[1]OB/GYN, NorthShore Univ. HealthSystem, Chicago, IL; [2]Obstetrics & Gynecology, Univ. of Chicago, Chicago, IL

Abstracts: Contemporary research has focused on the central nervous system's contribution to menstrual pain, yet the impact of peripheral factors remain inadequately characterized. This has hamstrung efforts to develop effective targeted therapeutic strategies for dysmenorrhea. Although it is reputed that cytokines elicit pain by increasing uterine contractility resulting in ischemia, studies investigating their effects on uterine function *in vivo* are limited. Studies in humans reported elevated levels of prostaglandin (PGF2α), oxytocin, platelet-activating factor (PAF) and transient receptor potential vanilloid (TRPV) in dysmenorrhea. To establish whether these candidate molecules are sufficient to elicit abdominal pain and what their effects are on uterine physiology, we characterized pain behavior following their administration in a mouse model. While oxytocin elicited torso stretching resembling labor in mice, there was no evidence of pain or hyperalgesia. In contrast, PGF2α and the PAF receptor agonist, Carbamyl PAF (CPAF) produced behavior indicative of abdominal pain and hyperalgesia, but not torso stretching. Uterine pressure was increased by oxytocin and CPAF, but not by PGF2α. In control experiments, no effects were observed in vehicle treated mice or when CPAF was administered to PAF-R KO mice. In wild-type mice, CPAF elicited hypoxemia mediated by the elevated intrauterine pressure. Following CPAF exposure, the TRPV agonist capsaicin improved perfusion and oxygenation. Thus, PAF may contribute to uterine pain by increasing uterine contractility, leading to hypoxemia, while TRPV may serve a protective role by increasing perfusion. Future work extending these findings using our *in vivo* model can be used to evaluate therapeutic approaches for menstrual pain.

Title: Changes in sensory and sympathetic innervation of pelvic organs and ectopic uterine growths during the development and stabilization of endometriosis (ENDO)-induced vaginal hyperalgesia in the rat

Authors: *S. L. MCALLISTER[1], B. K. GIOURGAS[2], K. J. BERKLEY[2];
[1]Program in Neuroscience/Psychology, [2]Florida State Univ., Tallahassee, FL

Abstracts: Endometriosis is a painful disorder defined by extrauteral endometrial growths (ectopic growths). How the growths contribute to pain symptoms, such as dyspareunia (vaginal hyperalgesia) is poorly understood. A rat model (ENDO) is created by autotransplanting on abdominal arteries pieces of uterus. These ectopic growths form cysts that accrue a sprouted sensory and sympathetic innervation that appears gradually over a six-week period and then later stabilizes (McAllister et al. 12; 13), giving rise to three distinguishable phases: initial, transitional (TRANS), and established (ESTAB): 1-2 wks; 4-6 wks; and 8-10 wks post-ENDO surgery, respectively. The hyperalgesia develops after the cysts are initially innervated and the innervation has become functional. The hyperalgesia then becomes variable during TRANS, and is stabilized by ESTAB (McAllister et al. 12). These and other findings strongly support the hypothesis that innervation of the cysts' contributes significantly to the vaginal hyperalgesia during the entire course of its development and stabilization (Stratton & Berkley 11). Additional studies from our lab during TRANS suggest that the sympathetic innervation of the vaginal canal also contributes to vaginal hyperalgesia, with no contribution from innervation of the eutopic uterus (McAllister et al 12, 13). Here we tested how innervation of the vaginal canal and eutopic uterus might contribute during the ESTAB phase. METHODS: The density of sensory and sympathetic innervation of both tissues was assessed with quantitative immunohistochemistry using antibodies to calcitonin gene related peptide (CGRP; identifies sensory C-fibers) and either tyrosine hydroxylase or vesicular monoamine transporter (TH; VMAT2: identifies sympathetic fibers). Three groups were studied (n=4/group): (i) ENDO, (ii) shamENDO (control surgery), (iii) and Naïve (no surgery). Vaginal canal and eutopic uterine samples were harvested when the rat was in proestrus during the ESTAB phase. RESULTS/CONCLUSIONS: There were no significant group differences in innervation of the vaginal canal or eutopic uterus during the ESTAB phase. These findings support the hypothesis that different peripheral neural mechanisms underlie ENDO-induced vaginal hyperalgesia during the course of its initial-to-transitional development and then during stabilization.

Title: Epigenetic modulation of stress-induced visceral hypersensitivity in female rats

Authors: D.-Y. CAO, G. BAI, J. M. KARPOWICZ, Y. JI, *R. J. TRAUB;
Neural and Pain Sci., Univ. of Maryland Sch. of Dent., Baltimore, MD

Abstracts: Visceral hypersensitivity induced by chronic stress is a laboratory model for irritable bowel syndrome (IBS) and can be used to explore the molecular mechanism underlying IBS. Stress may alter gene expression which in turn produces or modulates visceral sensitivity. Epigenetic mechanisms are heavily involved in stress and potentially in visceral pain. In this study, we examined the effect of histone acetylation as an epigenetic mechanism at the spinal level on stress-induced visceral hypersensitivity. Subchronic stress was produced by forced swim (FS) for three consecutive days (10, 20, 20 min) in female Sprague-Dawley rats. Histone hyperacetylation at the spinal level was induced by inhibition of histone deacetylase via intrathecal injection of suberoylanilide hydroxamic acid (SAHA). Visceral sensitivity was tested by the visceromotor response (VMR) to colorectal distension and expression of metabotropic glutamate receptor 2 and 3 (mGluR2, 3) in the lumbosacral (LS, i.e. L6-S1) dorsal spinal cord was examined. Our results show that stress significantly increased visceral sensitivity over baseline 1 and 5 days after the last FS. The immobility time during the first 5 minutes of FS increased on consecutive days suggesting the rats developed a depressed state. Spinal administration of SAHA (40 μg/day) both prevented (pre-treatment with drug 30 min before each FS) and reversed (post-treatment with drug for 3 days after the last FS) visceral hypersensitivity induced by FS. Western blot data showed SAHA pre-treatment significantly increased acetylation of lysine 9 on histone 3 (H3K9ac) in the LS dorsal spinal cord compared with vehicle treated rats. SAHA pre-treatment also increased expression of mGluR3, but not mGluR2, in the LS dorsal spinal cord 1 day post FS. Chromatin immunoprecipitation showed that SAHA pretreatment significantly increased binding of H3K9ac, but not H3K18ac, to the mGluR3 promoter. Intrathecal injection of the mGluR2/3 antagonist LY341495 reversed the SAHA-evoked attenuation of the stress-induced visceral hypersensitivity, but did not alter FS-induced visceral hypersensitivity in vehicle treated rats. These results reveal that increasing histone acetylation in the spinal cord attenuates psychophysical stress-induced visceral hypersensitivity by increasing mGluR3 activity and indicate a novel approach to relieve stress-induced visceral pain, especially for IBS patients.

Title: Effect of protamine sulfate and potassium chloride on the inhibitory rectovesical reflex in an isovolumetric bladder model

Authors: S. PERSYN[1], *L. A. BIRDER[2], J.-J. WYNDAELE[1];
[1]Dept. of Urology, Univ. of Antwerp, Fac. of medicine, Antwerp, Belgium; [2]Univ. Pittsburgh Sch. Med., PITTSBURGH, PA

Abstracts: ABSTRACT PURPOSE: In pelvic physiology a coordinated activity of the lower urinary tract and colorectum is necessary for normal function. A dysfunction in this neural cross-organ communication often leads to co-morbidity of bladder and colorectum. Previous studies have shown an inhibitory rectovesical reflex (IRVR), elicited by a noxious colorectal distension (CRD) (60mmHg). Increasing colorectal afferent activity, mechanically and pharmacologically, significantly enhanced the IRVR. Our goal was in part to explore the influence of a compromised urothelial barrier on bidirectional colon-bladder interactions. MATERIALS AND METHODS: We combined protamine sulfate (PS) (10 mg/ml for 30 min; transurethral injection), which has been demonstrated to compromise urothelial barrier function, and a high concentration of potassium chloride (KCL) (300 mM). Two different groups of female Sprague-Dawley rats (200-250 g) were compared. The first group underwent two different protocols: control saline and KCL filling. The second group underwent three different protocols: control saline filling, saline filling after PS treatment and KCL filling after PS treatment. In all animals isovolumetric contractions with ligated urethra were studied. The protocol was approved by the Animal Ethics Committee of the University of Antwerp (EC 2013-06). RESULTS: The inhibitory effect of a noxious CRD on isovolumetric bladder contractions was observed in a control experiment before starting the different parts of the study. KCL inhibited isovolumetric bladder activity, which is reflected in a decreased contraction frequency (BCF) (18.67%) and an increased intercontraction interval (28.59%) and bladder capacity (14.51%). The effect of noxious CRD was increased 3-fold during KCL compared with saline. In rats with a compromised barrier (PS treatment), the noxious CRD led to a 3-fold increased inhibition with saline alone and up to 5-fold with KCL. In addition, the KCL-induced bladder contractility in PS treated rats was inhibited (BCF reduction: 25.71%). CONCLUSIONS: This study shows an inhibitory effect of intravesical KCL filling on the isovolumetric bladder contractility which was greater in rats with a compromised urothelial barrier. In addition, KCL filling results into an increased IRVR elicited by a noxious CRD, which was stronger after PS exposure. Our results suggest a stronger IRVR in rats with an increased bladder afferent stimulation, which is more prominent with a compromised urothelial barrier.

Title: Chronic mechanical allodynia and visceral hyperalgesia induced by elevated amygdala corticosteroids: Importance of histone acetylation

Authors: *C. LIGON[1], L. TRAN[3], B. GREENWOOD-VAN MEERVELD[2];
[1]Oklahoma Ctr. for Neurosciences, [2]Physiol., Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK; [3]Mayo Clin., Scottsdale, AZ

Abstracts: Objective: We previously demonstrated that acute exposure of the central amygdala (CeA) to elevated corticosterone (CORT) induced persistent somatic allodynia, visceral hyperalgesia, decreased glucocorticoid receptor (GR) and increased corticotrophin-releasing factor (CRF) expression in the CeA. Using the same model, we hypothesize epigenetic mechanisms such as histone deacetylation contribute to the maintenance of chronic somatic allodynia and visceral hyperalgesia induced by elevated CORT in the CeA. Methods: Animals were stereotaxically implanted with CORT or CHOL micropellets and bilateral CeA cannula (n=7-8/group). Post-surgery (days 21-28), animals were infused daily with either 0.5µl of vehicle (VEH; 0.1% DMSO/Saline) or the histone deacetylase inhibitor suberoylanilide hydroxamic acid (SAHA; 100-500 ng/µl) bilaterally into the CeA. Somatic sensitivity was measured using an electronic von Frey test and visceral sensitivity was assessed via a visceromotor behavioral response (VMR) quantified as the number of abdominal contractions in response to colorectal distension (CRD). Results: Following 28 days, CORT implants onto the CeA significantly ($P<0.001$) lowered mechanical somatic threshold from 69.3 ± 4.45g to 44.7 ± 2.54g. SAHA treatment restored mechanical thresholds to 74.5 ± 2.11g ($P<0.001$). Results of the VMR following CRD showed that in CORT implanted rats there was a significant increase ($P<0.001$) in the number of contractions at the highest distension pressure of 60 mmHg pressure in CORT treated animals (33.9 ± 1.9) compared to CHOL (19.5 ± 0.8), indicative of visceral hyperalgesia. The increase in the number of abdominal contractions in response to CRD was attenuated by SAHA treatment ($P<0.001$; 20.75 ± 0.99). Conclusion: Protection of histone acetylation prevents

the sustained nociceptive behaviors induced by elevated CORT in the CeA, indicating that epigenetic programming, in particular histone modifications, may be critical in the maintenance of visceral and somatic pain induced by amygdala activation.

Title: Negative allosteric modulation of the mglu7 receptor reduces visceral hypersensitivity in a stress-sensitive rat strain

Authors: *R. D. MOLONEY[1], R. M. O'CONNOR[2], M. KALINICHEV[4], T. G. DINAN[3], J. F. CRYAN[2];
[1]Alimentary Pharmabiotic Centre/ Neurogastroenterology, [2]Anat. and Neurosci., [3]Psychiatry, Univ. Col. Cork, Cork, Ireland; [4]Addex Therapeut., Geneva, Switzerland

Abstracts: Introduction: Glutamate, the main excitatory neurotransmitter in the central nervous system exerts its effect through both ionotropic and metabotropic receptors. mGlu7 receptors, the most highly conserved isoform, are abundantly distributed in the brain, especially in those regions, such as the amygdala, known to be crucial for the emotional processing of painful stimuli. Understanding the role of mGlu7 receptors has been hampered by the lack of selective pharmacological tools. Visceral hypersensitivity, a hallmark of irritable bowel syndrome (IBS), is a poorly understood phenomenon manifesting as an increased sensitivity to visceral stimuli. The pathophysiology of visceral hypersensitivity is not well understood, however glutamate has long been associated with somatic pain processing leading us to postulate that crossover may exist between these two modalities. Moreover, stress has been shown to exacebate visceral pain. ADX71743 is a novel, recently described, centrally penetrant negative allosteric modulator of mGlu7 receptors. Thus we can use this tool to explore the possible involvement of this receptor in the mediation of visceral pain in a stress-sensitive model of visceral hypersensitivity, namely

the Wistar Kyoto rat. Methods: Colorectal distension (CRD) was performed to assess visceral sensitivity in adult male Wistar Kyoto (WKY) rats (250-300g;Harlan, UK). Postures defined as visceral pain behaviours were abdominal retractions and/or abdominal withdrawal reflex. ADX71743 (50, 100, 150mg/kg s.c.) was administered 30 minutes prior to commencement of CRD. All behavioural analysis was performed by a trained observer blind to treatments. Results: ADX71743 dose-dependently reduced visceral hypersensitivity in the Wistar Kyoto rat as exhibited by increased visceral sensitivity threshold ($F(3,30) = 3.092$, $p<0.05$) with concomitant reductions in total number of pain behaviours ($F(3,30) = 6.582$, $p<0.01$). Conclusion: These findings show for what is to our knowledge the first time that mGlu7 receptor signalling plays a role in visceral pain processing. Thus, negative modulation of the mGlu7 receptor may be a plausible target for the amelioration of visceral pain in disorders such as IBS where there is an immense medical need.

Title: Bladder hypersensitivity following cystitis is accompanied by altered bladder cytokine expression

Authors: *A. D. SHAFFER, J.-H. LA, G. F. GEBHART;
Anesthesiol., Univ. of Pittsburgh Ctr. For Pain Res., Pittsburgh, PA

Abstracts: Background: Painful bladder syndrome/interstitial cystitis (PBS/IC) is a chronic, debilitating disorder characterized by increased urinary frequency, urgency, and pain in association with small bladder volume. These symptoms are modeled in animals by administration of the antineoplastic drug cyclophosphamide (CYP) that induces dose-dependent

cystitis and bladder hypersensitivity. It has been theorized that constant, low-grade inflammation may contribute to PBS/IC. As a first step to test this hypothesis, we measured pro- and anti-inflammatory cytokines in the bladders of mice treated with CYP, and analyzed the correlation between the cytokines and bladder hypersensitivity. Methods: A chronic CYP treatment regimen (100 mg/kg i.p., 3 doses over 5 days) was used to induce bladder hypersensitivity in the absence of histologic damage to the bladder wall. The visceromotor response (VMR) to bladder distention was measured as an index of bladder nociception on the day following the last CYP treatment. Subsequently, gene expression of pro- and anti-inflammatory cytokines in the bladder was quantified using qRT-PCR. Results: CYP produced bladder hypersensitivity as indicated by an increase in VMR magnitude. This hypersensitivity was accompanied by an upregulation in the gene expression of Inhibin βA, the subunit of Activin A, in the bladder. Importantly, Inhibin βA expression was significantly correlated with VMR magnitude, suggesting a role for this cytokine in bladder hypersensitivity. In contrast, the gene expression of IL-1β, TNF-α, IL-6, TGF-β1, and IL-10 were not altered by chronic CYP. Conclusions: CYP-induced cystitis can change Inhibin βA gene expression in the bladder, which is correlated with the degree of bladder hypersensitivity. This supports the notion that low-grade inflammation involving altered cytokine expression may contribute to bladder hypersensitivity in PBS/IC. Manipulations targeting Activin A may reveal potential treatments to reduce symptoms in PBS/IC.

Abstracts: Debilitating neurological conditions are often accompanied by motor or behavioral impairments which are replicated in rodent experimental models. Scientists must test new treatments by measuring functional recovery in fast moving, small animals like mice. We aimed to develop and test a quantitative behavioral and locomotor assessment system for mice with spinal cord injury (SCI). Using markerless motion tracking during open field locomotion, we collected 3 dimensional kinematics with 10 cameras (100Hz) for 2 minutes. Twenty-two mice were analyzed - naïve (n=8); mild (n=5), moderate (n=5) and severe SCI (n=4). The animal's 3D shape was reconstructed in each video frame using background subtraction and shape-from silhouette techniques. The total animal volume was divided into front and rear halves, and the two centers of volume (CoV) provided a measure above and below the mid-thoracic SCI. The rear CoV height and speed served to classify mouse behavior and motor impairments. Behaviors included directed locomotion, exploratory locomotion, meandering, standing, and rearing. SCI decreased behaviors, speed and rear CoV height which were significantly correlated with greater lesion size ($r=.65-.7$; $p<.01$). Further system-generated metrics are being explored to better differentiate mild from moderate SCI. This automated system appears to generate behavioral and motor outcomes that are sensitive to SCI severity, which will reduce errors and personnel resources.

Title: Only moderate intensity of gamma fusimotor drive can stabilize a single joint in neuromorphic emulation

Authors: *C. M. NIU, W. SOHN, T. D. SANGER;
Dept. of Biomed. Engin., USC, Los Angeles, CA

Abstracts: An important role of the gamma system is to allow the spindle to maintain its high sensitivity over a wide range of muscle lengths during reflex and voluntary contractions. Due to the difficulty of intervening gamma systems in-vivo, the quantitative linkage between gamma activity and movement behavior has not been established. To this purpose, we developed the technique of emulating a sensorimotor system using spiking neurons, realistic muscles and spindles on neuromorphic VLSI chips. The system allows us to create biologically realistic reflex accommodating 1 joint, 2 muscles, 256 spindles and 2,048 neurons. Using the emulated system, we sweep different combinations of gamma dynamic and static values and analyze their effects in stretch reflex. We show that the perturbed joint will retain its original position at a speed that is significantly affected by gamma fusimotor drive, which provides both the position-dependent component via gamma static and a dynamic damping via gamma dynamic in the closed-loop control. We also show that in certain combinations where gamma static exceeds 200Hz, the joint fails to stabilize by either oscillating or swinging out of physiological range; in contrast. Our results suggest that only moderate intensity of gamma drive is allowed to stabilize a joint. In voluntary movements, the contraction of the agonist muscle tends to slack the spindle fiber that undermines its sensitivity for proprioceptive feedback. In order to maintain spindle fibers taut, it is suggested that gamma fusimotor drive would coactivate with inputs to the alpha-motoneuron pool. In future work we will vary the intensity of alpha-gamma coactivation to test its effect on voluntary movements. The hypothesis is that alpha-gamma coactivation effectively suppresses the stretch reflex in the antagonist muscle, and therefore establishes a new equilibrium position in the limb with minimal co-contraction.

Title: Grasping ability impairment after unilateral corticospinal tract lesion

Authors: *W. A. CARVALHO[1], J. C. TEIXEIRA[2], S. J. V. CRUZ[2], W. G. LEAL[3], P. BAHIA[2], A. PEREIRA[4];
[1]CESUPA, BELEM, Brazil; [2]Neuroplasticity LAB, FFTO/ICS/UFPa, Belém, Belém, Brazil; [3]LNNE, ICB/UFPa, Belém, Brazil; [4]Brain Intitute/UFRN, Natal, Brazil

Abstracts: Rodents can use their forepaw in dextrous ways to manipulate and eat food pieces of various shapes and textures. We investigated the effect of unilateral corticospinal tract lesion (UCTL) on skilled-reaching forepaw movements. Nine adult (both sex) Wistar rats (CEPAE/UFPA protocol BIO0079-12) weighing 250-300g were divided in sham (n=3) and lesioned (n=6) groups. Animals were anesthetized with 0.1ml xylazine (9mg/kg) and 0.7ml ketamine (72mg/kg). A partial laminectomy was performed at C4 level to expose the dorsal columns. Using a micropipette we injected 20pMol of the vasoconstrictor endothelin-1 close to the medial dorsal artery at a depth of 1 mm from the pial surface. Five minutes later, the micropipette was gently withdrawn, the animal was sutured and then returned to its home cage. The staircase test was used to evaluate forepaw (PP: preferred and NPP: non-preferred) movements before and 3, 7 and 14 days post-lesion (DPL). The sham group showed no difference in the average number of pellets retrieved compared to the baseline (PP: 9.00±1.00, NPP: 7.33±0.58) 3 DPL (PP: 7.67±1.53, NPP: 7.00±2.00) 7 DPL (PP: 8.67±2.52, NPP: 8.00±1.00) 14 DPL (PP: 9.33±0.58, NPP: 8.33±1.53). The lesioned group, however, displayed a significant impairment 3 and 7 DPL with spontaneous recovery in 14 DPL: baseline (PP: 9.67±1.37, NPP: 5.17±1.17) 3 DPL (PP: 2.33±1.03, NPP: 4.67±1.37) 7 DPL (PP: 2.67±0.52, NPP: 5.83±1.17) and 14 DPL (PP: 5.67±1.75, NPP: 6.33±1.03). Our results show that UCTL impairs skilled forepaw movements in rats. The staircase test was efficient to provide quantitative measures of skilled reaching for both the preferred and non-preferred paw.

Title: Morphological changes and neuronal hyperactivity in lumbar locomotor networks remote to mid-thoracic spinal cord injury

Authors: *T. D. FAW[1,2,3], C. N. HANSEN[1,3], L. C. FISHER[1,3,4], S. D. KERR[1,3,4], J. A. BUFORD[1,2,3,4], D. M. BASSO[1,2,3,4];

Abstracts: Spasticity occurs in ~75% of people with spinal cord injury (SCI), with most reporting a negative impact on quality of life. While spasticity is clinically defined as a velocity dependent increase in tonic stretch reflexes, its pathophysiology is largely unknown. One possible mechanism involves dysfunction of spinal interneurons. It is unclear how spasticity and/or interneuronal dysfunction relate to learning and plasticity after SCI. Previously, we showed learning and adaptive plasticity in the lumbar cord at chronic but not acute time points after mid-thoracic SCI only in the presence of sparing. To identify the role of interneurons in this effect, we used Golgi staining and neuron tracing software to quantify morphological changes of interneurons in Lamina VI/VII of L3-L6 from naïve and spinal cord injured, female Sprague-Dawley rats. We quantified 5 dendrites / animal to model reactive plasticity and examine the effects of sparing in naïves (n=3) and at acute (7d) and chronic (42d) time points after T8 spinal cord transection (TX; Acute TX n=5; Chronic TX n=4) or severe SCI contusion (SCI; Acute SCI n=4; Chronic SCI n=5). Dendritic spines increased up to 90μm from the soma after chronic injury regardless of sparing (Naïve = 70.5 +/- 10.2, Chronic TX = 113.4 +/- 9.4, Chronic SCI = 112.2 +/- 3.5; $p<.05$). After TX, the greatest spine density occurred close to the soma (0-30μm) and increased over time (Naïve = 18.4 +/- 3.6, Acute TX = 30.7 +/- 3.2; Chronic TX = 38.6 +/- 4; $p<.05$). Interneuron volume decreased over time with TX (Acute TX = 17871.8μm3 +/- 1207; Chronic TX = 8535.1μm3+/- 1147; Naïve = 22759μm3 +/- 460; $p<.05$) and was partially attenuated by sparing (Chronic SCI = 16789.1μm3 +/- 528). In sister groups, neuronal excitability was quantified by stimulus intensity to produce an ankle flexion force of 0.4-0.5N in the tibialis anterior muscle. Stimulus intensity decreased over time after TX (Acute n=6, 1.53mA +/- 0.23; Chronic n=5, 0.64mA +/- 0.19; Naïve n=8; 2.3mA +/- 0.14; $p<.05$) and was partially attenuated by sparing at 42d (Chronic SCI n=17; 1.53mA +/- 0.14). We are now differentiating excitatory vs. inhibitory dendritic spines with VGLUT1,2 and GAD67 in Thy1-YFP mice to better understand the spine density changes observed after SCI and TX. Together, we show maladaptive interneuronal changes following SCI that worsen over time with complete SCI and are mitigated in the presence of sparing. This aligns with the clinical manifestation of

hyperreflexia and spasticity. Evaluating spine density, soma size, and neuronal excitability provide novel outcome measures for interventions designed to reduce spasticity and promote functional recovery following SCI.

Title: Prolonged immobilization and unloading leads to profound and long-lasting changes in spinal excitability

Authors: ***E. L. LAWRENCE**[1], A. NAGAMORI[1], F. J. VALERO-CUEVAS[1,2], J. M. FINLEY[2];
[1]Dept. of Biomed. Engin., [2]Div. of Biokinesiology and Physical Therapy, USC, Los Angeles, CA

Abstracts: Both strength losses due to atrophy and increases in spinal excitability as measured by Hoffman's reflex (H-reflex) have been associated with prolonged unloading of the lower extremity (Clark et al., 2006; Leukel et al., 2014). However, these studies only consider the effects of unloading or immobilization in healthy subjects, and may not reflect the time course of recovery following unloading due to injury. Therefore, the purpose of this study was to evaluate the time course of recovery of spinal excitability and muscle contractile efficacy after prolonged immobilization and unloading after injury. Our study consisted of a sample of convenience in which the experimental participant (34F) was prescribed a regimen of lower limb unloading following a surgical procedure (open reduction and internal fixation) to repair a fibula fracture and ankle dislocation in the lower left extremity. The participant underwent 37 days of non-weightbearing ankle immobilization post-surgery and an additional 15 days of ankle immobilization during ambulation. On the first two days after cast removal and at one-week

intervals up to 5 weeks, we assessed spinal excitability and muscle contractile properties by measuring H-reflexes and maximal M-waves in the soleus bilaterally. During each experimental session, we first recorded recruitment curves for the M-wave and H-reflex. Then, for each leg, we recorded 20 H-reflexes at a stimulation intensity that produced a controlled M-wave equal to 10% of the respective limb's M-max. We found reduced Mmax values in the unloaded limb compared to the loaded limb ($p=0.005$) over all data collections, which is suggestive of atrophy and is consistent with previous studies (Clark et al., 2006; Leukel et al., 2014). We further report a significantly higher ratio of Hmax/Mmax for the first two weeks after cast removal ($p=0.05$) and nearly significant differences the third week post-cast removal ($p=0.1$). While not significant, differences continued to exist for 2 more weeks. These results suggest that spinal excitability is heightened following immobilization, consistent with previous reports. Surprisingly, we found that the changes in spinal excitability and muscle contractile required five weeks to return to baseline despite an immediate increase in weight-bearing activity after the cast was removed. These results add to our understanding of the time course of central changes in lower-limb neuromuscular function following prolonged unloading by demonstrating that changes in spinal excitability and muscle contractile properties may persist for much longer than a single week as demonstrated previously.

Title: The modulation of corticospinal input to the legs during arm and leg cycling

Authors: *R. ZHOU[1], S. KIM[2], S. CHONG[2], V. MUSHAHWAR[2];
[1]Ctr. for Neurosci., [2]Univ. of Alberta, Edmonton, AB, Canada

Abstracts: Locomotion is a complex task that relies on the integration of cortical input, sensory feedback, and activity in spinal networks. Arm activity can significantly modulate the performance of the legs in various types of locomotion including walking, cycling and swimming. While some studies have demonstrated the coupling between the cervical and lumbar regions of the spinal cord, there are scarce findings about how cortical input to the legs is modulated by active arm involvement during locomotion. The goal of this study was to investigate the modulation of the corticospinal input to the lower limb muscle, vastus lateralis (VL), while actively engaging arms in coordination with the legs during rhythmic cycling. VL was chosen due to its dominant contribution during leg cycling. Sixteen adults with intact nervous system were recruited. Each participant underwent four experimental conditions: leg cycling only with the arms stationary (ASLC), arm cycling only with the legs stationary (ACLS), arm and leg cycling (ALC) and stationary arms and legs (ASLS). For each participant, the maximum electromyographic (EMG) activity of VL was maintained at the level of ~10% of the maximum isometric voluntary contraction (MIVC) across all conditions. During each condition, transcranial magnetic stimulation (TMS) was delivered, in a randomized order, at four different time points of VL activation within a cycling revolution. The time points included the time of onset, mid-rising, peak and mid-descending EMG activity in VL. The intensity of TMS stimuli was selected to evoke half of the maximal motor evoked potential (MEP) with ~10% MIVC of VL muscle. The MEPs in VL were collected and compared across all conditions and time points using a two-way ANOVA. The results showed significant differences in the amplitudes of MEPs across conditions and time points ($p \leq 0.05$). In particular, Fisher's LSD post-hoc test indicated that ALC ($p=0.02$) and ASLC ($p=0.018$) are significantly different from ASLS. However, ALC and ASLC were not significantly different from ACLS. This finding suggested that dynamic arm and leg activation strongly modulate the corticospinal pathway to the legs. Furthermore, arm cycling alone may modulate the descending drive to the legs to the same extent that simultaneous arm and leg cycling does. While further investigations are needed, the findings indicate the importance, and perhaps equivalent impact, of active arm movement in modulating the strength of the corticospinal drive to the legs. The work provides support for the need to engage the arms actively in lower limb rehabilitation for people with stroke or spinal cord injury for a more effective restoration of leg function.

Abstracts: Current urodynamic rat models are not directly translational to humans since most measurements are made in anesthetized animals and since the external urethral sphincter function is not considered. Narcotics highly influence lower urinary tract function. The assessment of sphincter activity is essential to understand detrusor sphincter dyssynergia, a common consequence of spinal cord injuries. We developed a urodynamic model with electromyography (EMG) of the external urethral sphincter for quantification of lower urinary tract function in awake female rats. Urodynamic catheter and EMG electrodes were implanted into female Sprague Dawley rats. Starting one day postoperatively, urodynamic measurements including urethral sphincter EMG were performed in awake, slightly restrained animals. Controls had catheter implantation only. Rats were also assessed under urethane anesthesia for comparison to standard models. There was no difference between catheter only and the EMG electrode implanted animals. Voiding activities (volumes, bladder compliance, voiding pressure) in awake animals were very different from animals under urethane anesthesia. Implanted rats could be followed with repeated measures over up to 6 weeks without complications. The model is currently applied to rats with large lesions of the thoracic spinal cord.

Title: Effects of attention and acute physical exercise on cutaneous reflexes in children with cerebral palsy

Authors: *J. I. VOISIN[1,2], C. GANE[2], S.-K. DUFOUR[2], D. WYSS[3], K. ZABJEK[3,4], J. ANDRYSEK[3,5], D. B. MALTAIS[1,2], L. J. BOUYER[1,2];
[1]U Laval, Québec, QC, Canada; [2]CIRRIS-IRDPQ, Québec, QC, Canada; [3]Bloorview Res. Institute, Holland Bloorview Kids Rehabil., Toronto, ON, Canada; [4]Dept. of Physical Therapy, Univ. of Toronto, Toronto, ON, Canada; [5]Inst. of Biomaterials and Biomed. Engineering, Univ. of Toronto, Toronto, ON, Canada

Abstracts: Background: Individuals with cerebral palsy (CP) commonly experience physical fatigue related to physical activities such as walking. This may negatively impact on functional mobility skills (Maltais et al, 2013, Gane et al., 2013) and on academic performance (Berrin et al., 2007,). However the mechanisms by which these negative effects arise remain poorly understood. To begin to address this issue, we examined the effects of acute fatiguing physical exercise on attention and on cortical control, the later as measured by cutaneous reflexes. Methods: Eight children with spastic CP (6-13 years old, 5 males, GMFSC level I) were evaluated pre and post fatiguing physical exercise. The exercise was a maximal graded shuttle run test (SRT) specific for children with CP (Verschuren et al., 2006) where the children ran back and forth on a 10 m track at increasingly faster speeds until they could no longer maintain the pace. Cutaneous reflexes were tested in a seated position, while the stimulated foot was dorsiflexing against resistance. The participants were lightly touched over the dorsal part of the right or left foot (stimulation unseen but side known). They were instructed to pay attention to this stimulation and report it. They were to ignore the (stronger) mechanical cutaneous stimulation used to evoke the cutaneous reflexes (which were on either the same or opposite foot). Independent variables were focus of attention (directed to the same foot as the stimulated one or to the opposite foot) and pre/post exercise. The dependent variable was the amplitude of the short latency reflexes (peak2peak amplitude from 20 to 50 ms post stimulation) recorded from the right and left anterior tibialis following the cutaneous stimulation of the corresponding foot (cutaneous branch of the sural nerve). Results and Discussion: Increased cutaneous reflexes were found after SRT (from 0.13 to 0.16 mV) and when attention was oriented to the stimulated

foot (from 0.12 to 0.17 mV) (paired t-test, $p<0.05$). These results suggested that both divided attention and acute physical fatigue may negatively impact performing motor-based activities of daily life such as walking in cognitively demanding environments.

Title: Exercise-dependent increase in mTOR activity regulates KCC2 expression and reflex recovery after SCI

Authors: S. F. CHOYKE, *M.-P. COTE;
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstracts: Plasticity in spinal pathways is a key target for therapeutic strategies aiming at restoring both sensory and motor function after spinal cord injury (SCI). The serine-threonine kinase mammalian target of rapamycin (mTOR) has recently emerged as a promising pharmacological target for the treatment of SCI. mTOR expression is up-regulated in an exercise-dependent manner after SCI and can be regulated by tyrosine kinase receptor activation. We recently showed that BDNF expression is correlated with exercise-dependent reflex recovery and with the expression of the potassium chloride cotransporter 2 (KCC2), and that both required TrkB activation. Not only is mTOR involved in the regulation of neuronal cell growth, survival and differentiation, but also in dendritic development, synaptogenesis and synaptic plasticity. Interestingly, although KCC2 function primarily influences the efficacy of GABAergic signaling, its abundant presence in dendritic spines has attracted growing interest. Suppressing KCC2 in mature neurons influences synaptic efficacy independently of GABAergic function whereas an increase in KCC2 levels promote dendritic spine development. Motoneurons display marked loss of dendritic membrane and branching after SCI which is not observed in exercised animals. We hypothesized that mTOR contributes to KCC2 upregulation in SCI animals that are exercised. Adult female Sprague-Dawley rats underwent a complete spinal cord transection at T12. Animals were assigned to one of these 3 groups: vehicle, rapamycin or rapamycin + Ex. Rapamycin treatment (i.p.) was given every other day starting 1 day after surgery for the

duration of the study. In a terminal experiment, H-reflexes were recorded from interosseus muscles following stimulation of the tibial nerve at 0.3Hz, 5Hz and 10Hz. Our data show that preventing mTOR action during exercise hindered spinal reflex recovery, with KCC2, BDNF and TrkB upregulation in the lumbar spinal cord. Our results suggest that the exercise-dependent increase in KCC2 expression and return of spinal reflexes requires mTOR activity. The role of KCC2 in restoring endogenous inhibition and remodeling of the dendritic tree of motoneurons with exercise will be discussed.

Title: Interlimb cutaneous reflex transmission after thoracic hemisection during walking on a flat treadmill or on a ladder treadmill

Authors: *A. KUNDU, M. ESCALONA, H. DELIVET-MONGRAIN, J.-P. GOSSARD, S. ROSSIGNOL;
Neurosci., Univ. De Montreal, Montreal, QC, Canada

Abstracts: Previous work has shown that adult cats can recover quadrupedal stepping within about three weeks following a unilateral hemisection even if some deficits such as left-right asymmetry persist. Treadmill training can further improve the locomotor performance. Thus neuroplastic changes occur in the remnant supraspinal structures and also at the level of the spinal cord. The present work aims at assessing the potential role that could be played by cutaneous spinal reflexes in such recovery. Adult cats were selected based on their ability to walk regularly for several minutes on the flat treadmill (FTM) and on a ladder-treadmill (LTM) consisting of rungs attached to the treadmill at regular intervals of 8 cm which requires more supraspinal control. The cats were chronically implanted with EMG electrodes in seven muscles (four hindlimb, one back and two forelimb muscles) and a cuff electrode on the right and left Superficial Peroneal Nerve (SPN). A left hemisection was performed at the T10 level. Cutaneous reflexes were elicited systematically in various phases of the step cycle by stimulating the SPN while the cats were walking on the FTM or on the LTM, before and after the hemisection. Preliminary results show that the cutaneous reflexes measured in Semitendinosus (knee flexor-hip extensor) on the FTM and LTM are phase-dependent, being increased during the swing phase and mostly absent during stance. One week after hemisection, the peak reflex amplitude is about half of that seen in the control. When walking on the FTM with an intact spinal cord, reflexes were generally smaller than on the LTM. Post hemisection, their amplitude first

decreased but then gradually increased. Cutaneous reflex in the contralateral and forelimb extensor muscles were also observed. During a terminal acute experiment (decerebration and curarization), SPN on both sides were stimulated during fictive locomotion. Plots of reflex amplitude vs St burst amplitude showed an increased gain of transmission on the left as compared to the right. This work suggests that crossed and interlimb reflexes participate in the adaptation of walking on the LTM and also after hemisection, two conditions requiring more supraspinal controls. Title: Mitigation of pressure ulcers using intermittent electrical stimulation

Authors: L. R. SOLIS[1], P. SERES[2], *V. K. MUSHAHWAR[3];
[2]Biomed. Engin., [1]Univ. of Alberta, Edmonton, AB, Canada; [3]Univ. Alberta, Edmonton, AB, Canada

Abstracts: Pressure ulcers are a major medical complication that affects people with reduced mobility and impaired sensation. Pressure ulcers can develop at the skin and progress inwards, or at the bone-muscle interface and progress outwards. The latter is classified as deep tissue injury (DTI) and is caused by prolonged loading of soft tissue between a bony prominence and a surface. The excessive mechanical deformation of the muscle triggers the onset of damage, which is then exacerbated by ischemia and reperfusion. We suggested the use of intermittent electrical stimulation (IES), delivered through a system called “Smart-e-Pants” to prevent the formation of DTI in populations at risk, particularly those with spinal cord injury (SCI). The use of IES can counteract both the mechanical and vascular pathways leading to DTI formation (Solis et al 2007, 2011). More importantly, IES can effectively prevent the formation of DTI (Solis et al 2007, 2013. Curtis et al 2011). IES accomplishes this by mimicking the subconscious

postural adjustments (fidgeting) that people with full mobility perform as a result of discomfort. This intermittent activation of loaded muscles consists of bouts of stimulation lasting for 10 sec, followed by 10 min of stimulation cessation. In this study we explored the effectiveness of IES to mitigate tissue damage that has already occurred. The study was conducted in rats with a SCI in which a DTI was caused by externally loading the triceps surae muscle. The applied load was proportional to the load that people with SCI experience while sitting in a wheelchair. IES was applied for 4 hours initiated at different time points (1, 3, and 6 days post onset of DTI). Tissue damage was assessed through the use of MRI and histological methods. The effectiveness of IES to mitigate damage was compared against the natural progression of DTI at the same time points in control groups of rats. In rats that received IES, DTI in the muscle was mitigated by ~50% compared to the groups that did not receive IES. This result is significant because it provides evidence that IES while effective at preventing DTI, can also mitigate damage that had already started. This is of particular importance for its clinical implementation, as in practice, DTI develops unbeknownst to caregivers due to the current lack in effective DTI detection methods. For this reason, a system that can be used both to prevent the onset of DTI as well as mitigate damage that had already taken place could help to reduce the incidence of pressure ulcers, particularly those of deep origin. This not only improves quality of life but also reduce the large costs associated with their treatment, which in the USA are at least $11 Billion/year.

Title: Comparing locomotion on a flat and on a ladder treadmill in cats before and after spinal hemisection

Authors: *M. ESCALONA, A. KUNDU, H. DELIVET-MONGRAIN, J.-P. GOSSARD, S. ROSSIGNOL;
Neurosciences, Univ. De Montréal, Montreal, QC, Canada

Abstracts: Locomotor evaluation after spinal lesions is usually done on a flat treadmill which requires little voluntary adaptation. To evaluate the effect of spinal hemisection affecting ascending and descending pathways we modified our conventional treadmill to evaluate cats walking at various speeds on a flat treadmill (FTM) or on a ladder treadmill (LTM) by fixing quadrangular rungs (35cm w, 5cm h) spaced at every 8cm on the FTM. This set-up allows us to record and average EMG activity and kinematics for several consecutive cycles in various conditions (on FTM or LTM, with an intact cord and after hemisection). Four cats were implanted with EMG electrodes in the main flexor and extensor muscles of the forelimbs and hindlimbs on both sides and recorded together with synchronized video of the left side. After a control period of 3wks to collect baseline values, a left hemisection was performed at T10. For the next 6 weeks 2 cats were trained on the LTM and the 2 others on the FTM. Once a week, for 6 weeks, the stepping (EMG, Kinematics) were evaluated at speeds from 0,4 to 0,8 m/s on the FTM. All protocols were approved by the Université de Montreal´s Ethics Committee. The hindlimb movements of the 2 cats walking on the LTM with an intact cord were very similar to those recorded during walking on the FTM: there was a small increase in knee and ankle flexion and increased velocity of knee and ankle extension in the later part of stance before contact with the rungs. This normalization of kinematics was however achieved through some significant EMG changes. In one cat the hip extensor-knee flexor Semitendinosus (St) discharge occurring at the end of stance was increased in amplitude; more remarkably, a 2nd burst occurring just before foot contact was as large as the first, suggesting a voluntary control to place the foot accurately on the rungs. After hemisection, the second St burst disappeared on the left but was maintained on the right which continued to walk on the rungs as did the forelimbs. The knee extensor was markedly increased in the second part of stance. This cat walked in between the rungs with the left hindlimb while the second cat was able to step on the rungs for several but irregular step cycles. Kinematic changes on the FTM might have reflected not only the effect of the hemisection but also the effect of training on the LTM since the 2 other cats not trained on the LTM did not show these changes on the FTM. This paradigm thus allows to investigate more accurately the contribution of spinal pathways to voluntary locomotion and help understand the mechanisms of locomotor recovery after partial spinal cord lesions. Title: Evaluation of the antioxidant effect of dapsone in a model of traumatic spinal cord injury in rat based on the amount of reduced glutathione

Authors: *A. S. ROJAS[1], C. RIOS[2], A. DIAZ-RUIZ[2], D. NICOLAS[2], G. BALDERAS[2];
[1]Neurochemistry, Natl. Inst. of Neurol. and Neurosurg. D, Mexico City, Mexico;
[2]Neurochemistry, Natl. Inst. of Neurol. and Neurosurg., Mexico City, Mexico

Abstracts: Introduction: Traumatic spinal cord injury(TSCI) is a condition caused by irreversible damage on neurological function. One mechanism observed after TSCI is apoptosis, inducing the loss event of adjacent healthy tissue.Therefore, the search for treatments aimed at reducing the process is paramount.Dapsone(DDS) is a drug capable of inhibiting oxidative damage, inflammatory response after a process of ischemia/reperfusion in rats.Previously in the laboratory showed that the DDS protects tissue damage and promotes functional recovery in rats. **Objective:**To evaluate the antioxidant effect of dapsone based on the reduced amount present in the acute phase after trauma in a rat model glutathione. **Method:**Female Wistar rats(200-250g) were used, being assigned randomly into 11 groups: sham 4 groups(n=16), 7 groups of rats with TSCI(n=56). The animals were anesthetized with pentobarbital and underwent a laminectomy or TSCI level T-9 using the New York University team Spinal Cord Impactory.Subsequently, three different doses of Dapsone depending the group they belonged to(12.5,25 and 37.5mg/kg) were administered.The animals were sacrificed 24 hours after surgery. **Results:**The values obtained from the analysis of the amount of GSH in the injured groups are similar no significant when compared with the control group(TSCI+Vehicle) differences. **Conclusions:**The findings of this study showed that the antioxidant effect of dapsone is unrelated to the regulation of GSH, because there is no reduction in the neurodegenerative effects when using dapsone treatment in the acute phase of TSCI(first 3-5 hours), so that the evaluation of other markers of oxidative damage is suggested.

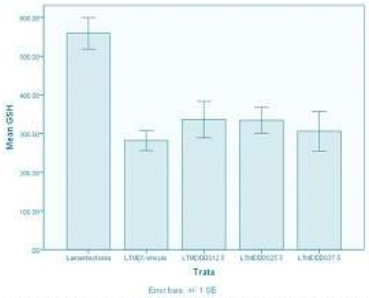

Figure 1. Chart in which the mean values ± standard error of the determination of GSH in animals with laminectomy and TSCI evaluated 24 h after the surgical procedure are shown, values are expressed in mg of GSH / mg protein. Laminectomy: A surgical procedure without injury. TSCI: Traumatic injury to the spinal cord. TSCI / vehicle: spinal cord injury + saline. TSCI /DDS12.5: spinal cord 12.5mg/kg + dapsone. TSCI /DDS25: spinal cord 25mg/kg + dapsone. TSCI /DDS37.5: spinal cord 37.5mg/kg + dapsone. GSH: reduced glutathione. One way ANOVA followed by Tukey test.

Title: Evaluating the necessity of the KOR in the morphine-induced attenuation of function after SCI

Authors: ***M. ACEVES**, M. A. HOOK;
Neurosci. and Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr., Bryan, TX

Abstracts: Opioids are one of few effective analgesics for the treatment of pain following spinal cord injury (SCI). Unfortunately, we have shown that morphine administered in the acute phase of SCI, irrespective of the route of administration, compromises recovery of locomotor function, increases mortality and pain reactivity, and suppresses weight gain in a rodent contusion model

(Hook et al., 2007, 2009, 2011). These adverse effects appear to depend on activation of the kappa opioid receptor (KOR). Selective activation of the KOR, using GR89696, undermined locomotor recovery and decreased weight gain. In the current study, we tested whether activation of the KOR is necessary to produce the adverse effects of morphine using norBNI, a selective KOR antagonist. Subjects received a moderate spinal contusion (T12), and an intrathecal cannula was implanted. Baseline locomotor function (BBB) and pain reactivity (tail-flick) were assessed 24 hours following injury. Subjects were then pretreated with norBNI (0, .08, or .32 μmol), followed by morphine (0 or .32 μmol). Pain reactivity was re-assessed 30 minutes after drug treatment. Locomotor recovery was evaluated across a 21-day period, with additional tests of motor and sensory function conducted after day 21. Our results show that pretreatment with norBNI blocks the morphine-induced effects on recovery in a dose-dependent manner. At higher doses, norBNI eliminates morphine's adverse effects on recovery, but analgesia is also abolished. Conversely, at low doses, analgesia is maintained, but the adverse effects persist. This suggests that activation of the KOR system is necessary and sufficient for morphine-induced attenuation of recovery. However, as the protective dose of norBNI also diminished analgesic efficacy, simply blocking KOR activity is not sufficient for improving the efficacy and safety of clinical opioid use. Further understanding of the specific molecular changes induced by KOR activation is necessary to improve pain management strategies and facilitate functional recovery after SCI.

Title: Lumbosacral spinal cord epidural stimulation enables full weight bearing standing in motor complete paraplegics

Authors: *E. REJC[1], C. ANGELI[1,2], S. HARKEMA[1,2];
[1]Neurolog. surgery, Univ. of Louisville, Louisville, KY; [2]Frazier Rehab Institute, Kentucky One Hlth., Louisville, KY

Abstracts: Epidural stimulation of lumbosacral spinal cord, combined with the sensory input associated with weight bearing, enabled a motor complete paraplegic to progressively regain full weight bearing standing. The aim of this study was to investigate whether this same strategy was effective to regain full body weight bearing standing in three more individuals. The effects of different stimulation parameters on EMG pattern, spinal cord evoked potentials (scEP) characteristics and behavioral responses during standing were studied. Four motor complete SCI participants with a chronically implanted epidural electrode array over the segments L1-S1 of the spinal cord participated in this study. EMG, kinematics and ground reaction forces were recorded. In this study, we showed that four out of four individuals with a clinically motor complete spinal cord injury achieved full weight bearing standing with little assistance when the lumbosacral spinal cord was stimulated with individual-specific parameters optimal for standing. During sitting, little or negligible EMG activity of lower limb muscles was induced by such stimulation. The sit to stand transition and full body weight bearing standing promoted remarkable levels of continuous EMG activity in most of the lower extremity muscles. We assessed the individual specificity of stimulation parameters by testing the stimulation configurations optimal for standing across participants. In all cases, when an individual was stimulated using parameters specific for other participants, additional assistance was needed to stand; EMG patterns were also different than the one recorded when individual-specific parameters optimal for standing were used. EMG patterns were also different across individuals when the same stimulation parameters were tested in standing. Stimulation parameters selectively modulated the lumbosacral neural networks during standing. Different electrode configurations induced remarkably different behaviors and EMG patterns. EMG activity of several muscles changed from continuous to rhythmic above certain stimulation strengths, when higher frequencies (i.e. 25 Hz and 50 Hz) were used. Finally, higher stimulation frequencies induced scEP with greater variability and lesser amplitude than lower frequencies. These results have important implications with respect to: 1) how lumbosacral neural networks can be selectively modulated by varying the epidural stimulation parameters, and 2) identifying strategies that are likely to be most efficacious in enabling improved motor function for standing after motor complete paralysis.

Title: Intra-spinal microstimulation implants for humans

Authors: *A. TOOSSI[1], D. G. EVERAERT[2], R. C. BUTZ[3], C. R. DENNISON[3], V. K. MUSHAHWAR[4];
[1]Ctr. For Neuroscience, Univ. of Alberta, Edmonton, AB, Canada; [2]Div. of Physical Med. & Rehabil., [3]Biomed. Instrumentation Lab, Dept. of Mechanical Engin., [4]Ctr. for Neurosci. and Div. of Physical Med. & Rehabil., Univ. of Alberta, Edmonton, AB, Canada

Abstracts: The overall goal of this study is to develop an electrochemically safe and mechanically stable implant for chronic intra-spinal neural implants. Spinal cord injury (SCI) affects approximately 12000 people every year in the US. One of the important functions lost after SCI is the ability to stand and walk. Our lab has developed an electrical stimulation approach for restoring standing and walking called intraspinal microstimulation (ISMS). The technique involves implantation of ultrafine microwires in the ventral horn of the lumbosacral enlargement targeting the motoneuron pools. Low electrical currents (<0.1 mA) delivered through these wires produce coordinated movements of the legs. Extensive testing in cats (Mushahwar et al, 2000) and rats (Bamford et al, 2010) demonstrated that the wires remain stable in place and functional for long durations. These results suggested that ISMS may be a viable clinical approach for restoring leg movements in people with SCI. Preparing ISMS for clinical testing requires design adjustments to accommodate human anatomy and surgeons' needs. Of utmost importance are the stimulation safety of the new electrodes and the mechanical stability of the implant in large animals. To assess the stimulation safety of the new electrodes,

arrays consisting of 24 Pt/Ir (80% Pt) microwires with different diameters and extents of tip deinsulation were fabricated and implanted in 1 adult cat for acute testing. Voltage transient measurements (VTM) were obtained. The stimulation safety boundaries of the VTMs are determined by oxidation limits of water. VTMs indicated that electrodes made of 50µm-dia Pt/Ir with 200µm tip exposure can be used to deliver currents up to 50% higher than ISMS requirements for cats, while remaining within the safe limits. To determine the mechanical forces leading to electrode dislodgment, in-Fiber Bragg Grating (FBG) sensors (Dennison et al, 2010) were mounted in line with the microwires (50µm dia). The FBG sensors were calibrated using masses ranging from 1-200 g and were deemed reliable in the range of interest. Tofu was initially used as a surrogate model of the spinal cord (Snow et al., 2006) in bench-top testing. Force was applied in-line with 4.7 mm long Pt/Ir ISMS electrodes. In the 3 trials conducted, the average dislodgment force was 0.024 ± 0.03 N. The same procedure was applied to 3 freshly extracted pig spinal cords in which 18 trials were conducted. The average dislodgement force was 0.028 ± 0.019 N. In this study the stimulation safety of 50µm Pt/Ir ISMS electrodes was demonstrated and the minimal forces leading to electrode dislodgment were determined. This information will guide the design of a chronic ISMS implant.

Abstracts: Spinal cord injury (SCI) is one of the most prevalent, devastating neurological conditions. Less than 1% of SCI survivors will experience full recovery. This statistic highlights the need for further research to advance effective therapy during long-term SCI recovery, including interventions to facilitate locomotor function. To this end, we conducted a preliminary study of a novel intervention using robot-assisted locomotor training triggered by EEG in complete SCI. Eight participants (7 AIS-A, 1 AIS-B) participated in 4 hours of intervention, 3 times per week for 4 months. Intervention consisted of clinical conditioning and robot-assisted locomotor training on a body weight-supported treadmill with virtual reality features, tactile feedback, and brain-computer interface. To maximize participants' cortical processing, our multidisciplinary team structured intervention 1) to ensure intensive, progressive challenge to each participant; and 2) to elicit participants' mastery of internal and external feedback. Further in keeping with this neuroplasticity-based paradigm, training required highly repetitive performance of tasks. All participants were able to trigger EEG in the brain-computer interface with the robot-assisted treadmill training. Overall, our initial findings demonstrate that clinically informed robotic rehabilitation technology has enormous potential to advance restoration of locomotor function in complete SCI.

Title: Effects of deep brain stimulation on short and long-latency stretch response in childhood generalized dystonia

Authors: *E. ARGUELLES, N. H. BHANPURI, T. D. SANGER;
USC, Los Angeles, CA

Abstracts: Dystonia is a movement disorder characterized by involuntary muscle contractions, overflow, and abnormal postures. Furthermore, there is evidence to suggest that the long latency stretch response (LLSR) is increased in dystonia, while the short latency stretch response (SLSR) remains normal. Although the pathophysiology of dystonia is still an active area of investigation, dystonic symptoms are associated with basal ganglia dysfunction and increased cortical excitability. Deep brain stimulation (DBS) of the internal globus pallidus (GPi) has been used to treat dystonia, despite an incomplete understanding of its mechanisms of action. A common proposal is that GPi-DBS reduces cortical excitability. Since the LLSR is thought to have motor pathways travelling through cortex and is abnormal in patients with basal ganglia dysfunction such as Parkinson's disease, Huntington's chorea, and hypertonic dystonia, it is possible that they are directly affected by GPi-DBS. SLSR, on the other hand, which do not directly involve cortical pathways, may not be influenced by dystonia. There is little research on the interaction between DBS and LLSR; therefore, we investigated the effects of GPi-DBS on LLSR in children with generalized dystonia. Since DBS is thought to reduce overall excitability, we hypothesized that the amplitude of the LLSR will be attenuated in response to DBS. To test this, we measured EMG activity of the first dorsal interosseous (FDI) during rapid index finger perturbation for two conditions: DBS-on and DBS-off. During this experiment, subjects viewed a display and were instructed to keep the finger in the start position to the best of their ability. In addition to FDI, we recorded EMG from the abductor digiti minimi (ADM) in order to observe changes in overflow. Our results indicate modulation of the LLSR during DBS-on compared to DBS-off. The SLSR was less affected and overflow was present in both conditions. These results suggest that GPi-DBS may cause an immediate change in the activity of efferent cortical pathways that drive muscle activation during rapid corrective movements, yet has little effect on the short latency response, which involve only spinal pathways. Interestingly, we observe changes in EMG just minutes after switching on/off the stimulation, in contrast to the observation that clinical benefits can take weeks to months to fully manifest. Thus, DBS may affect motor output on different timescales.

Title: Selective stimulation of spinal sensorimotor circuits by multipolar stimulation of the spinal cord

Authors: *M. CAPOGROSSO[1,2], N. WENGER[1], A. MORTERA[1,3], J. GANDAR[1], N. PAVLOVA[1], S. MICERA[2,1], G. COURTINE[1];
[1]Ecole Polytechnique Federale De Lausanne, Lausanne, Switzerland; [2]Inst. of Biorobotics, Scuola Superiore Sant'Anna, Pisa, Italy; [3]Politecnico di Torino, Turin, Italy

Abstracts: Epidural electrical stimulation (EES) of lumbosacral segments is a promising intervention to improve motor function after spinal cord injury (SCI). Recent experiments in rat models of SCI and in humans with motor complete paralysis showed that continuous EES applied over specific lumbosacral locations could facilitate distinct aspects of standing and walking and even enable supraspinal control of the paralyzed legs. In these experiments, electrode configurations and stimulation parameters were selected based on empirical observations during time-consuming mapping experiments. These restrictions are mainly due to the limited understanding of the mechanisms underlying site-specific facilitation of movement with EES. To remedy this issue, we developed and validated an advanced computational model of EES to uncover the optimal configurations and use of multi-electrode arrays to facilitate movement after SCI. Using combinations of computerized simulations and electrophysiological experiments, we identified unique configurations of electrodes to increase the selectivity of responses elicited by EES. We could induce side-dependent movement of extension versus flexion, which could not be achieved previously using monopolar EES. These simulations aim to activate afferent proprioceptive fibers, which recruit excitatory pre-motor interneuronal networks with multi-segmental projections to specific sets of synergistic motor pools. Our results define new strategies for the design and use of more effective multi-electrode arrays to facilitate specific limb movements in humans with SCI.

Title: Transcutaneous spinal cord stimulation to modulate spinal reflex excitability and locomotor output after SCI

Authors: ***B. FARRELL**[1], J. BRUCE[1], W. B. MCKAY[1], K. TANSEY[2,3];
[1]Shepherd Ctr., Atlanta, GA; [2]Sch. of Medicine/Physiology, Emory Univ., Atlanta, GA; [3]SCI Clin., Atlanta Veterans Admin. Med. Ctr., Atlanta, GA

Abstracts: Spinal cord stimulation (SCS) has been shown to both modulate and generate locomotor like electromyographic activity as well as to alter spasticity in individuals with spinal cord injury (SCI). Recent evidence has shown that transcutaneous (t)SCS can generate reflex responses similar to those elicited by epidural SCS but with reduced cost and invasiveness. It remains unclear however if there are certain stimulation frequencies at which tonic tSCS is most effective at reducing spinal reflex excitability and/or spasticity and whether the addition of stepping related afferent feedback further augments motor output. Therefore the goal of this research was to examine the effects of tSCS frequency on posterior root motor reflexes (PRMRs) and electromyographic muscle activation patterns recorded from healthy non-injured individuals and individuals with incomplete spinal cord injury during stepping in a robotic gait orthosis. We hypothesized that as frequency increases from 10-50Hz, excitability will first rise and then fall as some previous evidence has suggested. To achieve this, tSCS was delivered through stimulating electrodes placed over the T11/T12 inter-vertebral space (source) and reference electrodes placed on the abdomen (sink) and was applied at sub-motor threshold levels in non-injured and incomplete SCI subjects for up to 30 minutes. The results from the four healthy non-injured subjects, indicate that resting-state excitability is significantly modulated by sub-motor threshold tSCS though the effects of the individual frequencies varied. In the individuals with incomplete SCI, tSCS at higher frequencies (50 Hz) demonstrated the ability to depress reflex excitability both during tonic stimulation and up to 5 minutes after the tonic stimulation was removed.

Furthermore, during robotic assisted stepping in individuals with SCI, tSCS brought significant reduction in ankle clonus during the stance phase. These results and previous evidence support the idea that transcutaneous spinal cord stimulation, like its epidural predecessor at or above 50 Hz tends to decrease responsiveness to afferent inputs and that future studies should focus on training with tSCS.

Abstracts: The effects of locomotor training and spinal cord stimulation depend on the central excitability of the networks caudal to a spinal cord injury [1]. Peripheral nerve stimulation allows targeting these networks to alter their excitability. Here, we studied the effects of peroneal nerve stimulation on the central state of the lumbar spinal network. The modifications of lumbosacral motoneuron elicitation were tested by non-invasive, transcutaneously elicitation of posterior root-muscle (PRM) reflexes simultaneously in lower limb muscles. In five subjects (3f.) with intact nervous system we applied a conditioning test paradigm. One-second trains with a pulse rate of 15, 30 and 50 pps peroneal stimulation were applied as a conditioning input at 1.2 and 1.5 times of the motor threshold (MT). Test PRM reflexes were elicited following 50, 100, 500 and 1000 ms through surface electrodes over T11-T12 vertebrae referenced to large paraumbilical

electrodes [2,3]. The major observed effect was a suppression of ipsilateral motoneuron pools that increased with increasing conditioning rate and intensity and persisted over at least 1 second. This suppression was more prominent in the distal than in the proximal lower limbs muscle groups, e.g. applying 30 pps and 1.5 MT conditioning the PRM reflexes were reduced significantly by 40 % and 80 % in the thigh and shank muscles, respectively. No significant group results were observed in the contralateral leg, although both excitatory and inhibitory tendencies were found. In individuals with intact nervous system peroneal nerve stimulation had a suppressive effect more expressed in the motor nucleus of stimulated nerve and least of not stimulated contralateral limb nerves of thigh muscles. Within our ongoing studies we are interested in the effects of the same conditioning on the altered central state of excitability after spinal cord injury and whether excitatory influences could be delivered via nerves with different innervation zones and profiles. 1. Title: Short- and long-term effects of intermittent transcutaneous spinal cord stimulation on spinal spasticity and residual motor control

Authors: *U. HOFSTOETTER[1], M. KRENN[1], S. M. DANNER[1,2], B. FREUNDL[3], H. BINDER[3], F. RATTAY[2], W. MAYR[1], K. MINASSIAN[1];

Abstracts: Spinal cord injury (SCI) leads to altered brain control over the spinal cord, manifested as paralysis or paresis below the lesion as well as spasticity, one of the most disabling secondary complications. Clinically, spasticity includes muscle hypertonus, hyperreflexia, clonus, and involuntary muscle contractions and may further diminish the functional utility of residual motor control. In a proof of concept study, we demonstrated the usability of 50-Hz transcutaneous lumbar spinal cord stimulation (tSCS), a non-invasive analog of epidural SCS, applied for 30 minutes to temporarily alleviate spinal spasticity and facilitate voluntary movements in motor-incomplete SCI individuals [1]. Here, we present the persistence of the therapeutic effects after a single application of tSCS in a cohort of seven subjects of our ongoing clinical study with different profiles of motor-complete and -incomplete SCI. To this end, clinical, functional, and neurophysiological methods were used to evaluate the different manifestations of spasticity and residual motor control capacities before, immediately after, and two hours after a 30-minute session of 50-Hz tSCS applied at a sub-motor level. Preliminary analysis of the various outcome measures indicates a reduction of spinal spasticity with preserved residual mobility. The primary parameter, the index of spasticity calculated on basis of the Wartenberg pendulum test, showed a significant improvement two hours after stimulation. In one of the subjects with motor-incomplete SCI, we tested potential summation effects of tSCS applied 5 times a week over a period of six weeks. Stimulation parameter settings were the same as used for single application. Spasticity and residual motor control were evaluated before the first stimulation as well as once a week, 24 hours after the last application of stimulation. We found that the tSCS-induced antispastic effects persisted for 24 hours and, over the course of time, were progressively increasing. After six weeks, the subject discontinued the stimulation and two further evaluations were conducted one and two weeks later, respectively. Persisting tSCS-induced effects could still be detected after one week. These interim findings suggest that short- and long-term changes of altered motor control after SCI can be induced with repetitive exposure to tSCS. Further analysis and recruitment of additional subjects are ongoing to identify SCI profiles of responders. Essential future steps include testing combinations of tSCS with other treatment modalities to further potentiate the obtainable therapeutic effects. [1] Hofstoetter et al. Title: Long-latency spinal reflexes predict rhythmicity in response to epidural lumbar cord stimulation

Authors: *S. M. DANNER[1,2], M. R. DIMITRIJEVIC[3], U. S. HOFSTOETTER[4], M. KRENN[4], W. MAYR[4], K. MINASSIAN[4], F. RATTAY[2], J. C. ROTHWELL[5];

Engin., Med. Univ. of Vienna, Vienna, Austria; [5]Inst. of Neurol., Univ. Col. of London, London, United Kingdom

Abstracts: It is known that repetitive lumbar epidural stimulation can give rise to rhythmic activity in leg muscles in individuals with clinically motor complete spinal cord injury. However, the effect can vary in different people, in different muscles, and at different frequencies. Here, we examined what factors might influence the appearance of rhythmic activity. We applied epidural stimulation to the posterior lumbar spinal cord in 10 individuals with clinically motor complete spinal cord injury. Motor unit activity was assessed by electromyography (EMG) recordings from thigh and leg muscle groups. Stimulation was applied at various stimulation frequencies (2-80 Hz) at motor threshold intensity. Rhythmicity occurred most often at 50 Hz, only above 20 Hz and most frequently in tibialis anterior. Rhythmic activities in single muscle groups occurred in all subjects, yet the frequency of occurrence differed substantially between the subjects ranging from 1.3% to 25.9% of the recordings. Thus, tonic activity was always dominant and besides stimulation frequency additional factors must influence the motor pattern. In response to low frequency stimulation (2-5 Hz), in addition to the well described monosynaptic reflex components, three types of long-latency responses (>50 ms post-stimulus) were found: i) Interference-like tonic as well as ii) phasic asynchronous EMG activities spanning the time of analysis, and iii) stimulus time-related compound muscle action potentials. Amplitude and quality of late responses could change independently of the short-latency responses during constant stimulation conditions. In one subject with a laterally located electrode, stimulation of up to 10.5 V induced monosynaptic reflexes in the ipsilateral leg only. Yet, starting with 5 V long-latency responses were recorded on the contralateral side. Thus, it is possible with unilateral stimulation to elicit a contralateral response. Finally, we found that the root-mean-square of the late responses (50-150 ms post-stimulus) observed to follow 2 and 5 Hz trains of test stimuli in all muscle group EMG recordings from one leg significantly predicted the

probability of occurrence of rhythmic activity at higher stimulation frequencies but unchanged impulse width and amplitude ($p<.001$; $R^2=.624$). The fact that long-latency responses predict rhythmicity at higher frequencies suggests that the state of the spinal networks, i.e., the relative excitability of different neural pathways, determines the response to stimulation. Externally modulating the central excitability would thus allow for better control of the outupt to high frequency epidural stimulation.

Title: Muscle co-activation as function of crank angle when cycling on an ergometer with altered power output

Authors: *J. LACZKO[1,2,3], P. KATONA[4], A. VALY[3];
[1]Information Technol. and Biorobotics, Univ. of Pecs, Pecs, Hungary; [2]Wigner Res. Ctr. for Physics, Budapest, Hungary; [3]Information Technol., Pazmany Peter Cath. Univ., Budapest, Hungary; [4]Semmelweis Univ., Budapest, Hungary

Abstracts: Cycling on an ergometer is often applied in medical rehabilitation for individuals who have suffered a stroke or other CNS lesion. If pedaling cadence or crank resistance increases than larger total muscle work is required from the cycler. This might be ensured by reducing of muscle co-activation and/or by increasing individual muscle activities. We examined cycling movements of able-bodied individuals, in particular how co-activation of knee muscles alters if pedaling cadence or crank resistance changes. Methods: 15 participants (age 20-28 y.) were involved in the study. They performed cycling movements on a stationary bike (SCIFIT, Germany). Cycling was performed with 2 velocities (45 and 60 revolution per minute) against 3

crank resistances. Surface EMGs of vastus lateralis (VL), vastus medialis (VM), rectus femoris (RF), biceps femoris (BF) were measured with the ZEBRIS CMS-HS movement analyzing system (sampling frequency 900Hz). In parallel, ZEBRIS recorded the positions of markers placed on the lower limb and on the crank of the ergometer (100Hz). Crank direction (crank angle respect to the upward vertical direction) was computed from coordinates of markers placed on the ergometer's crank and on the participant's foot. We investigated the co-activation of BF with 3 parts of the quadriceps separately (BF-VL, BF-VM, BF-RF muscle pairs). Muscle co-activations were quantified by the range of crank angles in which both muscle in a flexor-extensor muscle pair was simultaneously active. Student's t-tests ($p<0,05$) were applied to compare the size of co-activation ranges (SCR) under different cycling conditions. Results: The size of co-activation range of BF-VL muscle pair significantly decreased when the crank resistance increased in a given cycling cadence. This was true for the BF-VM muscle pair too. The SCR decreased for the BF-RF muscle pair but this change was not significant. When cycling cadence was increased and crank resistance remained constant, than no significant change was observed in the SCR of BF-VM, neither in the SCR of BF-VL nor in the SCR of BF-RF. Conclusion: Knee extensor muscles are mainly responsible for generating sufficient force during cycling movements but if crank resistance is increased than neural control may help to generate higher power output by reducing the ranges where flexor-extensor muscles co-activate. In contrast, when cycling cadence increases and resistance remains constant than purely the increased individual muscle activities ensure higher power output. Thus, lower limb cycling against increased crank resistance may be advantageous in those rehabilitation procedures in which the aim is to improve neural adaptation.

Abstracts: Electrochemical neuromodulation of spinal sensorimotor circuits improves motor control in animal models and human patients with spinal cord injury (SCI). Currently, stimulation parameters are tuned manually and remain constant during movement, which is likely suboptimal to mediate maximum therapeutic effects. The potential of spinal neuromodulation therapies to improve locomotor performance through multiple electrodes at distinct locations and at specific time of the gait cycle remains poorly explored. Here we developed a neuroprosthetic system composed of a multi-electrode array and a real-time control system that enabled closed-loop tuning of multisite spinal cord stimulation during locomotion in rats. We leveraged these integrated developments for the design of multisite stimulation strategies that mimicked the oscillating activity of flexor and extensor motor neuron pools underlying locomotion in healthy rats. These algorithms were designed based on computational models and comprehensive mapping experiments. Detailed analysis of kinematic, kinetic and muscle activity revealed significantly increased modulations of gait features and more physiologically relevant stepping patterns when delivering physiologically relevant, phase-dependent multisite stimulation compared to continuous stimulation. Our integrated developments show the potential to markedly improve gait execution with real-time control of electrochemical neuromodulation after spinal cord injury. These results emphasize the need to develop similar conceptual and technological framework to facilitate rehabilitation in human patients with spinal cord injury.

Title: Neuromodulation of motor cortex and spinal circuits facilitates locomotor training and promotes recovery following spinal cord injury in mice

Authors: *J. A. KREIDER, E. DE SAINT-EXUPERY, L. ASBOTH, Q. BARRAUD, G. COURTINE;
EPFL SV BMI UPCOURTINE, EPFL, Lausanne, Switzerland

Abstracts: Traumatic spinal cord injury usually preserves bridges of intact neural tissues. Spontaneous reorganization of spared circuits and residual connections mediate improvement of function after partial lesions, which is enhanced with rehabilitative training. These results stress the importance of developing interventions that take full advantage of activity-dependent plasticity to repair the injured central nervous system. Here, we hypothesized that concomitant neuromodulation of motor cortex and spinal circuits during robot-assisted gait training would promote ubiquitous remodeling of preserved neural systems, leading to superior recovery after a partial lesion. Mice received a severe thoracic spinal cord contusion that spared less than 20% of descending fibers. During robot-assisted gait training, the mice received electrochemical neuromodulation of spinal circuits to enable locomotor permissive states, and optogenetic neuromodulation in the leg area of the motor cortex to force the brain to regain control of locomotion. After a few weeks of training, all the mice showed coordinated, weight bearing locomotion overground during concomitant neuromodulation of motor cortex and spinal circuits. Some of them were even capable of initiating and sustaining locomotion without any stimulation. In absence of training, only a few mice were able to sustain locomotion with neuromodulation therapies, and all of them failed to initiate walking voluntarily. These preliminary results highlight the remarkable potential of neuromodulation therapies across the nervous system to take advantage of residual connections and spared circuits to regain locomotor capacities after spinal cord injury.

Title: Optogenetic activation of the motor cortex unmasks supraspinal access to locomotor circuits caudal to a severe spinal cord injury in mice

Authors: ***L. ASBOTH**, Q. BARRAUD, J. KREIDER, J. VON ZITZEWITZ, G. COURTINE; EPFL SV BMI UPCOURTINE, Swiss Federal Inst. of Technol., Lausanne, Switzerland

Abstracts: We previously demonstrated that robot-assisted training enabled by electrochemical neuromodulation of spinal circuits restored supraspinal control of locomotion in rats with a spinal cord injury (SCI) leading to permanent paralysis. Training encouraged the motor cortex to elaborate alternative relay pathways that restored graded access to electrochemically-enabled lumbosacral circuits. However, the mechanisms underlying the cortical control of leg movements remain unknown, if not controversial. To address this question, we performed experiments in mice expressing channelrhodopsin in motor cortex neurons. An optic fiber was chronically implanted into the region of the motor cortex that induced rhythmic leg movements in healthy mice. After baseline evaluations, mice received a contusion SCI that completely interrupted the corticospinal tract, and led to severe impairments of both legs. Locomotor capacities were evaluated using a high-fidelity robotic interface that provided bodyweight support against gravity, but did not facilitate walking in the forward direction. Photoactivation of the motor cortex during chemical neuromodulation of spinal circuits instantly triggered continuous, weight-bearing locomotion in mice that failed to initiate walking voluntarily. The degree of limb extension and overall locomotor output directly correlated with the intensity of photoactivation. These findings suggest that chemical neuromodulation of the spinal cord raises excitability of lumbosacral circuits to a level that allows the motor cortex to control and modulate leg movements following a severe spinal cord injury that abolishes direct corticospinal inputs and only spares 20% of original descending pathways. These preliminary results establish the settings to dissect and enhance the contribution of descending pathways to recovery after SCI.

Title: Closed-loop control of multisite spinal cord stimulation to improve locomotion following spinal cord injury

Authors: ***J. GANDAR**, N. WENGER, E. M. MORAUD, P. MUSIENKO, S. MICERA, G. COURTINE;
EPFL, Lausanne, Switzerland

Abstracts: Epidural electrical stimulation of lumbosacral segments improved motor control after spinal cord injury in animal models and human patients. In these studies, electrical neuromodulation of spinal circuits has been delivered continuously based on empirical observations, which is suboptimal to facilitate walking with this intervention. Multi-electrode arrays provide the intriguing possibility to access specific subsets of sensorimotor circuits at specific time of the gait cycle in order to maximize facilitation of gait with neuromodulation therapies. However, the development of effective multisite stimulation algorithms rely on advanced control infrastructures that interface rapid movement feedback with instantaneous tuning of stimulation parameters. To support these developments, we established a real-time stimulation platform that allows triggering site-dependent stimulation at any specific time of the gait cycle. To define triggering-times over the entire cycle duration, we developed robust algorithms that derived gait timing from the virtual angle of the foot trajectory around its center of rotation. We exploited this platform to uncover the effects of site- and time-dependent stimulation on the production of gait in rats with complete spinal cord injury. We found that the timing of stimulation onset and end mediated adjustments of locomotor kinematics that depended on the location of the electrode. We leveraged this mapping to conceive a closed-loop control algorithm that triggered stimulation at distinct locations and specific times with the aim to improve locomotor performance. Compared to continuous stimulation paradigms, closed-loop control of multisite stimulations significantly ameliorated gait execution in all the tested rats. The

control platform and developed stimulation protocols provide tools and concepts for the personalization of neuromodulation therapies during rehabilitation in human patients.

Title: Electrochemical stimulation of the spinal cord using a soft intrathecal interface

Authors: ***I. MINEV**, P. MUSIENKO, A. HIRSCH, Q. BARRAUD, J. GANDAR, N. VACHICOURAS, N. WENGER, N. PAVLOVA, E. MARTIN-MORAUD, S. DUIS, G. COURTINE, S. LACOUR;
Ctr. for Neuroprosthetics, École Polytechnique Fédérale De Lausanne (EPFL), Lausanne, Switzerland

Abstracts: Electrical and chemical neuromodulation of spinal circuits restored advanced motor control capacities in animal models and human patients with spinal cord injury (SCI). These developments have created an urgent need for an implantable neural interface capable of delivering electrical and chemical stimulation over multiple spinal cord locations for extended periods of time. For this purpose, we designed a biologically transparent neural interface that resides in the intrathecal space, in direct contact with the dorsal surface of the spinal cord. The use of soft, mechanically compliant engineering materials that match the mechanical properties of the dura mater enabled chronic implantation without detrimental damage to spinal tissue. Contrary to conventional epidural electrode arrays, this novel interface allows electrical stimulation currents to bypass the dura mater, which increased stimulation specificity for lower current amplitudes. Direct access to the cerebrospinal fluid enables local, micro-delivery of chemical agents through a microfluidic system integrated within the interface. Iterative

optimization of technological and surgical approaches allowed us to develop a highly stable, biologically transparent neural interface that restored full weight-bearing locomotion in paralyzed rats with a complete spinal cord injury.

Title: Noradrenergic neuromodulation of spinal circuits facilitates locomotion following spinal cord injury

Authors: *Q. BARRAUD, P. MUSIENKO, K. A. BARTHOLDI, G. COURTINE;
EPFL - Ctr. For Neuroprosthetics, Lausanne, Switzerland

Abstracts: A large number of studies have investigated the ability of monoaminergic neural pathways to engage spinal locomotor networks after the interruption of descending pathways. In particular, alpha2 noradrenergic receptors have historically been amongst the first identified pathways capable of inducing robust locomotion in paralyzed cats with complete spinal cord injury (SCI). These results encouraged the development of noradrenergic neuromodulation therapies to facilitate locomotion and rehabilitative training in paraplegic patients. However, application of these pharmacological agents in humans with SCI has yielded conflicting results, with outcomes ranging from modest facilitation of stepping to a complete suppression of motor outputs. Surprisingly, similar effects were found in rats with complete SCI. These discrepancies emphasize the need to conduct in-depth studies to decipher the specific function of alpha2 noradrenergic receptors subtypes in the production of locomotion after SCI, and to dissect the circuits underlying these effects. To address this question, we performed a comprehensive series of pharmacological experiments in mice, rats, and cats with complete SCI. We combined functional analyses with advanced anatomical evaluations to deconstruct the neuronal circuits underlying the effects of noradrenergic pathway activation. These experiments allowed us to

identify novel targets to facilitate standing and walking with noradrenergic neuromodulation therapies in in humans with SCI.

Abstracts: The quality of locomotor movements and amount of weight bearing play a central role in the outcome of gait rehabilitation after spinal cord injury (SCI). These results triggered the development of various exoskeletons that aim to reinforce kinematic consistency and increase loading during training. However, most of these support systems disregard the importance of trunk posture, which is often completely blocked or at least strongly impeded. To demonstrate the importance of trunk posture and dynamic trunk movement during gait execution, we designed and fabricated a robotic trunk neuroprosthesis that automatically optimizes dynamic trunk posture during locomotion in rats. The system employs a servo-controlled back-plate to which the rat is attached with a custom made jacket. Rotation of the back-plate around an adjustable center of rotation allows online control of trunk posture. Due to careful choice of components and materials, the robot exhibits dimensions and weight comparable to traditional adapters used for bodyweight support on a treadmill. To adjust trunk posture dynamically during locomotion, we developed a closed-loop interface that tuned the back-plate position based on whole-body kinematic performance. The evaluation of the robot was achieved by testing rats

with complete SCI and severe contusion SCI during locomotion enabled through electrochemical neuromodulation of spinal circuits. In both models of SCI, closed-loop control of dynamic trunk movement increased the level of weight bearing in both legs during stance, and improved the consistency and symmetry of bilateral leg movements. These results stress the importance of incorporating dynamic trunk control into traditional gait rehabilitation for patients suffering from different neuro-motor disorders.

Title: Translational robotic platforms to evaluate, enable, and train locomotion and balance after neuromotor disorders

Authors: *J. VON ZITZEWITZ, L. ASBOTH, G. COURTINE;
EPFL - SV - Upcourtine, Lausanne, Switzerland

Abstracts: We previously introduced a robotic interface providing motor impaired rats with multi-dimensional bodyweight support during over-ground locomotion. This robotic interface immediately enabled motor control after partial spinal cord injury, and restored refined locomotion in combination with training and electrochemical neuromodulation therapies after more severe lesions. We aimed to establish similar conditions for mechanistic studies in mice, and to translate this robotic training into an effective rehabilitation environment for patients. Compared to rats, mice showed a 10-fold reduction in bodyweight, which imposed increasing the precision of force control by a similar factor of magnitude. To achieve this high-level of performance, we developed new solutions based on deformable elastic structures and high-precision 3D force sensors. When attached to the trunk, the robotic interface did not interfere

with quadrupedal locomotor movements of healthy mice, even when progressing along complex paths combining sinuous turns and slopes. The robotic interface was also capable of providing spinal cord injured mice with finely-adjustable support in the vertical and walking directions. We evaluated this enabling mode in mice that had received a severe thoracic spinal cord contusion. In the presence of chemical stimulation, the otherwise paralyzed mice showed coordinated, weight bearing steps with vertical oscillations of the body, resulting in continuous locomotion over-ground. To establish similar conditions in humans, we contributed to the development of a novel cable-based robotic body-weight support system. This low-inertial, cable-based robot creates a large 3D workspace in which versatile force fields can be applied to the user along the vertical, medio-lateral, and antero-posterior directions. This robotic portfolio opens new avenues for translational research in gait rehabilitation across species.

Abstracts: The level of weight-bearing, walking speed, interlimb coordination, and kinematic consistency play essential roles to maximize recovery with rehabilitative training after spinal cord injury (SCI). To optimize these parameters, current strategies rely on manual assistance. Closed-loop electrical neuromodulation of spinal circuits provides an alternative strategy to promote the best possible patterns of leg movements during training. To test this hypothesis, we designed robust algorithms that adjust stimulation parameters in real-time based on movement feedback. The control structure integrates two independent layers operating in parallel. Each control layer tunes stimulation parameters during the appropriate phase of gait in order to maintain left and right foot heights within a desired window. We found that closed-loop electrical neuromodulation of spinal circuits automatically restored interlimb coordination, increased kinematic consistency, and improved balance in rats with complete or severe contusion SCIs . The control policies instantly corrected side-specific gait deficits that otherwise would require skilled manual assistance. Moreover, closed-loop neuromodulation of spinal circuits allowed training under more demanding conditions, including increased weight-bearing levels and faster treadmill belt speeds, while maintaining gait quality regardless of idiosyncratic deficits. Closed-loop neuromodulation of spinal circuits holds promises to augment activity-dependent plasticity and recovery after SCI in human patients.

Abstracts: Electrochemical neuromodulation of spinal circuits restored motor control after spinal cord injury, but the underlying mechanisms remain unclear. Transgenic mice provide the unique opportunity to investigate the neural structures and circuits recruited with this treatment paradigm. However, these experiments rely on the development of multi-electrode array for chronic spinal cord stimulation in freely behaving mice. The small size of the mouse spinal cord and extensive spine motion during movement create a highly challenging environment for neural interfaces. Here, we exploited conductive Polydimethylsiloxane (PDMS) to design stretchable conductive leads that can survive such high mechanical stress during chronic implantation. This all-elastomeric technology provides high compliance to the implant, thus allowing the array to act as a second skin in close contact with the spinal cord. Optimization of surgical techniques ensured long-term stability and bio-compatibility of the implant, which we demonstrated histologically and functionally. Despite the small size of the mouse spinal cord, the multi-electrode array was capable of mediating site-specific facilitation of left and right leg movement. Electrical neuromodulation of spinal circuits induced continuous, weight bearing locomotion in mice with complete spinal cord injury. This novel multi-electrode array provides the opportunity to conduct mechanistic studies in mice in order to guide and optimize the translation of spinal neuromodulation therapies in human patients with spinal cord injury.

Abstracts: Epidural electrical stimulation of lumbosacral segments has restored supraspinal control over refined leg movements in animal models of spinal cord injury, and in paraplegic patients. Real-time adjustment of the timing, location, and parameters of electrical neuromodulation has achieved high fidelity control of leg kinematics during locomotion in rats. Experiments in non-human primates are essential along a roadmap for eventual human implementation. To this aim, we have developed a polyimide-based multi-electrode array that is specifically optimized for epidural implantation over the dorsal aspect of primate lumbosacral segments. Electrode positions, array configuration, and surgical procedures were established based on functional and dissection studies, high-resolution computed tomography (CT) scans, and motor-neuron tracing experiments. The stimulation array was connected to a RestoreSensor® implantable pulse generator (IPG) designed by Medtronic (MN, USA), which is controlled externally in closed-loop via custom software package. The IPG integrates a new firmware enabling real-time control of complex stimulation patterns based on external signals. This innovative technology provided us with the unique opportunity to deliver multisite patterns of electrical spinal cord stimulation that are tuned based on ongoing muscle activity, movement feedback, or neuronal modulations. We integrated this new stimulation interface within an advanced neuromotor analysis platform that enables wireless recording of motor cortex population dynamics, muscle synergies, and whole body kinematics in freely moving, unconstrained and untethered non-human primates. Using this unconventional platform, we mapped adjustment in electrical spinal cord neuromodulation with specific changes in leg kinematics, muscle activity, and neural states of the motor cortex during continuous locomotion in non-human primates. These technological developments establish the settings for the translational design of neuromodulation therapies after spinal cord injury.

Abstracts: Many molecules have been identified that can influence tissue repair, neural plasticity or axon growth by acting on glial cells, neurons, axons or extracellular matrix. Clinical application of these molecules requires neurosurgical intervention and delivery directly into the brain or spinal cord. Injectable biomaterials have the potential to serve as depots and scaffolds for *in vivo* delivery of bioactive molecules and cells. We have been developing di-block copolypeptide hydrogels (DCH) as fully synthetic biomaterials that can safely and easily be injected into specific tissue sites after spinal cord injury (SCI) to deliver molecules in order to study, dissect, and manipulate mechanisms of repair, plasticity and recovery. Using a mouse model, we found DCH are biocompatible after injection into the brain or spinal cord. The hydrogels self-assemble into depots with finely controllable properties that can provide prolonged release of protein growth factors and hydrophobic small molecules. Current work shows that DCH depots can safely and routinely be implanted into the lesion core at 2 days after SCI in mice, and can simultaneously deliver multiple growth factors that (i) stimulate production of growth permissive extracellular matrix and (ii) directly stimulate axon growth through the lesion core. We are now testing DCH depot delivery of bioactive molecules and stem cells in a rat model of crush SCI with the objective of combining this regenerative strategy with neuroprosthetic neurorehabilitation. Abstracts: We previously introduced a robotic interface providing motor impaired rats with multi-dimensional bodyweight support during overground locomotion. This robotic interface immediately improved motor control after partial spinal cord injury and stroke. We aimed to translate this robotic training into an effective rehabilitation environment for patients with neuromotor disorders. For this purpose, we leveraged a new robotic support system, named Free Levitation for Overground Assisted Training (FLOAT). This low-inertial, cable-based robot creates a large 3D workspace in which versatile force fields can be applied to the user along 3 independent directions. The FLOAT provides adjustable bodyweight support without impeding gait movements while the subject progresses overground within a safe environment. To evaluate the transparency of the FLOAT, we conducted kinematic, kinetic and muscle synergy recordings in healthy individuals during the execution of complex locomotor tasks including passing obstacles, steering curves, and climbing staircases. Principal component analysis applied on all the computed gait parameters demonstrated the absence of interferences between the robotic motion and gait movements. In turn, the robot was capable of delivering well-controlled postural perturbations, which allowed evaluation of dynamic balance control during walking. We also assessed whether the FLOAT mediated improvements of locomotor execution in individuals with spinal cord injury and stroke, as previously observed in rodents. Preliminary analyses suggest that optimized levels of robotic bodyweight support significantly improved the production of gait in all the tested patients. These results validate our novel robotic platform to enable gait rehabilitation under natural conditions in individuals with neuromotor disorders.

Title: Reticulospinal neurons play a key role in the recovery of voluntary locomotion in response to neuroprosthetic rehabilitation after a severe spinal cord contusion

Authors: *C. MARTINEZ GONZALEZ, L. FRIEDLI-WITTLER, J. BEAUPARLANT, G. PIDPRUZHNYKOVA, L. BAUD, S. DUIS, G. ULRICH, G. COURTINE;
EPFL, Lausanne, Switzerland

Abstracts: We found that neuroprosthetic rehabilitation combining electrochemical neuromodulation of spinal circuits and robot-assisted training re-established supraspinal control of locomotion after a severe mid-thoracic contusion of the spinal cord. Here, we sought to identify the mechanisms underlying functional recovery. Combination of anterograde and retrograde neuronal tract tracing revealed that the degree of functional recovery correlated with the amount of spared tissue and the extent of corticospinal, reticulospinal, and serotonergic fiber reorganization. To demonstrate the essential role of descending fiber reorganization in the recovery of supraspinal control of locomotion, we performed two sets of complementary experiments. First, we delivered deep brain stimulation in the midbrain locomotor regions to activate reticulospinal fibers that were spared by the lesion. Continuous stimulation of the midbrain locomotor region near-instantly triggered coordinated leg movements. This ability emerged and improved conjointly with voluntary motor control capacities. Second, we exploited a virus-mediated inactivation technique to reversibly silence reticulospinal neurons with spared synaptic projections to lumbar spinal circuits located below the injury. Inactivation of reticulospinal neurons in rats that had regained voluntary locomotion induced a marked decline in gait performance. Our results demonstrate that neuroprosthetic rehabilitation promotes

activity-dependent reorganization of spared reticulospinal fibers and that these synaptic projections significantly contribute to supraspinal control of locomotion during electrochemical neuromodulation of spinal circuits.

Title: Changes in spasticity-related reflexes after two forms of walking retraining in individuals with incomplete spinal cord injury

Authors: *A. KHAN[1,2], S. PATRICK[3], F. ROY[4,2], M. GORASSINI[5,2], J. YANG[6,2];
[2]Ctr. for Neurosci., [3]Fac. of Pharm. & Pharmaceut. Sci., [4]Dept. of Surgery, [5]Biomed. Engin., [6]Physical Therapy, [1]Univ. of Alberta, Edmonton, AB, Canada

Abstracts: Spinal cord injury (SCI) results in reduced mobility and spasticity. Spasticity manifests in various ways, such as repetitive and sustained muscular contractions (clonus and spasms, respectively), and hyperactive withdrawal reflexes (a cutaneomuscular reflex). Exercise has been shown to reduce some manifestations of spasticity and improve walking ability after incomplete SCI. Here, we examine the effects of two forms of training on spasticity and walking ability after incomplete SCI: 1) Endurance training (i.e., treadmill walking) and 2) Precision training (i.e., precise walking over obstacles and on targets overground). Twenty participants

with motor-incomplete SCI were randomized to undergo Endurance or Precision training (1hr/day, 5x/week) for two months, then crossed over to the other form of training (2 mo.) with a two-month rest period in between. A cutaneomuscular reflex (CMR) and clonus were recorded using electromyography (EMG) from the soleus muscle during treadmill walking before and after each form of training. The CMR was induced by surface electrical stimulation of the posterior tibial nerve at the ankle during walking. EMG responses were averaged as a function of time of stimulus arrival during the step cycle. EMG from undisturbed walking was then subtracted to extract the response. Time window of the average inhibitory response was determined on an individual basis, beginning and ending anywhere between ~35 to 200ms after the first stimulus. Clonus was quantified using spectral analysis of the soleus EMG during undisturbed walking. The signal power in the clonus frequency range of 4-10Hz was determined, and normalized to overall power from 0-40Hz. The 10-Meter Walk Test and 6-Minute Walk Test were also used to quantify walking speed and distance, respectively. There was a significant increase in reflex inhibition after Endurance (-2.1 to -4.9μV, p=0.032), but not Precision training (-3.5 to -2.3μV, p=0.39). There was a trend for reduction in clonus after Precision (1.1 to 0.94, p=0.36), but not Endurance training (1.0 to 0.96, p=0.79). There was a significant correlation between: 1) increase in walking speed and reflex inhibition after Endurance training (comfortable speed: p=0.025, r=0.64; fast speed: p=0.084, r=0.61), and 2) increase in walking distance and reduction in clonus after Precision training (p=0.013, r=0.59). Overall, reduction in spasticity after both types of training was related to improvements in walking ability. Changes in CMR hyperexcitability and clonus did not always change in the same way; considerable individual differences were seen. The findings will need confirmation with larger studies or meta analyses.

Title: Studying motor compensation and spinal motoneuron regeneration in mice with genetic absence of the corticospinal tract

Authors: *L. ZHOU, Y. DING, C. CAO;
GHM Inst. of CNS Regeneration, Jinan Univ., Guangzhou, China

Abstracts: The corticospinal tract (CST) makes direct and indirect connections with spinal motoneurons invovled limb movement, particular skilled movement control. We previously generated *Celsr3|Emx1 mice*, in which corticospinal axons fail to course through the internal capsule and to innervate the spinal cord. In the present work, we used those mice to carry out two studies: (1) The compensation of motor components and its mechanisms. Results: Mutant mice had no paresis, but displayed hyperactivity in open-field tests and disabled skilled movement in food pellet-taking tests. Both retrograde and anterograde labeling shows projections from red nuclei to the spinal cord are significantly increased in mutants compared to control animals. In contrast, no difference in labeling of vestibulospinal and reticulospinal projections was noted. Contrary to control mice, mutants developed severe disability of forelimb use following section of the rubrospinal tract (RST) at the C4 spinal level. In the mutant, the number of motoneuronswas reduced and terminal axon arbors at the neuromuscular junction (NMJ) displayed atrophy, which was accompanied with NMJ functional deficits. Conclusion: The RST spontaneously compensate to play a crucial role in spinal motor control following genetic ablation of the CST, but not in skilled movements, and genetic absence of the CST affects locomotion rhythm, the maturation of spinal cord and NMJs. (2) Spinal motoneuron regeneration and functional recovery following root avulsion and reimplantation. Results: In adult mice, we tore off right C5-C7 motor and sensory roots and re-implanted the right C6 roots. Behavioral studies showed impaired recovery of elbow flexion in *Celsr3|Emx1* mice compared to controls. Five months after surgery, a reduced number of small axons, and higher G-ratio of inner to outer diameter of myelin sheaths were observed in mutant versus control mice. At early stages post-surgery, mutant mice displayed lower expression of GAP-43 in spinal cord and of myelin basic protein (MBP) in peripheral nerves than control animals. After five months, mutant animals had atrophy of the right biceps brachii, with less newly formed neuromuscular junctions (NMJs) and reduced peak-to-peak amplitudes in electromyogram (EMG), than controls. However, quite unexpectedly, a higher motoneuron survival rate was found in mutant than in control mice. Conclusion: Following root avulsion/re-implantation, the absence of the CST hampers axonal regeneration and remyelination, as well as target re-innervation and formation of new NMJ, resulting in lower functional recovery, while fostering motoneuron survival.

Title: Treadmill training reduces mechanical allodynia in a mouse model of spinal cord contusion injury

Authors: *T. A. NEES[1,2], M. MOTSCH[1], A. TAPPE-THEODOR[2], R. KUNER[2], N. WEIDNER[1], A. BLESCH[1];
[1]Spinal Cord Injury Ctr. Heidelberg, Heidelberg Univ. Hosp., Heidelberg, Germany; [2]Inst. of Pharmacol., Heidelberg, Germany

Abstracts: Below-level central neuropathic pain (CNP) affects a large proportion of spinal cord injured subjects. Patients suffering from CNP experience sensory disturbances including hyperalgesia, mechanical or thermal allodynia and spontaneous pain. Effective pharmacological means for treating this type of pain are limited. Despite the clinical relevance of spinal cord injury (SCI)-induced CNP, animal models have mostly been studied in the context of regenerative plasticity and recovery of motor function, and not in the context of pain plasticity. To better define the dynamic changes in the spinal cord contributing to the development of central neuropathic pain after SCI, we characterized the behavioral correlates of CNP in female C57BL/6 mice following a moderate T11 spinal cord contusion injury (50 kDyn) between 10 and 35 days post-injury. We further examined the influence of moderate physical activity on pain behavior and associated morphological changes. Spinal cord injured mice developed significant mechanical allodynia two weeks after injury when tested with small-diameter von Frey hair filaments ($p < 0.001$ for 0.16g and $p < 0.01$ for 0.4g filaments) but presented significant hypo-responsiveness to normally noxious stimuli ($p < 0.001$ for 1.4g filament). The mechano-sensory alterations lasted until the end of the experiment, 35 days post-lesion. Compared to sham operated animals, the response latency to heat stimuli already decreased significantly ($p < 0.05$) ten days post injury reaching a plateau three weeks after the spinal cord contusion. In contrast, injured mice developed a 1.67 fold increase in the time to respond on a 2°C cold plate demonstrating remarkable hypo-sensitivity to cold stimuli. To examine the influence of physical activity on CNP, animals underwent moderate treadmill training twice a day for 15 minutes, five days per week over a total of 25 training days. The training intensity was adjusted increasing from 0.12 m/s to 0.19 m/s. Treadmill training led to a significant reduction in the response rate to light mechanical stimuli. The positive training effect was already detectable after 6 days of

training (=day 14 post-lesion; $p < 0.05$) and remained evident for the rest of the experiment. In contrast to mechanical allodynia, thermal abnormalities were not influenced by physical activity. Treadmill training had also no influence on white matter sparing or functional recovery measured by BMS scoring. To define potential underlying mechanisms, structural changes in the spinal cord including sprouting of peptidergic and non-peptidergic nociceptive fibres are currently analyzed.

Title: Regaining over-ground locomotor function following severe contusion injury with epidural stimulation and treadmill training

Authors: ***Y. D. AL'JOBOORI**, R. M. ICHIYAMA;
Sch. of Biomed. sciences, Univ. of Leeds, Leeds, United Kingdom

Abstracts: Spinal contusion injuries result in a loss of motor, sensory and autonomic function. Electrical epidural stimulation (ES) of the lumbar spinal cord (L2 to S1) has previously been shown to improve locomotor function in complete transection models of rat spinal cord injury in conjunction with monoaminergic and serotonergic agonists and bipedal locomotor training; however, ES has never been assessed in incomplete contusion lesions where some descending and ascending pathways remain. Here we demonstrate that the use of epidural stimulation (40 Hz; L2) and locomotor training following severe spinal contusion injury (T9/10) leads to improved locomotor function. Adult Sprague-Dawley rats received a severe spinal contusion injury (T9/10) and epidural implantation at segmental levels L2 and S1 and were randomly assigned to one of four groups: cage control, training only, ES only or ES+training. Rats in either trained group stepped bipedally on a body weight supported treadmill (5-16 cm/s) (5 days/week,

20 mins/day) for 8 weeks. By the end of the 8-week period rats in the ES+training group showed improvements not only in supported treadmill stepping ability but also in open field locomotion, which was not previously observed in the complete transection models. Therefore these results suggest that a combination of step training and epidural stimulation in an incomplete model of SCI successfully improved locomotor function further than either therapy administered alone.

Title: Longitudinal assessment of spinal cord injury in monkeys by multi-parametric mri at 9.4t

Authors: F. WANG[1], A. MISHRA[1], Z. ZU[1], H. QI[2], C. TANG[1], J. GORE[1], *L. CHEN[1]; [1]Radiology, [2]Psychology, Vanderbilt Univ., Nashville, TN

Abstracts: This study aims to monitor quantitatively the spontaneous recovery of injured spinal cord (SC) using structural, cellular and molecular biomarkers obtained from serial multi-parametric MR images including MT (Magnetization Transfer), DTI (Diffusion Tensor Imaging) and CEST (Chemical Exchange Saturation Transfer) imaging. High-resolution MR images were acquired using a saddle-shaped surface transmit-receive coil in anesthetized squirrel monkeys at 9.4T. Three monkeys underwent surgery to introduce unilateral dorsal column lesions at C4-C5 level, and exhibited behavioral impairments on a food reaching and retrieval task within the first two-weeks after lesion. MT, DTI and CEST images were collected repeatedly at different time points for up to 24 weeks after the surgery. By comparing measures of ADC (Apparent Diffusion Coefficient), FA (Fractional Anisotropy), MTR (Magnetization Transfer Ratio), and MTRasym from CEST obtained before and after lesions, we observed dynamic changes in spinal cord evident from MT contrast images, in the number of tracked white matter bundles (by DTI tractography), water content and cell density (by ADC), integrity of white matter microstructure (by FA), and levels of macromolecules (e.g. proteins) by MTR and metabolites (e.g. amides,

amines or hydroxyls) by MTRasym of the SC tissue at and surrounding the injury site. We found that as early as two weeks after the lesion, a cyst formed rostral to the lesion site. By eight weeks post-lesion, the lesion cavity shrank while the cyst enlarged, exhibiting high water content and low cell density. The white matter surrounding the lesion and cyst was disrupted, with a reduced number of white matter tract bundles compared to the normal side. Concentrations of specific macromolecules and metabolites within the cyst peaked. By 24 weeks post-lesion, the lesion cavity continued to shrink, as did the cyst, which at this time showed increased cell density, sustained mobile protein levels, and decreased levels of amides, amines or hydroxyls. The number of tractable white matter bundles increased, indicating a recovery. Subsequent post-mortem histological evolution of the spinal cord tissue with GFAP and HE staining confirmed the nature of the cysts. In conclusion, our data demonstrate the power of multi-parametric MRI for the longitudinal and comprehensive assessment of the spontaneous recovery from SC injury, and highlight the potential of *in vivo* MRI for the evaluation of outcomes of therapeutic interventions in preclinical animal models.

Title: Spinal cord motor tract integrity, muscle architectural alterations, and volitional motor control following motor incomplete spinal cord injury

Authors: ***A. C. SMITH**[1], T. B. PARRISH[1], M. WASIELEWSKI[1], H. E. KIM[2], T. G. HORNBY[2], J. M. ELLIOTT[1];
[1]Northwestern Univ., Chicago, IL; [2]Rehabil. Inst. of Chicago, Chicago, IL

Abstracts: Background: In humans following motor incomplete spinal cord injury (iSCI), prognosis for motor recovery is a challenging yet important issue (Burns et al, 2012). Magnetic resonance imaging (MRI) is a valuable tool used to augment prediction of motor return after SCI,

but there exists a variety of pulse sequences reported to use for this purpose, each with differing levels of efficacy. A majority of studies utilized conventional sagittal T1 and T2 weighted imaging, with the American Spinal Cord Injury Association (ASIA) motor impairment scale as the motor outcome measure of choice, and report a range of correlation strengths (R values = 0.53-0.83) (Boldin et al, 2006, Lundell et al, 2011, Miyanji et al, 2007). Moving beyond standard clinical imaging, 1 study used both diffusion weighted and magnetization transfer MRI techniques to characterize white matter tract integrity in SCI, and found correlation with the ASIA motor scale (Cohen-Adad et al, 2011). The purpose of this ongoing study is to quantify and establish relationships between tract integrity, muscle alterations, and volitional motor control following human SCI. Methods: 1 subject with C5-7 iSCI completed the study so far (28 year old male, 2.5 years s/p injury). White matter integrity was quantified using a MRI magnetization transfer application (Cohen-Adad et al, 2011). Fat infiltration in the neck and lower extremity muscles was assessed using a MRI chemical shift application (Smith et al, 2014, Elliott et al, 2013). Volitional control was quantified using a central activation ratio (CAR) (Hornby et al, 2009), a value obtained by comparing maximum voluntary isometric plantarflexion torque production with a superimposed peak electrically elicited torque. Values were compared to previously collected control data. Results: The magnetization transfer ratio (MTR) was 40% of control value (38) at the level of the spinal lesion, indicating a disruption of myelin along the axonal projections of the cord. There was 63% greater fat infiltration in multifidus muscles (control = 19%), and 166% greater value in plantarflexor muscles (control = 6%), compared to controls. The central activation ratio was 25% of control (0.96), demonstrating decreased voluntary motor recruitment. Conclusions: Preliminary results from 1 subject with iSCI show feasibility for the quantification of integrity, muscle alterations, and volitional control in this population. As expected, MTR and CAR values were less than controls and corresponded to greater fat infiltration values in musculature. Next steps will be to collect data from additional subjects and establish relationships between these variables.

Title: Acute exercise after spinal cord injury modulates the regenerative profile of axotomized neurons

Authors: *R. SACHDEVA[1], A. KALINSKI[2], S. SAVANT[1], J. TWISS[2], J. HOULE[1]; [1]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Dept. of Biol. Sci., Univ. of South Carolina, Columbia, SC

Abstracts: Peripheral nerve grafts (PNGs) support significant regeneration of central nervous system (CNS) axons after spinal cord injury (SCI) in rats, yet many more injured axons fail to regrow. CNS regeneration can be enhanced by a combination of treatment strategies, such as neural tissue transplantation, matrix modulation and use of exogenous neurotrophic factors. Work from our lab and others has utilized post-SCI exercise (Ex) to promote neuronal survival and regeneration after CNS trauma but the mechanism by which sensorimotor stimulation mediates this effect is poorly understood. We examined whether passive cycling exercise is associated with modulating the mRNA levels of growth associated molecules in CNS neurons post SCI. In addition to examining the overall changes in gene expression in neuronal soma, axonal compartments were analyzed for the presence of regeneration-associated mRNA transcripts and markers of protein synthetic machinery. All rats received a lower thoracic (T12) transection (Tx) and some received peripheral nerve grafts (PNG) to support the regeneration of ascending sensory axons. Retrograde tracing using True Blue (TB) was used to identify injured and regenerating neurons, in Tx only and Tx-Ex rats, respectively. Rats received exercise using motorized bikes for one or three weeks, starting five days after injury. Control rats were not exercised. Using fluorescent *in situ* hybridization (FISH) to identify mRNAs of growth-associated protein 43 (GAP43), β-actin and Neuritin/CPG15 in TB positive neurons, we show that acute exercise upregulates growth associated genes in axotomized neurons in spinal cord. Analysis of mRNA expression in neurons that are regenerating their axon is continuing. Confocal analysis of regenerating axons in PNGs using FISH/Immunofluorescence was utilized to examine axonal localization of these mRNAs and key molecules involved in protein synthesis [4EBP1, phosphorylated-4EBP1, phosphorylated ribosomal protein S6]. We show that in non-exercised animals CNS axons localize growth associated mRNAs and protein synthetic machinery as they regenerate within PNGs, suggesting the possibility of intra-axonal protein synthesis. Whether exercise is associated with alteration of axonal mRNA trafficking is currently under investigation. Our results show that acute exercise after spinal cord injury is associated with upregulation of growth promoting genes in injured neurons. Ongoing studies using combined analysis of axonal and somal compartments of injured and regenerating neurons will provide a better insight on the effect of exercise in modulating the overall regenerative profile of injured CNS neurons.

Abstracts: Spinal cord extracellular matrix is densely packed with growth inhibitory chondroitin sulphate proteoglycans (CSPGs), which become more abundant after injury. Thus, matrix modification has become a leading experimental strategy for promoting repair following spinal cord injury. Despite the beneficial effects that have been achieved by digesting CSPGs with the bacterial enzyme chondroitinase ABC (ChABC), the potential for achieving long term efficacy in traumatic injuries that mimic a human spinal cord injury has been limited, due to suboptimal delivery methods and issues of enzyme instability. However, we have recently demonstrated that gene therapy, using a mammalian compatible ChABC gene, offers a route to achieving stable and continuous delivery of ChABC, resulting in a dramatic reduction in pathology and significant improvements in functional recovery when used to treat a clinically relevant spinal contusion injury model in adult rats. Following on from these findings we now demonstrate the efficacy of chondroitinase gene therapy in contusion injury models at differing spinal levels (cervical and thoracic). When used to treat a contusion injury at either C5 or T10 spinal level, ChABC gene therapy resulted in increased spinal conduction through the injury epicenter, improved functional performance in skilled locomotion, significant neuroprotection and enhanced plasticity of intact spinal circuitry. Further to this, we present findings from recent experiments in which we have assessed the efficacy of different viral vectors (both adeno-

associated viral vectors and lentiviral vectors) containing the modified ChABC gene in order to determine the optimal vector structure to be used for ChABC gene therapy. We find that the use of different promoters results in differing patterns of ChABC expression, due to which cell types are transduced. Furthermore, this change in expression pattern affects the efficacy of ChABC gene therapy. The use of a PGK promoter primarily leads to transduction of neuronal cells, resulting in widespread CSPG degradation throughout the spinal cord and the most dramatic improvements in functional and anatomical outcome measures. Thus, we demonstrate the therapeutic potential of ChABC gene therapy to treat clinically relevant injury models at different spinal levels and present findings on optimizing the delivery mechanism for chondroitinase gene therapy.

Title: Investigating functional plasticity and synaptogenesis following experimental spinal cord injury and chondroitinase gene therapy

Authors: ***E. R. BURNSIDE**[1], K. D. BOSCH[1], F. GRILLO[1], S. B. MCMAHON[1], J. S. CARP[2], J. BURRONE[1], E. J. BRADBURY[1];

Abstracts: The CNS has a poor intrinsic capacity for regeneration, although some functional recovery does occur. This is mainly in the form of sprouting, dendritic remodelling and changes in neuronal coding, firing and synaptic properties; elements collectively known as plasticity. Following spinal cord injury (SCI), an important approach to repair the injured CNS is therefore to harness, promote and refine plasticity. This is partly limited by some components of the extracellular matrix, key inhibitory molecules of which may be manipulated by therapeutic delivery of chondroitinase ABC. The corticospinal tract (CST) is an important descending motor

pathway involved in locomotion, posture and voluntary skilled movements. Therefore regeneration and anatomical reorganisation of this projection is often examined in studies of experimental SCI. Techniques such as anterograde tracing have been combined with immunolabeling for synaptic proteins or electron microscopy to elucidate connectivity; however whether active synaptogenesis occurs following SCI and potential therapeutic manipulations has not been studied. Genetically encoded reporters of presynaptic vesicular release represent novel tools to assess synaptogenesis and gain insight into the anatomical and functional status of new connections. Here we use an adeno-associated viral (AAV) vector encoding SynaptopHluorin (SpH), as a tool to measure functional synaptogenesis resulting from therapies which promote plasticity following experimental SCI. We utilise an ex-vivo acute cervical spinal slice preparation from adult rats in which we electrophysiologically stimulate the CST and real-time image fluorescence indicative of vesicular release. We are currently performing this ex-vivo preparation on rats which have undergone a unilateral pyramidotomy lesion and in which the intact contralateral CST is transduced by AAV-SpH in order to investigate the functional synaptogenesis resulting from plasticity of a known, spared population of fibres following injury. Furthermore we are investigating how this changes following therapeutic delivery of chondroitinase via gene therapy.

Title: Electro-magnetic stimulation over T2 spinal level combined with transgene delivery of neurotrophin NT-3 and exercise training improved synaptic transmission and locomotor function after contusion spinal cord injury in rats

Authors: *H. A. PETROSYAN[1,3], V. ALESSI[1,3], S. A. SISTO[2], V. L. ARVANIAN[1,3]; [1]Neurobio. and Behavior, [2]Physical Therapy, Stony Brook Univ., Stony Brook, NY; [3]Northport Veterans Affairs Med. Ctr., Northport, NY

Abstracts: Locomotor training is widely used to facilitate recovery after spinal cord injury (SCI). Overall, the best results of training have been seen in young animals and children. This has been attributed to the higher level of plasticity in the spinal cord of young mammals. Our previous studies revealed that repetitive spinal electromagnetic stimulation over intact T2 vertebrae (sEMS) induces an LTP-like facilitation of synaptic responses in damaged spinal cord, thus promoting synaptic plasticity in spinal circuitry following chronic lateral hemisection SCI. In the current study we examined whether sEMS alone or combined with transgene delivery of neurotrophin NT-3 (AAV-NT3) will reinforce beneficial effects of exercise following contusion SCI. Adult rats received T10 150 kdyn contusion and were divided into five groups. 1) Control (SCI, no treatment), 2) sEMS only (over T2; 0.2Hz, 30min, 2.8Tesla), 3) Exercise (training in exercise ball and swimming) only, 4) Exercise plus sEMS, 5) Exercise combined with sEMS and AAV-NT3. Behavioral testing, multiple electrophysiological recordings (i.e. intracellular and extracellular from lumbar spinal cord and MEP from hindlimb muscles), immunocytochemistry analysis, and anatomical tracing were performed to assess the effects of treatments. We found that a single train of sEMS (30 min duration) induced transient facilitation of transmission in neuro-muscular circuitry in chronically contused rats. Facilitation sustained for at least 2 hours and amplitude of synaptic responses returned to the initial low levels after termination of stimulation. These physiological changes were associated with the increased immunoreactivity of GluR1 and GluR2/3 glutamate receptors in lumbar neurons. In contrast to a transient facilitation of synaptic responses evoked by a single train of sEMS, administration of sEMS every other day for 5 weeks, followed by exercise training, induced sustained and cumulative strengthening of transmission. These physiological improvements were associated with (i) improved anatomical plasticity (fluoro-ruby retrograde tracing) and (ii) improved locomotor function (BBB, challenging behavioral tests and CatWalk analysis). Chronic administration of sEMS alone or exercise training alone, however, did not induce significant changes of transmission or locomotor function. Importantly, improvements lasted for at least 4 weeks after chronic treatments were stopped. The best improvements were seen in the group that received exercise training in combination with sEMS and transgene delivery of NT-3 (AAV10-NT3). The potential of translating these results to clinical applications is discussed.

Abstracts: The need for increased integration between imaging and physiological data has become increasingly important in experimental evaluation with advancing technological approaches in recent years. Many experimental protocols would benefit from rapid feedback on the quality and substance of data acquired at the physiological setup during, or immediately after, data acquisition. This is especially true in applications using optogenetic approaches to study activity within a population of neurons, when it is important to quickly know how light stimulation is affecting the system. To improve beyond the current state of conventional approaches, we have extended the open source program, ImageJ, to provide functionality that allows easier integration of imaging/electrophysiological data in tandem with the image-acquisition plug-in Micro-Manager. This offers a substantial improvement beyond the previous patchwork approach to analyses and interpretation using multiple tools, which is time-consuming and laborious, and often requires substantial time off-line to evaluate the quality of data. Furthermore, the software aids post-hoc high-throughput analysis of physiological data. The latter heretofore being a major challenge for the neurophysiological discipline despite being greatly advanced in other areas of neuroscience. We have utilized this software to begin investigating the intercellular interactions of embryonic respiratory circuits using holographic laser stimulation patterns on reduced subsets of a population of neurons.

Title: Spinal excitatory circuits as hub for the descending control of hindlimb motor activity

Authors: *A. E. TALPALAR, O. KIEHN;
Dept. Neuroscience, Karolinska Institutet, Stockholm, Sweden

Abstracts: Locomotion is normally initiated by descending commands originating in the brainstem. In various vertebrate species, excitatory interneurons in the spinal cord are necessary for generating the locomotor-rhythm. It remains unknown, however, if excitatory descending commands are acting directly through spinal excitatory circuits for generating motor tasks, or if the excitatory descending systems are able to induce movements without the contribution of excitatory spinal neurons. We experimentally tested these ideas using the *in vitro* lumbar spinal cord of Vglut2-KO mice are that devoid of excitatory neurotransmission. Locomotor-like activity (LLA) - mediated by reciprocally connected inhibitory Ia-interneurons (Ia-IN) - can be evoked in spinal cords from these mice by neuroactive drugs (Talpalar et al. Neuron 2011). When Vglut2 is selectively eliminated from the spinal cord by crossing Hoxb8::Cre with Vglut2lox/lox mice, resulting crosses breath and elicit spontaneous motor activities in the forelimbs but not in the hindlimbs (n=11). Electrophysiological studies showed that the isolated lumbar spinal cord from Hoxb8::Cre; Vglut2-KO mice exposed to neuroactive drugs was able to elicit LLA with similar characteristics as the full Vglut2-KO mice (n=5). DC recordings from the ventral roots showed that motor neurons received descending excitatory inputs that were able to generate action potentials (n=5). However, stimulation of descending pathways (and afferents) with protocols that elicit LLA in wild type mice were inefficient to evoke LLA in Hoxb8::cre; Vglut2-KO mice (n=5). Stimulation of putative vestibulospinal tract in Hoxb8::cre; Vglut2-KO was able to activate motor neurons directly, to depress Ia-IN - mediated synaptic potentials in motor neurons, and to inhibit the ongoing rhythmic activity elicited by drugs in the lumbar spinal cord. These results indicate that Hoxb8::cre; Vglut2-KO mice display normal glutamatergic descending brainstem systems and that in normal animals descending excitatory commands evoke locomotion through activation of excitatory spinal neurons. Our study also shows that spinal intrinsic inhibitory pattern-generating networks can be directly inhibited by descending excitatory commands thereby short-circuiting the on-going rhythmic activity. Title: The role of proprioception in stability control during aquatic station-holding

Authors: *M. E. HALE, R. WILLIAMS, IV;
Univ. Chicago, CHICAGO, IL

Abstracts: The limbs of vertebrates play central roles in postural stability. Fine-tuned movements adjust to subtle changes to the external or internal environment of the body. Proprioceptive feedback from the limbs is fundamental to an organism's sense of body position relative to its environment. Here we address the role of limb-based proprioceptive feedback for body stabilization in the aquatic environment. Our work focuses on the bluegill sunfish (Lepomis macrochirus), a model system for understanding the biomechanics of swimming and for bio-inspired design of engineered swimming devices. The bluegill beats its pectoral fins rhythmically, and in coordination with pelvic and median fin movement to maintain a stationary position while hovering. We have previously shown that pectoral fins are proprioceptive as well as propulsive structures. To determine how pectoral fin proprioceptive feedback is used in bluegill fin-based hovering, we performed a series of behavioral experiments in which we transected the sensory nerves innervating the pectoral fins and examined the effect on the hovering behavior of the bluegill. We hypothesized that the rhythmic movement of the pectoral fin would be maintained despite the absence of proprioceptive feedback, as these movements are believed to be driven by a central pattern generator (CPG). Two control groups were included in the experiments, a non-operated condition and sham-operated condition in which the full surgery was performed except for nerve transection. Full transection experimental conditions involved a transection of all sensory nerves innervating the fin rays either unilaterally or bilaterally. We found that transections of all the pectoral fin sensory nerves innervating a fin caused a decrease in overall fin displacement over the course of a fin beat cycle during hovering. Bilateral transections of pectoral fin sensory nerves resulted in a general increase in fin beat frequency. Our data also show that the amplitude of median fin movement increases as a consequence of

pectoral fin sensory nerve transection. Results of this study show that the complete absence of proprioceptive feedback alters movement patterns but does not abolish rhythmic movement altogether. These findings indicate a contribution of proprioceptive feedback to the rhythmic pectoral fin behaviors involved in maintaining a stable hovering position.

Title: The stability of the locomotor rhythm in the lamprey central pattern generator

Authors: N. MASSARELLI[1], A. YAU[2], K. A. HOFFMAN[1], T. KIEMEL[3], *E. D. TYTELL[2]; [1]Dept. Math. Stat., Univ. Maryland, Baltimore County, Baltimore, MD; [2]Dept. of Biol., Tufts Univ., Medford, MA; [3]Dept. Kinesiology, Univ. Maryland, Col. Park, College Park, MD

Abstracts: The central pattern generator (CPG) circuit is a conserved neural circuit, present in the spinal cord of all vertebrates, that can generate the basic muscle activation pattern for locomotion and can respond to proprioceptive sensory information. For example, regular rhythmic stimuli are well known to entrain the CPG rhythm, causing the circuit to burst at the same frequency as the stimulus. Pulsatile stimuli can also advance or delay the cycle. It is not well understood, however, how the CPG might respond to more natural stimuli and perturbations, which contain both a sinusoidal component and an irregular perturbation. Moreover, the CPG functions as part of a feedback loop: a change in sensory input might cause it to change its output, but the change output affects muscle activity, which may change the sensory inputs. We have developed a new theoretical framework based on harmonic transfer functions (HTFs) for understanding how the CPG responds perturbations as a function of the

phase of the cycle, and what effect those responses might have as part of a feedback loop. We conducted experiments on the lamprey spinal cord. The cord was bent back-and-forth to entrain the CPG's rhythm, and then a Gaussian band-limited white-noise perturbation was added to the sensory stimulus. We computed the HTF, which describes how a sensory perturbation at given frequency produces a change in the CPG's output at multiple frequencies. The HTF characterizes the open-loop response of the CPG to bending and allows us to predict stability and the effect of perturbations on the closed-loop system. We also developed mathematical models of the CPG circuit, including phase models, other simple oscillator models, and more complex neural circuit models. By using the same stimuli in the mathematical models, we can examine which features of the CPG circuit are necessary for the results we observe.

Title: Masticatory and brux-like motor patterns in the freely behaving rat:Electromyography and phase analysis

Authors: *D. B. WELCH[1], J. TAYLOR[2], J. WALL[2], P. WANDA[2];
[1]Growth, Development, and Structure, Southern Illinois Univ. Edwardsville - Sch. of Dent. Med., Alton, IL; [2]Biol., Southern Illinois Univ. Edwardsville, Edwardsville, IL

Abstracts: In humans, bruxism has been classically defined as an involuntary rhythmic or spasmodic non-functional gnashing and grinding of the teeth. Unfortunately, the multifactorial etiology of bruxism prevents a full understanding of its control. Clinical cases suggest that normal suppression of brux-like movements might become deregulated during certain pathological conditions, anxiety/stress, and/or by commonly prescribed medications. However, anxiety/stress-induced brux-like behavior seems to be functionally important in rats, as they have to wear down their continuously growing incisors. The central pattern generating (CPG) circuits in the brain stem producing rhythmic brux-like movements might be shared with those that

produce normal masticatory movements. Fine-wire electromyographic (EMG) recordings from the temporalis, masseter, and digastric muscles of freely behaving laboratory rats (Rattus norvegicus), were collected during masticatory and brux-like behaviors in order to characterize the task-related motor patterns (n=21). We found a significant difference in the cycle periods of each of the respective muscles between rhythmic brux-like and masticatory episodes ($p<0.05$, Student's t-tests). Referent phase analysis was used to measure the level of coordination between the same subset of jaw opening and closing muscles. Overall, the mean phase relationships are significantly different between masticatory and brux-like motor patterns ($p<0.001$, Watson Williams F-Test). Our results suggest that this experimental platform can be used to examine the brainstem commands, and trigeminal neural networks that underlie the activation and switching of masticatory and brux-like motor patterns of the jaw.

Title: Genetics, connectivity and function of brainstem inputs to spinal lumbar interneurons

Authors: *J. BOUVIER, C. BELLARDITA, A. MUNOZ-MANCHADO, Y. XUAN, K. MELETIS, J. HJERLING-LEFFLER, O. KIEHN;
Karolinska Institutet, Stockholm, Sweden

Abstracts: In mammals, locomotion is a crucial motor behavior that requires a precisely timed and coordinated activation of a large number of muscles in a recurrent manner. The neuronal elements sufficient to produce and pattern the rhythm are contained within neuronal networks of the spinal cord termed a Central Pattern Generators (CPG). The activation of the CPGs relies on supra-spinal structures that send locomotor commands and/or modulating signals to the spinal cord. Little is known about the precise nature of the locomotor descending drives and their

integration within the CPG. Yet, this question is of upmost importance to provide a unified understanding of the locomotor network with promising benefits for neurorehabilitation and repair strategies for motor defects and after spinal cord injury. Here we are addressing the organization of the descending motor command system with a particular focus on reticulospinal neurons, cellular contingents of the reticular formations of the medulla oblongata and the pons that send direct projections to the spinal cord. Using retrograde and mono-transsynaptic restricted labelling approaches from molecularly-identified neuronal populations in the lumbar spinal, we show that both excitatory (Vglut2-expressing) and inhibitory (VGAT-expressing) spinal interneurons receive direct inputs from overlapping medullary and pontine brainstem areas. We further demonstrate that descending neurons located in the ventral medullary reticular formation express the transcription factor Chx10, a signature of V2a neuronal subtype. In contrast, serotoninergic neurons of the raphe nucleus and glutamatergic contingents of the rostral medulla and the caudal pons are non-V2a but express the transcription factor Shox2. Using this segregation of molecular markers within distinct reticulospinal populations, we are investigating their role in locomotor control with targeted optogenetic activations on brainstem-spinal cord preparations *in vitro*. Altogether, these data provide the genetic first identification of brainstem populations standing immediately upstream the spinal cord interneuronal networks that controls hindlimb movements, and paves the way of functional studies aiming at bridging cellular fates to function in coordinating hindlimb mouvements. This work is supported by Söderberg's Foundation and ERC grant to OK.

Abstracts: Oscillatory rhythms in local field potentials (LFPs) are thought to coherently bind cooperating neuronal ensembles to produce behaviours, including locomotion. A variety of frequencies occur at LFPs recorded during locomotion, and have been used as a basis for identification of appropriate targets for deep brain stimulation (DBS) to enhance locomotor recovery in patients with gait disorders. The pedunculopontine nucleus (PPN) has been targeted to improve locomotor activity in Parkinson's disease (PD), for example, and the presence of gamma band activity (20-100 Hz) has been a basis for identification of this part of the presumed mesencephalic locomotor region (MLR). It is also evident that theta band activity (6-12 Hz) in the hippocampus as well as in the locomotor nuclei of the hypothalamus is associated with locomotor activity. There is sparse information available, however, about the LFPs that occur in the MLR during locomotion, the primary targets for DBS to improve locomotion in PD and after spinal cord injury. Here we use electrodes implanted in the MLR of rats to induce locomotion, and then to monitor the oscillatory activity that is associated with spontaneous locomotion. Thresholds for inducing locomotion were determined in awake rats sitting motionless in an open field. LFPs were then recorded from the same electrodes during treadmill locomotion. Here we show that the predominant oscillatory rhythms recorded from the most effective MLR stimulus sites (thresholds: 15-40 μA) are within the theta range of frequencies (n=5). Theta activity was minimal at rest, but it appeared at the onset of locomotion, and the amplitude was correlated with the speed of locomotion. In animals (n=5) with higher thresholds (70-300 μA), the correlations between locomotor speed and theta LFP oscillations were less robust. Changes in the gamma band were rather small and inconsistent. These results support the suggestion that the oscillatory rhythm responsible for the selection of locomotor output through the MLR is within the theta range of frequencies, with other frequencies, including the gamma band, being less important. These results indicate that theta and not gamma oscillations are suitable characteristics for identifying the functional MLR for DBS.

Title: Modulation of monosynaptic reflexes during development of spinal motor systems

Authors: *C. C. SMITH[1], S. CHAKRABARTY[1], J. F. R. PATON[2], R. M. ICHIYAMA[1]; [1]Biomed. Sci., Univ. of Leeds, Leeds, United Kingdom; [2]Univ. of Bristol, 2.School of Physiology & Pharmacology, United Kingdom

Abstracts: In the rat, the maturation of locomotion is relatively rapid, with near mature gait patterns observed by 21 days postnatally (PN 21). At PN14-16 there is an almost instant transition from a slow clumsy gait pattern to a more swift and accurate pattern, suggesting key changes during this period that leads to maturation of motor patterns. The monosynaptic reflex arc (MSR) provides a relatively simple, easily accessible circuit, providing insight into these developmental changes. This pathway, which is the fundamental unit of the central pattern generator (CPG), is established prenatally but there is evidence of postnatal adaptation and refinement. In order to track developmental changes in the MSR arc, the present study used an artificially perfused whole rat preparation to elicit MSRs in rats aged PN7, 10, 14 and 21. Rats were decerebrated under anaesthesia and then perfused with a modified, oxygenated ringer's solution containing 1.25% ficcol with the temperature maintained at 32°C. The tibial nerve was isolated and stimulated using a bipolar hook electrode and both EMG and ENGs were recorded from the gastrocnemius-soleus (Gs) muscle and its nerve branch at each age. Results show that this preparation is viable at all ages and therefore suitable for studying the development spinal networks responsible for movement control. MSRs could be elicited in animals of all ages; however at PN7-10 EMG responses could only be evoked at intensities of 6-8 times greater than threshold for ENG responses. The amplitude of monosynaptic responses was found to increase with age. Additionally, the excitability of the MSR was assessed using homonymous paired pulse stimuli ranging from 1-700ms administered to the tibial nerve. At PN14-21, decreasing inter stimulus intervals (ISIs) produced a depression at shorter intervals (<50ms), a response which is typical of mature animals. Importantly however, depression was still not at the level expected of a mature animal. In comparison, younger animals were relatively resistant to short

interval depression. We show that the decerebrate, artificially perfused whole rat allows the physiologically relevant study of the development of spinal networks throughout the post natal period. The results suggest that PN14 is indeed an important time point for spinal network development as is suggested by behavioral observations at this age. Furthermore, functional maturity observed in the open field at PN21 was not corroborated by mature circuit function in this study, suggesting additional subsequent post natal refinement.

Title: Removal of ankle extensors group Ia and Ib afferent feedback differentially affects walking mechanics and muscle activity in the cat: A computer simulation study

Authors: *S. N. MARKIN[1], A. N. KLISHKO[2], N. A. SHEVTSOVA[1], M. A. LEMAY[3], B. I. PRILUTSKY[2], I. A. RYBAK[1];
[1]Dept. Neurobio. and Anat., Drexel Univ. Col. of Med., PHILADELPHIA, PA; [2]Sch. of Applied Physiology, Ctr. for Human Movement Studies, Georgia Inst. of Technol., Atlanta, GA; [3]Dept. of Bioengineering, Temple Univ., Philadelphia, PA

Abstracts: It is well established that proprioceptive feedback modulates muscle activity during locomotion. However, relative contribution of length-dependent (Ia) and force-dependent (Ib) muscle afferents to control of locomotor activity is difficult to establish experimentally due to similar activation thresholds of these afferents and simultaneous increases in muscle length and force during muscle stretch. The goal of this study was to determine the relative contribution of Ia and Ib afferents of triceps surae to control of locomotion using computer simulations. We used a comprehensive neuromechanical model of cat locomotion (Markin et al. 2012) that included a

model of spinal circuits with the locomotor central pattern generator (CPG; Rybak et al. 2006) controlled by afferent signals from 18 hindlimb muscles modeled in the Hill-type style (Prilutsky et al. 2014). The spinal network incorporated basic circuits involved in the monosynaptic stretch reflex, Ia reciprocal inhibition, recurrent inhibition via Renshaw cells, and disynaptic excitation of extensor muscles via Ia and Ib afferents. Three groups of model parameters were tuned independently: (1) CPG parameters that allowed us to reproduce the effects of deletions and afferent stimulations observed during fictive locomotion in the cat (Rybak et al. 2006); (2) parameters of the musculoskeletal model of the hindlimbs that allowed reproduction of the recorded changes in joint angles, joint torques, and ground reaction forces during cat locomotion (Prilutsky et al. 2014); (3) parameters that defined weights of sensory feedback to the spinal circuits and allowed reproduction of realistic patterns of muscle activity during locomotion The combined neuromechanical model is able to qualitatively reproduce the activity patterns of Ia, Ib and II muscle afferents as well as the activities of paw pad cutaneous afferents described in the literature. To investigate the specific contribution of Ia and Ib afferents of triceps surae to locomotor activity, the gain of each afferent pathway was reduced to zero. Selective removal of Ia feedback did not substantially change the activity patterns of this and other muscles and the model maintained stable locomotion. When the Ib afferent feedback from triceps surae was reduced to zero, the model was unable to produce stable locomotion and failed. Our analysis has shown that Ib afferents from triceps surae are critical for providing stable locomotion due to their specific inputs affecting spinal circuits and locomotor CPG.

Title: Do humans use limb velocity signal to control locomotion?

Authors: *K. GALBREATH[1], E. OLESH[2], S. YAKOVENKO[2];
[1]Exercise Physiol., [2]Ctr. for Neurosci., WVU, Morgantown, WV

Abstracts: Vertebrates have the innate ability to precisely control locomotion to meet ever-changing demands of the environment. The neural pathways controlling locomotion are hierarchical, highly integrated, and well-characterized. The control of locomotion is achieved with feedforward and feedback signals converging on the rhythmogenic spinal networks responsible for regulation of timing and magnitude of muscle activity. We have previously developed accurate models of these control elements (Yakovenko et al. 2004; Prochazka & Yakovenko, 2008); moreover, we have recently proposed that the essential signal driving spinal networks is expressed in the modality of desired velocity (Yakovenko 2011). If the modality of locomotor control signal is indeed velocity then, according to the classical control theory, limb velocity should also be accurately sensed. We tested this consequent hypothesis by probing human ability to detect minute changes in the velocity of each leg. Healthy volunteers with no previous history of neurological conditions or serious musculoskeletal damage to the lower extremities were recruited to walk on a split-belt treadmill with separately controlled belt speeds. Subjects were exposed to randomized asymmetric speeds of left and right legs for approximately 4 steps. A high-pitch cue instructed subjects to report the fastest leg. In addition, we tested velocity discrimination skills in two other conditions when subjects were either supported or loaded by 10% of their body weight. The perception threshold defined as the velocity detected with better than chance probability (above 50%) was 0.02±0.02 m/s or Weber's fraction (dV/V) of 2%, which is equivalent to load detection in muscles. The accurate velocity discrimination ability supports the idea that the velocity signal is represented within the locomotor control pathways.

Title: Reciprocal functional interactions between the respiration/circulation center, the upper spinal cord, and the trigeminal system

Authors: *I. YAZAWA;
Pref Univ. of Hiroshima, Hiroshima, Japan

Abstracts: Decerebrate and arterially perfused *in situ* rat preparations and electrophysiological techniques were used to investigate: (i) whether fictive locomotion in the forelimbs can be autonomously generated by a certain sympathetic tone resulting from an increase in perfusion flow rate. (ii) Whether rhythm coupling of locomotion and respiration/circulation can be produced during locomotion. (iii) What rhythm coupling of respiration and opening movements of the mandible can be produced during locomotion. (iv) The central neural mechanisms of the entrainment of respiratory and locomotor rhythms. The results indicate that: (i) modulated sympathetic tone generates fictive locomotion in the forelimbs. (ii) The activated spinal cord, producing a left/right alternating discharge, affects the respiration/circulation center and the trigeminal system via ascending pathways and increases systemic pressure and respiratory rhythm during locomotion. (iii) Simultaneously, it generates opening movement in the mandible in both the inspiratory and expiratory phases, generated by increasing peripheral and central chemoreceptor discharges. Respiration during locomotion is autonomously performed, not only through nasal breathing but also mouth breathing, so improving ventilation. The modulated sympathetic tone triggers the forelimb pattern generator via descending pathways and generates fictive locomotion in the forelimbs and the locomotor rhythm in the cervical cord, while a left/right alternating activity occurs in the forelimbs, which entrains via ascending pathways both the respiratory rhythm and the rhythm of the opening movements in the mandible. (iv) The central mechanisms of the entrainments of respiratory and locomotor rhythms are spinal feedback mechanisms. Supported by KAKENHI (24500612).

Title: Primary somatosensory cortical area inducing jaw-opening in the rat

Authors: K. UCHINO, K. HIGASHIYAMA, R. TAKEDA, *F. SATO, A. YOSHIDA;
Dept. of Oral Anat. and Neurobio., Grad. Sch. of Dentistry, Osaka Univ., Osaka, Japan

Abstracts: Our previous study has shown that the dorsal part of the juxtatrigeminal region (dorVjuxt) and the dorsal part of the trigeminal oral subnucleus (dorVo) contain premotoneurons to the trigeminal jaw-closing (JC) and jaw-opening (JO) motoneurons, and receive direct

projections from the rostral part of the primary somatosensory cortex (S1). Short-train stimulation of the S1 is known to induce EMG activities or twitches of JO muscles with a JO in the rat. However it is unclear in the rat whether long-train stimulation of the S1 can induce jaw-movements or EMG activities or twitches of JO or JC muscles, and whether the distribution of effective long-train stimulation sites corresponds to that of effective short-train stimulation sites and also corresponds to that of S1 neurons projecting directly to the dorVjuxt or dorVo. Therefore we examined these issues by means of intracortical microstimulation techniques in rats anaesthetized with a combination of ketamine hydrochloride and xylazine hydrochloride. We intracortically stimulated the rostral S1 through a monopolar, glass-insulated Elgiloy electrode with low-frequency long-train stimuli (450 pulses of 0.5 msec duration and 30 Hz, 20 to 80 μA) and high-frequency short-train stimuli (three pulses of 0.1 msec duration and 500 Hz, 30 to 80 μA). Long-train stimulation of the rostroventral part of S1 (rvS1) induced a sustained JO and EMG activities of bilateral anterior digastric muscles (Dig); most effective sites were located in the rostralmost region of the rvS1. Short-train stimulation of the rvS1 induced EMG activities of the bilateral Dig and a twitch-like JO; the most effective sites were located in the rostralmost region of the rvS1. These effective sites and most effective site were very similar in long-train stimulation cases and in short-train stimulation cases. Importantly, these effective sites were well confined in the S1 which has projections to the dorVjuxt or dorVo, and most of them were in the S1 which has projections to both the dorVjuxt and dorVo. The present findings suggest that not only short-train stimulation but also long-train stimulation of the rvS1 induces a JO by activation of the Dig, and that the activation of the Dig is intimately involved in the direct pathways from the rvS1 to the dorVjuxt or dorVo.

Title: A11 neurons in the mouse project to the spinal cord, are dopaminergic and lack expression of dopamine transporter

Authors: *K. KOBLINGER[1], T. FÜZESI[2], J. E. EJDRYGIEWICZ[2], A. KRAJACIC[2], L. M. YOUNG[2], J. S. BAINS[2], P. J. WHELAN[2];
[2]Hotchkiss Brain Institute, Univ. of Calgary, [1]Univ. of Calgary, Calgary, AB, Canada

Abstracts: The A11 cell group has been suggested to be the primary source of dopaminergic projections to the spinal cord. However, it remains an understudied dopaminergic nucleus within the brain. The A11 region has been identified in several species including rats, mice, cats, monkeys, zebrafish, and humans where it may contribute to the control of pain, spinal locomotor network modulation, restless leg syndrome, and cataplexy. Given the importance of mouse dopaminergic models it is important to fully understand the phenotype of A11 cells. Our goal with this work was to identify and characterize the A11 in the adult mouse and examine whether A11 neurons contain the full complement of enzymes to produce and release dopamine. First we confirmed that A11 cells directly project to the spinal cord using tracing methods. Next we were able to show that neurons within the A11 of the mouse contain tyrosine hydroxylase as well as aromatic L-amino acid decarboxylase (AADC), the enzyme that converts L-DOPA to dopamine. Furthermore, we show that the A11 neurons contain vesicular monoamine transporter 2 (VMAT2), the vesicular transporter necessary for packaging DA into vessels. On the contrary A11 neurons in the mouse lack the dopamine transporter (DAT). In conclusion, our data suggest that A11 neurons in the mouse are dopaminergic and the lack of DAT could lead to prolonged DA actions within the spinal cord.

Title: Sensorimotor adaptation in speech and its effects on auditory monitoring

Authors: *C. A. NIZIOLEK, S. S. NAGARAJAN, J. F. HOUDE;
Univ. of California San Francisco, San Francisco, CA

Abstracts: How does speech motor learning influence speech error monitoring? During speech, talkers monitor their auditory feedback, adjusting their speech output to counteract deviations from what they intend to say. Evidence for this monitoring and adjustment comes primarily from two types of experimental paradigms: the first, often described as sensorimotor adaptation, probes *short-term speech learning* by applying consistent manipulations to auditory feedback, causing a temporarily remapping of articulatory commands that persists after feedback is returned to normal ("adaptation"). The second, described as feedback alteration, probes *rapid error correction* by employing sudden changes to auditory feedback that are sparse and random, such that they cannot be learned. In two complementary experiments, we used real-time auditory feedback alteration to examine how these two mechanisms, adaptation and error correction, interact. In each experiment, subjects produced 800 repetitions of the word "Ed". Their speech signal was recorded and delivered to insert headphones (< 12 ms delay), serving as a primary source of air-conducted auditory feedback. Unbeknownst to the subjects, the first and second formants (F1 and F2) of this feedback were altered, causing the vowel to sound different from what was intended. Experiment 1 employed a feedback alteration design in which a pseudorandom 25% of utterances were altered to sound like "id" and a pseudorandom 25% were altered to sound like "add." Experiment 2 employed a sensorimotor adaptation design in which feedback was gradually and consistently shifted toward "id" over the course of the experiment, inducing a short-term remapping of motor commands in the opposite direction, towards "add"; once this steady state adaptation was reached, a pseudorandom 25% of utterances were altered even further towards "id", while a pseudorandom 25% had the alteration removed. Preliminary evidence suggests that overall compensatory changes in output in Experiment 1 were no different than those in Experiment 2, despite the large differences in magnitude of absolute discrepancy between produced and heard formants. That is, responses to an unexpected vowel shift in the context of normal feedback were no larger than responses to a return to normal feedback in the context of a constant, learned vowel shift. Neural data recording using magnetoencephalography (MEG) is ongoing. These results inform models of sensorimotor adaptation in which the learned remapping of vowel articulatory movements become integrated into the auditory target being monitored under conditions of unexpected feedback alteration.

Title: Redefining the role of Broca's area in speech production

Authors: *A. FLINKER[1], A. KORZENIEWSKA[2], A. SHESTYUK[3], R. T. KNIGHT[3,4], N. E. CRONE[2];
[1]Psychology, New York Univ., New York, NY; [2]Dept. of Neurol., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [3]Helen Wills Neurosci. Inst., [4]Psychology, Univ. of California at Berkeley, Berkeley, CA

Abstracts: The neural organization subserving the production of speech has been debated for over a century. While Broca's area is considered critical for orchestrating articulation, it remains unclear during which stage of speech production it is recruited as well as what type of neural representations it coordinates. We used direct cortical recordings in neurosurgical patients together with novel effective connectivity measures to elucidate the temporal evolution of neural activity in Broca's area and its causal influence on peri-sylvian cortex during speech production. Seven patients with electrode implantations over peri-sylvian language regions, including Broca's area, consented and participated in the study during lulls in clinical management. Subjects participated in a battery of overt articulation tasks including word repetition and word reading. During auditory word repetition, cortical activation exhibited a systematic temporal propagation of high frequency power (high gamma: 70-150 Hz) from auditory cortices to Broca's area and culminating in motor cortices. Critically, by the time of articulation, processing in Broca's area was complete. Using measures based on granger causality we found that Broca's area communicates with temporal cortex during lexical access and then transforms cortical activity into an articulatory plan that is forwarded to motor cortex prior to articulation. Furthermore, production of pronounceable pseudowords significantly increased the load on Broca's area compared with real words controlled for sublexical properties (phonotactic

neighborhood density, transitional probability, positional probability). These unique electrophysiological data provide direct evidence that Broca's area coordinates the transformation of information into an articulatory code across large-scale cortical networks involved in speech production. In this role, Broca's area prepares motor cortex for articulation but is not engaged during the actual act of speaking. Supported by NINDS Grants NS21135, NS40596, and F31NS065656

Title: Investigating the role of the cerebellum in sensory processing during vocal behavior

Authors: ***Z. K. AGNEW**[1,2], J. GILL[2], S. NAGARAJAN[2], R. IVRY[3], J. F. HOUDE[2];
[1]UCL Inst. of Cognitive Neurosci., London, United Kingdom; [2]Otolaryngology, Head and Neck Surgery, UCSF Med. Sch., San Francisco, CA; [3]UC Berkeley, Berkeley, CA

Abstracts: Background: It has been proposed that the cerebellum serves to generate predictions about the sensory consequences of future movements. Complete or over reliance on sensory feedback results in unstable movements. Patients with cerebellar ataxia are known for their deficits in visually guided movement. Tellingly, their movements are known to improve in the absence of visual feedback. Thus it is suggested that patients with damage to the cerebellum are less able to make accurate predictions about the sensory consequences of movements and have to rely on reafferent information which ultimately leads to unstable movements. Whilst the majority of this work has been done in relation to visually guided movements of the upper limbs, speech and voicing are both strongly affected in cerebellar ataxia yet relatively little is known about the nature of vocal behaviour in this patient population. The present study aimed to investigate the nature of auditory feedback processing in patients with cerebellar degeneration by measuring various aspects of vocal behaviour. Methods: Patients were tested on a battery of vocal assessments designed to probe different aspects of vocalisation: we investigated ability to

produce spontaneous voicing, pitch tracking of a moving pitch target and pitch perturbation. Results: We confirmed previous findings that patients with cerebellar damage display increased variability in spontaneous pitch resembling vocal tremor. We then investigated the hypothesis that reducing auditory feedback during vocalisation would improve vocal stability. We report that under auditory masking conditions, variability in vocal pitch is significantly reduced. In order to investigate this idea further, a third experiment was carried out where we investigated how patients responded to perturbations in pitch production whereby auditory feedback is pitch shifted during vocalisation. As predicted, patients with cerebellar damage displayed significantly altered responses to the pitch shift compared to healthy age matched controls indicating an alteration in the way reafferent information is utilised. Conclusions: Together, these three experiments provide compelling evidence in favour of the idea of the cerebellum as a prediction system, the dysfunction of which leads to over reliance on sensory feedback and hence unstable auditorily guided vocal movements. These data will be discussed in relation to the function of the cerebellum in the neural control of vocal behaviour and current models of speech production.

Title: Jaw muscle activity profile during individual chewing cycles in people lacking periodontal mechanoreceptors

Authors: *M. G. TRULSSON, A. GRIGORIADIS;
Karolinska Inst., Huddinge, Sweden

Abstracts: Periodontal mechanoreceptors, located around the roots of the teeth, signal detailed information about the contact state between food and dentition during chewing. An earlier study examining the time-varying activation of the masseter muscle during natural chewing in young adults found that the increase in the excitatory drive of the masseter muscle was biphasic, showing an early component before tooth-food contact and a late component during tooth-food contact. We hypothesize that sensory signals from periodontal mechanoreceptors are required for the formation of the late increase in the excitatory drive of the masseter muscle during tooth-food

contact. Thirteen participants with implant-supported bridges in both jaws, thus lacking periodontal mechanoreceptors, and 13 with natural dentition chewed and swallowed model food of different hardness. Electromyographic (EMG) activity of the masseter muscle was recorded together with the position of the mandible. The muscle activity and the jaw kinematics were analyzed for different phases of the chewing cycles. Throughout the masticatory sequence, the increase in the excitatory drive of the masseter muscle during jaw closing was biphasic for the dentate participants, whereas for the implant participants a biphasic elevation was only observed during the middle and last segments. Dentate participants showed a significantly stronger boosting of the EMG activity during late jaw closing compared to the implant participants, irrespective of food hardness and segment of the masticatory sequence. On the contrary, the elevation of muscle activity early during jaw closing was similar between groups throughout the masticatory sequence. For both groups of participants, the adaptation of mastication to food hardness took place by proportional scaling of EMG amplitude without noticeably affecting the temporal structure of the muscle's activation profile. In conclusion, sensory information from periodontal mechanoreceptors is necessary for boosting the increase of the masseter muscle activity during tooth-food contact. However, this information is not needed for regulation of muscle activity before tooth-food contact. Furthermore, periodontal mechanoreceptors are not required for magnitude scaling of EMG activity to food hardness.

Title: Task dependent control of the jaw during food splitting

Authors: A. S. JOHANSSON[1], *K.-G. WESTBERG[2,3], B. B. EDIN[1];
[1]Integrativ medical biology, [2]Univ. Umea, Umea, Sweden; [3]Physiol., Integrative Med. Biol., Umea, Sweden

Abstracts: Splitting food items between the incisors often requires high bite forces but rarely do the teeth harmfully collide when the jaw quickly closes after food split. The prompt dissipation of the jaw closing force required to prevent harmful collisions has in previous studies been explained by the force-velocity relationship of the jaw closing muscles. If this mechanism was the only one, biting through heterogeneous materials could not be made in a smooth manner which is in contrast to every day experience. We present results from an experiment where we address the underlying control mechanisms in play when biting through such materials. The results suggest that the CNS regulates both bite force and jaw closing force dissipation by taking advantage of the anatomy in the jaw-closing muscles. Finally, we combine our results with previous work and present a model on how the dissipation of jaw closing force may be controlled according to task demands.

Title: Ultrastructural analysis of the vesicular glutamate transporters VGLUT1- and VGLUT2-expressing axon terminals on the rat trigeminal motoneurons

Authors: *Y. BAE, S. PAIK;
Dept. Anat. and Neurobio., Sch. of Dentistry, Kyungpook Natl. Univ., Daegu, Korea, Republic of

Abstracts: Excitatory neurotransmission is critical for the control of trigeminal motoneuron output and production of oral-motor activity. Recent study showed that projection pattern of the two subpopulations of glutamatergic neurons, i.e., vesicular glutamate transporters VGLUT1- and VGLUT2-expressing neurons, are different in each dorsolateral and ventromedial regions of

the trigeminal motor nucleus, suggesting differential glutamatergic regulation between jaw closing (JC) and jaw opening (JO) motoneurons. In the present study, to investigate the glutamatergic control of the JC and JO motoneurons, we analyzed VGLUT1-immunopositive (+) and VGLUT2+ boutons that make synaptic contact with the JC and JO motoneurons by retrograde labeling of JC and JO motoneurons, electron microscopic immunocytochemical staining of VGLUT1 and VGLUT2, and quantitative analysis. VGLUT1+ boutons frequently synapsed with JC motoneurons, while they were rare on the JO motoneurons. Frequency of VGLUT1+ boutons was significantly higher on the dendritic shafts than on the soma or primary dendrites of the JC motoneurons. VGLUT2+ boutons were far more frequently observed than VGLUT1 in the JC and JO motoneurons: Their frequency was not different between in the JC and JO motoneurons, and also among their soma, primary dendrites and dendritic shafts. Bouton volume, mitochondrial volume and active zone area, which are related to synaptic strength, were significantly larger in the VGLUT1+ boutons than VGLUT2+ boutons. These findings suggest that JC and JO motoneurons are differently regulated by VGLUT1- and VGLUT2-expressing glutamatergic neurons, and which may contribute to the production and maintenance of oral-motor activity.

Title: Neuroplasticity of rat orofacial sensorimotor cortex induced by dental manipulations: Are glial cells involved?

Authors: V. VARATHAN[1], M. SOOD[2], H. PUN[1], L. AWAMLEH[1], D. CHOCRON[1], P. BHATT[1], A. THAKORE[1], *B. J. SESSLE[3], L. AVIVI-ARBER[1];
[1]Fac. of Dent., [2]Univ. of Toronto, Toronto, ON, Canada; [3]Univ. Toronto, Toronto, ON, Canada

Abstracts: Rationale and Aims. Previous studies have documented that injury or other manipulations of orofacial tissues can induce neuroplastic changes in the adult rat orofacial sensorimotor cortex (oSMCx). Since glial cells have been shown to be critical for the manifestation of neuroplasticity in other parts of the orofacial sensorimotor system, the aims of this study were to determine (i) if oSMCx neuroplasticity occurs following dental manipulations involving orthodontically-induced tooth movement (OTM), maxillary molar teeth extraction, or acute noxious (mustard oil, MO) dental stimulation, and (ii) if glial cells are involved in any such oSMCx neuroplastic changes. Methods. In male adult Sprague-Dawley naïve rats and in rats receiving one of these manipulations or sham procedure, intracortical microstimulation (ICMS) was used to map oSMCx and test for any OTM or extraction-induced changes in oSMCx jaw (anterior digastric) or tongue (genioglossus) motor representations and to test for any MO-induced changes in oSMCx excitability. We also tested if any such oSMCx excitability changes could be attenuated by oSMCx application of the astroglial inhibitor methionine sulfoximine (MSO; 0.1mM), and if there was immunohistochemical evidence of astroglial (GFAP labelling) or microglial (Iba1 labelling) activation following any of these dental manipulations. Results. Compared with sham or naïve rats, rats receiving OTM or molar teeth extraction showed significant decreases in jaw or tongue motor representations (25-50%; ANOVA, $p<0.05$) that lasted up to 28 days, and acute noxious stimulation of the molar tooth pulp produced a significant decrease in oSMCx excitability (50%; ANOVA, $p<0.05$) that lasted for at least 60 minutes and that could be reversed following oSMCx application of MSO. Furthermore, these oSMCx changes induced by each of the 3 dental manipulations were associated with significant increases in both astroglial and microglial labelling in oSMCx (15-50%; ANOVA, $p<0.05$). Conclusions. These novel findings reveal that several different types of dental manipulations can induce oSMCx neuroplastic changes that may be involved in adaptation of orofacial sensorimotor behaviours in clinically related situations involving the teeth, and that glial cells may be integrally involved in the mechanisms underlying the induction and consolidation of these oSMCx neuroplastic changes.

Title: Glycine-mediated jaw-opening reflex excitability in rats

Authors: *K. ADACHI[1,2,3], S. HINO[4], R. ODAI[5], T. SHIMOYAMA[4], H. SAKAGAMI[1], G. J. LAVIGNE[6], B. J. SESSLE[7];

Sch. of Dent., Sakado, Japan; [6]Faculté de médecine dentaire, Univ. de Montréal, Montréal, QC, Canada; [7]Oral Physiol., Fac. of Dentistry, Univ. of Toronto, Toronto, ON, Canada

Abstracts: Recently we reported that the excitability of the jaw motor system (e.g., tongue stimulation-evoked jaw-opening reflex [JOR] and intracortical microstimulation-evoked rhythmical jaw movements) is depressed during quiet sleep (QS) in monkeys and that, consistent with these data, the electrical stimulation threshold for evoking the JOR in rats is significantly increased in quiet sleep (QS) compared with quiet awake (QW). Further, the systemic administration of glycine (75-150 mg/kg, i.p.) increased the JOR threshold in both QW and QS to a similar extent that was not, however, significantly different from that in QS of glycine non-treated rats. Glycine also reduced sleep latency (68.9-74.8%) and the incidence of micro-arousals (60.6-71.9%) without affecting the distribution of electroencephalographic (EEG) frequency bands (δ, θ, α and β). These results suggest that the central glycinergic system is involved in maintaining JOR excitability and improving sleep quality. In the present study, we investigated the effects of brain microinjection of glycine on JOR excitability and sleep quality in rats. Under general anaesthesia with isoflurane, male Sprague-Dawley rats (6 weeks old) received wire implantations for electrocardiographic (EKG) recording, electromyographic (EMG) recording of bilateral anterior digastric (AD) and masseter (MA) muscle activities, EEG and electrooculographic (EOG) recording, and electrical stimulation of the tongue (genioglossus muscle). Each animal also received guide cannula implantation bilaterally in the AD region of the trigeminal motor nucleus (AP -9.7 and lateral 1.7 mm from bregma) for microinjection of glycine (0.1 or 0.4 M, 0.2 μl). A week after the surgery, during QW before sleep, the threshold for evoking the JOR by tongue stimulation (200 μs) was defined. Then the animal was allowed to sleep and the JOR threshold was determined during QS as well as QW after sleep. After the microinjection of glycine, the JOR excitability and sleep-related physiological activity were determined again across sleep-awake states. The lower dose (0.1 M) of glycine failed to alter any physiological features, but the higher dose (0.4 M) of glycine reduced the JOR threshold during QS (96.2% of that before glycine) without affecting the JOR excitability during QW and, similar to its effect with systemic administration, also significantly reduced sleep latency (14.1% of that before glycine) and the incidence of micro-arousals (58.3% of that before glycine). These

findings suggest that the glycinergic system in the region of the trigeminal motor nucleus may have a role in maintaining jaw motor function during sleep and improving sleep quality.

Title: Spike-spike and spike-field coherence reveal mutual intercortical communication in the orofacial sensorimotor cortex

Authors: *F. I. ARCE-MCSHANE[1], C. F. ROSS[1], J.-C. LEE[3], B. J. SESSLE[3], N. G. HATSOPOULOS[1,2];
[1]Dept. of Organismal Biol. and Anat., [2]Committees on Computat. Neurosci. and Neurobio., Univ. of Chicago, Chicago, IL; [3]Fac. of Dent., Univ. of Toronto, Toronto, ON, Canada

Abstracts: We have shown recently that motor learning induces transient coherent firing of neuronal pairs within the orofacial motor (MIo) and in the somatosensory (SIo) cortices (Arce-McShane et al, J Neurosci 2014). However, it is unknown whether neurons or local field potentials (LFPs) exhibit functional connectivity across the two cortical areas. Here, we examined the intercortical spike-spike and spike-field coherence between pairs of MIo and SIo neurons or LFPs as monkeys (*Macaca mulatta*) learned to generate tongue-protrusive force. Coherence between the spiking of MIo and SIo neurons (MIo_{spk}-SIo_{spk}) was dynamically modulated within-trial for low frequencies (2-6 Hz) as seen in significant peaks in coherence around 50 ms after force onset. Spike-field coherence (MIo_{spk}-SIo_{lfp} and SIo_{spk}-MIo_{lfp}) was similarly modulated for low frequencies. Peak and time-to-peak coherence differed significantly between MIo_{spk}-SIo_{lfp} and SIo_{spk}-MIo_{lfp} (Mann Whitney, $p<0.01$); they were lower and earlier in SIo_{spk}-MIo_{lfp} (0.11 vs. 0.15 and 70 ms vs. 160 ms after force onset). The time-to-peak coherence in MIo_{spk}-SIo_{lfp} was coincident to the time that monkeys reached the required force level and the

time difference with SIo_{spk}-MIo_{lfp} corresponds to 90 ms or roughly a half-cycle at 6 Hz. Moreover, MIo_{lfp} showed significantly earlier time-to-peak coherence with the spiking of its own neurons (MIo_{spk}-MIo_{lfp}) compared to SIo neurons (50 ms vs. 70 ms after force onset, Mann Whitney, $p<0.01$). In contrast, time-to-peak coherence of SIo_{spk}-SIo_{lfp} did not differ from MIo_{spk}-SIo_{lfp}. The phase-at-peak coherence taken at 6 Hz exhibited a bimodal distribution with means at ~0° and ~180° (Rayleigh Test, $p<0.001$). Intracortical spike-field coherence also showed a bimodal phase distribution which did not depend on interelectrode distance (Circular correlation, $p>0.10$). Early in learning, the phase relations of MIo LFP oscillations to spiking in MIo and SIo were similar (Common median multi-sample test, $p>0.10$), suggesting that MIo LFP oscillations might have driven spiking in MIo and SIo neurons. On the other hand, phase relations of SIo LFP oscillations to spiking in MIo and SIo were significantly different ($p<0.01$), suggesting that MIo_{spk} and SIo_{spk} were driving the LFP oscillations in SIo. With increasing spike-spike coherence as monkeys learned, spike-field phase relations were altered transiently and became similar at the end of learning. The results provide evidence of mutual communication between MIo and SIo in the slow cortical rhythms and their reliance on inputs from within each of their own neuronal pool and those of the other during motor learning.

Title: Mechanisms and effects of stretch feedback in the heart of the American lobster, Homarus americanus

Authors: *K. HARMON, M. CHIN-PURCELL, E. S. DICKINSON, T. M. HARTLEY, O. ELLERS, A. S. JOHNSON, P. S. DICKINSON;
Bowdoin Col., Brunswick, ME

Abstracts: Although central pattern generators (CPGs) can produce rhythmic outputs in isolation, their outputs *in vivo* are often altered by both sensory feedback and neuromodulators. The interactions of these components are not well understood. We examined the neurogenic heart of the lobster, *Homarus americanus*, which is controlled by a small CPG, the cardiac ganglion (CG). Previous research suggests that crustacean heart muscle provides feedback to the CG about the degree of cardiac filling, mediated by stretch sensitive dendrites emanating from the CG neurons. We thus investigated the effects of stretch on CG output and the mechanisms underlying stretch sensitivity. Dendrites of CG motor neurons were identified using intracellular dye fills. To determine the role of stretch-sensitive dendrites, isolated hearts were stretched while heart contractions and CG motor output were recorded. Tonic stretches of the heart significantly increased contraction frequency in most preparations; the proportion that increased depended on direction of stretch. Frequency in the remaining preparations decreased or did not change. Removing stretch feedback either by severing the branches of the CG that are thought to contain the dendrites or by cutting the CG motor nerves decreased or eliminated the response to stretch, but increased the variability of the heartbeat. Additionally, both frequency and amplitude of heart contractions decreased slightly when the CG motor neuron dendrites were severed; frequency likewise decreased when the motor nerves were severed. Our data suggest that feedback is mediated largely by dendrites branching from the main CG trunk, and is triggered primarily by active muscle contractions. This feedback appears to stabilize the heartbeat and simultaneously enhance the activity of the CPG. To determine the cellular mechanism that underlies stretch sensitivity, we recorded intracellularly from CG motor neurons while manually stretching small bundles of muscle fibers. Stretch of a single muscle bundle did not alter cycle frequency, and we saw no changes in the membrane potential between bursts. Surprisingly, the amplitude of the driver potentials that underlie bursting in the CG neurons decreased when the attached muscle was stretched. Both the changes in heartbeat frequency in response to removal of the dendrites and the responses of the membrane potential to stretch differ considerably from those previously recorded in other species, suggesting a different mechanism underlying stretch sensitivity in this crustacean species. Experiments examining the effects of neuromodulators on this CPG-effector system are underway.

Title: Spinal interneuronal organization involved in the control of postural muscle tone in the cat

Authors: *K. TAKAKUSAKI[1], R. CHIBA[1], T. NOZU[2], T. OKUMURA[3];
[1]Reserach Ctr. for Brain Function and Med. Engin., [2]Dept. of Regional Med. and Educ., [3]Dept. of Gen. Med., Asahikawa Med. Univ., Asahikawa/Hokkaido, Japan

Abstracts: In the decerebrate cat preparation, microinjection of carbachol into the pontine reticular formation (PRF) induced muscular atonia by modulating the activities of reticulospinal neurons in the medullary reticular formation (MRF) (Takakusaki et al., 1993, 1994). The present study was designed to understand spinal interneuronal mechanisms involved in the control of postural muscle tone. For this purpose, extracellular activities of 105 interneurons were recorded from the lower lumbar segments (L6-L7) of acute decerebrate cats (n=28). Interneurons were divided into 3 types following inputs from the inhibitory region of the MRF and from peripheral sensory afferents. Type I cells (n=39) received excitation from the MRF and inhibition from volleys in flexion reflex afferents (FRA). They were located in the ventromedial part of the grey matter (lamina VII and VIII of the Rexed). Type II cells (n=38) received inhibition from the MRF. Type III cells (n=28) did not receive input from the MRF. Type II and III cells were located in the intermediate region (lamina IV~VII) and dorsal horn (lamina III) and exclusively received excitation from FRA. Firing rates of these groups of cells were further examined before and after injections carbachol (1.6~4.0 μg/0.1~0.25 μl) into the PRF. Before carbachol injection, or a state with higher level of muscle tone due to decerebrate rigidity, Type I cells were silent or had low firing rates (2.0 ± 2.7 Hz; n=18). On the other hand, spontaneous firing was observed in Type II cells (38 ± 11.5 Hz; n=13) and Type III cells (21.4 ± 10.0 Hz; n=7). During motor inhibition or muscular atonia induced by pontine carbachol inhibition, firing rates of the Type I cells was increased to 33 ± 11.7 Hz, while those of the Type II and III cells were reduced to 7.1 ± 5.2 Hz and 10.1 ± 5.8 Hz, respectively. Spike-triggered averaging revealed that some Type I cells exerted postsynaptic inhibitory effects upon α-motoneurons and interneurons mediating

reflex pathways, and presynaptic inhibitory effects upon primary afferents. These findings suggest the presence of functional topographical organization of spinal interneurons with respect to the control of postural muscle tone. Interneurons in the ventromedial grey matter (Type I cells) may be involved in muscular atonia, while those in dorsal horn and intermediate region (Type II and III cells) may contribute to maintenance of muscle tone. Because muscular atonia induced by pontine carbachol injection resembles to that of rapid eye movement (REM) sleep, the Type I cells may be responsible for motor inhibition during the preiod of REM sleep.

Title: REM sleep twitches drive Purkinje cell activity in the developing cerebellum

Authors: A. M. PLUMEAU[1], *G. SOKOLOFF[2], D. MUKHERJEE[2], M. S. BLUMBERG[2]; [1]Neurosci., [2]Psychology, The Univ. of Iowa, Iowa City, IA

Abstracts: One of the primary behavioral states in infancy is sleep. During active, or REM sleep, the spontaneous myoclonic twitches of the skeletal muscles provide discrete sensory feedback to the brain. It has been proposed that this information is important for the development and refinement of neural circuits involved in sensorimotor integration. One structure crucial for sensorimotor integration is the cerebellum, which in rats develops extensively after birth. Although the anatomical changes that occur in the first few weeks of postnatal life have been thoroughly characterized, less is known about the cerebellum's functional development. Despite the immaturity of the cerebellar circuit, recent work in our lab has shown that Purkinje cells in rats at 6 days of age show patterned activity, including the presence of complex and simple spikes, both of which show more activity during sleep immediately after twitches. Using 16-channel silicon electrodes, we recorded extracellularly from Purkinje cells in unanesthetized, head-fixed rats at 4, 8, and 12 days of age as they cycled between sleep and wake. EMG activity was recorded from nuchal and hindlimb muscles and behavior was scored concurrently. Complex and simple spikes were apparent at all ages, with firing rates for both increasing with

age. Additional age-related changes were observed in complex and simple spike auto-rhythmicity, both of which peaked at 8 days of age. Finally, state- and twitch-dependent Purkinje cell activity was also observed at all three ages. These results suggest that sleep-related twitching plays a key role in refining cerebellar circuits and strengthens the argument that activity-dependent development of the cerebellum is driven in part by twitching.

Title: Firing rate modulation of two antagonistic Purkinje cell populations during motor timing in mice

Authors: *S. OHMAE, K. OHMAE, D. SUBRAMANIAN, J. F. MEDINA;
Dept. of Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstracts: To examine the contribution of the cerebellar cortex to motor timing, we recorded the simple spike activity of individual Purkinje cells while mice performed well-timed conditioned eyelid movements. Mice were trained to make conditioned blinks in response to a visual stimulus (LED light) that was repeatedly paired with a periocular airpuff at one particular interstimulus interval (ISIs range: 220-370 ms for different mice). Regardless of the ISI used during training, all mice learned to adaptively regulate the speed of the conditioned blink and achieve maximum eyelid closure around the expected time of the airpuff. We found two types of Purkinje cells with movement-related activity: the firing rate of Type I cells was strongly suppressed and was negatively correlated with the speed of the conditioned eyelid movement, i.e. the firing rate was reduced soon after the presentation of the LED but returned to baseline by the time of the airpuff, when the eyelid speed was close to zero. In contrast, the firing rate of Type II cells ramped up

gradually and, similar to the eyelid position, reached maximum around the time of the airpuff. We have started making focal electrolytic microlesions and high-pressure dye injections to mark the locations of Type I and Type II cells in the cerebellar cortex of individual mice. Preliminary data suggests that Type I cells are clustered in a very small "hotspot" near the bottom of the primary fissure, while Type II cells can be found more widely distributed along the walls of the primary fissure. We are currently assessing the locations of Type I and Type II Purkinje cells relative to zebrin stripes.

Title: Dynamic modulation of anterior interpositus neuron activity during the performance of conditioned eyelid movements in mice

Authors: *S. A. HEINEY, J. F. MEDINA;
Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstracts: We examined the firing properties of neurons in an identified a region of the anterior interpositus (AIP) nucleus that is essential for the expression of learned eyelid movements in mice. Mice were head-fixed on top of a cylindrical treadmill and trained to blink in response to a light or vibrissal conditioned stimulus (CS) that was repeatedly paired with an airpuff to the eye. After the mice had learned to make well-timed conditioned eyelid movements we used electrical microstimulation to map out the AIP and localize putative eyeblink controlling regions. We found a small "hotspot" within the AIP from which discrete, graded, ipsilateral eyelid movements could be reliably evoked with low current stimulation. Functional disconnection of this small region in AIP, through reversible pharmacological inactivation or permanent electrolytic lesions, completely abolished learned eyelid movements with little or no effect on reflex blinks. Neurons recorded within and around this "hotspot" showed a variety of firing rate modulations during the performance of conditioned eyelid movements. However, a large

proportion of the neurons exhibited an idiosyncratic response profile starting with a transient pause in firing at a fixed latency after the onset of the CS, followed by an increase in firing rate to a level that was well above baseline and remained elevated until the time of the airpuff. On individual trials, the firing rates of many neurons showed strong correlations with the kinematics of the eyelid movement, such that the presence or absence of a conditioned response, and often its size, could be predicted based on the firing of a single neuron on a single trial. Our results demonstrate that neurons in this region of AIP are a critical component of the circuitry mediating conditioned eyelid movements, and that their activity is dynamically regulated to precisely shape motor output.

Title: Timed pauses of simple spikes and up-and-down patterns of deep cerebellar nucleus activity code cerebellar temporal processing during voluntary movement tasks

Authors: *K. YAMAGUCHI[1], S. TAKAHASHI[2], Y. SAKURAI[1];
[1]Kyoto University, Grad. Sch. of Letters, Dept. of Psychology, Kyoto, Japan; [2]Doshisha University, Grad. Sch. of Brain Science, Dept. of Neural Circuitry, Kyoto, Japan

Abstracts: Time is a fundamental and critical factor in daily life. Millisecond timing, which is the underlying temporal processing for speaking, dancing and other activities, is reported to rely on the cerebellum. Some studies have reported the relationship between temporal processing of several hundred milliseconds and the cerebellar neuronal spikes that may directly organize behavioral timing. As an example of the notable contribution of the cerebellar cortex activity to temporal processing, eyeblink conditioning studies using electrophysiological recording demonstrated that the simple spikes of Purkinje cells exhibited excitatory or inhibitory responses before the presentation of unconditioned stimuli in well-trained animals. On the other hand, evidences from the experiments that controlled some of the temporal properties in voluntary-movement tasks are limited although the contribution of the cerebellum to voluntary movements

is well documented. Here, we suggest that precise temporal control in the cerebellum may be realized by regular pauses of simple spikes of Purkinje cells and up-and-down activity pattern of deep cerebellar nucleus neurons. We used behavioral tasks that require the rats to touch a switch continuously at regular intervals of a few hundred milliseconds with their paw. When the rats fail to pause for a fixed interval between behavioral responses, the current trial is canceled and restarted. Consequently, the rats need to correctly perceive the intervals between the touch responses to successfully complete the trials. Behavioral timing in the task that requires only one interval to complete one trial is defined as 'duration-based timing', and the other requiring multiple intervals was defined as 'beat-based timing'. As the results of multiple Purkinje cell recording during the beat-based timing task, we found that simple spikes paused near the time of the touch only when the rat paused for the fixed intervals. The results also showed that deep cerebellar nucleus neurons show increasing activity toward the time of touch and a sudden decrease of activity after the touch. The pattern may reflect that there is a pause of the simple spikes of Purkinje cells for temporal processing. This is in line with the notion that deep cerebellar nucleus activity reflects disinhibition from Purkinje cellular inhibitory inputs. The simple spikes display regular activity patterns including successive firing and short/long pauses, and such regularity controls downstream deep cerebellar nuclei. In conclusion, these results suggest that precise temporal control in the cerebellum may be realized by such regularity of pauses.

Title: Predicting conditioned response profiles on a single trial from Purkinje cells population activity

Authors: *A. KHILKEVICH, H. E. HALVERSON, J. PILLOW, M. D. MAUK;
Univ. of Texas At Austin, Austin, TX

Abstracts: As the principle neurons of the cerebellar cortex, Purkinje cells (PCs) are thought to control the timing properties of motor responses. Eyelid conditioning provides a cerebellar-dependent behavior (conditioned responses, CRs), and therefore an ability to establish how PCs population encodes eyelid trajectory during CR. We employed a generalized linear model (GLM) approach to study to what extent CR trajectory on a single trial can be predicted from spike trains of simultaneously recorded PCs. We used data from nine New Zealand albino rabbits trained with delay eyelid conditioning protocols with ISI=200ms, 250ms, 500ms, 700ms. Tetrode recordings from PCs were made from the left anterior lobe of the cerebellar cortex while animals were showing a robust expression of conditioned responses. PCs were classified as "eyelid" PCs based on the presence of complex spike(s) during the unconditioned stimulus presentation. Only eyelid PCs were included into this analysis. With GLM based analysis we explored how PC spike history is integrated and transformed into the behavioral response, as well as how nonlinearities contribute to motor output transformation. Our results indicate that: 1) Purkinje cells control the time profile of conditioned responses; 2) the largest behavioral response is achieved via increased inhibition followed by disinhibition of downstream DCN neurons, consistent with previous findings; 3) even a small subset of simultaneously recorded PCs is sufficient to explain a high amount of trial-to-trial variability of CR trajectory profiles. Additionally, we investigated how prediction accuracy scales with the number of simultaneously recorded PCs. Interestingly, squared prediction error scales as one over the number of PCs included, with the exception of the single PC case, which gives much higher accuracy than would be estimated from the trend. This provides evidence that PC population activity is highly correlated and that we can estimate some features of CR profile even from the activity of a single PC.

Abstracts: Synchronous optogenetic activation of Purkinje cells (PCs) results in a transient suppression of firing in cerebellar nuclei neurons followed by rebound firing and correlated motor behavior in mice including twitches that occur with a short delay relative to the stimulus offset. We sought to determine if such stimulation in the anterior vermis of the cerebellum could interfere with ongoing locomotion patterns, or limb placements in head-fixed awake behaving mice that were placed on a transparent disc-based treadmill system. Our findings show that optogenetic activation of PCs during ongoing locomotion can either perturb locomotion causing the animal to slow down, or end locomotion altogether. When animals were resting, stimulation could trigger not only twitches relative to the stimulus offset, but also result in the initiation of locomotion that began with a fixed latency to onset of the optogenetic stimulus and resulted in a stereotyped stepping pattern. We will present data obtained using a three-fiber ferrule used for optogenetic stimulation of PC ensembles at distinct mediolateral locations and demonstrate the effects of stimulation at these sites on mouse locomotion patterns.

Title: Modulation of purkinje and cerebellar nuclear cell activity during running in awake mice

Authors: *R. SARNAIK, I. M. RAMAN;
Dept. of Neurobio., Northwestern Univ., EVANSTON, IL

Abstracts: Corticonuclear synapses, between GABAergic Purkinje cells of the cerebellar cortex and projection neurons of the cerebellar nuclei, are central to both correction of motor errors and regulation of well-learned movements. To investigate signaling at these synapses during periodic, predictable, coordinated movements, we recorded spiking in Purkinje and nuclear cells in awake, head-fixed mice allowed to run freely on a linear treadmill, while simultaneously recording the hindpaw position ipsilateral to recording site. Loose cell-attached recordings from Purkinje cells in simplex and crus 1 (Pkj, n = 13) or cerebellar nuclear cells in the interpositus (CbN, n = 8) were made in mice expressing channelrhodopsin-2 (ChR2(H134R)) in Pkj cells (L7-cre x Ai27). The average stride duration during running was 209 ± 10 ms (n=21). Spiking patterns of both Pkj and CbN cells were clearly reorganized between rest and running epochs, suggesting that the recorded cells were involved in the task. In addition, when local illumination was applied through an optical fiber to increase spiking of Pkj terminals in the vicinity of the recorded CbN cell, long light pulses (1-2 sec, 1-2 mW/mm2) elicited strong inhibition of the CbN cells and also caused a missed step on the ipsilateral side by making the animal slip on the treadmill during silencing of the CbN cell (at least 2 repeats in each of 6 recordings in 3 mice). Independently of absolute firing rates, spiking rates of Pkj and CbN cells rose and fell reliably during specific segments of the stance and swing phases of the step cycle. The two cell types showed similar maximal firing rates during running epochs (Pkj: 101 ± 12, CbN: 96 ± 10 sp/s), but CbN cells showed lower minimal firing rates (Pkj: 61 ± 12, CbN: 24 ± 7 sp/s). As a consequence, CbN cells showed a significantly greater modulation of firing rates with the step cycle compared to Pkj cells, measured either as (max rate-min rate)/min rate (Pkj: 1.2 ± 0.67, CbN: 13.6 ± 9.8, $p<0.01$) or as the normalized net vector on polar plots of the spike rate vs. step cycle phase (Pkj: 0.1 ± 0.03, CbN: 0.3 ± 0.05, $p<0.01$). Although individual Pkj and CbN cells increased their firing rates at a specific phase of the step cycle, across the population all phases of the step cycle seemed to be represented. Our results show that nuclear cells modulate their firing rates greatly to specific phases of the step cycle, possibly by integrating several moderately modulated Purkinje cell inputs.

Title: Cerebro-cerebellar encoding of motor actions involves dynamic formation of network assemblies

Authors: Y. BAUMEL[1], *D. COHEN[2];
[1]Gonda Brain Res. Ctr., [2]Bar Ilan Univ., Ramat Gan, Israel

Abstracts: The primary motor cortex (M1) and the deep cerebellar nuclei (DCN) are involved in the control and production of motor actions (Gross, 02; Williams, 09). Local field potentials (lfp) recorded simultaneously in the cerebrum and cerebellum display coherent activity in the low frequencies during anesthesia (Ros, 09) and in the high frequencies during expectancy and various motor tasks (Courtemanche & Lamarre, 05; Soteropoulos & Baker, 06). Yet, the interplay between these two structures and their synergistic contribution to the encoding of different actions in freely moving animals remains to a large extent unknown. By using chronically implanted microwire electrodes, we show in freely moving rats that the activity of single units recorded in M1 and the DCN correlated with the performed motor action. Analysis of the population activity showed that the neurons formed dynamic assemblies within and between structures that correlated with the performed action. In addition, lfps recorded in M1 and the cerebellar nuclei (DCN) displayed a significant power in the frequency range of 6-8Hz. The coherence between these lfps was modulated in relation to the preformed action. Also, the observed phase lag in the cross-correlation calculated between these lfps depended on (1) the performed action, and (2) whether the lfps were taken from the ipsilateral or the contralateral side. A Granger causality test suggested that the DCN drive M1 lfp oscillations during grooming and ambulation but not in the absence of overt movement. Surprisingly, the emerged single unit network assemblies were independent of the observed lfp cross-correlations. These data suggest a flexible, oscillations based, computation and provide a neuronal substrate for the performance of bi-manual movements.

Title: Cross frequency interactions of oscillations in the cerebellum

Authors: *J. GROTH, M. SAHIN;
Biomed. Engin., New Jersey Inst. of Technol., Newark, NJ

Abstracts: The cerebro-cerebellar pathways have long been known to play an important role in motor planning and control. The cerebellar signals contain oscillations in various bands. The most prominent are the high frequency oscillations (HFO), in the 150-400Hz range, and the oscillations in the 4-25Hz range. The HFOs arise due to the simple spike synchrony in the Purkinje cells. The 4-25Hz oscillations arise out of the granular layer and the inferior olive. Another feature of the cerebellum is that the Purkinje cells, granular layer, and inferior olive all show a resonance in the theta range (4-8Hz). How these oscillations are related to each other and to the motor cortex oscillations is not known. To this end, we have recorded neural activity from the cerebellar and the primary motor cortices using micro-ECoG arrays (4x8 matrix with 300 micron pitch). This allows simultanious observation of activity in a large area of the cortex with a dense matrix of electrodes. The recordings were performed on male Long Evans rats. The ECoG arrays were placed over the paramedian lobule of the posterior cerebellum and the primary motor cortex. All recordings were performed during a lever press task. All data analysis was performed using MatLab. The field potentials in HFO and 4-25Hz bands were analyzed using time frequency methods available with the Chronux tool box. Phase synchrony was analyzed using Hilbert transform and Shannon entropy. Spectral analysis shows significant similarity in temporal changes between the two frequency ranges during the movement. Our analysis also demonstrates that when two electrodes are coherent in the high frequency range they are also coherent in the 4-25Hz range. Furthermore, synchrony in the two frequency bands overlaps in time. The synchrony analysis also shows three distinct bands in the 4-25Hz range that are consistent with the theta, Mu, and beta bands in the cortex. Coherence and synchrony analysis between the two cortices reveal that there is a relationship between the cerebral and cerebellar oscillations. Stimulation of the motor cortex in the 4-25Hz range produces high frequency components with resonance bands similar to those seen in the cerebellar synchrony. Our results show that there are significant cross frequency interactions during the movement in the cerebellum as well as to those in the motor cortex. The data also indicate that high frequency oscillations can be modulated by afferent inputs through cross frequency interactions.

Title: Neighboring Purkinje cells in the cerebellum are synchronized during voluntary movements

Authors: H. GAO[1,2], C. POUZAT[3], M. SPOLIDORO[1], *C. LENA[1];
[1]CNRS UMR 8197 / INSERM U 1024, Inst. de Biologie de l'Ecole Normale Superieure, PARIS, France; [2]East China Normal Univ., Inst. for Advanced Interdisciplinary Res., Shanghai, China; [3]CNRS, UMR 8118, Lab. de Physiologie Cérébrale, UFR biomédicale de l'Université René Descartes (Paris V), Paris, France

Abstracts: Cerebellar computations are performed within functional microzones that process information in parallel and form distinct output streams. In the cerebellar cortex, sets of neighboring Purkinje cells belonging to the same microzone are organized in parasagittal bands. How neuronal activity is coordinated within each microzone is currently unknown. In this study, we have recorded simultaneously sets of neighboring cells activated during fast forelimb voluntary movements. Neighboring Purkinje cells exhibit millisecond-timescale synchrony during motor execution. This synchrony is maintained, embedded in high-frequency oscillations, during sleep and active exploration, suggesting that recurrent inhibition continuously shapes the correlations between neighboring cells. Our results indicate that during a fast and complex movement, local assemblies of Purkinje cells, whose projections converge in the cerebellar nuclei, dynamically form at the millisecond time scale and will thus produce very transient episodes of inhibition in the cerebellar nuclei.

Title: Role of the cerebellum in the motor system dysfunctions in Parkinson's disease

Authors: A. BOUSQUET, F. MENARDY, C. LÉNA, *D. POPA;
CNRS UMR 8197 / INSERM U 1024, Inst. de Biologie de l'Ecole Normale Superieure, Paris, France

Abstracts: Parkinson's disease is associated with a substantial functional reorganization of the motor system, particularly of the cortical motor areas and within the two main subcortical afferents to these areas: the basal ganglia -where the dopaminergic degeneration takes place- and the cerebellum. The consequences of the alterations of the cerebellum are not fully understood, but several reports already point toward its involvement in motor dysfunction and in the abnormal involuntary movements in dyskinesia, the side effects of the levodopa treatment in the late phase of the disease. In our study, we combine pharmacological manipulations, optogenetics and *in vivo* electrophysiology in anesthetized and behaving animals to examine the changes of activity in the cerebellum and the compensatory reorganisation of the cerebello-cortical pathway in a 6-hydroxydopamine (6-OHDA) rodent model of Parkinson's disease. In particular, we assess the impact of cerebellar stimulation on dyskinesias that occur in the late stage of Parkinson's disease and we observe a reduction of abnormal involuntary movements following these stimulations, suggesting that the cerebellum could offer a gateway for corrective treatment of the motor dysfunctions in Parkinson's disease.

Title: Plane specific zonal organization of Purkinje cell responses to vertical head rotations in the cat cerebellar nodulus and uvula

Authors: *T. KITAMA[1], J. KOMAGATA[2], K. OZAWA[2], Y. SUZUKI[1], Y. SATO[3];
[1]Ctr. For Life Sci. Res., Yamanashi, Japan; [2]Hlth. Sci. Univ., Yamanashi, Japan; [3]Dept. of Physiol., Univ. of Yamanashi, Yamanashi, Japan

Abstracts: Purkinje cells in the cerebellar nodulus and uvula have been shown anatomically to project topographically to the vestibular nuclei. However, the functions of topographically organized modules of Purkinje cells in the cat nodulus and uvula have not yet been demonstrated. In the present study, we investigated the neural responses of Purkinje cells during vertical head rotations, and their cellular distribution in the nodulus and uvula to clarify whether a modular organization exists in these regions. Four adult cats were chronically prepared for single-unit recording. All animal care and experimental procedures complied with SfN guiding policies and principles. We recorded simple spike (SS) and complex spike (CS) firing of Purkinje cells in the nodulus and uvula of awake head-restrained cats, during sinusoidal vertical rotation of the head in four stimulus planes: pitch, roll, and two diagonal planes, i.e., 45° clockwise, and 45° counterclockwise from the sagittal plane. The optimal response planes for SS and CS for each cell were estimated from the responses in the four stimulus planes using a sinusoidal function. Both SS and CS firing of the major population of cells were modulated by vertical but not horizontal head rotation. None of the sampled cells showed any sign of a response during either spontaneous saccades or quick phases of nystagmus (vestibular or optokinetic) in the horizontal or vertical planes. Individual cells have a preferred orientation of the head-rotation plane. In the best-response plane among the four that were explored, the phase of SS activity is close to that of either table (head) position or velocity. Two functional zones within the rostrocaudal extent of the nodulus and uvula can be recognized: a medially located band of cells with an optimal orientation in the pitch plane, and a lateral band located further than 1.0 mm from the midline with an optimal orientation in the roll plane. These findings suggest that the cat nodulus and uvula encode sensory information of head motion with regard to the vestibular signals through each plane-specific functional zone. These two zones are the same as previously reported zones in the cerebellar flocculus that are active during head rotation in the canal planes, in the point that both these cerebellar sagittal zones are plane specific functional zones. This suggests that anatomical sagittal zones serve as functional plane-specific zones, at least in the vestibulocerebellum.

Title: Mossy fibers in the cerebellar hemisphere show activity during an instructed delay period

Authors: *T. ISHIKAWA[1], S. TOMATSU[2], D. S. HOFFMAN[3,4], S. KAKEI[1];
[1]Dept. of Sensory Motor Systems, Project for Motor Control Res., Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan; [2]Inst. of Neurosci., Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [3]Dept. of Neurobio., [4]Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstracts: The cerebellar hemispheres receive their primary inputs from the cerebral cortices via pontine nuclei (PN) and therefore are called the cerebrocerebellum. The ponto-cerebellar projection terminates as mossy fibers (MFs) in the granular layer of the cerebellar cortex. MFs in lobules IV-VI of the cerebrocerebellum receive predominant inputs from the primary motor cortex (M1) and premotor cortex (PM) (Kelly and Strick 2003). Because of this anatomical structure, examination of the pattern of MF activity in the cerebrocerebellum may be key for understanding what information the cerebral motor cortices provide to the cerebellum for motor control. However, little information is available about activities of MFs in the cerebrocerebellum in behaving monkeys. We recorded unit activity of MFs in the cerebrocerebellum of 2 monkeys that were required to make step-tracking movements of the wrist joint after an instructed delay period (1-2 sec). We found 155 MFs with significant task-related activity and most of them (n=148) had clear somatosensory RFs in distal part of the ipsilateral arm. We compared their activity with that recorded in M1 and PM neurons during the same task in previous studies (Kakei et al., 1999, 2001), and found that MFs had several features of task-related activity that were observed in M1/PM neurons. First, a part of MFs (n=70) showed a prolonged modulation change during the delay period (between instruction cue presentation and go signal). Both increases and decreases of activity were observed. Second, all MFs (n=155) showed a phasic or tonic modulation change at movement onset. Modulation onset of the movement-related activity preceded the movement onset by -67 ms on average, and lagged that for PM and M1 neurons (-124 ms and -97 ms, respectively). Third, most MFs showed directional tuning in the delay period (n=57) and/or at movement onset (n=120). Forty-eight MFs showed continuous directional activity that started before go signal and maintained until the end of movement, and preferred direction for most (n=41) showed little change. Overall, we found that patterns of task-related activity in M1/PM neurons were well-preserved in MF activity in the cerebrocerebellum. This result indicates that the cerebellum receives an efference copy of motor cortical activity that can serve to predict results of an action. Given that many MFs showed delay activity, the cerebellum may be involved not only in movement execution but also in planning and/or preparation for an upcoming movement.

Title: Manipulations of visual feedback modulate Purkinje cell simple spike encoding of error signals during a manual random tracking task

Authors: M. STRENG, L. POPA, *T. J. EBNER;
Neurosci., Univ. Minnesota, MINNEAPOLIS, MN

Abstracts: The view that the cerebellum functions as a forward internal model necessitates a role for the cerebellum in the processing of motor errors. Specifically, this requires the generation of opposing predictive and feedback related signals, whose summation results in a sensory prediction error (SPE). Recent results from our lab have implicated simple spike (SS) discharge of Purkinje cells (PCs) in the processing of prediction and feedback signals corresponding to motor errors. Many PCs have this dual representation of both kinematics and performance errors, and the prediction and feedback signals have opposing effects on the SS, consistent with an SPE. To further test this hypothesis, we are investigating the effects of disrupting sensory information pertinent to both predictive and feedback signaling on motor errors and their modulation of SS activity. Single unit recordings of PCs were obtained from rhesus macaques performing a manual tracking task, in which the animals track a randomly moving target using a manipulandum. Spike trains were analyzed using multiple linear regressions, where kinematic and performance errors were regressed against firing residuals in which variability associated with other parameters is removed. Feedback information during the task in the form of cursor position was either disrupted by an artificial delay of 100-200msec or reduced by making the cursor visible only when it was outside the target. Feedback delay resulted in a significant increase in motor errors, whereas visual feedback reduction results, somewhat surprisingly, in a significant decrease in motor errors. These manipulations and resulting behavioral changes are reflected in SS activity by a degradation of predictive signaling in the delay condition, and a degradation of feedback signaling in the hidden cursor condition. In PCs that exhibit bimodal R^2 error profiles, a reduction in magnitude of the predictive peak and an

increase in the magnitude of the feedback peak are observed in the delay condition, and vice versa for the hidden cursor condition. Kinematic R^2 profiles showed less overt changes, suggesting that SS signaling related to cursor movement is a combination of both visual and proprioceptive information. Results suggest that visual feedback delay causes in an invalidation of the feed forward components of the internal model, resulting in an increase in feedback-related signaling. Conversely, reducing visual feedback increases the dependence on the feed forward aspects of the internal model, thus increasing predictive signaling. Taken together, these results further support a role for SS discharge in the encoding of SPEs.

Title: Responses of Purkinje cells during pursuit eye movement place limits on the amount of spiking synchrony across the population

Authors: ***M. H. PHILLIPS**, S. G. LISBERGER;
Neurobio., Howard Hughes Med. Institute, Duke Univ., Durham, NC

Abstracts: Person & Raman (2012) showed that synchronous spiking across a population Purkinje cells (PCs) could cause increased PC firing to lead to increases in the firing rate of target neurons in the deep cerebellar nucleus (DCN), even though PC synapses onto DCNs are inhibitory. They posed synchrony as an explanation for why researchers have failed to observe a consistent inverse relationship between PC and DCN firing rates. They also found that the Purkinje cell IPSC in DCNs shows a very short (tau = 2.4ms) time constant of decay at physiological temperatures. The rapid decay would facilitate conversion of synchronous PC firing into excitation, through rebound firing in DCNs. Our recordings from Purkinje cells in the

floccular complex of the cerebellum provide data that may constrain the degree of synchronous firing across the Purkinje cell population. For example, we find modest "neuron-behavior correlations" between PC firing rate and eye movement. The correlations account for 40% of the trial-by-trial variation in the firing rate of individual floccular PCs during the initiation of pursuit (Medina & Lisberger, 2007). Here, we ask whether the observed neuron-behavior correlations constrain the amount of synchrony across the population. We simulated populations of PCs with synchrony ranging from 5-33%, where 5% corresponds to the amount of synchrony arising from fully independently generated firing rates, and we simulated behavior. Individual model neurons mimicked the firing rates of neurons in the pursuit task of Medina & Lisberger and had interspike interval variation drawn from the empirical distributions. We decoded the discharge of the population of model PCs and simulated behavioral output by convolving population output spike trains with a causal exponential filter having a time constant of 2.4 ms. We found that the neuron-behavior correlations in synchronized populations with as little as 15% synchrony were considerably higher than those measured from the Medina & Lisberger data when the neural data was filtered similarly. Correlation strengths in populations with 5-10% synchrony produced neuron-behavior correlations similar to those in the data. Longer decoder time constants (13 ms, 34 ms) substantially reduced or eliminated the difference between synchronous and non-synchronous populations. Our simulations suggest that large amounts of synchronous spiking across the population of PCs may not be an important feature of cerebellar output in the behaving animal.

Title: Multiplexed coding by cerebellar Purkinje neurons

Authors: *S. HONG[1], M. NEGRELLO[2], M. JUNKER[3], A. SMILGIN[3], P. THIER[3], E. DE SCHUTTER[1];
[1]Computat. Neurosci. Unit, Okinawa Inst. of Sci. and Technol., Okinawa, Japan; [2]Dept. of Neurosci., Erasmus MC, Rotterdam, Netherlands; [3]Dept. of Cognitive Neurol., Univ. of Tübingen, Tübingen, Germany

Abstracts: The cerebellar cortex processes various aspects of sensorimotor information and sends out its output via Purkinje cells (PC). Previous studies demonstrated good correspondence between their population rate and motion variables (Shidara et al., Nature, 1993) that can be facilitated by weak correlation between the PCs (Medina and Lisberger, J Neurosci, 2007). On the other hand, the spike trains of individual PCs have a non-trivial temporal structure that cannot be captured by a rate-modulated point process (Shin et al, PLOS One, 2007). Therefore, it has been a question how this temporal information in the PC spike train is represented at the population level and used for information transfer (de Zeeuw et al, Nat Rev Neurosci, 2011). To address this question, we analyzed simultaneously recorded single PC spiking and cerebellar local field potential (LFP), the latter serving as a proxy for the network activity, in addition to saccadic eye movements from three rhesus monkeys (Macaca Mulatta). We found that the correlation of single PCs to the local network activity is dynamic and depends on the neuronal and behavioral context. More specifically, the spike-LFP correlation is stronger and temporally more precise when the spike begins or ends "pauses" in the spike train that intermittently interrupts the typically fast and regular PC firing (Schonewille et al., Nat Neuroci, 2006; Shin and De Schutter, J Neurophys, 2006) while only a small fraction of the pauses was caused by complex spikes. This results in the pause spikes coupling to particular phases of the β/γ component of the LFP whereas a much weaker spike-LFP phase relationship is found for other spikes. Across the saccades, we observed that the β/γ LFP is significantly synchronized, and therefore becomes a reliable network signature for these fast eye movements. As the pause spike-LFP correlation predicts, the pause spikes have sharply peaked firing rates with respect to saccade onset with significant synchronization across saccades, again forming a reliable representation for the timing of motion. Our results suggest that the PC spike code is multiplexed: the population rate code is effective since the overall correlation between PC firing rates is small, but a small fraction of the spikes can strongly couple to the network activity and encode different behavioral information from the rate (Ratté et al., Neuron, 2013). Our study provides a unifying perspective that integrates the opposing views on PC population coding.

Title: Individual neurons in the caudal fastigial oculomotor region (FOR) convey information on both macro- and microsaccades

Authors: *Z.-P. SUN[1], M. JUNKER[2], D. ARNSTEIN[2], A. SMILGIN[2], P. DICKE[2], P. THIER[2]; [1]Dept. of Cognitive Neurol., Hertie Inst. for Clin. Brain Research, Univ. of Tübingen, Tuebingen, Germany; [2]Cognitive Neurol., Hertie Inst., tuebingen, Germany

Abstracts: Microsaccades are small (<1°) amplitude saccades made during attempted fixation in order to move the images of small objects of interest into the highest acuity center of the fovea (Putnam et al., J Vis. 2005). Behavioral studies have indicated that microsaccades and macrosaccades share most, if not all properties. Physiological studies of two major centers of saccade control, the superior colliculus (SC) (Hafed et al., Science. 2009) and the brainstem reticular formation (Van Gisbergen et al., J Neurophysiol. 1981) have established that they serve both macro- and microsaccades. The cerebellum is well known to ensure the high degree of precision of visually guided macrosaccades. As microsaccade amplitudes require a precision in the order of 10 um and less, a contribution of the cerebellum in fine tuning microsaccade amplitude may be expected as well. Two findings meet this expectation: 1. Purkinje cell simple spikes encode both macro- and microsaccades (Arnstein et al., this meeting). 2. Unilateral inactivation of the FOR, the major gateway for saccadic control signals destined for the brainstem causes dysmetria of macro- as well as of microsaccades. (Guerrasio et al., J Neurophysiol. 2010). However, there has so far been no electrophysiological evidence for microsaccade-related activity in the FOR which is why it is not clear if the integration of macro- and microsaccade related signals characterizing cerebellar cortex is perpetuated at the level of the FOR. In this study, we explored the deep cerebellar nuclei of 3 rhesus monkeys in order to delineate the FOR and to compare the responses of FOR neurons to macro- and to microsaccades. Forty saccade-related FOR neurons could be allocated to the FOR based on electrophysiological criteria and the availability of histological reconstructions of recording sites in 2 monkeys. All neurons tested showed qualitatively similar saccade-related bursts for macro- and microsaccades with earlier burst onset for contraversive saccades and vice versa. When pooling saccades of similar amplitudes, independent of their directions, the resulting population averages exhibited a monotonic dependence on saccade amplitude, spanning the full range of macro- and microsaccade amplitudes. Taken together, our study supports the notion of a continuous representation of saccade-related information, independent of saccade size, at all stages of cerebellar processing.

Title: Lateral cerebellar activity correlated with microsaccades

Authors: *R. T. RAGHAVAN[1], V. PREVOSTO[2], M. A. SOMMER[2];
[1]Dept. of Neurobio., [2]Dept. of Biomed. Engin., Duke Univ., Durham, NC

Abstracts: Prior studies have demonstrated that medial cerebellar areas that participate in visually guided, saccadic eye movements also contribute to the execution of smaller amplitude, fixational microsaccades (Guerrasio et al. 2010). This is not necessarily surprising given that a main function of medial cerebellum is the fine control of saccade parameters. It remains unknown, however, if such findings extend to the lateral cerebellum, which is interconnected with association areas of cerebral cortex and is hypothesized to play a greater role in the planning and monitoring of saccades (Ashmore & Sommer 2013; Ohmae et al. 2013; Prevosto et al. 2013 SfN abstract) as opposed to saccade execution. To what extent is this lateral cerebellar activity related to fixational microsaccades? To answer this question, we recorded from 33 neurons in the oculomotor domain of the lateral cerebellar output nucleus (caudal dentate) in monkeys performing delayed saccade tasks. Comparing modulation in neural activity prior to microsaccade and saccade execution, we found that over half of the recorded neurons changed their activity during the execution of both kinds of movements (n=19). Typically, these changes in activity were perisaccadic bursts or pauses of activity aligned with the movement. The rest of the neurons were active for large saccades only. All of the neurons that were modulated by both microsaccades and saccades exhibited similar response profiles around the time of movement execution, though the vast majority (n=17) showed smaller amplitude modulations for microsaccades as compared to saccades. We hypothesize that the diversity of response profiles we record may be explained, in part, by the fact that caudal dentate neurons have different efferent projections to the frontal eye fields and the intermediate layers of the superior colliculus. These findings suggest that the lateral cerebellum, despite its putative role in higher-level motor planning and monitoring, maintains exquisite sensitivity to even the smallest of eye movements, thus underscoring its close relationship with motor acts.

Title: Estimated force during horizontal saccades controlled by monkey fastigial nucleus

Authors: ***F. R. ROBINSON**[1], Z. LINDBLOOM-BROWN[2,3], A. MUELLER[3,4], T. EGGERT[4], A. STRAUBE[4];
[2]Physiol. & Biophysics, [1]Univ. Washington, SEATTLE, WA; [3]Neurobio., Stanford Univ., Stanford, CA; [4]Neurol., Ludwig-Maximilians Univ., Munich, Germany

Abstracts: Cerebellar output modifies movement by changing the activity of motoneurons and thereby the force that agonist and antagonist muscles generate. By describing the size and timing of the force that the cerebellum controls during a movement we can characterize in detail how cerebellar output influences movement. No previous work characterizes the force contributed by the cerebellum to a voluntary movement. Here we estimate in 4 monkeys the force contributed by the cerebellum to 10° horizontal visual guided saccades. To do this we first estimated the force rotating the globe during a saccade by transforming eye position records into force using a model of the globe's mechanical properties (Anderson et al., '09). We then compared estimated force before and after we block saccade-related activity in the caudal fastigial nucleus (CFN) of the cerebellum. In all 4 monkeys the CFN contralateral to saccade direction contributes force in the direction of the saccade that increases from saccade start to a peak of ~16 grams at ~28ms later. In 3 monkeys the CFN ipsilateral to saccade direction contributes force in the saccade direction that peaks at ~6 grams ~18 ms after saccade start. From this peak force decreases and begins to oppose the movement by ~29 ms after saccade start. This opposing force increases to ~18 grams at saccade end. In the fourth monkey, the ipsilateral CFN contributes only opposing force that increases from saccade start to saccade end when it is ~31 grams. Net force resulting from activity in both the contra- and ipsilateral CFNs represents ~30-50% of the force on the globe during a 10° horizontal saccade. Finally, in one monkey we recorded 21 CFN neurons and compared the summed response of these neurons during 10° contraversive and ipsiversive a saccades to the force that we estimate is the result of this activity. The size, shape, and durations

of CFN activity and force records are similar but peak force does not lag peak activity by a fixed latency. Peak force from the CFN contralateral to saccade direction lags peak CFN activity by ~19 ms. Peak force from the ipsilateral CFN lags peak activity by ~30 ms.

Col. of Physicians and Surgeons, New York, NY

Abstracts: The role of the cerebellum in motor learning and motor control is well established. It is necessary for gain control, as demonstrated by its role in the adaptation of saccadic amplitude and the vestibule-ocular reflex, and for the classical conditioning of the eye blink reflex. Clinical

studies show that it contributes to the coordination, precision and accurate timing of movements. Although the cerebellum modifies movements it does not initiate them. However, the cerebellum has been shown to project to cortical areas not ordinarily associated with the control of movement (Strick, 2009 Buchner, 2011) and recent clinical studies suggest that patients with cerebellar disease exhibit frontal-like cognitive deficits (Schmamann, 2009). To see if the cerebellum were involved in the cognitive aspects of motor behavior, we recorded the activity of putative Purkinje cells from the lateral hemisphere of the cerebellar cortex in a Rhesus monkey performing an arbitrary visual motor association task. In this task the monkey had to learn to associate a novel abstract visual stimulus (for instance, a red square) with a well-learned right hand movement, and a second novel abstract stimulus (for example, a green square) with a left-hand movement. We used a new pair of stimuli for each learning session. Depending on the task the monkey had either to release its grasp on a bar by a finger extension or to release a lever by a wrist extension, both of which were well trained and required no new motor skill or gain learning. We found that the activity of putative Purkinje cells in the anterolateral cerebellar cortex correlated with the monkey's learning process in establishing the association of a well-trained movement with a new visual symbol. The activity of these cells changed gradually as the monkey's performance improved. The learning effect was apparent in different types of cell activity: some neurons' activity changed at the appearance of the stimulus, but did not continue to change during the movement, and other neurons' activity increased during the trial, peaking at the movement. Interestingly, this part of the cerebellum does not seem to be involved in the fine motor aspects of the behavior, but rather functions to associate a well-learned behavior with a new cue. It seems from these early data that the critical behavioral aspect for the cerebellum is the assignment of the cue to the movement: a cognitive decision, not a new skill or a gain change. Put differently, the question solved by this part of the cerebellum is not 'how can the brain control the movement so that it is smooth and accurate' but 'how can the brain choose what well-learned movement a new cue will trigger.

Title: Pharmacogenetic interrogation of a cortico-basal ganglia circuit that controls vocal-motor variability in zebra finch

Authors: *J. B. HESTON, J. SIMON, S. A. WHITE;
UCLA, Los Angeles, CA

Abstracts: Behavioral variability is posited to enable procedural learning. Indeed, studies in songbirds, rodents and humans has shown that variability positively predicts the rate, accuracy and even capacity for learning, and that variability is dynamically reshaped as a consequence of experience. The neural mechanisms responsible for generating this behavioral exploration remain unclear. In songbirds, a cortico-basal ganglia circuit is dedicated to the procedural learning of song, and plays an important role in generating song variability. However, the role of the song-dedicated basal ganglia region known as Area X is contentious, with lesions to Area X producing mixed results. We recently observed that experimental disruption of the dynamic, behaviorally-driven regulation of the FoxP2 transcription factor in Area X interferes with and even reverses transitions between states of low and high vocal variability that occur on the order of hours. This observation suggests that Area X may contribute to the control of vocal exploration which can be revealed on a relatively short time scale. Here, we test this hypothesis using viral-driven expression of designer receptors exclusively activated by designer drugs (DREADDs) to transiently and bidirectionally alter the activity of Area X neurons and measure the effect on song. These receptors only affect neural activity when activated by the otherwise biologically inert molecule, clozapine-N-oxide (CNO). Birds received bilateral stereotaxic injections to Area X of a virus that expresses one of the two types of DREADDS: one which increases neural excitability or one which decreases it. After recovering from surgery, song variability was measured following a systemic injection of CNO on a given day and compared to that following an injection of saline on another. Preliminary findings indicate that this manipulation birdirectionally alters song variability, supporting the idea that Area X can directly contribute to vocal-motor exploration, and offering a candidate neural mechanism that may be used for natural fluctuations in behavioral variability.

Title: Sensorimotor properties of different neuron types in basal ganglia song nucleus Area X

Authors: *L. KOLB[1], A. HANUSCHKIN[1], C. SCHARFF[2], R. HAHNLOSER[1];
[1]Inst. of Neuroinformatics ETH Zurich, Zurich, Switzerland; [2]Freie Univ. Berlin, Berlin, Germany

Abstracts: Young male zebra finches learn to produce their stereotyped song by vocal imitation of an adult conspecific 'tutor'. Using auditory feedback they transform an initially highly variable juvenile subsong into a stable copy of a memorized tutor song. This goal-directed motor learning requires a specialized anterior forebrain pathway (AFP), a basal ganglia-thalamocortical circuit, which is highly homologous to the mammalian counterpart. The AFP drives necessary motor exploration for vocal learning and includes song nucleus Area X that contains both striatal and pallidal neuron types. Several neurophysiological studies described the behavior of Area X neurons either in awake singing birds or in anesthetized birds exposed to playback of the bird's own song (BOS). However, the integrated sensorimotor properties of Area X neurons in awake birds have not yet been characterized. To address this issue, we recorded the firing patterns in different types of Area X neurons in awake and freely moving male zebra finches using chronically implanted single high impedance electrodes. Stable recordings were obtained from four striatal and two pallidal neuron classes while birds were singing and while they were subsequently exposed to their own songs that we broadcast in the dark through a loudspeaker. All six neuron classes were responsive during singing and mostly showed increased activity shortly before song onset. Two striatal neuron classes were almost exclusively spiking during song, whereas the remaining four classes were also tonically active when the bird was silent. Interestingly, three of these classes also responded to BOS playback, including the pallidal GPi-like neurons, the presumed only output neurons of Area X. With repeated BOS playback and starting roughly 0.5 s after playback onset these neurons developed a more structured, less tonic firing pattern, defined by increases in bursting density and duration of pauses. This sensory-evoked activity pattern qualitatively resembled the singing related activity. Our results demonstrate that Area X neuron firing is modulated by sensory stimulation. Understanding the structure of this auditory responsiveness may provide a better insight into how auditory feedback is used by Area X to guide vocal learning.

Title: Expressing mutant Huntingtin in the songbird basal ganglia increases song variability

Authors: *M. TANAKA[1], M. MURUGAN[2], R. MOONEY[1];
[1]Duke Univ. Sch. of Med., Durham, NC; [2]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstracts: The basal ganglia (BG) play important roles in learning, initiating, and terminating complex motor sequences. Consequently, genetic mutations that impair BG function often produce serious motor disorders. Huntington's disease (HD), which is caused by mutations with expanded CAG repeats in exon 1 in the *Huntingtin* gene (*HTT*), induces degeneration of BG neurons and causes various motor disorders, which include increased involuntary movements and impaired speech. Although speech impairment can be a severe problem for individuals afflicted with HD, how this disease disrupts speech remains poorly understood. Here we made a model of Huntington's disease in songbirds, one of the few non-human animals that produce complex learned vocal sequences to communicate with others of their species. We injected a lentivirus containing *HTT* exon 1 with expanded CAG repeats (i.e., mutant *HTT*) into a region (Area X) of a songbird cortico-BG pathway necessary for juvenile song learning and adult modulation of learned songs. Although adult zebra finches normally sing songs comprising highly stereotyped sequences of syllables, expressing mutant *HTT* in Area X increased syllable sequence variability and the amount a bird would sing each day. In contrast, the spectral features of individual syllables remained stable, indicating that mutant *HTT* selectively disrupts the neural control of vocal sequences. Prior studies have shown that augmenting activity in the output of a cortico-BG pathway, the song premotor nucleus LMAN, which is downstream of Area X, can also increase syllable sequence variability. Here we found that pharmacologically silencing LMAN reversibly rescued the increased variability of syllable sequence in adult zebra finches

expressing mutant *HTT*. These findings advance the zebra finch as a useful model for understanding how mutant *HTT* alters BG circuitry to disrupt the generation and execution of complex motor sequences, including those necessary to speech.

Title: Effects of the 5-HT1BR agonist CP94253 on cocaine-induced locomotion before and after abstinence from repeated cocaine administration in C57BL/6 mice

Authors: *T. DER-GHAZARIAN[1], S. BRUNWASSER[2], K. DAI[2], N. PENTKOWSKI[2], J. NEISEWANDER[2];
[1]Sch. of Life Sci., [2]Arizona State Univ., Tempe, AZ

Abstracts: We previously showed that 5-HT_{1B} receptors (Rs) modulate cocaine abuse-related behavior in opposite directions depending on the addiction cycle phase. Specifically, either viral over-expression of 5-HT_{1B}Rs or a 5-HT_{1B}R agonist given during maintenance of cocaine self-administration enhances cocaine intake in rats. In contrast, following 21 days of forced abstinence these same manipulations decrease cocaine intake, as well as cocaine-primed and cue-elicited reinstatement of cocaine seeking, suggesting adaptations in 5-HT_{1B}R circuitry may be involved in the pathology of protracted relapse. This study investigated the effects of a 5-HT_{1B}R agonist on cocaine-induced locomotion before and after an abstinence period in C57BL/6 mice. To that end, we first treated mice daily with either saline or cocaine (15 mg/kg, IP) for 21 days. On the last day of treatment, after a 1- h habituation period in test chambers, mice received either vehicle or CP94253 (10 mg/kg, IP) and were returned to their home cage for 30 min. Next, mice were injected with saline or cocaine (5 mg/kg) and placed immediately into test chambers for 1 h. The same test session was repeated after 21 days of abstinence. During the treatment phase (i.e., test 1), CP94253 enhanced cocaine hyperlocomotion, whereas after a 21-day abstinence period (i.e., test 2) CP94253 reversed cocaine hyperlocomotion. These findings suggest that 5-

HT_{1B}Rs may offer a novel approach to treating cocaine dependence as the treatment produces anti-cocaine effects during abstinence from chronic cocaine administration.

Title: The subthalamic nucleus keeps you high on emotion: Behavioral consequences

Authors: *Y. PELLOUX, J. MEFFRE, E. GIORLA, C. BAUNEZ;
Inst. de Neurosciences Timone, INT CNRS UMR7289, Marseille, France

Abstracts: The subthalamic nucleus (STN) belongs to the basal ganglia and is the current target for the surgical treatment of neurological and psychiatric disorders such as Parkinson's Disease (PD) and obsessive compulsive disorders, but also a proposed site for the treatment of addiction. It is therefore very important to understand its functions in order to anticipate and prevent possible side-effects in the patients. Although the involvement of the STN is well documented in motor, cognitive and motivational processes, less is known regarding emotional processes. Here we have investigated the direct consequences of STN lesions on emotional processing and reinforcement in the rat. We have used various behavioral procedures to assess affect for neutral,positive and negative reinforcers in STN lesioned and sham control rats. While STN lesions had no effect on responses for a neutral reinforcer (novelty induced place preference), they reduced affective responses for positive (sweet solutions) and negative (electric foot shock,

Lithium Chloride-induced sickness) reinforcers. Furthermore, when given the choice between a bland caloric glucose solution with sweet but non caloric saccharine solution, STN lesioned animals preferred glucose over saccharine, in contrast to sham animals. Taken altogether these results reveal that STN plays a critical role in emotional processing. These results, in line with some clinical observations in PD patients subjected to STN surgery, suggest possible side-effects of treatments targeting the STN. They could also be responsible for the decreased motivation for cocaine reported after STN lesions.

Title: Optical tagging of striatal medium spiny neurons

Authors: ***A. V. KRAVITZ**[1,2], S. F. OWEN[3], A. C. KREITZER[3];
[1]NIDDK, Natl. Inst. of Hlth., Bethesda, MD; [2]Natl. Inst. of Drug Abuse, Baltimore, MD;
[3]Gladstone Inst. of Neurolog. Dis., San Francisco, CA

Abstracts: The striatum integrates information from cortical, thalamic, and mesolimbic inputs to select and guide actions. There are two main projections from the striatum: one to the substantia nigra pars reticulata (SNr), comprised of direct pathway medium spiny neurons (dMSNs), and one to the external segment of the globus pallidus (GPe), made up of indirect pathway medium spiny neurons (iMSNs). Classic models of basal ganglia function suggest that dMSNs facilitate specific motor programs, whereas iMSNs inhibit competing motor programs. Many electrophysiological studies have examined the relationship between striatal activity and movement, particularly with respect to reward-directed movements. Historically, it was impossible to distinguish striatal dMSNs from iMSNs in such recordings using electrophysiological criteria alone; therefore most studies of the striatum have analyzed the two populations together. In recent years, the technique of "optical tagging" has been used to identify

specific cell types in *in vivo* recordings. Briefly, this involves expressing channelrhodopsin-2 (ChR2) in a specific cell type, and identifying ChR2-expressing cells by their response to light. Despite the apparent simplicity of this approach, we encountered multiple potential confounds when applying this approach to identifying dMSNs and iMSNS. Here, we discuss advances and difficulties in applying this technique to dMSNs and iMSNs in striatal recordings.

Title: Comparison of different powers and frequencies in optogenetic stimulation of striatal direct and indirect pathways

Authors: ***D. M. FRIEND**[1], A. KRAVITZ[2];
[1]Interdepartmental Program in Neurosci., NIH, Washington, DC; [2]NIDDK/NIDA, NIH, Bethesda, MD

Abstracts: Although optogenetic stimulation and inhibition has become a standard technique in behavioral neuroscience, few studies have quantitatively explored specific behavioral output in response to varying light powers or stimulation frequencies. Here, we examined motor output in animals with Channelrhodopsin-2 targeted specifically to striatonigral (direct pathway) or striatopallidal (indirect pathway) medium spiny neurons. Animals were placed in behavioral chambers outfitted with LED optical stimulation and tracking software. A range of light powers and frequencies were randomly presented. Following the completion of optogenetic stimulation movement parameters including speed were calculated for the range of light powers and frequencies. As previous work has demonstrated, we show that optical stimulation of striatonigral medium spiny neurons results in increased motor output whereas optical stimulation of striatopallidal neurons inhibits motor output. However, we expand the present knowledge by developing motor output response curves for a range light powers and stimulation frequencies. These data provide a possible mechanism though which optogenetic parameters can be optimized for behavioral experiments, providing a more complete description of behavioral output to a

range of light power and frequencies. Furthermore, these results may also provide novel insight into disease states where altered striatonigral and striatopallidal activity underlies symptoms of the disease.

Title: Optogenetic stimulation of dorsal striatal indirect pathway neurons increases anxiety

Authors: *K. H. LEBLANC[1], D. M. FRIEND[1], A. V. KRAVITZ[1,2];
[1]NIH/NIDDK, Bethesda, MD; [2]NIH/NIDA, Baltimore, MD

Abstracts: It has been well established that activation of the indirect pathway of the basal ganglia inhibits movement. However, indirect pathway medium spiny neurons (iMSNs) also play a role in negative affect. Stimulation of iMSNs in the dorsal striatum has been shown to be aversive, and a number of disorders involving the striatal dopamine system, such as Parkinson's disease, addiction, and obesity, are comorbid with anxiety. Based on this evidence, we hypothesized that iMSNs may respond to anxiety, and thus stimulating these neurons may have anxiogenic effects. Using *in vivo* electrophysiology we found that the firing rate of a subset of iMSNs in the dorsal striatum was substantially higher in either the open or closed arms of the elevated zero maze, suggesting that the firing of these neurons may be linked to anxiety state. Using optogenetic techniques, we have found that directly stimulating iMSNs in the dorsal striatum not only decreases movement but also induces anxiety as demonstrated by a reduction in the amount of time spent in the open arms of an elevated zero maze. This reduction of time in the open arms is separate from the movement effect, since limiting analysis to periods of movement still reveals a decrease in the percentage of time spent in the open arms. Our results indicate a potential role of indirect pathway neurons in the striatum in anxiety, which could have serious implications for a number of disorders, including Parkinson's disease, OCD, addiction and obesity.

Title: Ivestigating activity of striatal Fast-Spiking Interneurons using single unit recordings in rat

Authors: *J. KULIK, K. COFFEY, J. STAMOS, M. WEST;
Rutgers Univ., Piscataway, NJ

Abstracts: The striatum is the largest structure of the basal ganglia and functions as its main input relay. The principal neurons of striatum, Medium Spiny Neurons (MSNs), constitute about 95% of striatal neural population. The remaining 5% of neurons are made up by striatal interneurons. Striatal Fast Spiking Interneurons (FSIs) are parvalbumin positive neurons that contribute less than 1% to the total striatal population. It is becoming increasingly evident that these striatal interneurons play an important role in mechanisms by which competing striatal output is selected. Striatal FSIs are hypothesized to be a main source of inhibition for MSNs. They display a strong medial-lateral distribution gradient, which suggest that they are important for functioning of dorsolateral MSNs which receive direct synaptic input from regions of cortex representing discrete body parts. The aim of the current study was to determine whether it is possible to identify FSIs recorded with extracellular chronically implanted microwires in awake behaving animals and assess whether these identified FSIs display body part sensitivity. Body part sensitivity of recorded neurons was assessed using the same sensorimotor exam that identifies sensitivity of striatal MSNs. Multi-label immunoflourescnece histology was performed to identify parvalbumin positive cells. It was found that staining for parvalbumin can serve as a useful tool for determining the type of neuron recorded with extracellular microwires. A proportion of neurons that expressed characteristics typical of FSIs also showed body part sensitivity. This suggests that striatal interneurons also receive direct cortical input and that dorsolateral striatal interneurons participate in generation of motor output by striatum

Title: The role of basal ganglia beta band oscillations in blinking

Authors: *L. EVINGER[1], J. KAMINER[2], P. THAKUR[3], P. ENMORE[3];
[1]Neurobio. & Behavior, [3]Program in Neurosci., [2]Stony Brook Univ., Stony Brook, NY

Abstracts: Synchronized, exaggerated beta band oscillations in the basal ganglia-cortical networks are characteristic of Parkinson's disease (PD). The correlations of movement planning and movement cues with beta oscillations make it difficult to establish a causal relationship between exaggerated beta band oscillations and the abnormalities in voluntary movements with PD. Because reflex movements occur independently of modulations in beta band strength, however, it is possible to determine whether frequency specific oscillations cause PD reflex abnormalities. We investigated the causal role of beta band activity in the abnormal reflex movements of PD by testing the effects of beta frequency subthalamic nucleus deep brain stimulation (STN DBS) on blink reflex excitability, amplitude, and plasticity in **normal** rats. Delivering 16 Hz STN DBS produced the same increase in trigeminal reflex blink excitability, reduction in reflex blink amplitude, and impairment in blink reflex plasticity in normal rats as occurs in PD patients and rats with 6-OHDA lesions. These deficits were not an artifact of STN DBS because 130 Hz STN DBS did not affect blink characteristics. To demonstrate that the blink reflex abnormalities created by beta frequency STN DBS stimulation were frequency specific, we tested the same rats with 7 Hz STN DBS, a theta band frequency typical of dystonia. In contrast to beta stimulation, 7 Hz STN DBS increased reflex blink excitability, elevated reflex blink amplitude, and exaggerated blink reflex plasticity as occurs in the focal dystonia benign essential blepharospasm. Unlike the frequency specific modifications in blink reflex behavior and motor learning, however, neither beta nor theta band STN DBS modified spontaneous blinking in normal rats. Beta and theta STN DBS can create PD- or dystonic-like abnormalities

in the blink reflex and motor learning circuits of normal rats, but spontaneous blinking must utilize a different circuit.

Title: The role of the substantia nigra in licking behavior

Authors: ***M. A. ROSSI**, J. W. BARTER, H. H. YIN;
Duke Univ., Durham, NC

Abstracts: The substantia nigra pars reticulata, a major output nucleus of the basal ganglia, is thought to be involved in regulating a variety of behaviors including orofacial movements, but the specific relationship between neural activity in the substantia nigra and licking behavior remains unclear. To understand the role of basal ganglia outputs in licking and drinking behavior, we performed chronic, multi-electrode extracellular recordings from substantia nigra neurons as freely behaving mice licked for sucrose solution. We found two opposing populations of putative GABAergic projection neurons in the substatia nigra pars reticulata with activity reflecting the pattern of licks. One population of neurons was excited at the time of the lick, while the second population was excited just before each lick but inhibited at the time of lick. These two neuronal populations therefore show antiphasic activity during licking behavior. To test whether these neurons were involved in patterning the orofacial movements associated with licking, we selectively expressed channelrhodopsin-2 in GABAergic neurons of the substantia nigra. Stimulation of these neurons at the onset of a bout of licking disrupted licking behavior.

Title: Suppression of basal ganglia output selectively impairs the vigor of reaching movements in mice

Authors: K. MARTIN[1], J. BROWN[1], *J. T. DUDMAN[2];
[1]Janelia Farm Res. Campus, Howard Hughes Med. Inst., Ashburn, VA; [2]HHMI, ASHBURN, VA

Abstracts: Animals learn to perform arbitrary, purposive actions with the appropriate timing and vigor to efficiently obtain desired outcomes. The basal ganglia are a collection of subcortical nuclei that have been proposed to play diverse roles in the selection and specification of purposive movements as well as processing signals about reward and timing. However, these aspects of purposive behaviors are frequently correlated making it difficult to disambiguate specific roles of basal ganglia function. Perturbation experiments in primates performing goal-directed reaching tasks have shown that suppression of the basal ganglia output nuclei, the internal globus pallidus (GPi) and substantia nigra pars reticulata (SNr), cause reductions in movement vigor. By contrast, analogous experiments in rodent models have tended to reveal changes in the abundance of movement. We reasoned that these differences could stem (1) from differences in the tasks that the subjects were asked to perform during perturbation; and/or (2) the manipulations performed in primates have been done with pharmacological inactivation whereas experiments in rodents have often confounded movement parameters. To address these issues, we developed a task in which reward receipt was a function of the vigor of lever pressing in head fixed mice. We then used cell-type specific expression of a pharmacogenetic inhibitor to specifically suppress activity in the SNr during behavior. Consistent with prior results in the primate we reliably observed a primary effect on the vigor of purposive, lever pressing movements with relatively little effect on the total amount of behavior or the ability to collect rewards efficiently. However, we also observed changes in the timing of movements unlike recent observations in the primate. We suggest that the observed changes in the timing of actions in our experiments could either reflect the necessity of cell-type specific manipulations that have not been possible in prior experiments or could reflect compensatory strategies to maintain stable reward rates in the face of perturbed motor function. Taken together our results are consistent

with a role for the basal ganglia in the specification of parameters of purposive behaviors when required to obtain stable, high reward rates.

Title: Manipulation of specific movement parameters through pathway selective optogenetic stimulation of the basal ganglia

Authors: *E. A. YTTRI, J. T. DUDMAN;
Janelia Farm - HHMI, Ashburn, VA

Abstracts: The basal ganglia have been proposed to be involved in diverse aspects of voluntary, purposive movements including initiation and termination, selection, valuation, and/or specification of movement parameters. Projections from many areas, including motor or prefrontal cortex, converge in the striatum, the main input nucleus of the basal ganglia. The output neurons of the striatum, medium spiny neurons (MSN) expressing either D1 or D2 receptors, give rise to the direct (dMSN) and indirect (iMSN) pathways, respectively. A common feature of all theories of basal ganglia function mentioned above is that the balance of indirect and direct pathway activity is critical for control of voluntary movement. Using cell type specific gene expression and optogenetics in dMSN and iMSNs we can selectively activate either basal ganglia pathway. We therefore sought to test if the pathway-specific activation could elicit the specification of a movement parameter - namely velocity. We developed a reaching task in which we could monitor multiple movement parameters of single, discrete reaches in a head-fixed mouse. We then used a closed loop paradigm to photostimulate dMSNs or iMSNs in real time during the subset of reaches with suprathreshold velocities. Photostimulation corresponding to only the quickest reaches led to a progressive shift in the mean velocity of subsequent, unstimulated reaches. dMSN stimulation induced an increase in reach velocities while iMSN stimulation induced a decrease of reach velocities. Upon removal of photostimulation, distribution of reach velocities gradually returned to baseline. Importantly, in an open loop paradigm we failed to elicit reach initiation or termination with stimulation of either pathway. These results demonstrate that the basal ganglia can specify a particular component of movement and strongly suggest a role for the basal ganglia in the regulation of movement vigor.

Title: A center-out joystick task for quantifying motor variability in mice

Authors: T. BOLLU, *J. H. GOLDBERG;
Dept. of Neurobio. and Behavior, Cornell Univ., Ithaca, NY

Abstracts: Exploratory variability is a key component of trial and error learning, but the brain circuits that generate and/or control it remain poorly understood. Recent data from songbirds indicate that specific parts of dopamine-basal ganglia-cortical loops actively introduce variability into juvenile song [1,2], raising the possibility that homologous mammalian motor circuits are endowed with similar 'variability-generating' functionalities [3]. New genetic and optical methods make mice an ideal model system for dissecting mammalian circuits for motor control [4,5], but the expansion in experimental tools has not been matched by an expansion of behavioral paradigms for motor learning. To address this issue, we adapted a center-out joystick task, commonly deployed in primates [6,7], for use in mice. Mice learned to move custom-made joysticks for reward, allowing forelimb trajectories to be monitored and shaped with high (micron, sub-millisecond) spatiotemporal resolution. Because the joysticks were integrated into computer-controlled, rack-mountable home cages [8], our setup can be scaled up for high throughput behavioral experiments, and can thus be an effective platform for studying neural circuits for motor variability and learning. - 1. Title: Substantia nigra dopaminergic neurons are critical for the initiation of self paced actions

Authors: *J. ALVES DA SILVA[1], F. TECUAPETLA[2], V. PAIXÃO[1], R. M. COSTA[1];
[1]Champalimaud Neurosci. Programme, Champalimaud Ctr. for the Unknown, Lisbon, Portugal;
[2]Inst. de Fisiología Celular, Univ. Nacional Autónoma de México, Mexico City, Mexico

Abstracts: We frequently initiate new actions and transitions between actions. Although vital to our survival, most of the time we are not aware of this orchestration of action sequences. However for people with Parkinson's disease initiating movement when they want becomes specially daunting. Among other changes in the brain, these patients present with a loss of substantia nigra compacta (SNC) dopaminergic neurons. Recently, phasic activity of these same neurons has been found to be correlated with the start and stop of a learned action sequence. However, it is still not clear if this activity is necessary for action initiation. We are using an optogenetic approach to evaluate the role of SNC dopaminergic neurons in the initiation of self paced movement in mice. This strategy enables us to specifically inhibit or activate dopaminergic neurons, with millisecond resolution, while analysing mice behavior using 3-axis accelerometers and video recordings. We have found that inhibiting SNC dopaminergic neurons while mice were exploring an open field, lead to a decrease in motion and an increase in the time spent immobile. However if the mice were moving before inhibition started, their motion did not change until they stopped for the first time. Likewise, the latency to stop was not different during inhibition. On the other hand, if the mice were not moving before the inhibition, they stayed immobile or in a low acceleration state during the period of inhibition. Mice were also trained in a self-paced operant task and developed a particular sequence of actions to obtain an outcome.

We found that inhibiting SNC dopaminergic neurons just before action initiation, delayed the start of the action sequence. However, if the inhibition started immediately after the action sequence was initiated, the performance of the action remained unchanged. In preliminary experiments, a very brief activation of SNC dopaminergic neurons was sufficient to promote movement when the mice were immobile in the open field. These observations suggest that SNC dopamine neurons are specifically necessary for the initiation of movement but not for the maintenance of ongoing movements. To corroborate these findings, we are recording the activity of genetically identified dopamine neurons during movement/action initiation.

Title: Beyond reward prediction errors: Basal ganglia output and dopaminergic signaling correlates with movement kinematics

Authors: *J. W. BARTER, S. LI, T. SUKHARNIKOVA, M. A. ROSSI, R. BARTHOLOMEW, H. H. YIN;
Psychology and neuroscience, Duke Univ., Durham, NC

Abstracts: Using wireless recording from single neurons, we measured basal ganglia output from the substantia nigra pars reticulata and dopamine neurons in the neighboring pars compacta in freely moving mice, while quantifying their behavior with motion tracking. We found that the firing rate of nigral GABAergic output neurons reflected the Cartesian coordinates of the animal's head position in space, while the firing rate of nigral dopamine neurons reflected the acceleration of the animal's head in Cartesian space. GABA cells can be separated into two major groups: x-coordinate neurons and y-coordinate neurons. Together the firing rates of these two groups of GABA neurons can be used to accurately determine the (x,y) position of the

animal's head, while the activity of dopamine neurons is correlated with movement acceleration and deceleration, and can be used to determine movement velocity. Such correlations with kinematics, independent of outcome valence (rewarding or aversive), are found in the majority of recorded neurons (r as high as 0.99). Our results reveal the functional role of basal ganglia in controlling body position and movement. They suggest that previous results in support of the reward prediction error hypothesis for dopamine function can be explained by movement kinematics during the behavioral tasks. They have significant implications for understanding and treating movement disorders involving the basal ganglia, e.g. Parkinson's disease, which is characterized by postural deficits and slowness of movement.

Title: Striatal substrates for making and breaking habits

Authors: *J. O'HARE[1,2], K. ADE[1,2], T. SUKHARNIKOVA[3], H. YIN[3], N. CALAKOS[1,2]; [1]Neurobio., [2]Neurol., Duke Univ. Med. Ctr., Durham, NC; [3]Psychology & Neurosci., Duke Univ., Durham, NC

Abstracts: Habit formation is an adaptive form of motor learning employed broadly in the animal kingdom. Habitual behavior reduces attentional and computational demands for routine activities. However, it is also believed that mechanisms underlying habit formation may be co-opted by drugs of abuse and disrupted in neuropsychiatric diseases leading to harmful compulsive behavior. A mechanistic understanding of habit formation therefore stands to benefit a broad population by providing insights to a basic brain learning mechanism as well as informing development of treatments to facilitate adaptive habit learning and/or extinguish

pathological compulsions. Habit formation is known to require the dorsolateral striatum (DLS) and is accompanied by changes in firing activity in both DLS and cortical regions *in vivo*. Although DLS is required and its activity is altered *in vivo*, it is not known whether habit-related changes in DLS activity are a read-out of altered afferent activity or driven by plasticity local to the striatal microcircuit. To determine whether local striatal adaptations that alter striatal output are associated with habit formation, we examined action potential firing properties of striatal projection neurons (SPNs) in response to controlled activation of cortical inputs *ex vivo* in mice trained to varying degrees of habitualness using established lever press protocols. Firing properties were simultaneously measured in dozens of DLS projection neurons of defined projection type using a combination of BAC transgenics, calcium imaging and two photon laser scanning microscopy. We found that properties of DLS SPN firing correlated strongly with habitual behavior. Moreover, training aimed at extinguishing the learned habitual behavior eliminated habit-correlated activity changes. In some cases, inverse correlations emerged. Taken together, these findings indicate that the neural substrate for habit expression may reside locally in the striatal microcircuitry and provide general support for contemporary models of motor learning in the basal ganglia.

Title: Cell type specific coding of movement kinematics in the sensorimotor striatum

Authors: ***H. H. YIN**, N. S. KIM, J. BARTER;
Dept. of Psychology and Neurosci., Duke Univ., DURHAM, NC

Abstracts: Using wireless multi-electrode recording, we measured single-unit activity from neurons in the sensorimotor or dorsolateral striatum in mice, while monitoring their movement kinematics in real time with motion capture. We recorded from three types of neurons, which are classified according to their waveform, firing rate, and inter-spike-interval distribution: putative

medium spiny projection neurons, putative fast-spiking interneurons, and putative giant cholinergic interneurons. The firing rate of most recorded medium spiny neurons and fast-spiking interneurons reflects movement velocity, whereas the firing rate of most cholinergic interneurons reflects position in Cartesian coordinates (x and y). We are currently using 3D motion capture to study the correlations with movement in the additional z-axis. These results show for the first time cell-type specific "coding" of movement kinematics in the striatum, as proposed by a recent model (Yin, 2014). Yin HH (2014) Action, time and the basal ganglia. Title: The mesencephalic locomotor region integrates motor, cognitive, and emotional information: An anatomical substrate for differential roles of the pedunculopontine and the cuneiform nuclei

Authors: C. KARACHI[1,2], *B. LAU[1], A. ANDRÉ[2], D. TANDÉ[1], E. C. HIRSCH[1], C. FRANÇOIS[1];
[1]Inst. du cerveau et de la moelle épinière, Paris, France; [2]Dept. of Neurosurg., AP-HP, Hôpital de la Pitié-Salpêtrière, Paris, France

Abstracts: The mesencephalic locomotor region, including the pedunculopontine (PPN) and cuneiform nuclei (CuN), is thought to have a central role in gait and postural control. The MLR is also implicated in functions including sleep, attention, and emotion. We used tract-tracing in monkeys to understand how the inputs and outputs of the MLR relate to these diverse functions. We show the PPN receives inputs from motor, associative and limbic cortices, and projects back to the motor, associative and limbic territories of the basal ganglia and thalamus, as well as the substantia nigra pars compacta. In contrast, the CuN receives inputs exclusively from associative

and limbic cortices, and projects back to the limbic territory of the basal ganglia and thalamus, as well as the ventral tegmental area, basal forebrain and amygdala. Our findings suggest the PPN integrates motor, cognitive, and emotional information, whereas the CuN integrates cognitive and emotional, but not motor, information.

Title: Active avoidance in non-human primate, a behavioural paradigm to investigate neural bases and serotonin modulation effects on anxiety related disorders

Authors: *G. DRUI, Y. SAGA, A. RICHARD, V. SGAMBATO-FAURE, L. TREMBLAY; CNRS UMR5229 - Ctr. of Cognitive Neurosci., BRON, France

Abstracts: Each day, beyond the behaviors associated with positive outcomes (approach towards appetitive stimuli), a lot of stimuli or events is associated to a negative outcome and induces aversive anticipation to produce avoidance behaviors. Serotonin has been linked to anxiety as well as impulsivity behaviors, thus highlighting this neuromodulator in the aversive processes. To study the neurobiological and pharmacological mechanisms implied in aversive information processing, we have developed an update version of the classical instrumental delay task. The monkeys were trained to recognize and associate conditioned visual stimuli (CS) with appetitive outcome (juice) and visual CS with aversive outcome (air puff) in two different conditions. In a choice condition, on every trial, two opposite CS are presented simultaneously and the animal could select an action between approaching the appetitive and actively avoid the aversive outcome. In opposite, for imperative condition, one of the CS is presented, so they must either approach the appetitive stimulus or actively avoid the aversive ones, depending on the CS

presented. Thus, this task will allow us to determine the cerebral structures involved in the value-based decision making in appetitive or aversive contexts and their specific roles during different processes (CS presentation, decision and the delay periods). Moreover, the intrinsic value of stimuli in the behavioral response is also evaluated by using different type of motivational domain (e.g natural, social and learned stimuli). We showed that monkeys performed approach for appetitive trials (in imperative and choice context) and avoidance for aversive trials. Progressively during the daily session, the strategy of the animals to the aversive stimuli is modified and they produce premature responses facing negative CS, which could be interpreted as an escape reaction. Interestingly, we can retard this type of response by pharmacological manipulations of the serotonergic system. This task could allow the investigation of the role of the cerebral structures as ventral striatum (see Richard et al., *SFN* 2014) and the neuromodulator systems involved in aversive processes lays the foundation for a better understanding of the pathophysiology of psychiatric disorders such as obsessive compulsive disorders, panic disorder, depression, and anxiety, where anticipation, detection, and avoidance of aversive events or contexts appear to guide decisions and behaviors.

Title: Characterization of aversive-related neuronal activity and negative motivation disorders induced by local dysfunction inside ventral striatum in monkey

Authors: *A. RICHARD[1], Y. SAGA[1], G. DRUI[1], E. HOSHI[2,3], V. SGAMBATO-FAURE[1], L. TREMBLAY[1];

[1]Ctr. Des Neurosciences Cognitives, Bron Cedex, France; [2]Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan; [3]CREST, JST, Tokyo, Japan

Abstracts: The ventral striatum, which belongs to a limbic circuit, is involved in reward processing. Human brain imaging and animal pharmacological studies have suggested that ventral striatum is also involved in aversive information processing. To investigate the striatum implication in aversive encoding and behavioral disorders that characterized negative motivation dysfunctions, we recorded its neuronal activities and disturbed its different parts. Two monkeys were trained to perform two versions of a delay task (see Drui et al., SFN 2014) in which they had to associate visual conditioned stimuli (CS) with appetitive (juice) or aversive outcome (air puff). In the choice context, on every trial, the monkey can choose between approaching the appetitive stimulus and avoiding the aversive one. In imperative context, only one CS is presented by trial, so the monkey must either approach the appetitive stimulus or actively avoid the aversive one. Monkeys performed approach in positive CS trials (imperative and choice task) and active avoidance in the majority of negative CS trials. Among anterior striatum neurons exhibiting a task related activity, a large percentage (5-15% depending on the analysis period) of them encoded selectively or preferentially negative value during CS presentation or aversive outcome delivery and also before the aversive CS, an aversive anticipation. Interestingly, these neurons could be expressed and dissociated from the appetitive ones only in imperative context when monkeys have to actively avoid aversive outcome, but not in choice context. Moreover, these negative value neurons were not only located in the ventral and central part of the striatum, as expected on the basis of local disturbances study (Worbe et al., 2009), but widely distributed in various parts of the anterior striatum. Finally, results from reversible perturbations into different part of the anterior striatum strongly support the involvement of this structure in the negative stimulus value encoding as well as in learning how to avoid predicted negative outcomes. Indeed, the majority of local perturbations into the anterior striatum induced difficulties only to perform active avoidance in the aversive context. The monkeys produced premature responses or omissions which seemed to be underpinned by hypersensitivity toward negative CS stimuli and induced the escape reactions. All these results suggest that the whole anterior striatum encodes positive and negative information and plays a crucial role in controlling, not only involved in approach for reward, but also in active avoidances from predictable aversive events or contexts.

Title: Parcellating the internal and external globus pallidus using diffusion based clustering

Authors: *P. BEUKEMA[1,2], T. VERSTYNEN[3];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA;
[3]Carnegie Mellon Univ., Pittsburgh, PA

Abstracts: The internal and external segments of the globus pallidus have been difficult to distinguish in human neuroimaging due to poor visualization of nuclear boundaries with standard structural MRI based approaches. Segmentation of other sub-cortical nuclei has been shown using k-means clustering on the gray matter diffusion signal [Deoni et al. NeuroImage., 2007]. Similar diffusion weighted imaging (DWI) approaches may be useful for isolating the segments of the pallidal nuclei as well. Using an MNI-space orientation distribution function (ODF) reconstruction method [Yeh & Tseng, NeuroImage., 2011] on diffusion spectrum imaging data from 60 neurologically healthy adults (29 male, mean age = 26 years), we examined the diffusion structure of the internal and external segments of the globus pallidus using two metrics: quantitative anisotropy (QA) and orientation of the peak fibers in the ODF. Using euclidean distance, we segmented the pallidum into its approximate internal and external segments. For each segment, we then extracted the QA values for both the primary and secondary fibers as well as the fiber directions in the axial, coronal, and sagittal planes. We found that QA of both the primary and secondary fibers is higher in the GPe relative to the GPi. In the axial plane, orientation of the secondary fibers peaked at +/- 1.5 radians in the GPi whereas the GPe lacked any significant peaks. In the coronal and saggital planes, the distribution of the primary and secondary fibers largely overlapped. Using k-means clustering on euclidean distance, QA and peak fiber orientation, we generated probabilistic maps of the left GPi and GPe. The volume of the GPi is approximately 40% of the volume of the GPe, similar to others estimates of the relative sizes of the two nuclei in humans [Keuken M.C. et al. NeuroImage, 2014]. These results show that DWI can provide an unbiased and semi-automatic parcellation of the pallidum which will benefit future fMRI and structural studies of the basal ganglia pathways.

Title: Differentiating serial cue prediction from motor sequence learning during long term skill training

Authors: *B. T. LYNCH[1], A. TING[1], S. WILHELMI[2], D. MARCHETTO[1], T. VERSTYNEN[1]; [1]Psychology, [2]Biol., Carnegie Mellon Univ., Pittsburgh, PA

Abstracts: Acquiring a novel sensorimotor sequence requires either learning a serial order of response cues or binding a sequence of motor actions together, or both. Using an indirect cuing version of the serial reaction time (SRT) task, we measured the independence of cue and response learning across a 5-day training period. On each trial, a centrally presented symbol (Cyrillic letters) cued subjects to press one of 4 keys on a keyboard with their right hand. On each day, the mapping from cue to key was pseudo-randomly assigned and subjects were trained to learn this new mapping. After two blocks (144 trials per block) of randomly ordered cues, subjects were trained on a hidden 12 item sequence for two blocks, followed by another random block and then a final sequence block. Subjects were randomly placed into two groups (N=15, 6 males per group). The Cue group was exposed to the same sequence of visual cues over all 5 training days. The Response group was exposed to different orders of visual cues but repeated the same sequence of key presses across days. Learning-related changes in response time showed a significant group-by-day interaction ($F(4,112)=3.72$, $p = 0.007$). Response times during sequence blocks, relative to random blocks, reached asymptote in the Cue group by Day 3, but no such asymptote was present in the Response group. Accuracy improved over time (main effect: $F(4,112)=9.06$, $p<0.001$) but both groups learned to improve their accuracy similarly across days (group-by-day interaction: $F(4,112)=2.30$, $p=0.064$). This advantage for learning consecutive cues did not appear to relate to knowledge of the sequence since both groups showed similar levels of explicit awareness, based on a post-hoc questionnaire. These results show that there is an immediate advantage to learning sequences of visual cues over sequences of actions during long term skill training.

Title: Action monitoring by the striatum is critical for accurate execution of procedural memories

Authors: *P. E. RUEDA-OROZCO, D. ROBBE;
Inst. De Neurobiologie De La Méditerranée, Marseille, France

Abstracts: The striatum is crucial for the acquisition of procedural memories such as action sequences and motor skills but its role during the execution of already learned procedures is unclear. Here we created a task in which rats learned a running sequence with precise trajectory, running speed and acceleration timing. After training, tetrode recordings in the dorsolateral striatum (DLS) revealed robust representations of running speed, position and time but no correlates of acceleration. Speed and position representations were weak in naive rats performing the running sequence under guidance of the experimenter and increased after learning. Finally, DLS inactivation augmented variability of sequence execution. Altogether the data revealed a new moment-to-moment action monitoring function of the DLS operating through contextual and movement-related representations that is instrumental for accurate execution of learned action sequences. This finding provides a new framework to understand the contribution of the basal ganglia to motor control.

Title: The difference between stopping and deciding not to go: Behavioral, imaging and modeling evidence

Authors: *K. E. DUNOVAN[1,2], T. MOLESWORTH[3], T. VERSTYNEN[2,3];
[1]Psychology, Univ. of Pittsburgh, Pittsburgh, PA; [2]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA; [3]Psychology, Carnegie Mellon Univ., Pittsburgh, PA

Abstracts: While general inhibitory control relies on overlapping cortico-basal ganglia circuitry, the various subtypes of behavioral inhibition (e.g., stopping vs. go/no-go decisions) may reflect separable corticostriatal pathways (Swick. et al. NeuroImage 2011). We tested the behavioral and neural separability of two types of inhibitory control using a modified stop-signal task. Subjects were instructed to stop a rising bar when it intersected a target line (500ms after onset) by pressing a key. Subjects were instructed not to respond if the bar does not intersect the line. In Reactive stopping trials, the bar would stop at various intervals in its trajectory. In Proactive stopping trials, the bar would stop 50ms before intersecting the line and subjects were told to make a go/no-go decision based on a color cue indicating the probability that the bar will stop on any given trial. Behaviorally (N=61, 28 male) we found a weak correlation between stopping performance in Reactive and Proactive tasks ($r=0.24$, $p=0.03$, r-square = 0.06) suggesting that the ability plan a go/no-go decision is only weakly coupled with ability to suppress an unwanted action. In addition, performance in the Reactive task was modulated by reward contingencies, while Proactive task performance was not. Finally, event-related fMRI analysis (N=28, 7 male) showed that successful Proactive stopping differentially engaged rostral prefrontal areas in the superior frontal gyrus and anterior cingulate, while Reactive stopping engaged more caudal premotor and pre-SMA regions. From this behavioral and neural evidence, we propose a contingent two-stage decision model of behavioral inhibition. The model frames go/no-go decisions as a competitive drift-diffusion process in which the rate of evidence accumulation towards the go boundary is modulated by contextual factors (e.g.. probability or reward). In the event of a stop-signal, a second process is initiated in which a strong inhibitory signal must override the current level of evidence in order to suppress the response. This nested decision

model provides a plausible framework for how different executive processes interact during inhibitory control.

Title: Highway from the Danger Zone: Interactions between uncertainty and cost in spatial estimation

Authors: *K. JARBO[1,2], R. FLEMMING[3], T. VERSTYNEN[1,2];
[1]Psychology, Carnegie Mellon Univ., Pittsburgh, PA; [2]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA; [3]Univ. of Pittsburgh, Pittsburgh, PA

Abstracts: Cost calculations in spatial sensorimotor tasks are made in a statistically optimal manner (Wu, Delgado, & Maloney, 2009); however, the accuracy and precision of this performance is affected by the saliency of the sensory cues (van Beers, Baraduc, & Wolpert, 2002). It remains unclear how cost estimation is influenced by sensory uncertainty. In two experiments with a novel paradigm, we evaluated the interaction between cost calculations and sensory reliability. Adult participants used a mouse to estimate the mean location of a target zone defined by a Gaussian distribution of white dots presented for 300ms in a random screen location. In some conditions, a Gaussian distribution of red dots that defined a distractor (i.e., danger zone) simultaneously was presented to the left or right of the target. In Experiment 1 (N=6), we examined whether spatial decisions are affected by the presence of a distractor at different levels of spatial uncertainty: low or high target zone variance versus low or high danger zone variance. We observed a significant selection bias away from the danger zone, $t(5) = -2.68$, $p = 0.022$, and decreased accuracy, $t(5) = -4.95$, $p = 0.002$, in the high variance condition, with no effect of the danger zone on target mean estimation in the low variance condition. Given that the distractor did not affect spatial selections at low target variance, in Experiment 2 we examined the effects of penalty and spatial uncertainty of the distractor. Reward gains and penalty losses decreased exponentially as a function of the spatial distance between the final selection and the mean of the target and danger zones, respectively. Participants (N=7) were tested under three conditions: low danger zone variance with no penalty, and low or high danger

zone variance with penalty. Only the high variance penalty manipulation resulted in a significant selection bias away from the danger zone, $t(6) = 3.01$, $p = 0.012$, and reduced accuracy, $t(6) = 4.13$, $p = 0.003$. Taken together, these results confirm that sensory uncertainty can bias cost calculation processes during spatial estimation, whereby people are more influenced by penalty costs in high variance contexts.

Title: Learning to stop or waiting to go: Targets of adaptive Bayesian updating during inhibitory control

Authors: *T. D. VERSTYNEN, L. SCHOLL, T. MOLESWORTH;
Carnegie Mellon Univ., Pittsburgh, PA

Abstracts: When planning an action, it is sometimes necessary to terminate an initiated motor program before it is fully executed. This ability to stop is adapted probabilistically based on previous experience (Shenoy & Yu, 2011). Here we evaluated whether this process reflects the acquisition of internal Bayesian priors for stopping and whether this adaptation occurs at the motor inhibition process or action selection (i.e., go) process. In a modified version of the stop-signal reaction time (SSRT) task, participants saw a rising bar approach a target line near the top of the computer screen. The bar intersected the line 500ms after trial onset and participants were told to stop the moving bar as close to the target line as possible by pressing a key (Go trials). On a subset of trials (31%), the bar stopped before hitting the target line. Participants were instructed to not press the key if the bar did not intersect the line (Stop trials). On a vast majority of Stop trials (71%) the bar stopped at a randomly selected time, sampled from one of 3 distributions: Uniform, Early gaussian (mean=250ms, std=35ms), Late gaussian (mean=350ms, std=35ms). These context trials were used to establish a temporal probability of stopping and subjects were

assigned to one context type (N=25 per group). The remaining Stop trials were used to estimate the SSRT, with preset stop times ranging from 200-400ms. Consistent with a normative Bayesian updating model, the SSRT was modulated by context trials ($F(2,74)=10.96$, $p<0.001$), with the Early group having the longest SSRT (217ms), followed by the Uniform (206ms) and Late (188ms) groups. However, contrary to learning a prior on the stop-signal itself, it appears that the contextually-mediated behavioral changes were driven by changes in the Go trial reaction time (RT) instead of the stop signal itself ($F(2,74)=10.07$, $p<0.001$): Early (RT=535ms), Uniform (RT=542ms), Late (RT=556ms). Our results indicate that adaptive priors are learned on the trigger to initiate an action, by either accelerating or delaying the go decision, rather than on the inhibitory systems themselves.

Title: Simulating conditions in which striatal learning assigns behavior control to the fastest-computed reward-predictive representations of cues and contexts

Authors: *S. PATRICK[1], D. BULLOCK[2], A. GORCHETCHNIKOV[2], A. SOHAIL[2], M. VERSACE[2];
[1]Cognitive and Neural Systems, [2]Boston Univ., Boston, MA

Abstracts: Research has documented shifts during learning between the cortical representations that control behavior. A well-known case is the shift during maze learning from a place strategy, involving cognitions that depend on visibility of distal landmarks, to a habit/response strategy, involving only local cues. Whereas shifts to fast habitual behaviors occur when contingencies are stable, they need to be undone whenever contingency changes render formerly valid representations invalid as guides to rewarding behaviors. Viewed abstractly, the brain's action selection system needs to reassign behavior control to whatever representations are currently valid, and among those, to ultimately favor representations that can be computed in the shortest time, with least cost. Often the information that guides shifts is the pattern of behavior-dependent

reward occurrence and omission, which has systematic effects on dopamine signals. Research implicates different compartments of striatum in the mediation of behavior control by distinct types of representations. The research reported here used computer simulations of dopamine-dependent learning at cortico-striatal synapses to study how the direct and indirect pathways of the basal ganglia can assign and reassign behavior control among cortical representations that take different times to compute and that have predictive validities that change in accord with shifting contingencies of reinforcement. Besides representation validity and the time it takes to compute a representation, factors varied in these simulations included: distinct learning rates in different striatal compartments; distinct asymptotic values of cortico-striatal synaptic strengths in different striatal compartments; and the degree of asymmetry between effects of dopaminergic signal changes on synaptic plasticity in the direct and indirect pathways. Beyond control-switching, the model variants were also assessed for their ability to exhibit "savings" of previous learning across an interval when a contingency is temporarily inoperative or even reversed; such savings are indicated when reacquisition of behavior control by a representation is much faster than initial acquisition. Comparison of the successful model variants with unsuccessful ones illuminates factors that may be vital for the ability of the striatum, as part of an adaptive action selector, to use reinforcement learning to assign behavior control to the fastest-computed representation of cues and contexts that are currently valid guides to action selection.

Title: A neural model of sleep deprivation effects on motor preparation and response: simulating adenosinergic, dopaminergic and cholinergic effects

Authors: *D. H. BULLOCK[1], M. A. ST. HILAIRE[2,3,4];
[1]Psychological & Brain Sci., [2]Boston Univ., BOSTON, MA; [3]Div. of Sleep and Circadian

Disorders, Brigham & Women's Hosp., Boston, MA; [4]Div. of Sleep Med., Harvard Med. Sch., Boston, MA

Abstracts: Increases in reaction times (RTs) are observed on tasks of planned and reactive movements during sleep deprivation. These sleep deprivation effects are partly mediated by accumulations of extracellular adenosine in the basal forebrain (BF), which includes arousal-related corticopetal cell types such as cholinergic cells of the nucleus basalis. To compute predicted effects of adenosine within BF and on RTs, it is necessary to model the strong GABAergic projections to BF from the striatum, as well as pathways by which these subcortical interactions can affect cortically-mediated cueing of motor responses in RT tasks. We therefore extended an existing model of cued action control by circuits spanning cortex and basal ganglia (BG, including striatum). The enhanced model explains how the laminar frontal cortex interacts with parietal cortex, BG/BF, thalamus and the superior colliculus to generate planned and cued movements. In addition to modeling mean sleep deprivation effects on two standard saccade tasks, the model can generate RT distributions comparable to empirical distributions from the psychomotor vigilance task, a test of sustained attention that requires a manual response to a visual cue with a high signal rate. Under sleep deprivation, the RT distribution shifts towards longer RTs despite a co-occurring increase in premature responses. Analysis focuses on four key additions to the prior model: (1) a preparatory process that primes activity in the BG direct pathway in expectation of the cue to act; (2) habituative (thus waning) excitation of the BG's indirect pathway during the fixation interval; (3) BG-influenced cholinergic cell populations in the BF whose cortical projections modulate attention to fixation and cue stimuli; and (4) adenosinergic interactions, primarily in the BG's direct and indirect pathways, that modulate cholinergic cortical arousal as well as cue-dependent BG signaling. Beyond simulating effects of sleep deprivation on oculomotor and manual responses, this detailed circuit model helps understand the local actions in BG/BF of two wake-promoting pharmaceutical agents: caffeine, an adenosine antagonist and modafinil, a dopaminergic agonist.

Title: Decay of motor memories is independent of context change detection

Authors: *A. E. BRENNAN, M. A. SMITH;
Harvard Univ., Cambridge, MA

Abstracts: Recently learned movement patterns gradually decay without an error signal. The prevailing hypothesis for this is that recently acquired motor memories are intrinsically volatile, resulting in an inevitable decay in the absence of ongoing error signals that allow performance decrements to be corrected. A recently proposed alternative posits that motor memories decay only if a change in context is detected (Vaswani & Shadmehr 2013). This hypothesis would require a novel architecture for error-based learning and memory storage, with a bank of highly stable but rapidly addressable parallel memory stores accessed by context. However, this new hypothesis has not yet undergone widespread scrutiny. Using the same experimental paradigm as Vaswani & Shadmehr, we tested the context change hypothesis by masking the transition from a training period to a retention period. This was achieved using variable error clamp (vEC) trials during the retention period to enforce movement variability that matched the variability of the training period, since the context change hypothesis maintains that movement variability is a key contextual feature and that maintaining movement variability continuity can effectively mask the context change between training and retention blocks. The vEC retention period was compared to a zero-error clamp (zEC) based retention period, where all movements were clamped to have zero error with minimal movement variability, resulting in a sudden change from the training period variability. The context change hypothesis predicts that, compared to the zEC retention period, the vEC retention period would substantially delay the onset of decay and reduce the amplitude of decay as subjects would have greater difficulty detecting the context change. Despite the vEC-based retention period resulting in dramatically improved continuity in movement variability and reward frequency following the training period, we found with 95% confidence that the population average delay was only 1 trial or less in both the zEC and vEC retention periods and that the zEC and vEC retention periods had very similar decay magnitudes (58±6% vs 62±5%, $p>0.6$). These results are in stark contrast to the 90 trial delay and the nearly complete elimination of decay previously reported for the vEC retention period. Further analysis reveals that the previous findings were likely due to biased parameter estimation and unbalanced experimental design. These results suggest context detection does not drive the observed decay in the absence of error, but instead that trial-by-trial decay is an integral part of error-based learning.

Title: Time scales of motor memory in cerebellar ataxia

Authors: ***M. A. SMITH**, A. M. HADJIOSIF;
Sch. Engin., Harvard Univ., CAMBRIDGE, MA

Abstracts: The cerebellum is believed to be crucial for motor learning, and cerebellar damage can profoundly impair motor learning ability in humans and animals. Computational studies have demonstrated that multiple adaptive processes with different time scales contribute in parallel to motor learning; however, we do not yet understand whether the cerebellum differentially contributes to specific time scales of learning. Recent work from our laboratory has shown that the fastest time scale in motor adaptation is based on a temporally-labile motor memory that decays away rapidly with a time constant of just 15-20 seconds, whereas slower timescales display a level of temporal stability that is at least 100-fold greater. Here we performed a trial by trial reanalysis of the data from three recent studies (Smith & Shadmehr 2005, Hemminger et al 2010, Gibo et al 2013) that demonstrated impaired motor adaptation ability in participants with cerebellar damage in order to examine whether this damage differentially affects temporally-labile versus temporally-stable learning. . The main idea behind the new analyses we performed is that these studies had paradigms in which multiple movement directions were randomly interleaved and rest breaks between movements were occasionally offered during the training epoch, resulting in large movement to movement differences in the time interval between consecutive movements in the same direction. This allowed the temporal stability of the newly learned motor adaptation to be determined. Remarkably, we found significantly greater reductions in temporally-stable adaptation compared to temporally-labile motor adaptation in

individuals with cerebellar damage ($p<0.01$). Decreased temporally-stable adaptation was observed when either movements to different directions or rest breaks intervened between consecutive movements in the same direction. In contrast, temporally-labile adaptation appeared to be either entirely spared or even slightly improved in individuals with cerebellar damage. These results suggest that the different time scales of motor adaptation have distinct neural bases and that the fastest time scale does not depend on cerebellar function.

Title: A modified random walk describes the low dimensional structure of motor variability in reaching trajectories

Authors: *Y. R. MIYAMOTO, M. SMITH;
Harvard Univ., Cambridge, MA

Abstracts: Ever-present movement-to-movement variations in our motions prevent us from exactly repeating our actions. This motor variability is a fundamental feature of our motor system, but little is known about how it evolves during movement. Here we investigated this evolution in an experiment in which subjects performed rapid (300-450ms) point-to-point reaching arm movements to trace a smooth 20cm path displayed on a monitor, without visual feedback about hand position. Subjects demonstrated considerable trial-to-trial variability in their hand paths; however, this variability was surprisingly low-dimensional, as over 99% of the variance in hand path shape was explained by just 3 principal components (PCs). These PCs were strikingly consistent in shape ($r > 0.96$ between each individual's PCs and the group mean) and fraction of variance accounted for (90±3%, 8±3%, & 1±0.5%) across individuals. Remarkably, we found that a simple random walk could largely account for the low dimensional

structure we uncovered, predicting (1) the time course by which variability evolved during the motion (average R2 = 0.81 across subjects), (2) the shapes of the 1st three PCs (average R2 = 0.83, 0.89, & 0.86 across subjects), and (3) the fraction of the variability in hand path shape that each accounted for (predictions of 85%, 8%, & 3%). Despite the apparent success of this model in describing the pattern of variability we observed, we noticed that variance in subjects' hand paths often evolved superlinearly with time, whereas variance increases linearly for a pure random walk. To address this discrepancy, we modified the random walk model (Model: x(n+1) = x(n) + A*(x(n) - x(n-1)) + Gaussian noise), by supplementing each step of the walk (x(n+1) - x(n)) with a single "momentum" factor (A), representing the motion conservation present in viscoelastic dynamics, that propagates the previous step (x(n) - x(n-1)). This revised model, with only a single additional parameter, accounted for the vast majority of the remaining variation in the hand path shapes unexplained by the pure random walk model. In particular, it explained (1) the shape of how variability evolves during the course of subjects' hand paths (average R2 across subjects = 0.99), (2) the shapes of the 1st three PCs (average R2 across subjects = 0.99, 0.97, & 0.99 for PC1, PC2, and PC3 respectively), and (3) the dimensionality of the variability (the 1st three PCs accounted for 93%, 5%, & 1% of the modeled motor variability). The ability to accurately model the propagation of motor variability with such a simple model may prove to be a valuable tool for further understanding both the nature of motor variability and its consequences for motor control.

Title: The effect of visual feedback latency on the retention and internal representation of visuomotor learning

Authors: *A. M. HADJIOSIF, K. E. MALLETT, M. A. SMITH;
Harvard Univ., Cambridge, MA

Abstracts: Delays in visual feedback may have important consequences for motor learning, as this learning is often driven by the comparison between observed and expected sensory feedback. Previous studies (Kitazawa et al 1995, 2002) have suggested that delays in the presentation of endpoint-only visual feedback (VFB) reduce the rate and amount of visuomotor adaptation, even for delays as short as 50ms. This sensitivity to very small delays is especially important as LCD projectors used in some experimental setups can have latencies as large as 100ms. However, when VFB of motion is continuously provided rather than being relegated to the endpoint, the effects of visual latency are unknown. Here we investigate the effects of small VFB latencies between 25 and 300ms on the learning of a visuomotor rotation (VMR) during point-to-point reaching arm movements. Following a 240-trial baseline period, we trained 4 groups of subjects for 120 trials in a single movement direction on a ±30° VMR. Each group of 10-11 participants experienced a different visual latency (25, 50, 87 or 300ms) present in both the baseline and training periods. After training, VFB was removed and subjects were tested for retention after a 60s wait period and then tested for generalization in 19 different target directions. The smallest latency we tested corresponded to the base delay inherent in our experimental setup, which we optimized down to 25ms using the combination of a low-input lag, fast-response 120Hz LCD display and latency-optimized experimental software with asynchronous graphics output. Surprisingly, we found that VFB latency had little effect on the VMR learning curves, as neither early (trials 1-10) nor asymptotic learning (trials 100-120) were significantly affected by VFB latency ($p>0.17$ in both cases). However, we found large differences in retention of this learning following a 60s wait period with the 300ms group (57% retention) displaying smaller retention than the other groups (73-81% retention, $p<0.05$ in all three cases). VFB latency affected the generalization of motor learning even more profoundly. All groups displayed distinct broad and narrow components of the generalization across movement directions. However, the amplitude of the narrow component, and thus the fraction of the generalization it accounted for, was specifically reduced by feedback latency ($p<0.001$ vs. $p>0.5$ for the narrow and broad components, respectively), with reductions of 40 and 55% observed in the 87 and 300ms groups (both $p<0.01$). These findings indicate that visual feedback latency determines both the retention of learning and its internal representation, reflected in the pattern of generalization.

Title: MEG-based functional connectivity changes with motor imagery training: Evidence for motor imagery as an acquired skill

Authors: S. N. KRAEUTNER[1], T. BARDOUILLE[3], *S. G. BOE[2];
[1]Psychology/Neuroscience, [2]Physiotherapy, Dalhousie Univ., Halifax, NS, Canada; [3]IWK Hlth. Sci. Ctr., Halifax, NS, Canada

Abstracts: Motor imagery (MI) is a form of practice in which an individual mentally rehearses a motor task, facilitating skill acquisition in the absence of physical practice (Jeannerod, 1995). MI has many clinical applications, including brain-computer interface and stroke rehabilitation. Previous research suggests that skill acquisition via MI is facilitated by repetitive activation of brain regions in the sensorimotor network similar to that observed in motor execution (ME; Hetu, 2013). This activation is influenced by differences in one's ability to perform MI (Wei, 2010), suggesting that MI ability is an acquired skill. In fact, spatial activation patterns during MI become more similar to that of ME with training. These training-related changes in MI activation have yet to be investigated from a network connectivity perspective. In showing how MI training drives network changes, the current study further demonstrates that the ability to employ MI for skill acquisition is a learned skill. Non-disabled participants (N=10; 24.7 +/- 3.8 years) performed both ME and MI of a unilateral seven-sequence button press task over three days. Magnetoencephalography (MEG) was utilized to capture neural activity. Coherence-based functional connectivity analysis was examined between eighty cortical nodes in the beta frequency band (15-30 Hz) and a partial least squares analysis conducted to compare coherence-based functional connectivity between session 1 and 3 (McIntosh, 2004). Preliminary findings indicate that functional connectivity was altered as a function of session, with network composition differing ($p < 0.05$) from session 1 to 3. Network changes included more lateralized (ie. in the contralateral hemisphere) activity during MI with more similar patterns of activity observed between MI and ME across sessions. Taken together, the current results indicate that the brain network underlying MI changes with training, further indicating that MI itself is a learned skill. Future work will utilize graph theory (Rubinov, 2010) to quantify changes in network characteristics during MI training, and examine the amount of MI training necessary to effectively facilitate skill acquisition in the absence of physical practice.

Title: Acquisition of skilled trajectory control in both arms after multiple days of unilateral reach training

Authors: *M. D. HARRAN[1], J. C. CORTES[1], J. W. KRAKAUER[2], T. KITAGO[1];
[1]Motor Performance Lab., Columbia Univ., New York, NY; [2]Neurol., Johns Hopkins Univ., Baltimore, MD

Abstracts: In this study we sought to investigate how the control of planar reaching trajectories improves over multiple days of practice and whether the untrained arm also shows improvements. Most previous studies of motor learning and intermanual transfer have used either sequence or adaptation tasks. Here we used kinematics to examine changes in movement trajectories in both arms after unilateral training on a visually-guided reaching task. Seventeen healthy, right-handed subjects (mean age=23.94 yrs, 8M) participated in this study. The study was conducted over 5 consecutive days, and consisted a Pre-Test block on day 1, two Training blocks on days 1-4, and a Post-Test block on day 5. The task performed during Test and Training blocks was designed as a measure of motor control of the proximal arm: subjects were instructed to make out-and-back, gravity-supported planar reaching movements by moving a cursor from a center start circle to eight radially-arrayed targets (10 cm distance). Subjects were randomly assigned to train with either their dominant or non-dominant arm. For the Pre- and Post-Test blocks, both trained and untrained arms were tested, in random order. Each Test and Training block consisted of 24 trials per target, with targets presented in a pseudorandom order. We examined measures of endpoint and overall trajectory kinematics for the outward movement: systematic error (the distance between the mean endpoint position and the center of the target), variable error (square root of the determinant of the spatial covariance matrix at the endpoint), and curvature (area between the trajectory path and a straight line to the target, normalized for movement extent). We compared these measures in each arm under three conditions: without training, after training in that arm, and after training in the other arm. We found improvements in the trained arm for both curvature and systematic error, but not for variable error. Our preliminary analysis suggests that there is also improvement in motor skill in the untrained arm, with a marked reduction in systematic error. There was no improvement in variable error or

curvature for the untrained arm. This may due either to the fact that these measures came down less than systematic error in the trained arm or because only certain components of learned trajectory control manifest in both arms after unilateral training.

Title: Manual asymmetry in motor skill learning

Authors: R. L. MCGRATH, *S. S. KANTAK;
Moss Rehabil. Res. Inst., Elkins Park, PA

Abstracts: Motor skill learning involves a process wherein one learns to synthesize novel movement capabilities in absence of perturbation such that they are able to perform and retain the movement skill with higher accuracy, consistency, efficiency, coordination and flexibility. Performance asymmetry has been reported in motor control and adaptation to kinematic and dynamic perturbations of goal-directed actions. In this study, we investigated asymmetry in acquisition and retention of a complex motor skill that requires speed and accuracy for optimal performance. Further, we examined if skill learning asymmetry is influenced by arm dominance. 6 right-handed (RH) and 6 left-handed (LH) adults practiced 2 distinct tracks during different sessions separated by 2-4 weeks. During separate sessions, participants practiced with their dominant (DOM) or non-dominant (NDM) arm in a pseudo-randomized order. Performance changes during practice were characterized by improvements in accuracy while practicing within prescribed movement time ranges. Learning was quantified by changes in the speed-accuracy tradeoff (SAT) function measured at baseline and a day after practice ended. There were no baseline differences in the SAT function between the DOM and NDM arms. All participants improved their performance with their DOM and NDM arms with practice. With practice, the RH participants demonstrated significantly higher improvements in the SAT function for the dominant compared to the non-dominant arm. We did not find significant differences between the two arms for the LH group. With the limited practice provided for a complex motor skill, right-handed individuals demonstrate dominant arm advantage for learning. Extended practice

may be indicated for improving skill learning with the non-dominant arm in the RH individuals. In RH individuals, asymmetry in skill learning may likely be related to the hemispheric specialization effects reported for motor control.

Title: Stability of precision drawing skills acquired with the non-dominant hand and associated changes in functional connectivity between sensorimotor hand representations

Authors: *B. A. PHILIP[1], S. H. FREY[1,2];
[1]Dept. of Psychological Sci., [2]Brain Imaging Ctr., Univ. of Missouri, Columbia, MO

Abstracts: Patients may suffer from unilateral impairment of the dominant right hand from many causes, including neurological or peripheral injury or disease, which result in forced use of the non-dominant limb. Previous studies suggest that skilled left-hand behavior may entail a functional role of the left (ipsilateral) cerebral hemisphere, especially in dominant hand amputees. However, few studies have investigated the behavioral and neural changes involved in learning a new skill with the left non-dominant hand, and long-term retention. Here, we trained 19 healthy right-handed adults (age 27 ± 8, 13 female) to perform a precision drawing task (PDT) with their left hand. In this task, participants used a pen to draw continuous lines (45-180 mm) within provided boundaries (3, 4, or 5 mm tolerance); primary dependent measures included endpoint speed and smoothness. The training regime involved 10 days of left hand training, with a fixed number of training trials on each day (15-25 minutes). We tested participants' right hand performance before and after training. Participants returned for follow-up testing sessions 1 week, 1 month, and 6 months after the end of training. In addition, we identified training-correlated changes in functional connectivity with seed regions in bilateral hand sensorimotor cortex, via resting-state magnetic resonance imaging (fcMRI) before and after training. Seventeen participants (89%) showed significantly improved left hand performance across training. The performance difference between hands decreased significantly in the

smoothness domain. Despite discontinuation of left-hand training, performance improvements were stable over time: six months after training, 12/14 (86%) participants still showed significantly improved left hand performances. Preliminary fcMRI analyses indicate that a network of bilateral premotor-parietal areas showed a learning-correlated increase in functional connectivity with the right (trained) sensorimotor cortex. Critically, this network included the left (untrained) sensorimotor cortex. These results suggest that training-related improvements in left hand skill can be remarkably stable across time and may involve experience-dependent changes in interhemispheric connectivity. The implications of this work for rehabilitation are considered.

Title: An automated skilled reaching task to study fine motor control

Authors: *D. J. ELLENS, M. GAIDICA, S. PENG, D. K. LEVENTHAL;
Neurol., Univ. of Michigan, Ann Arbor, MI

Abstracts: Rodent skilled reaching is a well-established model for the investigation of fine motor performance and learning, with high homology to human reach-to-grasp movements. In this task, rats reach for, grasp, and eat food pellets in a sequence of stereotyped movements. Current incarnations require constant attention by the experimenter to place food pellets within reach of the animals. Furthermore, analysis of the reaching movements requires detailed evaluation of high-speed videos. Both are time consuming, limiting the number of animals that can be tested as well as the number of reaches that can be quantified per animal. An automated version of this task would allow more interventions to be tested in more animals, but must be robust and reproducible. The goal of this study was to develop such a task for use in future investigations of motor skill acquisition and performance. Our version consists of a standard skilled reaching chamber with a slot at one end through which the rat must reach to grab a pellet

off a shelf. Reaches are detected by a photobeam across the slot, which triggers acquisition of high speed (150-300 Hz) video. Individual video frames are triggered by TTL pulses that can synchronize the video with behavioral events or electrophysiological recordings. When the rats move to the back of the chamber, a photobeam break triggers a linear actuator to deliver another pellet to the shelf. Prior to test sessions, the rats' (adult male Long Evans) reaching paw is colored green with nail polish, allowing its trajectory to be tracked automatically. We found that, as reaching skill improves, the variance within multiple kinematic parameters decreases. This suggests that our automated analyses can track the refinement of motor skills over time, and will allow us to investigate the effects of multiple different interventions efficiently.

Title: Human left fronto-parietal cortices are associated with acquisition of skill-switching ability

Authors: *S. UEHARA[1,2], N. MIZUGUCHI[1], S. HIROSE[1], S. YAMAMOTO[3], E. NAITO[1,4]; [1]Ctr. For Information and Neural Networks (CiNet), Natl. Inst. of Information and Communications Technol., Suita City, Osaka, Japan; [2]Japan Society for the Promotion of Sci., Tokyo, Japan; [3]Sch. of Hlth. and Sport Sciences, Osaka Univ. of Hlth. and Sport Sci., Osaka, Japan; [4]Grad. Sch. of Medicine, Osaka Univ., Osaka, Japan

Abstracts: Learning motor skills is one thing, acquiring skill-switching ability is another. Here we provide behavioral and neuroimaging evidence to support this view. We scanned brain activity with fMRI, while thirty-two healthy right-handers practiced two different types of sequential finger movement tasks with their non-dominant left hands in randomized order. A half of the participants underwent the experiment without prior practice (non-prior-practice group), while the other half practiced the tasks in blocked manner on the day before the experiment

(prior-practice group). In the non-prior-practice group, the task performance gradually improved during the experiment. This represents the learning of motor skills themselves. Interestingly, detailed analysis showed that the performance was relatively worse when the participants should perform the different task from that in the previous trial (switched task) compared to performing the same task (non-switched task). This performance deterioration in the switched task gradually decreased through the experiment, indicating the acquisition of the skill-switching ability. Importantly, this phenomenon was also observed in the prior-practice group, although their skill learning was well promoted through the prior-practice. Compared with the non-switched task, the activity in the fronto-parietal regions increased only in the left hemisphere when the brain prepared to perform the switched task. However, the activity of these regions gradually decreased in parallel with the improvement of the switched task performance. These lines of evidence demonstrated that the ability of switching motor skills is acquired by the brain separately from the learning of motor skills per se, and that the fronto-parietal cortices in the human left hemisphere is involved in acquiring the skill-switching ability.

Title: Long-term deficits in performance of skilled forelimb pellet retrieval behaviour seen in rats with unilateral motor cortex lesion

Authors: *R. CHAUDHARY, J. VENKATESH, V. REMA;
Natl. Brain Resear Ctr., Manesar, India

Abstracts: Focal injuries to the brain produces loss of tissue at the injured site resulting in deficits in behavior. In addition contralateral intact cortex has been speculated to influence behavioral functions of the injured hemisphere. Here we examined whether behavioral functions of uninjured hemisphere will alter the deficits in behavioral functions of the injured hemisphere. Long Evans rats were trained on skilled forelimb pellet retrieval task. There was no forelimb

restraint during training or in their home cages. Based on the natural ability to use the forelimbs the rats were classified into two groups: (i) “Ambidextrous” animals could perform the task equally with both forelimbs and both forelimbs were trained; (ii) Unidextrous, animals could perform the task only with one forelimb and that forelimb was trained. In addition we had another group of ambidextrous animals in which only the preferred forelimb was trained, “pseudo-unidextrous”. Once the animals behavior attained plateau performance the forelimb motor cortex contralateral to the preferred forelimb was lesioned by sub-pial aspiration. Skilled forelimb pellet retrieving behaviour of the forelimb connected to the injured motor cortex was tested following the lesion. We found significant deficits in the behavioral performance. These deficit were long-lasting. Our result show that the prior training of the forelimb connected to the intact cortex, after unilateral cortical lesion does not alter the behavioral deficits exhibited by forelimb connected to the injured cortex. Title: Differential vulnerability of different forms of skill learning in Parkinson’s disease

Authors: *A. LUKACS[1], F. KEMENY[1], G. DEMETER[1], I. VALALIK[2], M. RACSMANY[1]; [1]Dept. of Cognitive Sci., Budapest Univ. of Technol. and Econ., Budapest, Hungary; [2]Dept. of Neurosurg., St. John's Hosp., Budapest, Hungary

Abstracts: The striatal dopaminergic dysfunction in Parkinson's disease (PD) has been associated with deficits in skill learning in a number of studies, but the results are inconclusive so far. Motor sequence learning (especially sequence-specific learning) is found to be deficient in the majority of studies using the Serial Reaction Time Task (SRTT; Siegert, Taylor, Weatherall, & Abernethy, 2006; Jackson et al., 1995; Ferraro, Balota and Connor, 1993; Pascual-Leone et al., 1993, Muslimovic et al., 2007; Gobel et al., 2013; but see Kwak et al., 2012), although results are contradictory when verbal response is required instead of button presses (Westwater et al. 1998; Smith, Siegert and McDowall 2001). While problems with motor sequences seem to be prevalent, PD patients show intact performance on Artificial Grammar Learning (AGL) tasks, suggesting that the sequencing problem may be response type- or task type-dependent (Smith, Siegert and McDowall 2001; Witt, Nühsman and Deuschl, 2002) Acquisition of nonsequential probabilistic associations also seems to be vulnerable as evidenced by impaired PD performance on a probabilistic category learning task (Knowlton, Mangels et al., 1996; Shohamy, Myers, Onlaor, & Gluck, 2004). Our aim was to explore the nature of the skill learning deficit by testing different types of skill learning (sequential versus nonsequential, motor versus verbal) in the same group of Parkinson's patients. 14 patients with PD (mean age: 59.77 range: 45.5-74) were compared to age-matched typical adults using 1) a Serial Reaction Time Task (SRTT) testing the learning of motor sequences, 2) an Artificial Grammar Learning (AGL) task testing the extraction of regularities from auditory sequences and 3) a Weather prediction task (PCL-WP), testing probabilistic category learning in a non-sequential task. In motor sequence learning on the SRTT task, the two groups did not differ in accuracy; PD patients were generally slower, and analysis of z-transformed reaction times showed no evidence of sequence learning in PD. A deficit in artificial grammar learning was present only as a tendency in the PD group. The PD group showed evidence of learning on the PCL task, and their learning performance was not statistically different from that of the control group. These results partly support and also extend previous findings suggesting that motor skill learning is vulnerable in PD, while other forms of skill learning are less prone to impairment. Results are also in line with previous assumptions that mechanisms underlying artificial grammar learning and probabilistic categorization do not depend on the striatum (Reber & Squire, 1999; Skosnik et al., 2002).

Title: Enhancement of motor skill memory through reconsolidation

Authors: *N. F. WYMBS[1,3], A. J. BASTIAN[3,2], P. CELNIK[1,2];
[1]Physical Med. and Rehabil., [2]Neurosci., Johns Hopkins Univ., Baltimore, MD; [3]Kennedy Krieger Inst., Baltimore, MD

Abstracts: Recent work on memory reconsolidation has shown that previously consolidated motor skill memory can be weakened following reactivation and subsequent exposure to destabilizing intervention. Since other forms of memory can be enhanced through reconsolidation, we wondered if motor skill memory could be strengthened following reactivation and exposure to a different type of intervention. Here, we tested if motor memory could be enhanced overnight following reactivation using a novel behavioral intervention. Participants learned a thumb-index finger pinch force task where force mapped logarithmically to lateral cursor displacement. Subjects moved the cursor sequentially to a set of 5 targets. There was 3 sessions (4 blocks of 30 trials each). Following an initial training session (0 hr), participants returned after a 6-hour delay, and the following day (24 hr). Memory for this SVIPT task has been shown to consolidate within 6 hours. Thus, participants first reactivated their consolidated memory when they returned after the 6-hour delay. Next, they either continued on the previously learned function, or given a "variable trial intervention." This involved the intermixed presentation of 6 new logarithmic functions, along with the original function. New functions were fit using cursor endpoint variance (+/- 3SD, 1SD increment) to each of the 5 targets derived from an independent dataset. These could not be distinguished from the original function. The effect of intervention was measured as offline learning: difference between the first block the following day (24hr) from the final block during the initial session (0hr). Exposure to the variable skill task after reactivation led to greater offline learning despite the lack of any performance improvement during the intervention. On the other hand, the group that trained only on the previously learned function showed little evidence of offline learning despite improved performance during the intervention session. Additional controls revealed that enhanced offline learning was specific to the reactivation of consolidated skill memory, and not simply variable practice in general. Moreover, how skillful participants responded to the intervention determined the magnitude of offline learning. In particular, those with high accuracy following large

fluctuations in trial-to-trial variability had greater offline learning. These findings provide evidence that reconsolidation of motor skill memory can be constructive. Subtle variability appears to provide a powerful means to protect and further enhance previously consolidated memory, likely through the continued engagement of plasticity-like processes.

Title: Minimal observational viewing of an animated model enhances the physical performance of a motor skill

Authors: *J. J. BUCHANAN, I. PARK;
Texas A & M Univ., COLLEGE STA, TX

Abstracts: Practice may take the form of physical repetitions of an action and practice may also be induced through observation of a model. This experiment examined the contribution of physical and observational practice to the development of a novel motor memory. The task had the forearm held in a supine position as the elbow and wrist rhythmically flexed and extended in the sagittal motion plane. The novel motor pattern was a -90° relative phase pattern between the elbow and wrist in combination with joint amplitudes of elbow = 92° and wrist = 70°. The -90° offset means that the wrist lags behind the elbow throughout the cycle. There were three groups that practiced for two days: 1) physical only (30 trials per day); 2) physical-observation (6 physical, 24 observe); and 3) observation only (30 trials). The stimulus for all three groups was an animated stick figure consisting of upper-arm, forearm-elbow, and wrist-hand segments. The stick-figure was displayed on a computer monitor. The primary hypothesis was that all three types of practice would benefit the learning of the relative phase offset, yet only physical and physical-observation practice would benefit the learning of joint amplitudes. The training of the physical and physical-observation groups was supplemented with visual feedback. The physical and physical-observation groups were characterized by large improvements on the -90° relative phase offset in two retention tests, with the observers showing only a moderate improvement. The physical practice group's performance was the most stable, with no difference in stability between the physical-observation and observation groups. The physical group also matched the required amplitudes better than the other two groups. The physical-observation group did not

benefit from their limited practice with regard to scaling joint amplitudes. Physical practice produces novel motor memories in the form of stable attractors in the landscape of relative phase, and also benefits the scaling of joint amplitudes. Very little physical practice is necessary to enhance the benefit of observation supporting the idea that relative phase provides a source of information that links the visual perception of actions to the production of actions and vice versa. Even though physical and observational training may activate many of the same neural areas in the action-observation network, scaling muscle activity patterns to produce required joint amplitudes requires extensive physical practice and proprioceptive feedback.

Title: Applying “unusual” action contexts to familiar tools: How tools adopt new functions

Authors: *J. C. MIZELLE, L. A. WHEATON;
Sch. Applied Physiol, Georgia Tech., ATLANTA, GA

Abstracts: As we interact with our environment, we build representations of objects and actions associated with those objects. Consider the act of stirring coffee, where we might normally associate the utensil “spoon” as the correct tool by which to best achieve the action goal of stirring. These associations are strengthened by repeated exposure, and our representations of tools develop canonical usage contexts. However, we may find ourselves in a position where the “normal” tool for a specific task is not at hand. With this work, we sought to identify the brain mechanisms by which we flexibly apply new behavioral contexts to tools with well-formed canonical usage contexts. Fifteen healthy, right-handed young adults participated in a functional MRI study in which images of correct, incorrect and "plausible" tool use were shown. Each image was preceded by a neutral text description of an action (e.g., “Stir coffee”), against which images were evaluated for contextual correctness. Participants were instructed to silently judge whether the images showed contextually correct, contextually incorrect or contextually unusual (but plausible) tool use, and made no overt motor or verbal responses. Our results suggest that left parietofrontal activations when viewing tool use in correct contexts (match with the text prompt) are augmented over both incorrect contexts (mismatch with the text prompt) and

plausible contexts (not a match, but possible). We further observed viewing tool use in plausible contexts activated right precentral and middle frontal areas over viewing tools use in both correct and incorrect contexts. No greater activations for viewing tool use in incorrect contexts were seen over correct or plausible contexts. These findings improve our understanding of the flexible nature of tool use and suggest a reliance on right-hemisphere structures related to encoding unusual tool-related actions.

Title: Effects of temporal delay on implicit and explicit representations of hand position in tool use

Authors: *M. K. RAND, H. HEUER;
Ifado-Leibniz Res. Ctr., Dortmund, Germany

Abstracts: To investigate how the CNS combines seen cursor positions and felt hand positions under a visuo-motor rotation paradigm, we previously examined implicit and explicit judgments of the proprioceptively sensed directions of hand movements performed on a digitizer while looking at a rotated visual feedback of those movements on a monitor. We found different biases in coupling seen and felt movement directions for the two types of judgment, indicating the existence of distinct explicit and implicit neural representations of hand direction. The present study further examined the effects of a short delay on the biases for each type of judgment in order to examine the memory dynamics of implicit and explicit representations. A delay of 6 s. was inserted between the end of the aiming movements and two types of judgment of the movement directions (delay condition). This condition was compared with a condition where no delay was inserted (no-delay condition). The results showed that the bias of the explicit judgments of the proprioceptively-sensed hand direction toward the visual direction of the cursor was about twice as strong as the bias of the implicit judgments. The explicit judgments of hand direction had significantly larger variability than the implicit judgments. These characteristics

were consistent with those of our previous study and unchanged by the inserted delay. Furthermore, when the individual biases within each judgment type were correlated between the delay and no-delay conditions, high correlations were found in both types of judgment. This indicates a stability of individual judgments within each judgment type. In contrast, when the individual biases were correlated between the implicit and explicit judgments, no correlation was found in both delay and no-delay conditions. Taken together, distinct characteristics of implicit and explicit representations were maintained over the inserted delay period, suggesting that both types of representations were enduring with respect to memory dynamics. The present results strengthen the notion of distinct explicit and implicit neural representations of hand direction.

Title: Changes in electrodermal activity during motor learning: A proxy for attention?

Authors: J. E. GARDNER[1], A. C. RAIKES[1], *S. Y. SCHAEFER[1,2,3];
[1]HPER, Utah State Univ., Logan, UT; [2]Physical Therapy, [3]Ctr. on Aging, Univ. of Utah, Salt Lake City, UT

Abstracts: Motor learning theories predict that humans require high levels of attention to perform novel motor tasks, but little to no attention for learned tasks. Thus, practicing a task may decrease the amount of attention required to perform it. To test the theoretical relationship between attention and task practice, we used a physiological proxy for attention known as electrodermal activity (EDA). We hypothesized that EDA would decrease as they practiced a novel motor task. We also hypothesized that EDA would be higher overall in older adults than in younger adults when performing the same task. Because advancing age tends to limit one's ability to divide attention among multiple tasks, we expected an age-related increase in attentional requirement during motor performance. Two groups of subjects (young, n=5;

age=22.4 ± 2.1 yrs and older, n=5; age=75.8 ± 5.2 yrs) trained on a novel upper extremity task over three days. For each trial, we measured 1) EDA using commercially available wrist-worn sensors and 2) task performance, defined as movement time. EDA data were decomposed offline into tonic (underlying) and phasic (responsive) components. Results showed that in both groups, tonic EDA varied substantially between subjects and between training days, with peak EDA levels occurring mid-training. Tonic EDA levels were, however, comparable between the older and young groups. Overall, both groups demonstrated improvements on task performance and decreases in EDA levels over the course of training. This non-invasive, wireless technique may be a feasible alternative to expensive, non-portable methods for measuring attention during movement. Future studies are needed to explore the relationship between motor performance and tonic vs. phasic EDA, and to test the extent to which EDA is a valid proxy for attention.

Title: Error detection ability contributes to the compromised motor learning in older adults

Authors: *Y.-T. CHEN, M. KWON, E. A. CHRISTOU;
Applied Physiol. and Kinesiology, Univ. of Florida, Gainesville, FL

Abstracts: Error detection, defined as the ability to detect the difference between the desired and actual motor performance, is a crucial part of motor learning. Nonetheless, it is unclear whether age-associated impairments in motor learning are related to compromised error detection ability. The purpose of this study, therefore, was to determine whether compromised error detection contributes to impaired motor learning in older adults. Twenty young (25.1 ± 3.9 yrs, 10 men) and twenty older adults (71.5 ± 4.8 yrs, 10 men) participated in this study. Half of the subjects practiced 100 trials of a rapid goal-directed task with ankle dorsiflexion and were tested one day later with elbow flexion (ipsilateral transfer). The other half of the subjects acted as the control group and only performed the task with elbow flexion. The targeted position was 9^{o} for ankle dorsiflexion and 18^{o} for elbow flexion. The targeted time was 180 ms for both tasks. After each

trial, subjects predicted the endpoint of their performance by reporting the endpoint coordinates (position and time) of the peak displacement followed by visual feedback of the movement trajectory relative to the target. Motor learning (ipsilateral transfer) was quantified with the performance error during elbow flexion. Error detection ability was quantified as the difference between the actual and predicted performance. Only young adults were able to ipsilaterally transfer the goal-directed task from ankle dorsiflexion to elbow flexion (Δ from control group: young: -27%; older: -3%). The enhanced ipsilateral transfer in young adults relative to older adults was related to their better error detection ability during ankle practice (R^2=0.29). Furthermore, older adults who exhibited better error detection ability during practice with the ankle task exhibited enhanced ipsilateral transfer (R^2=0.51). These findings provide novel evidence that compromised error detection ability with aging contributes to motor learning impairments in older adults.

Title: Skilled motor learning increases basilar dendritic spine density on pyramidal neurons in layer II/III of mouse motor cortex

Authors: *T. CLARK[1], A. SITKO[2], T. A. JONES[1];
[1]Inst. for Neurosci., The Univ. of Texas At Austin, Austin, TX; [2]Dept. of Neurosci., Columbia Univ., New York, NY

Abstracts: Two photon (2P) imaging has enabled repeated visualization of cortical dendritic spine dynamics over time *in vivo*, but analysis is generally restricted to the most superficial layers of cortex. Such imaging in mice has revealed that motor skill learning (of a skilled reaching task) leads to a rapid formation followed by selective elimination of dendritic spines on the apical dendritic tufts of layer V pyramidal neurons in trained motor cortex, without a net

change in dendritic spine density.(Xu et al., 2009, Nature, 462: 519). In contrast, prior rat studies have found that skilled reach training increases quantities of layer V apical and layer II/III basilar dendrites and spines, as well as synapse numbers in these layers, as assessed with traditional light and electron microscopy. It has been unclear whether to attribute these conflicting results to differences in species, imaging, behavioral methods or the dendritic subpopulations examined. Here we asked whether spine densities on a deeper subpopulation of dendrites, the basilar dendrites of layer II/III pyramidal neurons, change in mice as a result of training on the same skilled reaching task as used by Xu et al (2009). Fifty-two C57/bl6 mice were trained with one forelimb on the single seed retrieval task, an adaptation of the single pellet retrieval task used in rats. Following the last day of reach training, brains were stained with Golgi-Cox. Individual spines on the basilar dendrites of forked layer II/III pyramidal neurons in motor cortex contralateral to the trained limb were visualized. Results indicate an overall increase in dendritic spine density on the terminal segments of layer II/III basilar dendrites. These results suggest that subpopulations of pyramidal neuron dendritic spines are differentially influenced by skilled motor learning.

Title: Perception of hill steepness is altered by motor skill learning in winter sports athletes

Authors: *C. A. ERICKSON, A. R. ZAVILLA, C. B. WALTERS;
Psychology, Metropolitan State Univ. of Denver, Denver, CO

Abstracts: Perception is the process by which we make sense of the world, but rather than being a static filter, our perceptions of reality are dynamic and fluid. The physical state of our bodies changes our perceptions of the world. This effect is termed “Embodied Perception.” It has been postulated that embodied perception allows us to react to environmental stimuli without active thought, thus increasing efficiency in our actions (Proffitt, 2006). In a widely cited study, Proffitt et al. (1995) demonstrated that fatigue alters perception of the steepness of a hill. The current

study examined the role of motor skill expertise on perception of hill steepness. Skiers and snowboarders share the same mountain terrain, yet the skill sets for these sports are very different. Thus, we were able to examine the role of motor skill expertise on perception of hill steepness using a within-subjects design by asking experienced snowboarders with limited skiing experience to estimate the steepness of various runs at a ski resort while wearing either their own equipment (snowboard) or rented equipment (skis). Participants made three measurements (visual, verbal, and haptic) at multiple locations at a Colorado ski resort. Consistent with previous reports (Proffitt, 2006), participants overestimated the steepness of runs regardless of actual hill steepness or level of experience with equipment worn. Participants' estimations of the steepest runs were more dramatic than their estimations of the less steep runs. Visual estimates were highest when participants were wearing unfamiliar equipment (skis) and looking down from the top of the steepest run tested. For the visual estimate, there was an interaction between run difficulty and experience level using a repeated-measures ANOVA ($p<0.05$, $N=9$). This within-subjects result demonstrates that expertise in a motor skill alters perception of the visual world. The possible implications of this study are twofold. First, the results of this study are of interest to the winter sport industry. A better understanding of how students perceptions of mountain terrain changes as their skill level improves can provide ski and snowboard instructors with supplemental training tools. Second, the results expand our current understanding of embodied perception. Embodied perception provides us an instant evaluation of our ability to perform an action by adjusting our sensory experience as a function of resources available for performance of the action and potential consequences of the action. These results indicate that, in addition to temporary states, motor skill learning also alters visual perception of hill steepness.

Title: The curse of task specificity: Skill becomes more task specific with practice

Authors: *J. W. KRAKAUER, D. M. HUBERDEAU, P. ROY, K. MCNALLY, O. AHMAD, A. M. HAITH;
Johns Hopkins Univ., Baltimore, MD

Abstracts: Motor skills such as skiing, driving or riding a bike are characterized by long learning curves that take months to years to master. What is being learned for any given task, and how does it affect the behavior and actions in variants of that task? For instance, are expert skiers worse in an absolute or relative sense at snow boarding than novice or moderate skiers? That is to say, is increasing task-specificity the price of expertise? This can be tested by assessing generalizability at different time points during longitudinal training on a particular task. We hypothesized that prolonged training in a task would result in reduced generalizability; with more skilled participants performing worse in an absolute sense on a task variant than less skilled performers. Selective or partial generalization of acquired motor ability has been demonstrated before (Darainy, et al. Exp. Brain Res, 2006), while in some tasks, no generalization is evident, even for conditions that seemingly only differ in terms of context (Tremblay, et al. J. Neurosci. 2008). What is the difference between motor abilities that generalize to novel conditions and those that do not? There is evidence that neural representations of certain behaviors can shift over the course of training (Daw, et al. Nat. Neurosci, 2005). We predicted that in the course of learning a motor skill, the neural representation for the appropriate action will shift over the course of training and that this results in greater task-specificity (i.e. worse generalization). To test this hypothesis, we introduce a custom-built video game played on tablet computers such as the *iPad*. Our game simulates a driving scenario and can be tailored to test specific hypotheses. We set up an experiment in which participants practiced the driving game on a particular track for 30-minutes on each of 5 consecutive days. We assessed generalization by introducing a set of probe trials on either the third day of learning or the fifth day. Probe trials consisted of a track that is the mirror image of the training track. We found that participants degraded to the same performance level during the probes regardless of when the probe was introduced, even though participants had reached a higher level of performance on the training track on the fifth day. This result indicates that, in life-like motor tasks, performance improvements beyond a certain threshold level represent task-specific gains. One shortfall of this study is that with only 5-days of training, no participant reached what can fairly be called expert levels of performance at the task, which may explain why we failed to observe worse generalization on day 5 in an absolute sense.

Title: Cortical connectivity at rest predicts consolidation of a novel motor skill

Authors: *J. WU[1], F. KNAPP[3], N. VARZHAPETYAN[2], R. SRINIVASAN[1], S. C. CRAMER[2]; [2]Neurol., [1]Univ. of California, Irvine, Irvine, CA; [3]Maastricht Univ., Maastricht, Netherlands

Abstracts: Individuals show significant variation in motor learning. A previous study from our group found a resting-state measure of cortical connectivity was a good predictor of motor skill acquisition. The current study extends the previous study to examine whether resting-state connectivity is a good predictor of motor training consolidation. METHODS. Twenty-eight adults (age=19.6±0.4 years, m±se) underwent 3 minutes of resting-state dEEG recording prior to 20 minutes of motor training. Subjects returned 24 hours later to test consolidation of motor training. Motor learning task. The task was a precision targeting task in which subjects made flexion and extension wrist movements to 7 potential target locations in response to a visual cue. EEG methods. Continuous raw dEEG were filtered, segmented, and cleaned of extra-brain artifacts with visual inspection and Infomax-Independent Component Analyses. Mean coherence with left M1 seed region was derived for the high beta (20-30 Hz) frequency band, which is associated with motor system function, and regressed again behavioral scores using partial least squares (PLS). RESULTS. With training, the group demonstrated consolidation of motor training, improving from 25.0±1.8% targets hit at Day 1 to 40.4± 2.1% targets hit at Day 2 (m±se, $p<0.0001$). The PLS model of resting-state beta coherence with left M1 predicting this consolidation ($R^2=0.64$) identified significant electrodes in left premotor (PM), left primary sensory (S1), and left parietotemporal (PAR) region. Specifically, individuals whose resting connectivity prior to training, was greater in left M1-left PM ($p=0.04$, $r=0.38$) and left M1-left S1 ($p=0.06$, $r=0.36$) electrodes showed better consolidation; individuals with greater connectivity in left M1-left PAR ($p=0.01$, $r=-0.46$) electrodes showed worse consolidation. CONCLUSIONS. The current results demonstrate resting-state dEEG connectivity is a strong predictor of short-term motor learning. Similar to our previous study, M1-PM and M1-PAR coherence showed a strong relationship with behavioral performance. In conjunction with the previous study, the current results demonstrate measures of resting-state functional connectivity inform both motor skill acquisition and consolidation.

Title: Time course of plastic changes in brain structure accompanying skill acquisition

Authors: *E. WENGER[1], S. KÜHN[1], J. VERREL[1], J. MÅRTENSSON[2], U. LINDENBERGER[1], M. LÖVDÉN[3,1];
[1]Max Planck Inst. For Human Develop., Berlin, Germany; [2]Lund Univ., Lund, Sweden; [3]Karolinska Institutet, Stockholm, Sweden

Abstracts: Recent evidence suggests that the adult human brain structure shows potential for plastic changes in response to altered environmental demands. Many studies conducted in the field of structural plasticity follow the implicit assumption of a monotonic increase in brain volume accompanying learning. However, it has also been proposed, mostly based on work in animals, that learning-related volume increases can emerge relatively rapidly (e.g., within a few days), but then renormalize during further behavioral training and continuously stable performance. We set out to investigate the time course of plastic changes in brain structure accompanying motor skill acquisition. We trained 15 younger right-handed adults for 7 weeks to draw and write with their non-dominant hand (i.e. left) hand on a touch-sensitive tablet PC. In contrast to a standard pretest-posttest design, magnetic resonance (MR) images were acquired every other day, resulting in approximately 20 MR sessions per person over the course of the whole study, including both structural and functional imaging sequences. The data pre-processing of the structural T1-weighted images was performed using voxel-based-morphometry (VBM8 toolbox). Participants' performance level increased considerably in both writing and tracing tasks. We found that motor training of the left hand triggered changes in gray matter volume in task-relevant areas, namely left and right motor cortex as well as left and right putamen. In right motor cortex, the initial expansion was followed by a partial renormalization of structure in the presence of stable and heightened motor performance. A typical pretest-posttest design would not have uncovered these dynamics. Our findings corroborate the proposition that training-induced neural plastic changes may entail an initial increase in gray matter that is followed by partial renormalization. This is consistent with findings based on animal models, where plasticity often consists of an initial expansion of regional brain volumes, followed by a later phase of efficient reorganization and partial stabilization of new structures, combined with the elimination of pre-existing structures. Our results demonstrate the importance of including

multiple measurement occasions into MR study designs to accurately depict training-induced gray matter changes.

Title: Kinesthetic motor imagery of a newly learned dance is easier with eyes closed: Modulation of alpha power and subjective imagery ratings by eye state and expertise

Authors: *P. M. DI NOTO[1,2,3], J. M. CHARTRAND[1], G. R. LEVKOV[4,2], R.-A. ANDREW[1], M. J. WILAND[1], J. F. X. DESOUZA[1,4,2,3,5];
[1]Psychology, [2]Ctr. for Vision Res., [3]Neurosci. Grad. Diploma Program, [4]Biol., York Univ., Toronto, ON, Canada; [5]Canadian Action and Perception Network, Toronto, ON, Canada

Abstracts: Recordings of the alpha band (8-13Hz) reveal increased power (synchronization) when eyes are closed
(EC) and decreased power (desynchronization) when eyes are open (EO; Berger, 1929). Similarly,
anecdotal evidence on kinesthetic motor imagery (KMI) from an internal first-person perspective stipulates
clearer imagery when eyes are closed. This follows previous evidence for suppression of task-irrelevant
areas during motor imagery as reflected by alpha synchronization, and increased cognitive load and alpha desynchronization in task-relevant areas (Pfurtscheller et al., 1999). In order to test whether KMI clarity is affected by eye state or familiarity with the stimulus (Calvo-Merino et al., 2005), we examined alpha power among ballet dancers (n=21), dancers in other non-ballet genres (n=25), and non-dancers (n=15) during three tasks: baseline (with EC and EO), learning, and KMI (EC and EO). After each block of the learning and KMI tasks, subjects were asked to rate their learning or imagery on a scale from 1 (Perfectly accurate/clear) to 5 (No accuracy/imagery). Significant group effects were found for the learning task, with the unfamiliar non-dance group demonstrating higher alpha power compared to the highly-familiar ballet ($P<0.001$) and intermediate non-ballet ($P<0.001$) groups, indicative of decreased cognitive load in nondancers while observing and learning an unfamiliar dance sequence. Additional group effects were observed with ballet dancers providing significantly lower ratings during learning

(P<0.01) and KMI
(P<0.05) compared to non-dancers, reflecting enhanced learning and imagery in familiar experts relative to non-experts. Across all subjects, significantly more vivid imagery was reported during the EC condition
compared to EO (P<0.001) and, as expected, alpha power was significantly higher during KMI-EC
compared to KMI-EO (P<0.001) in all electrode sites except for left temporal and especially in occipital
sites. Consistent with preliminary findings in this sample (Di Noto et al., 2014), desynchronization was
observed during KMI-EC relative to baseline (P<0.001) while alpha power increased relative to baseline
during KMI-EO (P<0.001). This pattern of alpha (de)synchronization during KMI provides evidence for a
putative mechanism that facilitates clearer and more effective KMI when eyes are closed, with increased
cognitive load resulting in desynchronization during KMI-EC relative to baseline and additional suppression of visual signals resulting in alpha synchronization relative to baseline during KMI-EO.

Title: Network recruitment during motor visualization of a dance in controls and expert dancers

Authors: ***P. DHAMI**[1], L. J. WILLIAMS[2], S. MORENO[3], R. J. BAR[4], J. F. X. DESOUZA[1]; [1]York Univ., Toronto, ON, Canada; [2]Child and Family Res. Ctr., Women and Children's Hosp., Vancouver, BC, Canada; [3]Rotman Res. Inst., Baycrest Hosp., Toronto, ON, Canada; [4]Canada's Natl. Ballet Sch., Toronto, ON, Canada

Abstracts: The objective of the current study was to investigate what networks are recruited in both controls and expert dancers when visualizing dance movements to a piece of music that neither group had any previous experience performing to. The study included 5 controls that had no dance experience, and 5 expert ballet dancers. All subjects underwent functional magnetic resonance imaging (fMRI) that included baseline and motor visualization blocks. The motor visualization blocks consisted of subjects visualizing performing dance movements to 1 minute of music in a blocked design with fixation periods of 30 seconds and 5 repeats of the same music. In order to investigate what networks were recruited due to the visualization, task partial least squares (PLS) was used, a multivariate technique that can identify groups of brain regions that change as a function of the tasks. Task PLS provided a single significant latent variable ($p < 0.05$, that accounted for 52.73 % covariance in the data) that reflected a common whole brain activity pattern that differentiated the motor visualization task from the baseline task in both groups. The baseline network included the right superior frontal gyrus, right middle temporal gyrus, left middle temporal gyrus, left middle frontal gyrus, left anterior cingulate cortex, right supra marginal gyrus and the right middle orbital gyrus. The motor visualization network that was found to be common in both groups included the left superior temporal gyrus, right rolandic operculum, right inferior frontal gyrus, left precuneus, right cerebellum, the left insula lobe and the supplementary motor area. Largest areas of activation as based on the voxel cluster size in the motor visualization network included the left superior temporal gyrus, right rolandic operculum and the supplementary motor area. The results indicate that although the two groups were in stark contrast in regards to level of expertise in dancing, when asked to visualize performing dance movements to a musical piece that they never had performed to, the expert dancers recruited a similar network to that of the controls.

Title: Limited effect of temporal constraints on feedback in learning to control movement velocity

Authors: *S. HILLENBRAND, K. OKPARA, T. TU, R. IVRY;
Univ. of California--Berkeley, Berkeley, CA

Abstracts: Behavioral studies from a range of tasks, as well as computational models, suggest important temporal constraints for error based learning. Delay conditioning, visuomotor adaptation, and force field learning fall off when the interval between events relevant for learning extends beyond a few hundred milliseconds. This may reflect expiration of the eligibility for cerebellar plasticity, with reduced learning capacity as the predicted and actual feedback become temporally separated. Studies of these constraints typically introduce a delay between an action and feedback of that action. We used a range of temporal manipulations to investigate the importance of temporal regularity and ecological validity in a sensorimotor learning task. Participants performed a virtual shuffleboard task in which the terminal location of a puck was determined by hand velocity at the point of "release." Targets appeared at one of four distances from the start line, thus, ideal performance involved learning the mapping between hand velocity and distance. In a first experiment, we compared conditions in which the feedback appeared at the moment of release or after a 1 s delay. Contrary to studies of visuomotor adaptation, performance was unaffected by the delay. In a second experiment, we compared three groups. In the Random group, the feedback delay varied from trial to trial and was independent of hand velocity, ranging from 200 - 1200 ms. The same range was used for the Physics group, but the feedback time was defined by Newtonian laws (e.g., longer delay for longer throws). We also included a Reverse Physics group where we inverted the distance-time relationship (e.g., shorter delay for longer throws). Performance for the Physics group was superior to the Random group. Surprisingly, a similar improvement was observed in the Reverse Physics group. In a third experiment, the same three groups were tested, but the virtual friction was modified such that the range of feedback times was reduced to 200 - 700 ms, a range that may be more "cerebellar" and/or less subject to explicit strategies. Here we found no difference in performance between the three groups. Thus, temporal regularity can facilitate learning, but this effect is absent with shorter intervals. The cost observed with random timing in Exp. 2 may be attentional, related to the feedback occurring at unexpected times. The minimal sensitivity to temporal constraints exhibited in this task may stem from the fact that learning in this task requires modulation of hand velocity (e.g., gain) rather than hand position. Preliminary fMRI results using a variant of this task will clarify the neural contributions to movement velocity adjustments.

Title: Long-Term learning in adaptation paradigms: Cognitive versus motor memory

Authors: *D. M. HUBERDEAU[1], J. W. KRAKAUER[2], A. M. HAITH[2];
[1], [2]Neurol., Johns Hopkins Univ., Baltimore, MD

Abstracts: Adaptation paradigms are often thought to offer a model of long-term motor memory through the phenomenon of savings - faster adaptation the second time a perturbation is observed. However, recent findings have shown that behavior in adaptation paradigms is governed by both implicit motor learning and explicit, cognitive processes (Taylor et al., J Neurosci, 2014). The long-term memory exhibited through savings might therefore reflect implicit learning, explicit learning, or a combination of both. Here we attempted to determine the contribution of implicit and explicit processes to long-term learning based on differences in the amount of preparation time required by each process. We have recently shown that different components of learning can be dissociated based on their reaction time requirements (Haith et al., SfN 2013). If the RT is artificially limited - forcing a movement with less RT than would have otherwise been chosen by the participant - subjects express only a limited amount of their overall learning. Our interpretation of this finding is that the typical response time (RT) prior to initiating a reaching movement in the presence of a visuomotor perturbation includes a window of time for applying an explicit strategy. If preparation time is limited, application of the purported strategy is hampered (Fernandez-Ruiz et al., Behav Brain Res, 2011), leaving only implicit components of learning to be expressed on those trials. In the present study, we exploited this approach to determine which processes contribute to savings. To test this, we established a learn-relearn paradigm with occasional low RT probe trials interleaved among high RT trials within two adaptation learning sessions. We observed clear savings in high RT trials. However, in low RT trials, behavior was indistinguishable across days. This observation suggests that savings in adaptation tasks is due to the application of an explicit strategy and may not in fact represent a long term motor memory at all. Longer adaptation studies consisting of repeated exposures have shown that - under the appropriate conditions - the adaptation rate can increase further with subsequent exposure episodes (Gonzales-Castro et al., Curr Biol, 2014). We therefore asked if repeated exposure to the same perturbation leads to lasting changes in behavior

expressed during low RT trials. We demonstrate that under the appropriate conditions, behavior in low-RT trials can be influenced by prior experience, representing a more genuine example of long-term motor learning in adaptation paradigms.

Title: Rebuilding of motor memory: Increased efficiency at recall after time away from practice

Authors: *S. E. PEKNY[1], R. SHADMEHR[2];
[1]Biomed. Engin., [2]Johns Hopkins Univ., Baltimore, MD

Abstracts: Can we minimize inefficiencies in our actions? That is, how we learn to eliminate motor commands that are effortful and yet irrelevant to success of the task? To study this puzzle, we trained human volunteers to reach in a force field. With practice, participants learned to produce forces that compensated for the field, generating task-relevant motor commands. As expected, training also resulted in generalization, the transfer of learning to other movements. In our task, any generalized forces were unnecessary and task-irrelevant. Critically, these generalized forces did not lead to kinematic errors, leaving no explicit cues or errors to indicate that this component of behavior was resulting in task-irrelevant motor commands. Could this inefficient generalization be reduced? We found that practice alone could not provide the conditions necessary to eliminate generalization, as participants continued to produce effortful and unnecessary forces after hundreds of trials. A short break of 3 or 30 minutes following initial training also did not aid in improving the efficiency of movements, as generalization force output remained constant during additional practice. However, following a 6 hour break, the production of generalization forces significantly decreased when the task was resumed, despite a maintained level of performance to the training direction. The drop in generalization force output observed following a 6 hour waiting period was identical to the decrease observed following a 24 hour break, indicating that 6 hours fell within the critical time period necessary to achieve this drop in generalization. Further experiments showed that whereas time away from practice was necessary

for this reduction, it did not result in a spontaneous drop in these forces. Rather, passage of time made the task-irrelevant commands eligible for reduction, but recall of the task-relevant commands was necessary to allow for the reduction of the task-irrelevant commands. These results illustrate a previously unknown property of motor memory: practice (and not time) improves the task-relevant component of motor memory, whereas time (and not practice) makes the task-irrelevant component eligible for reduction, a process that may depend on reconsolidation of motor memory.

Title: Neural correlates of human motor control

Authors: M. S. D. KERR[1], K. KAHN[1], H.-J. PARK[3], S. THOMPSON[3], J. BULACIO[3], J. GONZALEZ-MARTINEZ[3], J. T. GALE[3], *S. V. SARMA[2];
[2]Biomed. Engin., [1]Johns Hopkins Univ., Baltimore, MD; [3]Cleveland Clin., Cleveland, OH

Abstracts: While the most common forms of neural data collected from humans are EEG and functional magnetic resonance imaging (fMRI), in our experimental setup we utilize stereo-tactic electroencephalography (SEEG). This includes the implantation of many depth electrodes, each of which can supply up to 10 independent channels of neural data. They collect a local field potential (LFP) style signal that represents the aggregate firing of many neurons in the region of the contact. A small number of epilepsy patients whose seizures do not respond to traditional treatment have this procedure done as a means to identify the seizure focus for resection. This modality gives a unique combination of temporal and spatial resolution than cannot be achieved using either fMRI or EEG. In this experiment, subjects with SEEG implants used a manipulandum to control a on-screen cursor and conduct a center-out reach task. Each trial, they were instructed to move in a specific speed range. Also, in approximately 1/5 of trials, a force field (perturbation) was applied of varying intensity and from a random direction. The perturbation started at the onset of movement and persisted until the subject held the cursor over

the target. While manipulandum based tasks are frequently done with health human subjects, they have never been done with similar neural data collection. The long-term purpose of this study is to tease out the neural correlates of human motor control and elucidate the mechanism by which the brain achieves such robust motor control in an uncertain environment. The unusual nature of the data collection method and patient pool will also provide the ability to ask a wide variety of questions. We can search for the neural correlates of movement speed and direction in structures such as the hippocampus. In addition, approximately 40% of subjects are clinically depressed and we are acquiring the relevant neurophycological test scores. Depression is associated with psychomotor retardation and this data set will provide an unprecedented way of comparing the motor processing of depressed versus non-depressed adults. While primary data analysis is ongoing, preliminary results indicate the right supracalcarine cortex modulates throughout the duration of movement. There is a substantial increase in the power in gamma and high gamma ranges (50-150 Hz) coexisting with a suppression of power in frequencies less than 30 Hz. Interestingly, this dual effect persists for the duration of the movement indicating that the area plays an ongoing role in feedback correction and not just a transient shift in attention.

Title: Hemisphere Specific Ipesilesional deficits in Predictive and impedance control mechanisms

Authors: *V. YADAV[1], D. C. GOOD[2], R. L. SAINBURG[1,2];
[1]Kinesiology, The Pennsylvania State Univ., University Park, PA; [2]Neurol., The Pennsylvania State Univ., Hershey, PA

Abstracts: Based on our previous empirical research with stroke patients and healthy young participants, we proposed that handedness arises from differential specialization of each arm for distinct control processes: that the dominant hemisphere/arm are specialized for predictive control, while the nondominant hemisphere/arm are specialized for impedance control. We now directly test this control-based hypothesis by investigating inter limb differences in adaptation to two novel robot-applied force fields; a predictable velocity squared field that benefits adaptations through predictive mechanisms, and an unpredictable curl field that should advantage impedance control mechanisms. Previous findings in healthy participants revealed that the nondominant arm showed superior adaptation in the unpredictable field, while the dominant arm showed superior adaptation in the predictable field. We now examine the neural correlates of these control mechanisms by examining the effects of unilateral stroke to either the right or left hemisphere on ipsilesional arm adaptation. Our results reveal that following unilateral stroke to the right side of the brain, the reliance on predictive mechanisms increases as indicated by larger aftereffects following motor adaptation to either fields. Where as, following left hemisphere stroke, the subjects showed more reliance on impedance mechanisms as indicated by small to none after effects. Our preliminary findings suggest that unilateral stroke to the right side of the brain degrades impedance mechanisms, whereas stroke to the left side of the brain affects predictive mechanisms.

Title: A computational model for learning reaching movement in 3-Dimensional Space and in force fields from scratch

Authors: *H. KAMBARA, H. SHIMIZU, D. SHIN, N. YOSHIMURA, Y. KOIKE;
Tokyo Inst. Technol., Yokohama, Japan

Abstracts: Human's musculoskeletal has many degrees of freedom and is actuated by dozens of muscles. The neural motor control system has to learn how to control such complex dynamics in a trial-and-error manner. In this study, we applied the motor control-learning model to reaching movements of upper limb moving in three-dimensional space. The motor control-learning model is based on the reinforcement learning algorithm that enables trial-and-error learning. We tested whether accurate reaching movements of complex musculoskeletal system can be acquired in a trial-and-error manner by reinforcement learning algorithm. The musculoskeletal of the upper limb was modeled as the two-link dynamical system composed of the shoulder joint with three degrees of freedom, the elbow joint with one degree of freedom, and twenty muscles with viscoelastic property. The feedback command signals to each muscle are learned by reinforcement learning algorithm and feedback-error-learning. The value of reward signal in the reinforcement learning is determined under the tradeoff between movement accuracy and energy consumption. As the result of simulation, we observed an increase in the amount of reward signal gained in each trial. In addition, the distance between target position and hand position at the end of each trial became smaller as the number of trial increased. We also applied the motor control-learning model to reaching adaptation to viscous-force and divergent-force fields in 2D-space. As the result of simulation, we observed several kinematic features, e.g. almost straight path and bell-shaped speed profile after adaption, huge after-effect after adapting to viscous-force fields, increase in the maximum speed after adaptation. The results of the computer simulations suggests that reaching movements of the upper limb with complex dynamics like biological musculoskeletal system could be trained in a trial-and-error manner based on the reinforcement learning algorithm.

Title: Changes in error-sensitivity account for sensorimotor savings

Authors: D. HERZFELD, *R. SHADMEHR;
Dept Biomed. Eng, Johns Hopkins Univ., BALTIMORE, MD

Abstracts: When a subject experiences a perturbation, they adapt their motor output on the next trial to reduce the error. We have suggested that the brain methodologically selects how much it is willing to learn from error. This modulation of behavior, or error-sensitivity, changes based on the history of errors that the subject experiences. Here, we asked whether changes in error-sensitivity, due to the history of experienced errors, can account for fundamental motor learning observations such as 'savings' and 'meta-learning'. Savings refers to the observation that when a subject practices a task with perturbation (A), and then the perturbation is removed, they exhibit faster re-learning of (A). We show that not only can a model which incorporates a memory of errors account for savings, but it can also account for meta-learning: prior exposure to a perturbation (B) generalizes to perturbation which has never been experienced. A prediction of our hypothesis is that we should be able to modulate savings by restricting the errors that are experienced during learning. Right-handed volunteers (n=50) participated in a visuomotor rotation experiment. The control group experienced a +30° (A) perturbation followed by washout and relearning of +30°, a protocol that should produce savings. According to our hypothesis, savings is present because the initial exposure of (A) represented a stable environment, increasing error-sensitivity to the errors, and these errors were revisited during subsequent test of (A). If so, we should be able to produce savings in a very different way: expose subjects to perturbation (B, -30°) and then present sudden washout (BNA), an example of meta-learning. When perturbation (A) is introduced gradually savings should be eliminated. That is, when the perturbation is introduced gradually (GNA), the magnitude of the experienced errors is significantly smaller than those experienced during testing of (A). Similarly, savings can be eliminated in the BNA group by reducing the magnitude of the experienced errors during washout. In the BGNA group, subjects learned (B) and then were gradually washed out (GN). During subsequent test of (A), we hypothesize that this group will not show savings. Our results confirmed our predictions: the ANA group showed significant savings (paired t-test, $p < 0.001$). In addition, the BNA group also showed savings of (A) compared to naïve ($p < 0.05$). In addition, we found no evidence of savings when the magnitude of the errors is significantly reduced: GNA ($p > 0.5$) or BGNA ($p > 0.1$). These results suggest the phenomena of savings and meta-learning may be partially explained by the history of errors that the subject experiences.

Title: Influence of the training schedule on intermanual transfer in the cart-pole balancing task

Authors: *N. LUDOLPH[1,2], M. A. GIESE[1], W. ILG[1];
[1]Cognitive Neurology, Section Computat. Sensomotorics, Ctr. for Integrative Neurosci., Tuebingen, Germany; [2]Intl. Max-Planck Res. Sch. for Cognitive and Systems Neurosci., Tuebingen, Germany

Abstracts: INTRODUCTION: A current topic in motor learning is how multiple learning and control mechanisms interact to produce overall improvement. In this study, we examined the intermanual transfer of control knowledge subsequent to different training schedules for the acquisition of the cart-pole balancing skill. METHODS: 17 right-handed subjects have been examined in the computer-simulated cart-pole balancing task. Continuous lateral forces were applied to the cart by the subjects using a joystick-like device in order to balance a pole which is attached to the cart. Subjects trained for 90 minutes using their right hand and switched afterwards for 30 minutes to the left hand. We tested two training schedules for the right-handed training: (i) gravity was gradually (g_inc=0.1) increased after every successful trial starting on g_0=1.0m/s^2 up to a maximum level of g_max=3.5m/s^2; (ii) subjects started directly on the maximum gravity level (g_max). Trials were counted as successful, if the pole angle and cart position remained within the valid ranges for 30 seconds. In addition to trial success or failure, subjects received up to 10 points per second depending on the system state and applied force. During the post-training phase gravity was constant (g_max) and performance of left-handed control was examined. RESULTS: First analysis shows that subjects in group (ii) instantaneously transfer the balancing skill to the left hand and do not further improve (N=9, $p \approx 0.57$, paired). In contrast, subjects in group (i) still improve during the left hand examination (N=8, $p<0.01$, paired). Accordingly subjects in group (i) tend to be worse at the beginning of the left hand examination. We did not find a significant performance difference at the end of the right-handed training between groups. Comparing group (i)'s left hand performance with the right-handed training of group (ii) yields that even though group (i) is better at the very beginning (first 10 minutes, $p<0.05$, unpaired) the performances are similar after 30 minutes. CONCLUSION: Previous studies suggested (Obayashi 2004, Anguera 2007) that control knowledge might be

shared between both hands. We hypothesize that the tested training schedules lead to the maintenance of different representations which allow intermanual transfer to a different extent. Brain imaging and stimulation techniques might provide further insight in which brain areas are involved and responsible for the representation in the tested conditions. Title: Anodal tDCS of dorsolateral prefrontal cortex and cerebellum enhance different aspects of motor learning in a visumotor adaptation task

Authors: ***S.-L. LIEW**[1], J. J. RAMIREZ[3], P. A. BUTCHER[4], L. G. COHEN[2], J. A. TAYLOR[4], P. A. CELNIK[3];
[1]Natl. Inst. of Neurolog. Disorders and Stroke, [2]NINDS, NIH, Bethesda, MD; [3]Sch. of Med., Johns Hopkins Univ., Baltimore, MD; [4]Dept. of Pyschology, Princeton Univ., Princeton, NJ

Abstracts: An increasing number of studies have suggested that learning in visuomotor adaptation tasks may be the result of both implicit and explicit learning processes. In a visuomotor adaptation task, implicit learning is thought to be the result of training an internal model to predict movement errors. The cerebellum has been shown to play a critical role in this form of implicit learning. Studies have shown that anodal tDCS of the cerebellum improves adaptation in healthy individuals and that patients with cerebellar damage show deficits in adaptation. In contrast, explicit learning involves the utilization of explicit instructions or the generation of cognitive strategies to improve performance. The dorsolateral prefrontal cortex (dlPFC), which has also been associated with working memory, fluid reasoning, and problem solving, is thought to play a critical role in this form of explicit learning In the present study, we predicted that anodal tDCS over the cerebellum would enhance the error-based learning mechanism, while anodal tDCS over dlPFC would enhance the strategy-based component of a

visumotor adaptation task. To test this, we recruited 47 individuals, split into three groups: anodal cerebellar stimulation (CB, n=16), anodal dlPFC stimulation (PFC, n=16), and sham stimulation (SHAM, n=15). We used a paradigm from Taylor and colleagues (2014), in which participants directed a stylus towards a target on a circle, flanked by numbers, presented on a computer screen. Participants were asked to try to get their cursor on the target, and also to verbally report the number they were aiming at in order to get their cursor on the target. In this way, both explicit (aiming report) and implicit (internal model) components of each movement were measured. Importantly, vision of the hand was occluded. After 120 baseline trials, a 45-degree clockwise rotation was introduced for 160 trials, followed by a block of 40 trials without feedback and 40 trials with feedback. Results suggest that individuals receiving anodal dlPFC and cerebellar stimulation reduced target errors faster than the SHAM group. In addition, the dlPFC group demonstrated a greater explicit component (aiming angle) compared to CB or SHAM groups, while the CB group showed a modest increase in the internal component (internal model) over both groups. Overall, these results suggest that anodal stimulation of either cerebellum or dlPFC enhance motor learning during a visuomotor adaptation task and may exert their effects through different aspects of visuomotor adaptation.

Title: Learning to coordinate a redundant motor system: The role of postural comfort

Authors: *S. L. BARTON, B. R. FAJEN;
Rensselaer Polytechnic Inst., Troy, NY

Abstracts: During the production of a movement, the central nervous system (CNS) must organize components of the motor system around some desirable goal or outcome. A difficulty in this process is the reality that there are often more motor components than are strictly needed to satisfy the constraints of the task at hand. This excess of components creates redundancy in the movements and configuration of the motor system such that there exist multiple ways of realizing action goals. While redundancy is a source of computational complexity, it can also

provide stability and flexibility in action. Studies have shown that the CNS can exploit redundancy to reduce variability in action goals by strategically co-varying the actions of redundant motor components (Latash, Scholz, & Schöner, 2002; 2007). Such co-variation reduces error in the action goal by distributing variability across the set of redundant motor solutions that yield the same outcome. While this strategy has been demonstrated in a number of well-learned movements, this account critically assumes that redundant motor solutions are generally equitable. This contradicts findings that the comfort associated with particular configurations of the body are strong determiners of how an action is performed (Rosenbaum, van Heugten, & Caldwell, 1996). To understand how comfort might impact how the CNS handles redundancy, we asked subjects to solve a novel motor control problem involving coordinated arm movements. Using a full-body motion capture system, the angles of six arm joints were mapped onto the position of a cursor in a 2D virtual environment (Ranganathan, Adewuyi, & Mussa-Ivaldi, 2013). Subjects were required to move this cursor between four targets by adopting different arm postures. The mapping between arm posture and cursor position was both redundant and unintuitive, meaning subjects needed to learn how to resolve the redundancy problem. We found that over the course of practice, subjects improved the accuracy of their cursor movements. However, we did not find evidence of strategic co-variation between arm joints. Instead, subjects constrained their movements to a subset of solutions that were consistent with more comfortable body postures. We also found a reduction in the overall complexity of movements, and an increase in the similarity between postures adopted at the targets. Taken together, these findings suggest that reducing variability through co-variation is not the only explanation for how the CNS coordinates a redundant motor system. The comfort of particular motor solutions is important for constraining the set of redundant actions, as well as improving motor performance in a novel motor task.

Title: Motivational influence on error-based motor learning in stroke

Authors: *G. QUATTROCCHI[1], J. M. GALEA[2], R. GREENWOOD[3], J. C. ROTHWELL[1], S. BESTMANN[1];
[1]Sobell, UCL Inst. of Neurol., London, United Kingdom; [2]Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom; [3]Natl. Hosp. for Neurol. and Neurosurg., London, United Kingdom

Abstracts: One of the main processes for learning new motor memories is through the correction of previous errors (error-based motor learning). Distinct components of this learning can be distinguished: adaptation, retention, and re-adaptation. It is largely unknown how reinforcement (punishment, reward) influences these components. Such knowledge would be important for devising more efficient rehabilitation schedules, e.g. following stroke. Adaptation and retention are thought of as distinct processes, with the former linked to the cerebellum, and the latter to the primary motor cortex (M1) (Galea et al., 2011). Given the role of the cerebellum in the processing aversive stimuli (Moulton et al., 2011), and of dopamine in both motivational processes and motor skills retention in M1 (Hosp et al., 2013), a dissociable influence of reward and punishment on error-based motor learning could be hypothesized (Galea et al., submitted). We tested here how reinforcement influences the components of error-based learning after stroke. Subjects affected by a first-ever chronic stroke, with no major cognitive deficits (MMSE >24), performed a force-field (FF) adaptation reaching task using a robotic manipulandum with their paretic arm. Patients affected by a cerebellar stroke, neglect or major psychiatric/cognitive/other neurological disorders were excluded. During baseline (day 1), patients performed 480 reaches towards eight targets. This permitted us to individually tailor the task for the subsequent days. In particular, we selected the two targets with minimal error at baseline and the FF direction (clockwise or counterclockwise) enhancing the main direction of error at baseline. On day 2 and 3, reaches to the two selected targets were performed. After 100 trials baseline, a velocity-dependent FF was applied (350 trials) on day 2 (adaptation) and 3 (re-adaptation), followed by a wash-out (150 trials). In three separate groups, comparable for age, sex and clinical impairment, patients received reward, punishment or null monetary feedback during day 2 adaptation, based on their end point angular error. Subjects were able to adapt in all groups, as shown by the progressive reduction of error and by the significant after-effects (in accordance with Patton et al., 2006). Preliminary results further reveal that patients in the reward group adapted (and re-adapted) faster and retained longer than patients in the punishment or null feedback groups. Ongoing analysis will investigate whether the response to feedback could be related to the lesion location/size. To date, these results support the use of motivational feedback to enhance error-based motor learning in stroke.

Title: Successful reward learning requires a balance between exploration and motor variability and outlasts error-based learning

Authors: *A. THERRIEN[1,2,3], D. M. WOLPERT[4], A. J. BASTIAN[2,3];
[1]The Johns Hopkins Univ., Baltimore, MD; [2]The Kennedy Krieger Inst., Baltimore, MD;
[3]Neurosci., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [4]Engin., Univ. of Cambridge, Cambridge, United Kingdom

Abstracts: Human motor learning depends on a suite of behavioral mechanisms that includes error based adaptation and reinforcement learning. Here we asked 1) how learning a new reaching movement via these two mechanisms differs in acquisition and retention, 2) why learning via reinforcement is often unsuccessful and 3) if a different reinforcement schedule can improve learning. We studied healthy volunteers learning a reaching movement under visuomotor rotations. The reaching movements were 10 cm rapid shooting movements to a single target in a KinArm exoskeleton robotic device. In experiment 1 (E1) participants learned to counteract a 15° visuomotor rotation that was introduced gradually over 320 trials. The adaptation group could see their errors via cursor feedback representing hand position throughout each movement. In contrast, the reinforcement group did not see the cursor and instead received binary reward feedback at the end of each movement informing them if were within the 12° target. After learning, participants performed 100 trials without visual or reward feedback in order to assess retention of any learning. All participants in the adaptation group showed complete adaptation to the visuomotor rotation, but participants in the reinforcement group were divided into those able (learners) and unable (non-learners) to track the rotation. Reinforcement learners tracked the target similarly to the adaptation group during acquisition, but retained the new pattern longer once feedback was removed. To assess differences between reinforcement learners and non-learners, individual subject data were fit with a model that has two components of variability in the movement: inherent motor system noise and variability stemming from exploration behavior. When rewarded, the model updates its estimate of reach direction based on

the exploration variability used on that movement. Fits showed that non-learners exhibited high motor noise relative to exploratory variability. In experiment 2 (E2), a new group of healthy volunteers received binary reinforcement feedback that rewarded reaches lying between the mean reach angle of their preceding 10 trials and the rotated 15° target. Despite being rewarded in approximately 50% of trials some individuals remained unable to track the rotation. The total number of learners, however, was increased relative to the reinforcement group of E1. E2 learners also showed improved learning and similar retention of the rotated movement compared to the reinforcement group in E1 suggesting that learning by binary reinforcement feedback may be improved by a reinforcement schedule that is modified based on subjects' behavior.

Title: Reward feedback accelerates motor adaptation

Authors: *M. K. O'BRIEN[1], A. A. NIKOOYAN[2], A. A. AHMED[2];
[1]Dept. of Mechanical Engin., [2]Dept. of Integrative Physiol., Univ. of Colorado Boulder, Boulder, CO

Abstracts: Recent findings have demonstrated that reward feedback alone can drive motor adaptation. However, a number of questions remain unanswered. For example, it is not yet clear whether reward feedback alone can lead to learning when a perturbation is introduced abruptly, or how it can modulate the learning process. Here, we provide a more informative reward feedback that decays continuously with increasing error. We asked whether it is possible to learn an abrupt visuomotor rotation by reward alone, and if combining both reward and sensory feedback could modulate the learning process. We designed a novel visuomotor adaptation task during which subjects experienced an abruptly introduced rotational perturbation. Subjects (N = 46) grasped the handle of a robotic arm and made 15 cm rapid out-and-back reaching movements

to move an on-screed cursor from a home circle to a target arc. After 50 Baseline trials, subjects experienced Rotation trials, where the cursor underwent an abrupt 30 degree rotation with respect to the hand. After 450 Rotation trials, the environment returned to a 0 degree rotation for the remaining 50 trials (Washout). Subjects were assigned to groups that received either visual feedback of the cursor alone, reward feedback alone, or a combination of reward and visual feedback. A continuous reward feedback (i.e. a reward gradient) was presented to the subjects in the form of trial score. We tested subjects in a linear reward landscape, where the reward decayed linearly with distance from the target, and a cubic landscape, where the reward decayed more steeply with distance from the target. Results demonstrate that it is possible to learn from reward feedback alone and that the combination of reward and sensory feedback accelerates learning. No significant differences were observed in average error at the start or end of learning between the groups that received only reward feedback (no visual feedback) and the group that received only visual feedback (no reward feedback) ($p > 0.05$). Interestingly, we also observed that the combination of reward and visual feedback accelerated learning. We fit an exponential function to the individual subject error data early in the learning phase to determine the learning rate, c. We found that learning rates in the groups that received a combination of reward and visual feedback were significantly faster than the learning rate measure for the group that received only visual feedback ($p = 0.047$, $c = 0.457 \pm 0.063$, $c = 0.212 \pm 0.063$, respectively). These findings suggest that it would be promising to use reward feedback, either to supplement or substitute sensory feedback, for the development of improved neurorehabilitation techniques.

Title: Responsibility-weighted multiple internal models explain stochastic decay in motor adaptation

Authors: ***Y. OH**[1], N. SCHWEIGHOFER[2];
[1]Neurosci., [2]Biokinesiology and Physical Therapy, USC, Los Angeles, CA

Abstracts: Following motor adaptation, performance level decays. However, the mechanism underlying this decay is unclear. In linear state-space models, performance decays passively in the absence of error as a sum of exponentials with different time constants (Smith et al., 2006; Kording et al., 2007). However, such a view may need to be re-evaluated because different unlearning protocols differently affect faster relearning or savings (Kitago et al., 2013), and because memory decay is specific to a context in which it was acquired (Ingram et al., 2013). In addition, a recent study showed that decay may not initiate immediately after the error is clamped to zero (Vaswani & Shadmehr, 2013). Instead, individuals had various lags before onset of decay, indicating that decay is a stochastic rather than a deterministic process. Moreover, subjects having experienced a loose clamp condition (errors varied around zero) exhibited longer decay lags. Because linear state-space models fail to explain both stochastic decay and savings after washout, we adopted the framework of multiple internal models (Lee & Schweighofer, 2009) with the Kalman filter banks (Hanlon & Maybeck, 1999). Each internal model makes its own prediction on sensory consequences, and a weight is assigned to each model based on its prediction error. Then, the motor output is determined from a weighted average of state estimations (Ghahramani & Wolpert, 1997; Wolpert & Kawato, 1998; Berniker & Kording, 2008, 2011). Here, we consider "the baseline model" as a natural internal model experienced from no perturbation, and rapid performance decay following adaptation is considered as a result of weight increase of the baseline model. This occurs when the prediction of the baseline model is more accurate than that of the adapted model. In error-clamped condition, such a rapid change in weight requires an accidental deviation of a motor command from the adapted one due to motor variability, thus the process is stochastic by nature. One prediction from this model is that individuals with larger motor variability are likely to experience shorter decay lags than individual with smaller variability, and our pilot data support this relationship. Similarly, savings is also explained as a recall of the adapted model: when the same perturbation is abruptly applied after washout, the prediction of the adapted model is much better than the baseline model, thus its weight increases quickly, and the motor performance changes "back" to adapted level. In our pilot data with repeated blocks of washout and relearning, subjects showed increased savings at every repetition, suggesting that savings is close to recall than relearning.

Title: A framework for updating optimal feedback control strategies that predicts continuous action selection in complex motor tasks

Authors: *A. SYLAIDI[1], A. A. FAISAL[1,2];
[1]Bioengineering, [2]Computing, Imperial Col. London, London, United Kingdom

Abstracts: The brain coordinates the continuous coupling between perception and action in the presence of uncertainty and incomplete knowledge about the world. From an engineering point of view, this mapping is enabled by control policies. However, the mechanisms that underlie learning such policies remain elusive, particularly in complex motor tasks. We propose here that in such tasks the brain makes continuous decisions for the generation of complex trajectories by learning Optimal Feedback Control (OFC) (Wolpert & Landy, 2012; Todorov & Jordan, 2002; Nagengast et al, 2009) based on the identification of unknown intrinsic and extrinsic task parameters (Sylaidi & Faisal, 2012). We present experiments and theory that can capture the temporal dynamics of motor learning on a trial-by-trial basis.Human subjects (N=15) were instructed to move a virtual tool of unknown dynamics from start to target locations in an unintuitive task that translated hand velocity into control forces on the object state. Subjects received a performance feedback after the completion of each trial in the form of a cost function capturing the end point error, a control penalty and an end state penalty. For the considered experimental setting we proposed a motor learning model, which tests the hypothesis that the brain selects actions by updating the unknown task parameters. These determine both arm and object dynamics and are updated in a locally linear system identification process, which in turn enables a decision on the form of the Optimal Feedback Control policy. The proposed framework updates learned parameters in gradient descent steps driven by the error between predicted and actual object movements in each trial. Our approach expands previous studies on mechanisms of task parameter adaptation, which considered fixed control policies throughout the examined experimental sessions (Berniker & Kording, 2008). Our model predicts accurately the gradual progression of human learning from trial to trial. Furthermore, the model's end-performance predictions outperform an ideal observer model, which assumes complete knowledge of task dynamics and can thus not capture partial learning, to which humans commonly converge in naturalistic task contexts. Our results suggest that the brain employs simple learning rules to support decisions implemented by near optimal control in complex object manipulation tasks. This psychophysically verified, abstract mechanism of motor learning can guide neurophysiological investigations of the underlying cortical foundation of action selection and motor learning principles.

Title: Altering effort costs in Parkinson's disease using non-invasive brain stimulation

Authors: *Y. SALIMPOUR[1], Z. MARI[2], R. SHADMEHR[1];
[1]Dept. of Biomed. Engin., [2]Neurol. and Neurosurg. Dept., Johns Hopkins Sch. of Med., Baltimore, MD

Abstracts: We considered an isometric task in which people held the handles of two robotic arms, one in each hand. The goal was to push on the left and the right robotic arms in such a way as to move a cursor toward targets distributed around a circle. The position of the cursor was the sum of the force vectors produced by each arm. For each direction of target the subjects chose how much force to produce with their right and left arms. This choice was remarkably consistent over repeated days, suggesting that a consistent cost dominated the choice of action. We hypothesized that the choice that people made was due to a cost that had two components: a cost for variability, and a cost for effort. To measure variability, in a unimanual task we measured variance of force for each arm at each direction of force. To measure effort, we measured the maximum voluntary force for each arm and each direction. Using an optimal control model, we estimated cost of effort in n=15 right-side affected PD patients and found that this cost was elevated on the affected side. Therefore, in PD effort costs are abnormally large on the affected side. All participants in this study developed asymmetric motor symptoms from disease onset. We applied anodal tDCS to M1 of the affected hemisphere and cathodal in contralateral M1 of PD patients (n=10). This increased the use of the unaffected side in the bimanual task, worsening symptoms. However, changing the polarity of stimulation in another group (n=10) produced an immediate reduction in variance on the affected side in the unimanual task. That is, in PD cathodal stimulation of affected M1 reduced the variance for control of movements on the contralateral side. Consistent with this, the patients altered the choices that they made in the bimanual task and cathodal tDCS made their choices more similar to healthy controls. We followed this with a 10-day study (n=8 patients). We observed consistent improvements in clinical motor scores, increased use of the affected side in the bimanual task, and reduction in noise on the affected side. In summary, we found that choices that PD patients made in their actions could be explained by a cost that had two components: variance, and effort. On the

affected side, variance is significantly increased with respect to controls, and the choices of PD patients are generally consistent with this increased variance. We can improve the choice of the PD patients in bimanual task by using cathodal tDCS on affected side while they are on dopaminergic medication. This improves the unimanual variance on the affected side and increases use of the affected side in a bimanual task. The repeated application of tDCS improved motor symptom of PD by decreasing clinical symptoms.

Abstracts: It is widely recognized that adapting an identical reaching movement simultaneously to conflicting dynamical environments is quite difficult due to the interference. However, several recent works have demonstrated that simultaneous adaptation is not impossible: For example, we have showed that participants can easily develop distinct motor memories for a reaching movement depending on whether the opposite arm is stationary or moving (i.e., unimanual or bimanual movement) (Nozaki et al., Nat Neurosci 2006). These results suggest that distinct neural representations of a movement depending on different behavioral contexts are associated

with different motor memories. That is, the distinct motor memories observed for unimanual and bimanual movements would stem from their partially distinct neural representations (Donchin et al., J Neurophysiol 2002). Here, to confirm this idea in a more causal way, we tried to examine if artificially induced changes in neural representations using transcranial direct current simulation (tDCS) could contribute to the formation and retrieval of distinct motor memories. Sixteen participants performed forward reaching movement (10 cm) while holding a handle of manipulandum with right hands (KINARM End-Point Lab, Bkin Technologies, Canada). Clockwise (CW) or counter-clockwise (CCW) force field was applied to the handle in a blocked manner (Each block consisted of 20 trials for each force field). tDCS was applied by electrodes placed over left and right primary motor cortices (M1) (i.e., bihemispheric tDCS). In the 6 blocks of training session, the CW or CCW force field was associated with anodal and cathodal tDCS to left M1, respectively. Following the training session, 2 blocks of test session were set up to assess whether the motor memory acquired in the training session was read-out according to the polarity of tDCS. To quantify the acquired motor memories, we adopted the error clamp method in which any force perpendicular to the force channel during movement was measured as aftereffect of the learning. Surprisingly, we observed that the aftereffect was clearly modulated with the polarity of tDCS. In contrast, tDCS in the test session was ineffective to modulate the aftereffect for the participants who trained the force fields with sham tDCS (N=6). These results indicate that tDCS could help to differentiate motor memories between the conflicting force fields and to retrieve appropriate motor memories. The present results are also consistent with our hypothesis that distinct neural representations of identical movements can contribute to develop the distinct motor memories.

Title: Formation and destruction of motor policy alter the position and the velocity dependences during motor adaptation

Authors: *J. IZAWA[1], T. YOSHIOKA[2], R. OSU[2], H. GOMI[1];
[1]NTT Communication Sci. Labs., Atsugi, Japan; [2]ATR, Kyoto, Japan

Abstracts: Motor primitives essentially characterize formation of motor memory. When the brain encounters a novel force environment, the brain initially updates gains of the position sensitive components of the limbs movements and, then, gradually updates gains of other components so that it can produce the ideal motor commands as a sum of these components in order to cancel the given force perturbation (Smith 2009). However, in an alternative view, motor adaptation is a process of re-optimization of motor commands for maximizing the task performance and for minimizing the motor costs (Izawa 2008, 2011). Here, we aimed to capture the effect of optimization on forming the gains of the motor primitives. To this end, we recruited two groups of subjects who were asked to reach in the curl force-field with holding the handle of the robotic manipulandum. One group experienced 450 trials of the force manipulation task in advance of the force-field adaptation block where they were asked to reach in the force channel pushing the wall perpendicularly to the reach direction. As a control, the other group experienced the same number of reaching trials without producing the additional force. Since both groups of subjects leaned to decrease the trajectory error in the comparable level, the prior force manipulation task did not influence the basis of the brain to achieve the reach adaptation. In contrast, the estimated two gains (i.e. position and velocity dependency) from the acquired motor commands were significantly dissociable between two subjects' groups. These learned gains were reasonable in terms of energy efficiency because the estimated motor costs were also distinguishable between two groups. When they encountered the second force field which had the opposite-sign with respect to the first force-field without any break, the optimality of the learned gain was collapsed. Updating gains of motor primitives for producing the ideal motor commands alone is not enough to explain these observed trial-to-trial profiles of the position and the velocity gains. Rather, the brain updated these gains to form optimal policy as a function of the neural encoding of limb movements. When the brain encountered the second novel environment after it had adapted for the first environment, it started to re-optimize the policy which is specific for the second environment. As a result, the optimality appeared to be collapsed after imposing the second environment. We captured this process by modulating the sensitivity to the motor cost by introducing the force manipulation task in advance of the force-field adaptation.

Title: Prismatic adaptation of movements toward visual and proprioceptive targets

Authors: *F. R. SARLEGNA[1], H. LEFUMAT[1], A. HETU[2], P.-M. BERNIER[2];
[1]CNRS & Aix-Marseille Univ., Marseille, France; [2]Univ. de Sherbrooke, Sherbrooke, QC, Canada

Abstracts: Arm movements can be performed toward visual but also proprioceptive targets. Sober and Sabes (2005) and Sarlegna and Sainburg (2007) showed that distinct planning mechanisms underlie these two types of movements. Bernier et al. (2007) also argued for different control mechanisms by showing that prismatic adaptation of movements toward visual targets does not affect subsequent movements toward a proprioceptive target. Here we studied whether distinct mechanisms underlie the adaptive control of movements toward visual and proprioceptive targets. Two groups of 10 healthy right handed subjects reached with their seen right hand toward a visual (VT group) or a proprioceptive target (PT group). The P was the unseen left hand index. There were 3 experimental phases: pre-test (30 reaching trials), adaptation phase (100 trials with prismatic goggles deviating the visual field by 17°) and post-test (30 trials). In both groups, the target was continuously present, at the same location. A beep instructed subjects to reach as fast and as accurately as possible toward the target. Results showed that in the VT group, the hand path was altered rightward by the prisms on the first trial of the adaptation phase. As previously shown, subjects systematically adapted after a few trials, restoring baseline performance. In the PT group, we observed that the first reaching movement in the adaptation phase was unaffected by the prismatic goggles as the right hand index continued to accurately land above the left hand index as in the pre-test. Then, as trials were repeated during the adaptation phase, initial movement direction (at peak velocity) and final hand position drifted leftward of the target position. After-effects did not significantly differ between groups (mean=9°). When subjects in the PT group performed their first movement with prisms, their felt right hand was accurately located above the felt left hand while the seen right hand was rightward of the felt left hand. The fact that adaptation was observed subsequently suggests that vision dominates proprioception to determine the position of the reaching hand and that the comparison of right hand visual signals and left hand proprioceptive signals led to a sensory error signal and thus to adaptation. Another possibility is that a prediction error, derived from the comparison between the predicted visual hand position and the actual visual hand position, may have led to the adaptation of the reaching movements in both VT and PT groups. This would suggest that when we reach with our seen hand toward visual or non-visual targets, the error in predicting the visual consequences of the movement drives adaptation.

Title: The decay of motor adaptation to novel movement dynamics reveals hysteresis in motor primitive gain-space

Authors: K. P. NGUYEN, E. A. HOSSEINI, *W. M. JOINER;
Bioengineering Dept., George Mason Univ., Fairfax, VA

Abstracts: Studies of motor adaptation have consistently demonstrated that subjects adjust their movements when exposed to an external perturbation, such as a force-field applied to reaching movements. This adaptation is largely driven by the experienced movement error and various computational models have successfully described this process. One recent model by Sing *et al.* (2009) showed that the evolution of motor output during adaptation to different force-field perturbations was effectively explained as a combination of motion state primitives, specifically position and velocity. We investigated the interaction of these components during the decay of adaptation. In the first experiment, we tested subjects with either position (N=8) or velocity-dependent force-fields (N=9) and following training, immediately exposed them to a series of error-clamp trials to directly measure the decay of the learning. Similar to Sing *et al.* (2009), we found that motor output in early adaptation to either perturbation was a combination of both relevant (the motion state of the force-field) and irrelevant motion components. Additionally, in late adaption, the contribution of the task-relevant component increased to account for the majority of the adaptive response (91% for velocity-dependent learning, 85% for position). During the decay period, motor output gradually reverted to baseline levels, but throughout this period the task-relevant component was significantly greater ($\geq$ 82%) than the irrelevant component ($\leq$ 18%). Interestingly, when the respective gains were depicted in state space there was substantial hysteresis—the trajectory during learning was further from the task-relevant axis than during the decay period. In a second experiment we trained subjects (N=5) in the position-dependent force-field over two days to determine how additional training influenced the interaction of the task-relevant and irrelevant components, limb position and velocity

respectively. Training was the same on both days, but decay was only assessed on the second. We found clear savings on the second day of training (a faster learning rate) which resulted in a difference in the orientation of the respective gain space learning trajectories: the initial trajectory for learning on the second day was significantly greater in the task-relevant position component than on the first ($p = 0.012$). In summary, we find that the decay of adaptation to novel dynamics travels through a different gain-space trajectory than initial learning and the resulting hysteresis reveals the stability of the task-relevant learning. In addition, we show this hysteresis is diminished with multiple trainings.

Title: Dual adaptation is facilitated by intrinsic contextual cues and saturates upon extended training

Authors: *M. N. AYALA[1], D. Y. P. HENRIQUES[2];
[2]Kinesiology and Hlth. Sci., [1]York Univ., Toronto, ON, Canada

Abstracts: When reaching towards objects, the human central nervous system (CNS) can actively compensate and adapt to two different perturbations simultaneously (dual adaptation), though this does not simply occur upon presentation. In fact, the CNS requires distinctive contextual cues to differentiate between adaptive states. Furthermore, not all contextual cues are effective in facilitating dual adaptation. In two experiments we investigated the efficacy of contextual cues which are intrinsic to the CNS including hand and body posture, as well as the role of extended training in adapting to two opposing visuomotor rotations concurrently. Using a virtual reality paradigm, participants manipulated a projected hand-cursor using a digitizing tablet in a semi-dark room with an opaque board occluding the view of the arm. Cursor rotations of 30° clockwise and counter-clockwise were each associated with 2 distinct hand postures (i.e. precision and power grips) respectively in the first experiment and 2 distinct body rotations (i.e. leftward and rightward turn of the seat, while fixating straight) respectively in the second

experiment. Participants completed pre-training where they were instructed to reach towards visual targets with an aligned cursor, training, where they reached with misaligned cursors, and post-training where they reached without visual feedback of the hand in order to capture any aftereffects following adaptation. In addition, because recent work from our lab and others have shown that the learning rate in dual adaptation is not as steep as that of single adaptation, we implemented an extended training set in the first experiment to examine the effect of greater practice. We found that how people held the tool or oriented their body while reaching is sufficient for recalling an adaptive state (or previous visuomotor mapping) such that over time, reach errors significantly decrease despite being presented both perturbations in a randomized, concurrent manner. This adaptation was further reflected in the presence of significant aftereffects following training. No significant reduction in reaching errors nor increases in percent improvement in reach adaptation were found following extended practice suggesting that dual adaptation training reaches a saturation point. Our results suggest that intrinsic cues which produce distinct muscle synergies are effective at facilitating dual adaptation while extended training provides no additional benefits.

Title: Investigating the mechanisms of repetitive trans-cranial magnetic stimulation using motor learning paradigms and *in vivo* 2 photon imaging

Authors: *A. CANTY[1], B. BENNETT[1], A. TANG[1,3], J. RODGER[3], M. HINDER[2], M. GARRY[2], J. SUMMERS[2,4];
[1]Wicking Dementia Res. and Educ. Ctr., [2]Sch. of Med., Univ. of Tasmania, Hobart, Australia; [3]Sch. of Animal Biol., Univ. of Western Australia, Perth, Australia; [4]Res. Inst. for Sport and Exercise Sci., Liverpool John Moores Univ., Liverpool, United Kingdom

Abstracts: **Introduction/Objective** Brain function is underpinned by electrical activity inducing chemically mediated communication between cells, both of which are crucial in establishing normal brain structure and function during development and maintaining them throughout life. Modulation of electrical activity by repetitive transcranial magnetic stimulation (TMS) is becoming widely recognised as a clinically applicable non-invasive intervention to improve and repair neural function. However, the mechanisms whereby such neuromodulation occurs, and how long they last, are largely unexplored. Rodent models can be useful in establishing structural and molecular mechanisms associated with neuromodulation. To this end, we have combined TMS with either a motor learning behavioural paradigm or live *in vivo* 2 photon imaging of motor cortex circuitry to investigate neuroplasticity resulting fromTMS. **Methods** We use a rodent specific TMS 8mm outer diameter circular coil to deliver intermittent theta burst stimulation (iTBS) over the motor cortex of awake adult male mice (*Mus musculus*). Thy1-GFPM mice undergo cranial window insertion overlying the right motor cortex to enable visualisation of excitatory cortical neurons in the upper layers of the motor cortex. Images of cortical circuitry are collected at regular intervals before and after iTBS and analysed for alterations in connectivity resulting from daily stimulation (600 pulses, 190 sec). For motor learning paradigms, adult C57Bl6/J mice are maintained at 90% body weight, habituated to experimental conditions and learning assessed by pellet reaching through a narrow vertical slit in a Perspex box over a period of 10 days. Mice receive either daily iTBS (600 pulses, 190 sec) or sham stimulation immediately prior to being placed in the box. All experiments are approved by University of Tasmania Animal Ethics Committee. **Results** We have established a baseline trajectory for skilled reaching task comparable to published data. Preliminary analysis on day 4 of training indicates no change in motor learning with the application of iTBS. Analysis of imaging data is ongoing. **Conclusions** The use of rodent models to address the mechanism of action of TBS, will undoubtedly pave the way forward to more appropriate uses and therapeutic applications of non-invasive brain stimulation in health and disease.

Title: Joint kinematics and synergies during motor learning with a redundant arm exoskeleton in individuals with sub-acute stroke

Authors: *C. WANG[1], O. REMY-NERIS[2], D. MOTTET[3], I. LAFFONT[3], N. SCHWEIGHOFER[1,3];
[1]USC, Los Angeles, CA; [2]Faculté de Médecine, Univ. de Bretagne Occidentale, Brest, France; [3]M2H Laboratory, Euromov, Univ. of Montpellier I, Montpellier, France

Abstracts: The improvement in performance during recovery and motor training post-stroke has been thoroughly investigated via changes in hand kinematics (e.g. Rohrer et al. 2002, Van Dokkum et al. 2014). However, the longitudinal changes in the redundant arm joint kinematics space, and how these changes relate to performance improvement in hand space, are less well understood. Here, we investigated changes in hand kinematics, joint kinematics, and joint synergies in 7 post-stroke individuals with mild to moderate impairments in the sub-acute phase. Participants received motor training with the redundant ARMEO Spring device arm exoskeleton (Hocoma) twice a day over 4 consecutive weeks, 5 days per week. Each training session consisted of series of serious games in which the patients controlled a cursor via 3D displacement of the hand and forward kinematics transformation of the 6 joints (3 at the shoulder, 1 at the elbow, pronation-supination and wrist flexion-extension). We tested performance with a vertical pointing test repeated at the beginning and end of each session. We analyzed hand and joint kinematics as well as joint coordination via principal component analysis (PCA). We compared the performance measured by hand kinematics with healthy subjects (Schweighofer et al. 2013, SFN), and discussed how the improvement of performance in hand space may be influenced by joint kinematics and joint synergies.

Title: Suppression of visual feedback during force-field adaptation impairs motor acquisition without affecting next-day retention

Authors: *C. S. BATCHO[1,2], M. GAGNÉ[2], L. J. BOUYER[1,2], J.-S. ROY[1,2], C. MERCIER[1,2]; [1]Univ. Laval, Quebec, QC, Canada; [2]Ctr. interdisciplinaire de recherche en réadaptation et intégration sociale (CIRRIS), Quebec, QC, Canada

Abstracts: Motor rehabilitation is important to optimize recovery of function after neurological impairments. Previous studies have suggested that visual feedback may help enhancing motor performance during learning. The aim of this study was to investigate the role of visual feedback in the acquisition and retention stages of motor learning associated with training in a reaching task. Twenty-eight healthy subjects made ballistic reaching movements with their dominant arm towards two targets (Far and Near), on 2 consecutive days using a robotized exoskeleton. They were randomly assigned to a group with (VFb) or without (noVFb) visual feedback of index position during movement. On Day 1, the task was performed without (baseline) and with a force field (adaptation). To assess retention, participants repeated the task with the force field on Day 2. Motor learning was characterized with: (1) the initial angle (iANG) between the trajectory and a straight line to the target ("motor planning") and (2) the final error (fERR) ("movement accuracy"). Two-way ANOVAs (Time X Group) were performed for each condition (Baseline and Adaptation), variable (fERR and iANG) and target (Near and Far). Results showed no significant differences between groups at baseline. During force field adaptation, a significant Time x Group interaction ($p \leq 0.033$) was found for both targets. Contrast analysis revealed that the VFb-group decreased their fERR faster than the NoVFb-group on Day 1. However the fERR was similar between groups on Day 2. iANG showed a change in the feedforward control of movement during training on Day 1, and this effect was maintained on Day 2. However, little difference was found between groups. Indeed, a significant Time x Group interaction was found only for the Far target, and the contrast analysis showed a significant difference between groups only at the end of Day 1. These results suggest that despite a slower motor acquisition on Day 1, the NoVFb-group showed a similar retention on Day 2. This finding is consistent with previous studies showing that larger gains during training are not always predictive of better long-term retention. Therefore, assessing retention in the actual task is critical to determine optimal feedback conditions during motor training in rehabilitation.

Title: Neural basis for motor learning: Sensorimotor cortical ensembles multiplex spatial, temporal and reward-related information

Authors: ***A. RAMAKRISHNAN**[1,2], K. P. RAND[3], M. A. LEBEDEV[1,2], M. A. L. NICOLELIS[1,4,5,2,6];
[1]Neurobio., [2]Ctr. for Neuroengineering, [3]Pratt Sch. of Engin., [4]Dept. of Biomed. Engin., [5]Dept. of Psychology and Neurosci., Duke Univ., Durham, NC; [6]Edmond and Lily Safra Intl. Inst. of Neurosci. of Natal, Natal, Brazil

Abstracts: Motor learning is the hallmark of brain plasticity. Although motor learning has been studied extensively, the neural mechanisms that drive such motor plasticity are not well understood. A recent study suggests that reward pathways project to human M1 (Kapogiannis et al., 2008). However, how reward and reward anticipation might modulate sensorimotor cortical ensembles remains a question. We designed a task that dissociated spatial characteristics of movements from reward anticipation. Monkeys performed a center-out reaching task that incorporated a delay period between target acquisition and the reward. The duration of this period (1s vs. 3s) was signaled by the target color (red vs. blue). Monkeys were involved in the task in three different ways in different sessions: they passively observed a computer-controlled avatar arm performing the task, manually moved the joystick to control avatar arm movements, or moved the avatar arm with their brain activity. Large-scale recordings from several hundred neurons from sensorimotor cortex and posterior parietal cortex revealed robust reward anticipatory activity that preceded the reward. While some neurons (~36%) showed a buildup or sustained firing rate until reward long after movement ended, some others (~10%) fired just around reward delivery. A KNN-classifier applied to the neuronal ensemble revealed that the neuronal tuning underwent a transformation: the ensemble encoded the target location during the reach movement, and then transformed to encode reward anticipation. Furthermore, with long-

term training, the ensemble represented the anticipation earlier in the trial and sustained this activity longer during the hold time. These results show that spatial, temporal and reward-related signals are represented in a highly distributed way by cortical networks. We suggest that adaptations of these representations underlie motor learning and understanding the process of adaptation would allow optimization of reward-based learning in neuroprosthetic control.

Title: Scaling errors down improves retention of motor adaptation

Authors: *R. J. VAN BEERS, E. BRENNER, J. B. J. SMEETS, K. VAN DER KOOIJ;
VU Univ. Amsterdam, Amsterdam, Netherlands

Abstracts: Many studies on motor adaptation have focused on the factors that determine how fast subjects adapt to a perturbation. A more recent development is that motor adaptation is also studied to determine the factors that determine how well adaptation is retained. Here we examined how scaling the sensory feedback about motor errors affects retention of motor adaptation. Subjects reached to visual targets in eight directions from a fixed start location. They adapted to a visuomotor rotation, such that they had to move in a direction that differed 30 deg from the actual target direction in order to reach the target. This rotation was introduced gradually over 48 movements. Moreover, the error in the movement direction with respect to the required direction was multiplied by a gain factor to determine the displayed hand position. We tested three groups of subjects with gains of 0.5, 1 and 2. An analysis of the initial movement directions after adaptation showed that subjects in all groups had adapted to about two-thirds of the perturbation. After the adaptation phase, subjects made 200 error-clamp movements, in which they always received visual feedback that suggested that they moved in the correct direction. During this error-clamp block, the level of adaptation decreased in all groups. However, the extent of the decrease differed strongly between groups. Whereas the gain-2 group

retained only 52% of what they had learned, the gain-1 and gain-0.5 groups retained 63% and 90%, respectively. Our results show that scaling the sensory feedback about movement errors has a strong effect on retention of motor adaptation. Whereas scaling errors up may lead to faster learning, it has a negative effect on retaining what has been learned. Scaling errors down, in contrast, may lead to somewhat slower learning, but what is learned is retained very well. Downscaling of errors may therefore be a useful technique for training when it is important that what has been learned is not quickly forgotten, such as in movement rehabilitation following brain injury or stroke.

Title: Recovery in upper body mobility through practice with body machine interface

Authors: *C. PIERELLA[1,3,4], F. ABDOLLAHI[1], A. FARSHCHIANSADEGH[1,5], J. PEDERSEN[2], D. CHEN[2], E. THORP[5,1], I. SEÁÑEZ-GONZÁLEZ[5,1], F. A. MUSSA-IVALDI[1,5,4], M. CASADIO[3];

Abstracts: People with high-level spinal cord injury (SCI) face two related problems: recovering motor skills and regaining functional independence. Assistive technologies are instrumental for them to interact with the environment and partially replace the lost functionalities, but their use is often challenging because the users need to reorganize their residual ability in unintuitive ways, e.g. sip-and-puff or head arrays. Moreover, most SCI survivors receive intense rehabilitation treatments that promote motor recovery only shortly after injury, when they are hospitalized. However, they do not continue with the same frequency after being released from the hospital. Body-machine interfaces (BoMIs) can be a valid solution to these problems. They empower people with severe motor disabilities with the possibility to control external devices, and they concurrently offer the opportunity to focus on achieving rehabilitative goals. In this study we developed a portable and low-cost body machine interface that addresses both problems. The proposed BoMI remaps the user's residual upper body mobility to the two coordinates of a cursor on a computer screen. This mapping is obtained via standard techniques for dimensionality reduction, such as principal component analysis (PCA). We hypothesize that the BoMI can be specifically programmed to engage the users in functional exercises aimed at partial recovery of motor skills, while simultaneously controlling the cursor and carrying out functional tasks, e.g. playing games. Specifically, PCA allows us to select not only the subspace that is most comfortable for the user to act upon, but also the degrees of freedom and coordination patterns that the user has more difficulty engaging. In this case study, we attempted to change the body-motion symmetry of a single SCI participant with an incomplete lesion at the C4 level. At the beginning of the experiment, the participant demonstrated a marked reduction in the mobility of the right side of the upper body compared to the left side. Thus, we changed the parameters of the BoMI so as to increase the role of the right side and tested the effect of this alteration after 2 weeks of practice. Results showed that this approach restored a higher level of symmetric mobility. The present study is the first proof of concept of the use of the BoMI in the rehabilitation field. Engaging the user in functional and entertaining tasks while practicing the interface and changing the map in the proposed ways is a novel emerging approach to home-based rehabilitation treatments provided by portable and low-cost technologies.

Title: Robot-assisted training of the non-paretic arm contributes to recovery for chronic stroke survivors

Authors: *M. CASADIO[1], A. DE LUCA[2], H. VERNETTI[2], C. LENTINO[3], G. CHECCHIA[3], P. GIANNONI[4];
[1]Univ. of Genova, Genova, Italy; [2]Recovery and Functional Reeducation Unit, Santa Corona Hospital, ASL2 Savonese, Pietra Ligure, Italy; [3]Recovery and Functional Reeducation Unit, Santa Corona Hospital, ASL2 Savonese, Pietra Ligure (Italy), Italy; [4]ART Educ. and Rehabil. Ctr., Genova, Italy

Abstracts: To quickly regain independence in daily life activities, stroke survivors develop and strengthen compensatory strategies that involve trunk movements and posture, as well as the unimpaired side of the body. Sixteen chronic stroke survivors (7 male, 9 female, age 63.06 ± 8.84 years, 11 right and 5 left hemiplegia, 5.96 ± 4.28 years from the acute event) participated on 20 therapy sessions based on active movements of the unaffected arm supported by exoskeleton Armeo Spring (T-Wrex). A physiotherapist helped subjects maintaining a correct sitting posture. During the treatment, unaffected limb performance was evaluated with the training device in a reaching test performed at the beginning and at the end of each session. With training, all subjects improved the not paretic arm performance (duration -0.79±SE 0.09 seconds, $p<0.0001$, accuracy $p=0.01$, smoothness $p=0.008$). The paretic arm performance of seven subjects was tested at the beginning and the end of the treatment with the Armeo evaluation test. We found a significant improvement in the task execution time (-0.72±0.22 SE seconds, $p=0.01$) and in the number of targets reached with the un-treated impaired arm. A clinician evaluated subjects before and after treatment. We found a significant improvement in the scores of the Trunk Impairment scale (+2.06±0.6 SE $p=0.005$) and in the impaired arm function: +3.87±0.99 SE points of the Fugl-Meyer Scale upper arm section ($p=0.001$). 12/15 subjects improved also the Wolf test score. The amount of improvement in the FM score is comparable to the results obtained with rehabilitation robotic treatments focused directly on the impaired arm. We plan to further investigate these findings. However, as it stands, this result highlights the importance of taking into account in the rehabilitation robotic program all body schema, instead of focusing exclusively on the most impaired side of the body. This study also suggests that the recovery we observed in chronic stroke survivors after robot-assisted rehabilitation could be mainly due to the control of compensatory strategies and the empowerment of weak or silent skills, rather than to the re-acquisition of new or lost abilities on the affected side.

Title: Age related effects on motor learning when using a novel body-machine interface

Authors: ***M.-H. LEE**[1], A. FARSHCHIANSADEGH[2];
[1]Michigan State Univ., East Lansing, MI; [2]Northwestern Univ., Chicago, IL

Abstracts: Do children and adults learn differently? This issue has important implications both from a theoretical motor development standpoint - e.g., whether particular brain regions are critical for motor learning - and from a practical/translational perspective - e.g.. whether rehabilitation protocols for children with disabilities should be similar to those used for adults. In typical motor tasks, comparisons between children and adults are often difficult since any changes in learning strategies are also confounded by changes in task familiarity and anthropometric changes such as muscle strength or body size. In order to minimize these confounds, we investigated how children and adults acquire a motor skill in a novel virtual task using a body-machine interface (BoMI). Both children and adults who were completely naïve to the task learned to use their shoulder movements to control a computer cursor in a center-out reaching task to 8 different targets. Participants wore a customized vest that had 4 inertial measurement units (IMU) attached to the participants' upper body. These 8 signals (roll and pitch from the 4 IMUs) were mapped on to the 2-D position of a cursor. The map was established using a calibration procedure to ensure that both children and adults could accomplish the task using their existing movement abilities. Both children and adults practiced for a total of 160 trials toward 4 targets. Three generalization tests during learning (pre, during and post-practice), where participants reached toward all 8 targets, were used to examine learning and generalization. Preliminary results show that initially in practice, children had longer movement times (~50%) compared to adults. This difference in movement time was also

associated with a change in the movement strategy. The analysis of the task and null space variance showed that children tended to use greater exploration (i.e. greater task space and null space variance) when compared to adults initially in learning. However, by the end of practice, the performance and exploration for the two groups were similar. These results suggest that children tend to use greater exploration initially in learning. Future studies will investigate how this difference in learning strategy may be exploited to facilitate motor learning in children.

Title: Remapping upper-body movements of individuals with spinal cord injuries to control a power wheelchair

Authors: *E. THORP[1,3], F. ABDOLLAHI[1], D. CHEN[2], A. FARSHCHIANSADEGH[1,3], M.-H. LEE[5], J. PEDERSEN[2], C. PIERELLA[1,6,4], E. J. ROTH[2,4], I. SEÁÑEZ-GONZÁLEZ[1,3], F. A. MUSSA-IVALDI[1,4,3];
[1]Sensory Motor Performance Program, [2]Rehabil. Inst. of Chicago, Chicago, IL; [3]Biomed. Engin., [4]Dept. of Physiol., Northwestern Univ., Evanston, IL; [5]Dept. of Kinesiology, Michigan State Univ., East Lansing, MI; [6]Dept. of Informatics, Bioengineering, Robotics, and Systems Engin., Univ. of Genoa, Genoa, Italy

Abstracts: Traditional power wheelchair control interfaces are often inadequate for individuals with high-level spinal cord injuries who may have impaired upper-limb function. Additionally, alternative wheelchair controllers such as a head array, sip-and-puff or most EEG controllers offer only a limited vocabulary of commands and do not take advantage of what residual movement may remain. Here, we present a body-machine interface (BoMI) that uses shoulder movements to drive a power wheelchair. Specifically, shoulder movements are used to continuously control the speed and direction of a power wheelchair to achieve proportional

control. Our approach involves dimensionality reduction, where we map high dimensional shoulder kinematics as measured by inertial measurement units to a low dimensional control signal. To test the efficacy of such a control interface, after training in a simulated virtual environment, subjects performed a set of maneuvers driving a real power wheelchair using first a joystick and then our BMI. A preliminary study of skilled power wheelchair users whom had suffered injuries to the cervical level of the spinal cord, revealed that after only a few driving sessions, mastery of the interface was achieved. Performance was quantified by the path length and time needed to complete each maneuver as well as the smoothness of the maneuver. During the first session driving the wheelchair, even though performance was lower for the BoMI compared to a traditional joystick, all participants were able to complete all maneuvers using the BoMI. After only seven training sessions, all performance measures increased across participants. In the final session, performance using the BoMI was comparable to performance using the joystick. These results suggest that training in a virtual environment can translate to using the interface to control a real power wheelchair. The results also suggest that despite sufficient virtual training, there is a learning process that occurs when controlling the real wheelchair for the first time, but that high performance can be achieved over relatively few training sessions. Overall this work presents a proof of concept for a BoMI controlled power wheelchair that affords maximum flexibility while promoting continued engagement of residual motor function.

Title: Reorganization of finger movements to improve hand dexterity in stroke

Authors: *R. RANGANATHAN;
Dept of Kinesiology, Michigan State Univ., East Lansing, MI

Abstracts: The loss of hand dexterity after stroke results significantly impacts the ability to perform activities of daily living. Hence there is a need to discover new techniques to improve hand dexterity. Here, we examine the use of a body-machine interface to induce reorganization and increase the repertoire of finger movements in stroke. The goal of the participants was to learn to control a computer cursor using finger movements. 8 individuals with chronic stroke (average 6 years post-stroke) wore a Cyberglove and the signals corresponding to flexion/extension of the MCP joint of the four digits were mapped linearly on to the position of a cursor. The task was to move the cursor back and forth between two targets positioned at the left and right of the screen. In order to encourage participants to reorganize their movements, we gradually changed the weightings in the map between the finger movements and the movement of the cursor. For example, the weights of the index, middle, ring, and little fingers (I,M,R,L) were initially set to (1,1,1,1) - which requires a power-grasp pattern. This weights would be gradually changed during the course of the trial to (1,1,-1-1) - which requires individuation between the IM and RL fingers. Each trial consisted of between 50 and 100 targets, and participants practiced the task for 4 sessions spread over two weeks. We measured the repertoire of finger movements generated in these trials using a principal component (PCA) analysis. Results showed that stroke survivors were able to reorganize their finger coordination patterns to adapt to the changing weights and reach the targets. Moreover, in 6 out of 8 subjects, the variance accounted for by the first PC (which indicated the dominant coordination pattern) decreased with practice (from 82 to 77%), indicating that participants were able to expand their repertoire of finger movements. These results suggest that the use of a body-machine interface facilitated the reorganization of finger coordination patterns in stroke survivors. There was exploration of novel coordination patterns, which may provide a way of breaking maladaptive synergies. This technique may provide a potentially powerful paradigm in rehabilitation to alter existing coordination patterns.

Title: Kalman-based control of a virtual wheelchair using shoulder movements

Authors: *I. SEÁÑEZ-GONZÁLEZ[1,2,5], E. THORP[2,5], A. FARSHCHIANSADEGH[2,5], C. PIERELLA[3,5,6], F. ABDOLLAHI[5], F. A. MUSSA-IVALDI[2,3,4,5];

Abstracts: We describe a novel body-machine interface for the continuous control of a 2D cursor and a virtual wheelchair using four inertial measurement units (IMUs) placed on the user's upper-body. A calibration paradigm where human subjects follow a cursor with their body as if they were controlling it with their shoulders generated a map between shoulder motions and cursor kinematics. This map was used in a Kalman filter to estimate the desired cursor coordinates from upper-body motions. The cursor's position was then mapped into the coordinates of the virtual joystick controlling the virtual wheelchair. Subjects performed a center-out reaching task with blind and generalization trials. After practice, subjects were instructed to navigate through a virtual map and perform a variety of maneuvers commonly used to asses wheelchair control. All subjects improved their performance with practice on the center-out reaching task and were able to successfully complete the virtual navigation task. Our work demonstrates the potential of non-invasive IMU-based body-machine interface systems as an alternative or complement to brain-machine interfaces for accomplishing wheelchair control in 2D space. The engagement of users of assistive devices in control actions performed by the available mobility has the potential to connect the performance of functional tasks with the practice of rehabilitation-oriented physical exercises. The present study may serve as a platform for people with high-tetraplegia to control assistive devices such as powered wheelchairs using a joystick.

Title: Time required to predict movement distributions

Authors: *Z. WRIGHT[1,2], M. FISHER[1,2], F. HUANG[2], J. PATTON[1,2];
[1]Bioengineering, Univ. of Illinois At Chicago, Chicago, IL; [2]Rehabil. Inst. of Chicago, Chicago, IL

Abstracts: While human motor ability is often described in terms of the average performance in goal directed actions, such an approach ignores the natural variation of movement in daily life. Allowing human subjects to perform self-directed motor exploration in an experimental setting could reveal information about their unique movement tendencies. Before such an experimental tool can provide meaningful insights, methods are needed to determine the best practices for interpreting variable movement. One important feature is how much information (data) is required to construct a probability distribution that reliably predicts an individual's movement patterns. In this study, we analyzed the movement of stroke survivors (n=10 from a previous study) and healthy individuals (n=5) derived from self-directed motor exploration to investigate whether simple kinematic variables differed in terms of the amount of data required. We found that the amount of data required for such characterizations decreased with order (i.e., 13.7 ± 1.7 minutes for position (mean ± SE), 9.6 ± 1.9 minutes for velocity, and 6.4 ± 2.4 minutes for acceleration for healthy individuals). Data requirements for stroke survivors followed a similar trend, but required less time (i.e., 44% less for position, 35% less for velocity and 61% less for acceleration, but only significant for position information; $p < 0.05$). These results from self-directed movement identify the characterization time as an important feature for tracking movement differences using statistical distributions. Such tools can complement more standard clinical and engineering assessments, help track recovery, and can guide the design of novel neurorehabilitation training.

Title: Inter-limb transfer effects following leg motor skill learning

Authors: *C. KRISHNAN[1], R. RANGANATHAN[4], M. TETARBE[2], L. L. LETHERWOOD[3]; [1]Physical Med. & Rehabil., [2]Physical Med. & Rehabilitation; Biomed. Engin., [3]Physcial Med. & Rehabilitation; Mechanical Engin., Univ. of Michigan, Ann Arbor, MI; [4]Kinesiology, Michigan State Univ., East Lansing, MI

Abstracts: Several lines of research indicate that motor learning is a key component of recovery after neurological injuries such as, stroke or spinal cord injury. There is also evidence to suggest that learning in one limb transfers to the other limb, which is termed as inter-limb transfer. We have recently developed a novel functional motor learning paradigm for gait rehabilitation; however, less is known on the retention and inter-limb transfer effect of our paradigm. Therefore, the purpose of this is study is to evaluate the consolidation and inter-limb transfer effects of a leg motor skill learning task in a group of neurologically intact adults. A secondary purpose was to evaluate whether the inter-limb transfer effects are side-specific. Twenty-two young adults (11 dominant group, 11 non-dominant group) were tested on two consecutive days. Participants performed a foot target-tracking task that necessitated modifications in their hip and knee flexion while walking on a treadmill. On Day 1, the dominant group performed testing with their dominant leg (i.e., preferred leg for kicking). On Day 2, they were tested for their dominant leg retention and non-dominant leg transfer effects using the same paradigm. The non-dominant group performed the same sequence beginning with their non-dominant leg instead. The changes in tracking error were computed to study the learning effects. The results indicate that repeated practice of the leg motor learning task resulted in significant reduction in target-tracking error in both the groups ($P < 0.05$). For the right group, the error in target-tracking during the first block of Day 2 was similar to those observed on block 10 of Day 1, indicating that subjects retained their performance improvements. In contrast, the error in target-tracking during the first block of Day 2 was slightly lower to those observed on block 10 of Day 1 in the left group ($P < 0.05$), indicating that there was some offline learning. Similarly, inter-limb transfer effects were better for the left group in comparison to the right group, although both groups showed transfer effects ($P < 0.05$). These results indicate that inter-limb transfer effects are present for our leg motor skill learning task and appear to be side-specific. The inter-limb transfer effects of learning observed in our target-tracking paradigm provide an opportunity to facilitate recovery of the impaired limb via training of the less impaired limb. The results have meaningful implications for gait rehabilitation in individuals with stroke or other neurological disorders.

Title: Parameterization of error in time versus space for goal-directed movements

Authors: ***M. FISHER**[1,2], F. HUANG[1,3], Z. WRIGHT[1,2], J. PATTON[1,2];
[1]Rehabil. Inst. of Chicago, Chicago, IL; [2]Univ. of Illinois at Chicago, Chicago, IL;
[3]Northwestern Univ., Chicago, IL

Abstracts: Manipulation of error feedback has been of great interest to recent studies in motor control and rehabilitation. Typically, researchers examine motor adaptation in terms of scalar metrics, for example, the initial direction error or maximum deviation for each trial. However, yet such an approach overlooks details about how error evolves through the movement. We believe that statistical distributions of movement error through the extent of the trajectory can reveal unique patterns of adaption and possibly reveal clues to how the motor system processes information about error. Using multiple data sets where subjects experience intermittent distortions to sensorimotor conditions, this study describes different possible ordinate domains, focusing on representations in time and state-space, used to quantify reaching errors. We hypothesized that error described in various ordinate domains would differ in their predictive power. We calculated the coefficient of determination (R2) between the probabilistic error model and the experimental data. We found that the R2 values for error during intermittent exposure differed between ordinate domains (ANOVA with repeated measures, p=0.0042), with larger values for time (mean: 0.3390, CI: 0.254, 0.425) compared to path length (mean: 0.0965, CI: 0.0675, 0.1255) and distance along target path (mean: 0.2435, CI: 0.1884, 0.2985). These results show that errors represented in a time domain exhibit the least variance and allow for the highest predictive model of reaching errors. The development of such predictive models will give rise to specialized methods of robotic feedback for training of motor skills, improving upon previous techniques of error augmentation.

Title: A BMI-based robotic exoskeleton for neurorehabilitation and daily actions: Elbow and wrist movements controlled by EEG and EMG signals

Authors: ***T. KAWASE**, Y. SATO, K. KANSAKU;
Sys Neurosci Sect, Dept of Rehab for Brain Funct, Res. Inst. of Natl. Rehabil. Ctr., Saitama, Japan

Abstracts: The brain-machine interface (BMI) or brain-computer interface (BCI) is an interface technology that utilizes neurophysiological signals from the brain to control external machines or computers, and we have developed a BMI-based occupational therapy-assist suit (BOTAS) for paralyzed upper extremities. Sensorimotor rhythm, P300 (Komatsu et al., 2010), steady-state visual evoked potential (SSVEP) (Sakurada et al., 2013) and electromyography (EMG) signals (Kawase et al., 2012, 2013) were used to drive the in-house assist suit for reaching and grasping movements. We developed a wearable BMI-based exoskeleton for neurorehabilitation and daily actions (BRENDA) for reaching and grasping movements with an elbow and fingers (Kawase et al., 2014). In this study, we developed a BRENDA (type II) for reaching movements with an elbow and a wrist. The BRENDA had a two motors to assist reaching movements with flexion/extension of an elbow and a wrist. The motors were controlled based on signals extracted from EEG and EMG. A LED panel for eliciting SSVEP with 38Hz green/blue flickering stimuli was attached to a forearm portion of the BRENDA. Electrodes for EMG measurement were attached to an arm sleeve beneath the BRENDA. An amplifier of the biological signals, batteries and a PC for controlling the whole system were stored in pouches, and the user wore the pouches

at the waist. In an experiment, the BRENDA worn by an able-bodied subject (a 29-year-old male) realized reaching movements with flexion of the elbow, which were triggered by EMG signals, and with flexion of the wrist, which were triggered by SSVEP elicited by 38Hz green/blue flickering stimuli. The new exoskeleton may be useful for practical rehabilitation and support of daily actions based on the users' intention.

Title: Development of virtual integration environment sensing capabilities for the modular prosthetic limb

Authors: ***B. A. WESTER**[1], K. FISCHER[1], T. GION[1], G. HOTSON[2], J. DOWNEY[5], M. FIFER[3], F. TENORE[1], J. BEATY[1], A. RAVITZ[1], M. MCLOUGHLIN[1], R. GAUNT[5], J. COLLINGER[5], N. CRONE[4], S. SWETZ[1];
[1]JHU/APL, Laurel, MD; [2]Electrical and Computer Engin., [3]Biomed. Engin., [4]Neurol., Johns Hopkins Univ., Baltimore, MD; [5]Univ. of Pittsburgh, Pittsburgh, PA

Abstracts: The Virtual Integration Environment (VIE), a software emulation of the Modular Prosthetic Limb (MPL) with shared communication interfaces, was designed as an integration and training tool for clinical research in the fields of upper extremity prosthetics and rehabilitation. The VIE provides both a 3D graphical visualization and physical simulation of the MPL including the 26 articulating joints and 17 independently controllable virtual motors operating and interacting within a virtual world. The VIE simulates physical object interactions with the virtual MPL (vMPL), including contact, grasping and fingertip force, and allows

grasping, transporting, and repositioning of objects. Limb data and virtual sensors percepts are generated through control of the vMPL, from object interactions, and event handling within the environment. Via defined communication interfaces, these data and percepts are available to the clinical operator. In addition, the data and percepts mimic those reported by the physical MPL. The VIE has been developed as a framework allowing creation of multiple virtual scenarios that facilitate clinical training and real-time operation of the vMPL, as well as offline data analysis. Because of its versatility and portability, the VIE is well suited to support development of closed-loop experimental systems for both motor control and sensory feedback, and for eventual clinical use of a physical MPL system. Here we describe the architecture and capabilities of the VIE for closed-loop control, as well as its implementation in clinical work within the scope of the DARPA's Revolutionizing Prosthetics and other programs.

Title: Neural mechanisms of mirror feedback: An EEG study based on virtual reality

Authors: *G. GARIPELLI, V. LIAKONI, D. PEREZ-MARCOS, T. TADI;
Mindmaze SA, Ecublens, Switzerland

Abstracts: Recent research in neurorehabilitation has found mirror therapy to be more effective than conventional treatment for improving motor function. However, the neural mechanisms underlying mirror therapy remain unclear. On the other side, virtual reality (VR) based cognitive therapy has been shown to be helpful in inducing cortical plasticity and promoting functional recovery of arm/hand movements. We have combined both approaches into a novel VR platform (MindPlayPRO, MindMaze SA, Switzerland) for effective neurorehabilitation. In the current study, we explored the neural markers associated with the execution and observation of goal-directed movements under mirrored visual feedback in a virtual environment. Understanding these neural mechanisms will guide customization of neurorehabilitation procedures using VR systems. We recorded EEG data (64 electrodes) of nine healthy participants (22-35 years) while

they performed a reaching task in VR under three visual feedback modes: a) direct mapping, with the right arm mapped onto the virtual right arm; b) mirror mapping, with the right arm mapped onto the virtual left arm; and c) passive video control, with action observation of pre-recorded movements of the virtual left arm. Mirror mapping led to higher negative slow cortical potentials (SCPs) (0.1-1.5 Hz) compared to direct mapping in central electrodes (maximum at Cz; paired t-test, $p<0.001$, Bonferroni corrected). Interestingly, the hemispheric laterality (difference between C3 and C4) was significantly lower in the mirror mapping ($p<0.001$). Additionally, we conducted single-trial analysis for elucidating the neural signatures of mirrored feedback using linear discriminant analysis (LDA) between direct and mirror mapping. The performance of LDA revealed a source of discriminability on the ipsilateral electrodes (maximal at C2 and C4 electrode), with ROC area under curve of 67+/-4%. The mere action observation in passive video control led to significantly weaker activity compared to direct and mirror mapping in the central electrodes (C3, Cz and C4, $p<0.001$). The analysis of SCPs suggests that the proposed mirror visual feedback in a virtual environment can increase the cortical excitability of the hemisphere ipsilateral to the movement. This finding is in line with observations of previous neurophysiological studies on mirror therapy and may have important implications in the design of effective rehabilitation procedures using virtual reality. Further studies with hemiparetic patients may reveal how the current evidence is translated into clinical settings.

Title: Psychophysical, neural, and learning curve metrics toward optimizing training with a brain-computer interface

Authors: ***J. J. WILLIAMS**[1], R. N. TIEN[2], A. B. SCHWARTZ[1];
[1]Systems Neurosci. Inst., [2]Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstracts: Training is an oft mentioned yet infrequently analyzed component of a brain-computer interface (BCI) paradigm. Numerous studies using multiple recording modalities have

documented evidence of neural adaptation that occurs during BCI learning with the help of biofeedback. However, a standardized training regimen to optimize the rate of this adaptation through task difficulty has not been well developed to date. This concept of an "optimal difficulty" is not trivial. Making a task too difficult may cause the subject to lose interest and stop trying, effectively halting further learning or even regression. Conversely, making a task too easy may provide insufficient feedback (i.e. errors) for further learning and refinement of motor control. Thus, finding a difficulty "sweet-spot" that balances motivation with error feedback would be paramount to optimizing the learning curve for a novice BCI user. With this in mind, the objective of this project was to more closely examine markers of BCI skill acquisition and propose a framework for accelerating this process. In this study, we examined the time course of learning in a non-human primate utilizing single-unit recordings for control of a robotic arm in a 3D BCI task. We first established a baseline difficulty metric using software simulations as well as robot simulations with randomized neural signal playback. By systematically adjusting the difficulty of the task and parameterizing the subject's learning curve based on his history of trial successes and failures, we then estimated the subject's level of skill acquisition both on a trial-by-trial basis as well as across sessions and adjusted task difficulty accordingly. In addition to using performance metrics derived from binary successes and failures to evaluate skill level, we also examined continuous-valued psychophysical metrics of the BCI reach path in order to define skill level in terms of traits corresponding to natural reaching movements. Finally, we correlated neural activity metrics (R^2, depth of modulation, network dynamics, etc.) against learning curve trends in order to develop complementary markers of BCI skill acquisition. Using this training approach, our test subject showed consistent improvement in the 3D task over a period of weeks, as well as examples of within session learning and skill acquisition even as motivation appeared to decline. In addition, our method of characterizing difficulty may be generalized to various methods of altering task difficulty or assistance. Overall, the results presented here may have implications not only for improving BCI user training, but also for optimizing physical rehabilitation regimens.

Title: The Walk Again Project: Analysis of brain activity of spinal cord injury patients during training with a BMI

Authors: *R. C. MOIOLI[1], F. L. BRASIL[1], S. SHOKUR[1], A. L. LIN[1], K. FAST[1], N. PERETTI[1], A. TAKIGAMI[1], D. SCHWARZ[2,3], E. MORYA[1], M. A. L. NICOLELIS[1,4,2,5,3]; [1]Edmond and Lily Safra Intl. Inst. of Neurosci. of Natal (ELS-IINN, Natal, Brazil; [2]Biomed. Engin., [3]Ctr. for Neuroengineering, [4]Neurobio., [5]Psychology and Neurosci., Duke Univ., Durham, NC

Abstracts: Brain-machine interfaces (BMI) rely on electrophysiological signals to operate. These can be recorded using invasive and non-invasive methods: the first provides deeper insights into neuronal information processing whilst the latter overcomes current operational and technical obstacles, especially in studies involving human subjects. As such, spinal cord injury (SCI) patients can greatly benefit from non-invasive BMIs to alleviate locomotion impairment. In this work, we characterize the neuronal activity represented by EEG recordings from 8 paraplegic patients involved in a novel, hybrid EEG/EMG based control training paradigm, towards learning how to control an exoskeleton. More specifically, at each of the 4 phases of training - motor imagery, virtual actuator, commercially available gait orthosis (Lokomat, Hocoma) control, and 15 dof lower limb lower limb exoskeleton control - we recorded and analysed the data from 32 active EEG electrodes (BrainAmp, BrainProducts) carefully distributed above specific motor areas of the patients' scalp surface. The analyses include the motor imagery performance as well as the spatial and temporal patterns of neuronal activity. Independent component analysis (ICA) was employed to identify independent cortical sources and highlight any evidence of learning and neuronal plasticity over the training process. Through this data analysis paradigm we intend to determine the impact of diverse training approaches to brain dynamics, but also to devise novel algorithms that can enhance the clinical relevance of BMIs. Univ. Munich (TUM), Munich, Germany; [14]Colorado State Univ., Fort Collins, CO

Abstracts: As part of the Walk Again Project, a state-of-the-art robotic exoskeleton was designed to enable patients with spinal cord injury (SCI) to perform lower-limb locomotion via brain activity. Hydraulic generators were used to control 15 degrees of freedom (DOF) of the exoskeleton. Real-time trajectory corrections were calculated from data gathered by gyroscopes, strain gauges, force-torque, and pressure sensors positioned along the exoskeleton's limbs, giving it the ability to pivot laterally to stabilize its center of mass. At the interface of the subject's body and exoskeleton, multi-modal sensors were placed to monitor interaction with the exoskeleton. To enable brain-controlled locomotion, movements were discretized into higher level control

states. A small computing unit was utilized to 1) receive biosignals from subjects, 2) interpret them as state transitions for the exoskeleton, 3) provide visual and tactile feedback, and 4) monitor user interaction with the exoskeleton. The control system and exoskeleton functioned without the need of an external operator. Sixteen EEG and two EMG channels served as the inputs for discrete state control. EEG during motor imagery tasks was classified by linear discriminant analysis (LDA) using features extracted by common spatial pattern (CSP). The resulting classifier was visualized by the subject via a custom display. Muscle contractions detected by EMG were used to confirm the classifier and initialize state transitions. The transition was sent to the exoskeleton controller, which performed the indicated mechanical trajectory with aforementioned online corrections. Participants received tactile feedback along their inner forearms synchronized with the exoskeleton walk phase. The subject's interaction with the exoskeleton was compared for both static and dynamic walking. A total of eight SCI patients were trained using this control strategy. Results indicate that BMI-based control of an exoskeleton can become a feasible rehabilitation tool for severely paralyzed patients.

Engin., Durham, NC; [8]Duke University, Psychology and Neurosci., Durham, NC; [9]Duke Ctr. for Neuroengineering, Duke Univ., Durham, NC

Abstracts: As part of the WAP project, we developed a state-of-the-art, 15 degree-of-freedom (DOF) autonomous exoskeleton (EXO) with hydraulic actuators for restoration of locomotion for patients with complete spinal cord injuries (SCI), who neither have the ability to control their lower limbs, nor to experience any tactile or proprioceptive sensation from the level of the lesion down. To address these issues, we proposed an innovative solution for a bidirectional communication between the patients and the exoskeleton. While the EXO is controlled using hybrid biosignals (EEG + EMG), an array of multimodal sensors covering the legs of the EXO records relevant locomotion information that is then transmitted to the patients through a vibrotactile interface placed on their upper body and arms (thus closing the loop patient-exo). After an extensive 3 month testing period with this system, starting in a virtual reality environment, subjetcs (8 SCI patients) could experience tactile/proprioceptive sensations related both to foot contact on the floor and ankle or knee position. Additional experiments investigated body representation plasticity after long term use of the EXO's tactile feedback system. Our results showed the importance of providing this type of artificial tactile/proprioceptive feedback for the subject's incorporation of a virtual (avatar) or prosthetic lower limbs (exoskeleton). As such, we propose that in order to become clinically relevant, exoskeletons will have to provide rich sensory feedback to their operators. Acknowledgments: The authors thank Alberto Santos Dumont Association for Research Support (AASDAP)and the 156 people involved in this project.

Abstracts: A brain-machine interface (BMI) can facilitate direct communication from the brain to actuators in spinal cord injury (SCI) patients. Here, we propose to employ this novel approach to restore lower limb mobility by using cortical neuronal signals to control an external neuroprosthetic device known as an exoskeleton. The main challenge we faced was devising a system that was capable of reliably recording and processing electrophysiological data while remaining portable and resistant to noise and external perturbations. To address these issues, we developed a hybrid BMI (EEG + EMG) training protocol designed to operate an exoskeleton using a shared control approach. For our study, eight paraplegic patients learned a structured protocol that included: 1) executing a motor imagery task using EEG, 2) learning to use EEG to move a virtual reality based actuator, 3) using the EEG+EMG signals to control the movements of a commercially available gait orthosis (Lokomat, Hocoma), and finally 4) controlling the movements of a lower limb exoskeleton. During this training, patients were subjected to visual and auditory distractors to simulate a crowded and noisy open-air environment. A head-mounted, portable peripheral display, attached to a custom designed helmet, allowed the patients to reliably control this non-invasive BMI in a real life situation. Flowing LEDs in the helmet display provided cues and feedback to patients without need of any other external devices. All

eight patients learned to use their EEG and EMG signals to operate this BMI at comparable levels of performance obtained in a silent and controlled environment. This further supports our claim that BMIs can become clinically relevant tools for sensorimotor rehabilitation.

Abstracts: Worldwide, millions of people suffer from walking impairments. Brain-machine interfaces (BMI) offer a promising alternative for restoring motor behavior in patients affected by lower limb paralysis. Here, we present a new paradigm for patients affected by a complete lesion of the lower spinal cord to learn how to operate, in a safe and reliable manner, a non-invasive BMI for controlling a 15 degree-of-freedom exoskeleton, capable of generating autonomous walking. During a 6-month training period, eight patients learned to use EEG signals as part of a BMI designed to restore bipedal locomotion. This training paradigm was divided into 4 sequential steps: 1) brain-controlled virtual avatar presented on a common 2D monitor; 2) brain-controlled virtual avatar shown from a first person perspective using a head

mounted 3D display; 3) brain-control of a commercially available gait orthosis (Lokomat, Hocoma); and 4) brain-control of a custom designed 15 degree-of-freedom lower limb exoskeleton. All 8 patients were able to complete the training procedure. Specifically, they all learned how to employ EEG features to generate leg movements in all four stages. In addition, all eight patients utilized haptic feedback provided in each condition, including the exoskeleton walking, to establish a bidirectional interaction with different versions of artificial actuators (virtual and real). These preliminary results suggest that a bidirectional interaction between paraplegic patients and an exoskeleton, mediated by a brain-machine interface may serve as both a new rehabilitation tool and a new prosthetic alternative for severely paralyzed patients. Supported by: ELS-IINN, Alberto Santos Dumont Association for Research Support (AASDAP) / Association for Assistance to Disabled Children (AACD) laboratory in Sao Paulo, Brazil, which validated the proposed method. Title: Restoration of sensory and motor hand function via two Utah Slanted Electrode Arrays (USEAs) in residual arm nerves after prior hand amputation

Authors: *D. M. PAGE[1], S. WENDELKEN[1], H. A. C. WARK[1], T. DAVIS[1], R. A. NORMANN[1], D. J. WARREN[1], B. GREGER[2], D. T. HUTCHINSON[1], G. A. CLARK[1]; [1]Univ. of Utah, Salt Lake City, UT; [2]Arizona State Univ., Tempe, AZ

Abstracts: Peripheral nerve interfaces can selectively stimulate and record from individual nerve fibers, potentially helping to restore sensation and movement after hand amputation. We implanted two 100-electrode Utah Slanted Electrode Arrays (USEAs) in the residual ulnar and median arm nerves of one subject (one per nerve) 21 years after hand amputation. During the 4-week implant period, experiments included stimulation, recording, and simultaneous stimulation and recording via separate USEAs. 1) Stimulation via individual electrodes evoked 106 location-distinct percepts on a single day, with subjective qualities including "tingle," "vibration," "pressure," "sting," and "movement." In blind trials, the subject discriminated between 5 unique percept locations, evoked by individual and combined stimulation of 4 electrodes (35 of 35 trials, $p < 0.0001$). The subject also discriminated between two qualities (tingle and vibration) with the same location (tip of ring finger), evoked by two different electrodes (30 of 30 trials, $p < 0.0001$). Most percepts evoked by individual electrodes changed quality or location weekly. Of the 43 ulnar and 17 median nerve electrodes that evoked percepts over the implant duration, an across-week mean of 91% and 78% changed location or quality each week, respectively. For the 43 ulnar electrodes, 72%, 63%, and 67% changed percept quality on weeks 2, 3, and 4, respectively; and 70%, 79%, and 58% changed percept location (12 regions: front/back of each digit and the hand). For the 17 median electrodes, 71%, 59%, and 47% changed percept quality, whereas 53%, 53%, and 53% (*sic*) changed percept location. Longer-duration studies may reveal improved stability over time. 2) Recording via USEAs revealed electrodes with neural firing rates that correlated with fictive movements of the phantom hand, allowing 2-DOF real-time, neurally-driven decodes of little- or middle-finger extension. In most sessions, electromyographic (EMG) signals dominated recordings, limiting on-line decodes to 1 DOF. 3) Simultaneous stimulation and recording via separate USEAs allowed the subject to modulate 1-DOF (EMG-driven) virtual-hand movement via sensorimotor feedback. The subject was instructed to flex all fingers (thus moving the virtual hand), and to indicate at which of two randomly presented finger positions (close or far) contact was perceived, as evoked by stimulation via a single electrode. Without any visual feedback of the virtual hand, the subject identified the correct contact position for 41 of 47 trials ($p < 0.0001$). These results indicate that USEAs can help to restore sensation, movement, and closed-loop sensory feedback after hand loss.

Title: Sensing capabilities of the modular prosthetic limb

Authors: M. JOHANNES[1], K. KATYAL[1], R. ARMIGER[1], J. HELDER[1], M. PARA[1], J. BEATY[1], A. RAVITZ[1], M. MCLOUGHLIN[1], O. LASOWSKY[2], E. SCHLUTER[2], S. BENSMAIA[2], *F. TENORE[1];
[1]Johns Hopkins Univ. APL, Laurel, MD; [2]Univ. of Chicago, Chicago, IL

Abstracts: The Modular Prosthetic Limb (MPL) is an upper extremity neuroprosthesis designed to closely match the characteristics of the human arm it seeks to replace. It consists of 26 articulating joints driven by 17 independently controllable motors, thus allowing for anthropomorphic limb motion from the shoulder down to individual fingers. In addition, the MPL is equipped with over one hundred sensors of different types, which can provide a user with tactile and proprioceptive feedback. With these capabilities, the MPL is an ideal prosthesis with which to implement closed loop control, where a user's intent is decoded into appropriate arm and hand motions and interactions of the prosthesis with its environment are relayed back to the user in real time. Here, we review two different approaches to sensorizing the MPL's fingertips and describe sensor data from both systems that relate to contact location, contact pressure, and motion. These results will demonstrate that the depth and breadth of sensory data that can be acquired from the prosthetic fingertip meets or exceeds the sensory encoding capabilities of the neural interface in upcoming closed-loop control experiments within the scope of DARPA's Revolutionizing Prosthetics and other future programs.

Abstracts: Supraspinal centers have the capacity to tune the activity of spinal circuitries throughout gait to implement volitional changes in locomotor states. We hypothesized that neuronal ensemble modulation from the motor cortex should reflect supraspinal control of leg movements during locomotion across tasks requiring perceptually-guided adjustments of gait. Rats were trained to walk on a treadmill, overground along straight and curved runways, onto a staircase, and over the irregularly spaced rungs of a ladder. After completion of training, the rats were chronically implanted with a microwire array that spanned the left hindlimb motor cortex, and with EMG electrodes into a pair of flexor and extensor muscles for each joint of the right hindlimb. Ensemble cortical modulations and motoneuron outputs were recorded simultaneously with whole-body kinematics and kinetics during all the trained tasks. We found reproducible modulation of motor cortex neurons over the gait cycle of the right hindlimb. Population dynamics could be approximated with a sinusoidal firing pattern whereby the firing rate was minimal during mid-stance, rose before the stance-swing transition, and peaked within the swing phase. These results are consistent with previously documented firing patterns in cats and rodents during locomotion. In addition, we detected task-dependent recruitment of neuron sub-populations. This recruitment, defined as neurons modulating significantly differently than at rest, increased with task complexity. Changes in population dynamics reflected task-dependent adjustments of muscle synergies and leg kinematics. These results suggest that the rodent motor cortex continuously supervises leg movements, and becomes increasingly active when the performed task requires high-level control signals to fine-tune gait patterns based on contextual information.

Title: Single neuron activity and population dynamics in the leg area of the motor cortex in the freely moving rhesus macaque

Authors: ***J. LAURENS**[1], D. BORTON[1], E. BEZARD[2], G. COURTINE[1];
[1]Ecole Polytechnique Federale De Lausanne, Lausanne, Switzerland; [2]Univ. de Bordeaux, Bordeaux, France

Abstracts: We leveraged a recently designed multimodal neuromotor analysis platform to record population dynamics in the leg area of primary motor cortex (MI) in conjunction with contralateral hindlimb electromyography and whole-body kinematics in 4 freely moving, unconstrained, and untethered rhesus monkeys. The animals were trained to walk quadrupedally on a treadmill, across a flat runway, and over horizontal ladders of varying difficulties. Since the experiments were conducted within untethered environments, we additionally could capture spontaneous behaviors, such as bipedal walking and even backward locomotion. We exploited this rich database to conduct the first high-resolution analysis of neuronal activity in the primary motor cortex of non-human primate during locomotion. We found that the majority of neurons showed vigorous and highly reproducible modulation during locomotion. Furthermore, many neurons exhibit strikingly diverse response profiles between the locomotor tasks. Evaluation of population dynamics uncovered a strong similarity between responses during walking along a corridor or onto a treadmill regardless of whether the animals adopted a bipedal or quadrupedal gait. In contrast, locomotion along a horizontal ladder requiring precise paw placement was

associated with distinct and intrinsically more complex neuronal activity. We then built a Maximum Likelihood decoder based on neuronal population dynamics. The decoder distinguished the type of performed locomotor task with accuracy (80-95%), and could even detect the position of the leg within the gait cycle with high precision ($r2 > 0.95$). These results demonstrate that the primary motor cortex of non-human primates contains rich gait-related information encoding key kinematic parameters during the execution of natural locomotor tasks.

Title: A little elastic for a better performance: Kinesiotaping of the motor effector modulates neural mechanisms for rhythmic movements

Authors: *R. BRAVI, E. COHEN, E. QUARTA, D. MINCIACCHI;
Univ. of Florence, Florence, Italy

Abstracts: A rhythmic motor performance is brought about by an integration of timing information with movements. We have recently demonstrated that the precision of an isochronous performance, defined as performance of repeated movements having a uniform duration, was insensible to auditory stimuli of various characteristics (Bravi et al., 2014, Exp. Brain Res.). Such finding has led us to further investigate where do the determining factors of precision reside. For this purpose we used manipulation of cutaneous afferents by kinesiotaping (KT), an approach that was previously shown to improve some isokinetic performances. Subjects, tested without KT and with KT, have participated in sessions in which sets of repeated isochronous wrist's flexion-extensions (IWFEs) were performed under various auditory conditions and during their recall. Kinematics was recorded and temporal parameters were extracted and analyzed. Various degrees of improvement in the isochronous performances were evident for the KT recordings especially in terms of temporal precision. Our results indicate that, in the precision of repetitive rhythmic movements, the manipulation of cutaneous afferents plays a significant role. Whether this increase in precision is achieved by augmentation of the

efficiency in central or local neural mechanisms is to be determined, but what remains certain is that when it comes to precision, a little elastic makes the difference.

Title: Partial muscle regenerative peripheral nerve interfaces for prosthetic control

Authors: S. L. WOO, M. G. URBANCHEK, M. K. LEACH, J. D. MOON, P. S. CEDERNA, *N. B. LANGHALS;
Plastic Surgery, Univ. of Michigan, Ann Arbor, MI

Abstracts: Objective: Nonvascularized partial skeletal muscle grafts are notorious for their limited force-generating capacity and tendency to degenerate in the absence of reinnervation. Accompanied by peripheral nerve implantation, however, partial muscle grafts can survive and transmit detectable electromyographic (EMG) signals capable of prosthetic control. Our study investigated partial muscle graft survival in the construction of regenerative peripheral nerve interfaces (RPNIs) and further characterized their electrophysiological properties across various muscle donor sites. Methods: Twenty F344 rats were assigned to 1 of 5 groups based on muscle graft type used for RPNI construction: 1) control-whole extensor digitorum longus; 2) partial biceps femoris; 3) partial rectus femoris; 4) partial lateral gastrocnemius; and 5) partial vastus medialis. Each graft (approximately 140-mg at initial harvest) was suture-anchored to the femur, wrapped in small intestinal submucosa for tissue isolation, and implanted with the transected common peroneal nerve. After 4 months of recovery, *in situ* EMG [figure] and force testing were performed. Results: All control RPNIs (n=4) transmitted detectable EMG signals, compared to 75% of partial muscle RPNIs (n=12 of 16). Significant differences between control and partial muscle RPNIs included average mass [118±42 mg vs. 66±25 mg], EMG peak-to-peak amplitude [6.7±2.3 mV vs. 1.16±1.5 mV], and maximum tetanic force [500±615 mN vs. 137±152 mN].

Amongst partial muscle RPNIs, donor muscle was not a significant predictor of EMG amplitude after adjusting for final mass and length. Conclusions: Partial muscle graft RPNIs transmit detectable EMG signals with a 75% success rate at 4 months. This proof of concept underscores the potential to develop and refine partial muscle graft-based interfaces to harness peripheral nerve signals for high-fidelity prosthetic control. While signal size remains favorable (i.e. 10-100 times larger than signals recorded directly from peripheral nerves), further studies are warranted for optimization of partial muscle graft regeneration and signal acquisition.

Title: Neural correlates of task dynamics in motor cortex

Authors: *A. HADDOCK[1,2,3], C. MATLACK[2,3], H. CHIZECK[2,3];
[2]Electrical Engin., [3]Ctr. for Sensorimotor Neural Engin., [1]Univ. of Washington, Seattle, WA

Abstracts: Learning to use a brain-machine interface (BMI) requires adaptation to a novel dynamical system mapping neural signals to output kinematics. Current BMI decoding algorithms derive velocity signals from neural populations in motor cortex to control prosthetic motion. This study seeks to clarify the cortical mechanisms accompanying the change to velocity-controlled task dynamics. We studied the tuning properties of neurons recorded in the right arm area of primary motor cortex. A macaque was trained to apply isometric wrist force to a manipulandum to control computer cursor position in a 2D pinball task. We tested two task dynamics conditions: in the first, force mapped directly to cursor position (position control, or PC); in the second, force was integrated to increment the cursor position at each time step (velocity control, or VC). Thus, there were no changes in posture or directional mapping of force

between each task, as has been studied previously. Instead, each task condition required a different temporal force profile. We analyzed the activity of 50 directionally tuned neurons ($p < 0.05$, Rayleigh test) as the macaque performed blocks of trials first in PC, then in VC, then in PC again. In this analysis we characterized each neuron by its preferred direction (PD). We found that 8 of 50 cells showed significant changes in PD ($p < 0.05$, z-test) as task dynamics shifted from PC to VC; 7 of 50 cells showed changes as dynamics shifted back from VC to PC; and, finally, 6 of 50 cells showed changes when comparing PC conditions. The top plot shows PD changes for each change in task dynamics, and the bottom plot shows that the magnitude of significant PD changes are greater when dynamics change versus the control condition ($p < 0.05$, Wilcoxon rank sum test). These results show that although most motor cortical neurons studied have fixed PD across task dynamics conditions, some neurons incur large PD changes in response to VC dynamics, suggesting a possible role in corrective movements. Further analysis will investigate the temporal characteristics of motor cortical neurons during changes in task dynamics.

Abstracts: Peripheral nerves are a promising source for neuroprosthetic control signals, as the information carried downstream of cortex is increasingly functionally selective and thus easier to interpret. However, the clinical viability of current approaches is still hampered by low signal amplitude, interface instability, and low functional resolution within the nerve. Here, we address these issues by demonstrating the successful implantation of a Regenerative Peripheral Nerve Interface (RPNI) in a rhesus macaque, as well as the design of a neural recording system capable of low-power, wireless operation. The electronics platform can also be used with other neural signal modalities such as intracortical spiking data. The RPNI is constructed by selecting individual nerves at any level (e.g. individual fascicles) and suturing them into a small graft of unvascularized, denervated donor muscle. The graft then revascularizes, regenerates, and is reinnervated by the transplanted nerve, acting as a bioamplifier for the efferent action potentials. We transplanted three terminal branches of the median nerve, two of which acted to flex the fingers (FDS and FDP) and the third to flex the thumb (FPL), into three separate 1x3cm muscle grafts taken from the same arm. Six months after implantation, we could record a 700-1000uVp-p EMG signal from the FDS-RPNI via percutaneous fine-wire electrodes. Correct function of the RPNI was verified by correlation of EMG with finger flexion and non-correlation with finger extension and wrist flexion during a four-finger flexion/extension task. The location of the RPNI in the forearm made accidental recording of intact finger flexor muscles unlikely. Using EMG power within 100-500Hz we were able to detect flexion with 98.7% accuracy within 50ms. To complete the interface, we designed a low-power neural recording system consisting of all off-the-shelf components: an Intan bioamplifier and an Atmel microcontroller and wireless transceiver. The system is designed expressly to generate prosthetic control signals instead of higher bandwidth research-oriented data. We reduced the required amplifier power by lowering the cutoff and sampling frequencies to 1kHz and 2kSps, and the wireless data rate by only transmitting average signal power every 64ms. For 8 channels of (previously recorded) neural data, the system draws 2.3mA at 3.3V (7.6mW). For 16 channels, the system draws 9.1mW, an increase of only .19mW/channel. Together, the RPNI and low-power recording system represent a path towards clinical viability for generating long-lasting, functionally specific prosthetic control signals from peripheral nerves.

Title: Wireless implantable multichannel myoelectric system validation

Authors: *D. R. MERRILL, S. HIATT, K. S. GUILLORY, C. SMITH, D. MCDONNALL; Ripple, Salt Lake City, UT

Abstracts: Modern hand and arm prostheses provide multiple degrees of freedom (DOF) of motion, yet their use is severely limited by the biological control interface. Current prostheses are controlled by EMG signals recorded from surface electrodes on the residual limb. These recordings are a composite of signals from several muscles and typically do not provide enough independent sources for simultaneous multi-DOF control. Additionally the surface recording sites are unreliable. These impediments limit transradial prostheses to two DOF with sequential control. Our objective is to provide simultaneous multi-degree of freedom prosthesis control, ultimately providing an intuitive control experience. We have developed an implantable device to detect EMG from multiple residual muscles and send the signals wirelessly to a prosthesis. This approach supports a high number of independent control signals and provides access to EMG from deep muscles that cannot be accessed with surface electrodes. The system consists of a hermetic implanted module from which six EMG leads emerge. Each lead comprises four electrode sites for 24 total recording channels. The implant receives power inductively from an external transceiver and sends digitized EMG data to the external transceiver by reflected impedance modulation. By using a single subcutaneous module for telemetry from which several leads emerge, power coupling efficiency remains high. The implant consists of established biocompatible materials including alumina and zirconia ceramics, titanium, gold, silicone, and stainless steel. We have completed initial safety and performance testing. Electrical safety and EMC were verified according to IEC 60601-1 and -1-2. Biocompatibility was confirmed per ISO 10993-1. Benchtop implant performance demonstrated the amplifier to have an input-referred noise of < 2 μVRMS, common mode rejection ratio greater than 55 dB, and neighboring channel isolation averaging 66 dB. The system was validated in a six-dog study. Devices were implanted bilaterally with electrodes implanted in deltoideous and lateral head of triceps. One week after

implantation EMG was recorded as the dogs walked freely. EMG displayed very low noise and clearly indicated swing/stance phases of gait. These efforts demonstrate the ability to amplify and transmit muscle signals and confirm safety and performance requirements. This approach has the potential to provide simultaneous multi-degree of freedom prosthesis control, especially if used with advanced hand and arm prostheses, targeted muscle reinnervation patients, and recently developed pattern recognition algorithms.

Abstracts: Although we have shown how prosthetic arms controlled by motor cortex activity can aid people with tetraplegia in their day-to-day lives, we have found that standard brain-computer interface (BCI) decoders can induce undesired neuroprosthetic behavior, such as early grasping, during object manipulation (Wodlinger et. al., In Review). Some of these effects can be mitigated by training the decoder in both the presence and absence of objects to capture differences in neural activity. Training on multiple contexts can be time consuming and possibly ineffective, so a more ideal method would be to account for changes in neural firing during online neuroprosthetic use. Data for this study are from BCI control sessions of a subject with tetraplegia implanted with two 96-electrode Utah Arrays using an optimal linear estimator decoder. Initial analysis failed to reveal a consistent significant difference in single unit firing

rates when the robotic hand was interacting with objects versus when it was not. However, the summed firing rates of all recorded units had higher firing rates when the hand was interacting with objects (K-S Test, $p<0.001$). This object-interaction related increase in global activity violates the decoder's assumption of a baseline firing rate that is only modulated by desired movement kinematics. Here we show results from an online normalization procedure which corrects for the global firing rate changes. During online BCI control, the observed firing rate is normalized by a ratio of the recent (1 second) summed firing rate and the "baseline" summed firing rate observed during decoder training. Performance was evaluated using various tasks. The reach-to-grasp task required the subject to move the robotic hand to a cylindrical target and grasp it. During three sessions of testing, the grasping was successful 65% of the time without normalization, and 80% of the time with normalization. The reach-to-touch task required the same movement, except the hand had to stay open at the target, to test whether object interaction was causing undesired grasping. Success rates for this task were 65% and 85% without and with normalization, respectively. The object-transfer task required the subject to move a weighted cylinder from one side of the table to the other as many times as possible in 2 minutes. Without normalization the subject completed 0.79 transfers/min, but with normalization she completed 1.79 transfers/min. These tests show that renormalizing unit firing rates based on changes in the global firing rate improves decoder performance for object interaction tasks.

Title: Neural ensemble response to learning challenges in brain-machine interfaces

Authors: *M. ARMENTA SALAS[1], S. I. HELMS TILLERY[2];
[2]Biomed. Engin., [1]Arizona State Univ., Tempe, AZ

Abstracts: The underlying neural mechanism of motor learning is a process that involves several brain structures such as motor and premotor cortices, cerebellum and the basal ganglia

(Georopoulos et al, 1982; Jueptner et al, 1997; Hikosaka et al, 2002). Detecting changes in these structures associated with learning, however, is challenged by the main variables dictating neural firing, which are kinematic and kinetic variables. Thus, we are interested in an approach which helps test the limits of neural adaptation without being constrained by such variables. We achieve this by using brain-machine interface technology, which allows us to directly relate changes in brain activity to an output experiment variable, i.e. movement of a computer cursor (Carmena et al, 2003; Jarosiewickz et al, 2008; Taylor et al, 2002). We have trained two non-human primates to perform a 3D center-out task, using microwire arrays implanted in motor and premotor cortices to drive the movement of a computer cursor using the population vector algorithm (Georgopoulos et al, 1986). After the task was well learned (accuracy $\geq$ 65%), we introduced two types of perturbations. First, a visuomotor rotation (VMR) where we perturbed the movement by 30° about the anteroposterior axis. An ideal solution to this perturbation would be to rotate the preferred directions (PD) of the contributing cells by an equivalent amount. Second, a decorrelation paradigm, where we rotated by 90° the PDs of a small subset of cells (ca. 20%), selected from the highest correlated cell pairs. An ideal solution to this task would be to identify the perturbed cells and selectively rotate their PDs. We hypothesized that the monkeys would be able to adapt and bring performance back to baseline for both perturbations. However, we expected the learning curves to be different for each perturbation. Our interest then was the neural solution found for each task. We report that the monkeys adapted to the VMR task faster than to the decorrelation one, shown when comparing performance accuracy and movement to target angles. Moreover, we observed different trends in the activity of the cells used for brain control in each task: cells' PDs changed as expected for the VMR but not for the decorrelation task, and the estimated target that the monkeys were redirecting the movement to (Chase et al, 2010) differed in each case. These discrepancies in behavior and neural activity suggest that the brain engages different mechanisms and solutions when challenged with diverse tasks, even if they are still within a motor context. We propose that the solution found may also be dependent on task difficulty, specifically on the underlying characteristics of the task perturbations

Title: Cortical control of nonlinear, musculoskeletal systems with a brain-machine interface

Authors: F. R. WILLETT[1,2,3], H. KALODIMOS[2,1,3], J. COX[2,3], *D. M. TAYLOR[2,1,3];
[1]Biomed. Engin., Case Western Reserve Univ., Cleveland, OH; [2]Neurosciences, Cleveland Clin. Lerner Res. Inst., Cleveland, OH; [3]Cleveland Functional Electrical Stimulation (FES) Ctr. of Excellence, Louis Stokes VA Med. Ctr., Cleveland, OH

Abstracts: The majority of brain-machine interfaces to date have focused on decoding a kinematic command signal (e.g., hand position or velocity) from the brain and rerouting that signal to a computer cursor, robotic limb, or a functional electrical stimulation (FES) system that reanimates paralyzed muscles. When controlling a computer cursor, the relationship between the cortical command signal and the cursor movement is linear and straightforward. In the case of a robotic or musculoskeletal limb, a control algorithm typically solves the nonlinear control problem for the user, transforming the user's kinematic commands into the joint torques or muscle stimulations needed to make the desired movement. Here, we take a different approach and explore the feasibility of a nonlinear command interface that puts the user in direct control of muscle stimulators implanted in a dynamic musculoskeletal model of the arm in a virtual world. While a direct brain-to-muscle command interface might be more difficult to control than a kinematic one (i.e., requires the cortex to approximate more complex, nonlinear functions of the movement goal and limb state), it would also give the user more freedom. Specifically, a direct brain-to-muscle command interface would give the user control over limb stiffness (through co-contraction) and over the forces exerted by the limb on the environment (useful for pushing, pulling, or picking up objects of different weights). In our experiments, we investigated the ability of motor cortical areas to learn to directly control musculoskeletal systems through two nonlinear command interfaces. In interface one, firing rates were linearly mapped to two independent muscle synergies in a dynamic simulation of a paralyzed human arm with six muscle stimulators confined to make 2D movements in a horizontal plane. In interface two, firing rates were linearly mapped to opposing muscles (brachialis and triceps) at the elbow joint alone with the shoulder joint locked. We characterized the control strategies employed by three Rhesus macaques when controlling these systems and report on the extent and limitations of their neural adaptation.

Title: Sensorimotor control of self-timed vs. externally-timed nonspeech movements in adults who stutter

Authors: A. DALIRI[1], J. R. FLANAGAN[2], *L. MAX[1,3];
[1]Univ. Washington, SEATTLE, WA; [2]Queen's Univ., Kingston, ON, Canada; [3]Haskins Labs., New Haven, CT

Abstracts: Stuttering is a disorder that disrupts speech fluency. Speaking in certain conditions (e.g., in synchrony with a metronome, single words) enhances fluency for many affected individuals. Over the past decades, studies have demonstrated that stuttering is associated with atypical sensorimotor processing for both speech and nonspeech movements. Thus, the disorder may involve instabilities in fundamental sensorimotor mechanisms that underlie the neural control of voluntary movements in general. Here, we aimed to investigate the trial-to-trial stability of two main components involved in the planning of natural nonspeech movements. Using a task that involved grasping and moving an object, we compared stuttering and nonstuttering adults with regard to (a) the control component involved in generating appropriate motor commands to move the arm, and (b) the prediction component involved in anticipating the appropriate amount of grip force for each phase of the movement. We examined the stability of these components in conditions with self-timed vs. externally-timed movements and with cyclical vs. discrete movements. The subjects were 8 male stuttering adults and 8 age-, sex-, and handedness-matched nonstuttering adults. Subjects held between their thumb and index finger a test object instrumented with a force/torque transducer, and moved it (targeted displacement ~30 cm) without visual feedback in a sagittal plane to the side of the body. Auditory cues were used for the external timing condition. Continuous up-and-down movements were performed in the cyclical condition whereas single up or down movements were performed in the discrete condition. Variability of movement extent was used as a measure of the stability of the control component. Variability of the strength of coupling between grip force and movement

acceleration was used a measure of the stability of the prediction component. The latter measure is based on the fact that preventing slip of the object requires the central nervous system to accurately predict changes in movement acceleration, and to appropriately adjust -- in an anticipatory manner -- the grip force applied to hold the object. Movement extent variability was significantly larger for the stuttering group than for the control group. This variability decreased significantly for externally-timed vs. self-timed movements in the stuttering group but not the nonstuttering group. There was no between-group difference in the coupling between grip force and movement acceleration. Findings suggest that stuttering is associated with deficits in generating movement control signals rather than predicting the consequences of those movements.

Title: Neural activation of reading words aloud in adults who stutter

Authors: *S. CHU, J. OGURA, M. WADA, K. MORI, K. OCHI;
Natl. Rehabil. Ctr. For Persons With Disabilities, Tokorozawa, Japan

Abstracts: The purposes of this investigation were 1) to trace the distributed neural network of overt speech and 2) to characterize brain activation specific to reading aloud Japanese words of different lexical properties in adults who stutter and neurotypical controls. Word form stimuli of four Japanese lexical properties (familiar words, unfamiliar words, pseudowords, elongated vowels), and of Cyrillic letters as non-reading visual control were presented and compared between stuttering and nonstuttering speakers using a 1.5 Tesla MR-scanner. A clustered image acquisition technique was used to minimize speech-related movement artifacts. The stuttering group showed higher activation than the control group in the right premotor areas (BA6) and right supramarginal gyrus (BA40) for familiar, unfamiliar and pseudo- words, and vowels subtracted by the Cyrillic letter condition. Higher activation of the right insula was observed in the stuttering group for the pseudowords than the Cyrillic letter condition. The fact that increases

activity in the right insula during pseudowords condition suggests that insula may be involved in rather complicated word production and recruitment of this area for articulatory movement ensures fluent production among stuttering speakers. These preliminary results suggest that stuttering and nonstuttering speakers produce different patterns of brain activation during word production.

Title: White matter differences in young children who stutter

Authors: *S.-E. CHANG[1], A. CHOO[1], M. K. ANGSTADT[1], D. C. ZHU[2];
[1]Psychiatry, Univ. of Michigan, Ann Arbor, MI; [2]Radiology, Michigan State Univ., East Lansing, MI

Abstracts: Stuttering affects 5% of preschool-age children, with typical symptom onset at 2-4 years of age. Despite the fact that onset and eventual recovery versus persistence of stuttering mostly occur during childhood, few studies have yet examined the neural bases of childhood stuttering. Here we present a diffusion tensor imaging (DTI) study that examined measures of white matter integrity (fractional anisotropy; FA), in a relatively large group of children who stutter between 3-10 years of age. We asked whether previously reported anomalous white matter (WM) measures in adults and older children who stutter were also present in younger children who stutter, and whether stuttering severity is correlated with FA. Specifically, we hypothesized that children who stutter would exhibit decreased WM integrity in major WM tracts (i.e., SLF) interconnecting frontal motor and auditory areas, particularly in the left hemisphere. We also hypothesized that stuttering severity may be negatively correlated with FA in the left SLF. A total of 89 monolingual English-speaking children participated in this study as part of an on-going longitudinal investigation of developmental stuttering. All children exhibited normal speech, language, IQ, and hearing development as assessed through a battery of

assessments. Stuttering and control groups were matched in chronological age and socioeconomic status. DTI data were acquired with a dual spin-echo echo-planar imaging (EPI) sequence (48 contiguous 2.4-mm axial slices in an interleaved order, FOV = 22 cm × 22 cm, matrix size = 128 × 128, number of excitations (NEX) = 2, TE = 77.5 ms, TR = 13.7 s, 25 diffusion-weighted volumes with b = 1000 s/mm2). A total of 77 volumes (40 controls, 37 stuttering) were analyzed (after excluding 12 due to excessive movement) using FSL's TBSS processing stream for whole-brain based comparison of FA between the two groups. 10,000 permutation tests were performed using the randomise program in FSL and statistical inference was based on an uncorrected threshold of $p<0.001$ with an extent threshold of minimum 10 voxels. Stuttering children exhibited significantly reduced FA relative to controls in the bilateral inferior frontal (IFG; BA44), motor and auditory regions and left cortical spinal tract, but increased FA in the right IFG (BA45). Stuttering severity was negatively correlated with FA in the BA44, motor, and parietal areas along the left SLF. These results provide first glimpses into the neural bases of childhood stuttering, which includes bilateral attenuation of WM integrity underlying sensorimotor cortical areas, and greater stuttering severity associated with left hemisphere decreases in WM integrity.

Title: Focal intraoperative cooling modifies speech production in a location-specific manner

Authors: ***M. A. LONG**[1], K. A. KATLOWITZ[1], R. C. CLARY[1], T. J. F. DI CASTRI[1], M. A. SVIRSKY[1], D. R. HANSEN[2], M. A. HOWARD, III[2], J. D. W. GREENLEE[2];
[1]NYU Sch. of Med., New York, NY; [2]Univ. of Iowa, Iowa City, IA

Abstracts: Humans are capable of learning and executing a wide range of motor sequences, but the means by which premotor brain regions coordinate their activity to produce these behaviors is still poorly understood. Perhaps the most closely studied complex human behavior is the production of spoken language. The neural dynamics correlated with speech production have been explored using electrophysiology (Sahin et al., 2009; Bohland et al.,2010; Tankus et al., 2012; Bouchard et al., 2013; Cogan et al., 2014) or functional magnetic resonance imaging (Price, 2012). To uncover the specific roles of individual brain regions in speech production, we developed a method to quickly, reversibly, and focally lower the temperature of the cortical surface in order to slow down local circuit activity (Pires and Hoy, 1992; Yamaguchi et al., 2008; Long and Fee, 2008; Tang et al., 2010). We built a custom cooling device to affect 1 to 6 regions (mean: 2.6) in series in 15 awake patient volunteers undergoing craniotomy while they recited word lists. We measured two primary effects of cooling on speech production. First, cooling in some regions, such as the pars opercularis, resulted in a slowing of the timing of produced speech, as measured using custom-built software to identify repeatable spectrotemporal landmarks within each word. Second, cooling in other regions, including the premotor cortex, resulted in speech degradation, as measured through a range of subjective and objective measures. Independent alterations in timing or degradation of speech sounds could sometimes be elicited as a function of cooling probe location, implying segregated roles for speech production circuitry. These results have implications for the mechanisms of speech sequence generation, and they support focal cooling as an alternative option to standard speech region mapping procedures, such as electrical stimulation.

Title: Dopamine drives left-hemispheric lateralization of brain activity and functional connectivity during speech production: An fMRI and neural modeling study

Authors: *K. SIMONYAN[1], J. C. ZINN[1], B. HORWITZ[2], S. FUERTINGER[1];
[1]Neurol., Mount Sinai Sch. of Med., New York, NY; [2]Brain Imaging and Modeling Section, NIDCD/NIH, Bethesda, MD

Abstracts: Hemispheric dominance of human speech and language is known since the time of Broca but the explanation for the physiological basis of left-lateralized brain activity and functional networks is still elusive. Our recent PET/fMRI findings suggest that left-lateralized striatal dopamine release during speech production contributes to the lateralization of functional brain networks. However, it remains unclear whether dopamine release drives or follows the lateralization of functional speech network. To address this question, we developed a physiologically informed stochastic neural population model to simulate brain activity coupled with dopaminergic neurotransmission during speech production. Twenty individual whole-brain simulations of neural activity were carried out for 70 cortical and 6 subcortical small-scale models, which were composed of excitatory and inhibitory neurons and coupled based on our experimental functional connectivity data. Speech-related dopamine release was simulated based on neural firing in substantia nigra pars compacta (SNc), and its modulatory effects were measured in the laryngeal motor cortex (LMC), which represents a final common motor cortical speech pathway. The resting-state activity without dopamine or firing rate modifications was simulated as control. Simulated functional networks were assessed using psychophysiological interaction analysis. Dopamine-induced functional networks were examined in relation to left-lateralized and bilaterally distributed structural connectivity between the SNc and LMC. Lateralization of simulated neural activity and networks was calculated using a laterality index. Simulated dopamine release from the SNc to LMC showed left-lateralization of brain activity and functional network. Compared to the bilateral release, left-SNc induced dopamine release showed more pronounced network lateralization, which was similar to that of the experimental data. Simulated resting-state activity and functional network did not show dopamine release-dependent lateralization. Artificial increases in simulated structural connectivity between left SNc and LMC did not amplify the observed dopamine-modulated lateralization of functional activity and networks. Comparisons with simulated structural connectivity suggest that left-lateralization of the functional network is not dependent on left lateralization of structural network. Rather, dopamine directly modulates the LMC activity and by this induces pronounced lateralization of simulated whole-brain activity and functional network during speech production.

Title: A multi-modal imaging system for simultaneous measurement of speech articulator kinematics compatible with human electrophysiology

Authors: *D. CONANT[1], K. BOUCHARD[1,2], G. ANUMANCHIPALLI[1], B. DICHTER[1], E. CHANG[1];
[1]UCSF, San Francisco, CA; [2]LBNL, Berkeley, CA

Abstracts: Speech articulation involves the rapid, coordinated movement of speech articulators (e.g. lips, jaw, tongue, and larynx). Most neuroscience investigations of speech have relied upon static, binary features instead of dynamic articulator kinematics. However, a complete neurobiological understanding of speech motor control requires determining the relationship between simultaneously recorded neural activity and the kinematics of all articulators. Many speech articulators are internal to the vocal tract, and so simultaneously tracking the kinematics of all articulators is difficult, especially in the context of human electrophysiology recordings. Here, we describe a noninvasive, multi-modal imaging system for simultaneously tracking the movement of the lips, jaw, tongue and larynx for articulator tracking in human neuroscience at the bedside. We combined three non-invasive methods previously used separately: videography to track the lips and jaw, electroglottography to monitor the larynx, and ultrasonography to track the tongue. To characterize this system, we recorded articulator positions and acoustics from six speakers during multiple productions of nine American English vowels. We first describe processing methods for the robust extraction of kinematic parameters from the raw signals and to alignment/scaling methods to account for artifactual variability across recording conditions. To understand the relationship between kinematics and acoustics, we used regularized linear regression between the vocal tract kinematics and speech acoustics to identify which, and how many, kinematic features are required to explain both across vowel and within vowel acoustics. These results generally confirm the relationship between tongue height and tongue frontness, and the first and second formants, but also identified contributions from other articulators. We used unsupervised matrix factorization techniques to extract ‘basis sets’ of vocal tract ‘shapes’ associated with different vowels. This data-driven approach may preserve information about vocal tract ‘shape’ better than traditional point extraction methods. Finally, we developed a statistical speech synthesizer to convert measurements of the vocal tract to audible speech and were able to reconstruct perceptible speech from measured articulatory features. These results demonstrate a multi-modal experimental system to non-invasively monitor articulator kinematics during speech articulation, and describe novel analytic methods for relating kinematic data to speech acoustics.

Title: Dynamics of variability and information encoding in electrocorticography recordings during production and perception of syllables

Authors: *B. DICHTER[1,2,5,3], K. E. BOUCHARD[2,4,6], E. F. CHANG[2,4,3];
[1]Univ. of California - San Francisco, San Francisco, CA; [2]Neurosurg., [3]Ctr. for Integrative Neurosci., [4]Physiol., UCSF, San Francisco, CA; [5]Grad. Program in Bioengineering, UC Berkeley - UC San Francisco, San Francisco, CA; [6]Lawrence Berkeley Natl. Lab., Berkeley, CA

Abstracts: Human speech production requires precise spatio-temporal patterns of neural activity in motor areas for articulation of phonemes, and in auditory areas for encoding the resulting auditory feedback. However, because of the inherent variability of neural processing, the representation of motor commands and sensory feedback vary from trial-to-trial. Understanding how the human brain manages neural variability during speech will give insight into neural processes underlying these functions. Here, we investigated the structure and dynamics of neural variability, and its relationship to information encoding, during human speech production of a large set of consonant-vowel syllables. Our goal was to understand across-trial variability of neural activity over the time course of articulation in the ventral sensory-motor cortex (vSMC, an area critical for speech motor control), and in the superior temporal gyrus (STG, an area critical for perception of speech sounds), during the ensuing auditory feedback. To this end, we recorded neural activity directly from the surface of vSMC and STG using high-density electrocorticography (ECoG) in two neurosurgical patients while they listened to and repeated consonant-vowel (CV) syllables multiple times. We extracted the analytic amplitude from the High-gamma band [75-150 Hz] (HG), which correlates well with multi-unit spiking activity, and has recently been shown to reveal important features of speech production and perception. We observed that, as with single-unit recordings from many species, the variability of HG was positively correlated with its mean. To isolate changes in across trial variability from changes in mean activity, we modeled variance as a function of mean activity and time for each stimulus on

each electrode. To better understand the nature of HG variability, we also calculated network variance by using factor analysis to distinguish between shared variability across the network and noise that is private to individual electrodes. We found that, similar to firing rate responses in primates, HG variability decreased upon stimulus presentation for individual electrodes and on a network level. We determined the time evolution of encoding each component of the CV syllable by computing information across trial-time about consonant identity, vowel identity, and CV identity. The time-course of information closely matched that of variance reduction, with maximum cross-correlations between information and variability occurring within 100ms for both brain areas. This analysis motivates studies into the neural mechanisms of variability reduction and performance gains it may provide.

Title: Beyond lateralization: Inter-hemispheric communication coordinates vocal feedback control

Authors: ***N. KORT**[1], P. CUESTA[4], J. F. HOUDE[2], S. S. NAGARAJAN[3];
[2]Dept. of Otolaryngology- Head and Neck Surgery, [3]Radiology, [1]UCSF, SAN FRANCISCO, CA; [4]Lab. of Cognitive and Computat. Neurosci. (UCM-UPM), Ctr. for Biomed. Technol. (CTB), Madrid, Spain

Abstracts: While speaking, modulation of the timing and frequency vocal pitch are key features of speech that convey important semantic and affective information. While it is known that auditory feedback is used to monitor and maintain proper pitch production, the neural control of

this important aspect of speech production remains poorly understood. In this study, we examined the neural control of pitch production using time-resolved whole-brain functional imaging with magnetoencephalography. Subjects respond to an unexpected pitch shift by changing their pitch production to oppose the change, and we found bilateral increases in high gamma power (HGP) early in response to the pitch shift change followed by predominantly right hemisphere HGP enhancement by 200ms. Speaking-specific induced HGP increases, obtained by subtracting out the cortical responses during passive listening, showed right parietal and premotor cortex (peak activity by 175ms) and left posterior temporal cortex activations (peak activity at 225ms) in driving the motor response to the shift. Neurobehavioral correlations demonstrated the involvement of right frontal regions and left posterior temporal cortex lobe in the amplitude of the behavioral response while bilateral auditory and right frontal regions correlated with individual subjects' response variations to pitch shifts. Finally, connectivity analysis revealed large scale increases in inter-hemispheric communication that coordinates vocal feedback control of pitch.

Title: Neural temporal information coding in sentence repetition - an ECoG study

Authors: ***J. GEHRIG**[1], M.-T. FORSTER[2], J. LEI[1], H. LAUFS[1], C. SENFT[2], V. SEIFERT[2], S. HANSLMAYR[3], C. KELL[1];

Abstracts: *Introduction* Little is known about how information is coded in the brain. Speech constitutes a hierarchically organized and temporally highly structured behavior in which different parts of the physical signal carry different information. We hypothesized that temporal information coding in speech directly relates to temporal coding in neural networks involved in speech production and perception. We thus investigated electrocorticography (ECoG) recordings

from six patients undergoing awake brain tumor surgery of the left hemisphere and focused on analyses of temporal similarity in neural signals associated with listening to, remembering and repeating the same versus different sentences. *Methods* Patients listened to prerecorded three word sentences (~1s, listening phase) and waited for 1.5s (maintenance phase) until visual presentation of a go cue for sentence repetition (speaking phase). A specific sentence was used in 30 trials (Same trials), while 70 further trials were based on 70 different sentences (Different trials). ECoG data were recorded with cortical grids (5 mm spacing, 5kHz sampling) and were analyzed using fieldtrip. Individual time-frequency spectra (2-120 Hz) were created by analyzing dpss multitapers. To identify temporal information coding in the different trials phases, we tested whether the difference in correlations between 1s sliding windows (100 ms timesteps) of Same and Different trials was significantly different from the mean difference in all trials. These temporal pattern similarity analyses were carried out both on raw timecourses and on time frequency data. *Results and Conclusions* The broadband gamma response in auditory cortex was stronger for listening to the patient's prerecorded voice compared to speech production of the same sentences while this effect was inversed in the motor cortex. Low frequency suppression during processing was most obvious in sensorimotor cortices and relatively absent in Broca's area. Here, activations were confined to the high beta/low gamma band during verbal working memory encoding and maintenance. Temporal pattern similarity was found in the raw time courses in auditory and motor cortices during listening and speaking. Spectral analyses revealed that these effects were driven by temporal information coding in delta, theta and alpha rhythms. Importantly, temporal information coding was observed in frontotemporal cortices during working memory encoding and maintenance in the beta band. Our results indicate that temporal coding in the brain is not only restricted to tracking rhythmic regularities of sensory stimuli but constitutes a more general mechanism of information coding.

Title: Possible neuroplasticity of swallow-related neural network

Authors: *M. INOUE;
Div. of Dysphagia Rehabil., Niigata Univ., Niigata, Japan

Abstracts: We examined effects of continuous pharyngeal electrical or liquid stimulation on swallowing behaviors in healthy humans. Effect on voluntary swallow was elucidated by repetitive saliva swallowing test (RSST), in which subjects were instructed to swallow their own saliva as quickly as possible for 30 sec and the number of swallows was counted. Involuntary swallow was elucidated by swallowing response time (SRT), in which 0.1-ml water was injected into the pharynx and the latency of initiation of first swallow was measured. In the first experiment, 10-min pharyngeal surface electrical stimulation (5 Hz, 1 ms pulse duration) was applied and effect of stimulation on voluntary and involuntary swallows were evaluated. RSST and SRT were recorded before stimulation as control and every 10 min after 10-min stimulation for 60 minutes. While SRT was less affected by 10-min pharyngeal stimulation, the number of swallows during RSST gradually increased in 60 min. In the second experiment, 10-min liquid stimulation using distilled water or carbonated water was applied. In this experiment, the subjects were instructed to swallow 5 ml of either liquid every 10 sec over 10 min. Following the liquid stimulation, voluntary and involuntary swallows were evaluated. While RSST was less affected throughout the recording period in both cases, SRT significantly decreased in 60 min in case of carbonated water. Possible neuronal mechanisms for the modulation of swallowing initiation were discussed.

Title: Adapting human videofluoroscopic swallow study (VFSS) methods to characterize dysphagia in animal models of human diseases

Authors: *M. J. ALLEN[1], T. E. LEVER[2];
[1]Dr. Lever's Lab., Columbia, MO; [2]Dept. of Otolaryngology - Head and Neck Surgery, Univ. of Missouri Sch. of Med., Columbia, MO

Abstracts: Objective: A logical first step in establishing animal disease models of dysphagia for translational research is the identification of objective measures (biomarkers) of swallow function/dysfunction that can be readily compared across species, including humans. However, published methods for evaluating dysphagia in animals are markedly different between species as well as between diseases, rendering it impossible to derive meaningful comparisons and predictions from these preliminary research efforts. In contrast, human dysphagia is predominantly studied using an x-ray procedure called a videofluoroscopic swallow study (VFSS). This test entails sitting or standing within the c-arm of fluoroscopy machine while voluntarily ingesting food and liquid consistencies mixed with an oral contrast agent. The goal of this study was to adapt the voluntary human VFSS methods for use with major model organisms (mice, rats, dogs, cats, and pigs) to facilitate comparative and translational investigations of dysphagia. Methods: Approximately 60 mice and 40 dogs of both sexes participated in protocol development. Mice were from our C57 and SOD1-G93A (model of amyotrophic lateral sclerosis or ALS) colonies. Healthy dogs and those with neurological diseases (e.g., ALS and Batten disease) were from existing colonies or the local community. Results: We have successfully designed species-specific methods for VFSS that include three key components: 1) recipes for flavoring oral contrast agents, 2) test chambers that permit self-feeding, and 3) a step-by-step test protocol that permits quantification of swallow physiology. Conclusions: We have developed novel methods for evaluating dysphagia that permit direct comparisons of swallow function/dysfunction between species and diseases. These methods are currently being used to establish several animal disease models of dysphagia that are suitable for translational research with humans and companion animals. Thus, this line of research has the potential to benefit human and veterinary patients with dysphagia.

Title: The cross-training and detraining effects of tongue exercise in the cranial sensorimotor system

Authors: *A. J. SCHASER, M. R. CIUCCI, N. P. CONNOR;
Univ. of Wisconsin-Madison, Madison, WI

Abstracts: Purpose: Exercise-based therapies are currently used to treat voice and swallowing disorders without a clear understanding of the mechanisms that alter the cranial neuromuscular system. For instance, it is not known if tongue exercise paired with a water swallow is associated with changes limited to the tongue alone or if cross-training effects are found in other swallow-related structures, such as the larynx. It is also unknown if behavioral changes endure after therapy is discontinued, and if changes are related to neurotrophic regulation. It is hypothesized that: 1) tongue exercise will result in improved behavioral and neurotrophic outcomes in the cranial sensorimotor system across the lifespan with greater effects in lingual versus laryngeal structures, and 2) that exercise effects will diminish when the exercise program is discontinued (detraining). Methods: Forty young adult (9m) and 40 old (32m) male rats were used. The rats were randomly assigned to either a tongue exercise group (n=20), 2-week detraining group (n=20), 4-week detraining group (n=20) or control group (n=20). Baseline tongue forces and ultrasonic vocalizations were recorded for all animals. Exercise and detraining animals performed a tongue press task paired with a water swallow for 8 weeks. Detraining animals then underwent 2 or 4 weeks of detraining, respectively. Behavioral outcomes of tongue force and ultrasonic vocalizations were recorded at all time-points. Following training, laryngeal and lingual muscles and brainstem areas were removed for analysis of neurotrophic factors. Results: Preliminary results showed a decrease in tongue force and number of vocalizations with age. Following exercise in both age groups, maximum voluntary tongue force increased, with a subtle detraining effect found at both 2 and 4 weeks. Changes in vocalizations did not appear dependent on tongue exercise, based on number of vocalizations alone. Additional analyses of vocalizations and protein and mRNA quantification of BDNF, NT4/5, and TrkB in muscles and brainstem nuclei will be presented to build on our previous immunohistochemical work which has shown a reduction in TrkB in the hypoglossal nucleus with age and an increase in BDNF with exercise in young adult animals. Conclusions: Tongue exercise is associated with increased tongue forces at all ages and gains are maintained after detraining up to 4 weeks. However, tongue exercise does not appear to have an impact on number of vocalizations. Ongoing analyses examining changes in neurotrophic regulation in the cranial sensorimotor system will be presented to determine the underlying mechanisms responsible for the behavioral changes described.

Title: Characterizing the laryngeal adductor reflex across multiple species: Implications for human and veterinary medicine

Authors: *T. E. LEVER;
Otolaryngology - Head and Neck Surgery, Univ. of Missouri-Columbia, Columbia, MO

Abstracts: Objectives: A recently proposed risk factor for dysphagia and aspiration in neurologic disorders is an impaired laryngeal adductor reflex (LAR), which entails brief closure of the vocal folds in response to contact of foreign material at the laryngeal entrance. The LAR is readily triggered in healthy, awake humans by delivering a puff of air to the laryngeal entrance via an endoscope passed through the nose into the throat. LAR impairment has been studied (but not well-characterized) in conditions of health and various neurological disorders that cause dysphagia, such as amyotrophic lateral sclerosis (ALS) and stroke. The goal of this study was to develop a protocol to evaluate the LAR in mice. Methods: We designed and constructed an elaborate prototype air pulse delivery system that interfaces with an endoscope that is small enough for oral insertion to the laryngeal entrance of mice. The endoscope contains a working channel through which calibrated puffs of air can be delivered at specific phases of the respiratory cycle. The system is currently being scaled up in size for use with larger animals (e.g., dogs, pigs and horses). Results: We have successfully used this prototype system to evoke and video record LAR responses in healthy mice and mouse models of ALS under light anesthesia, thus demonstrating proof of concept. Furthermore, we have objectively quantified several novel LAR parameters that have not been previously reported for human LAR, including total LAR duration, duration of adduction versus abduction phases, and velocity of dorsal angle adduction and abduction. Conclusions: This study provides new evidence that mice have an LAR similar to humans, which can be reproducibly induced and recorded in conditions of health and disease. We propose that LAR parameters may serve as novel outcome measures to objectively quantify the effect of treatment interventions for ALS and other medical conditions that cause dysphagia.

Title: Dysphagia after stroke: Use of hyper-acute anatomical MRI for the study of brain networks and dysphagia

Authors: *M. GONZALEZ-FERNANDEZ[1], C. ANDERSON[1], A. E. HILLIS[2];
[1]Physical Med. and Rehabil., [2]Neurol., Johns Hopkins University, Sch. of Med., Baltimore, MD

Abstracts: Introduction: Lesion analysis is a classic technique used to identify brain-deficit correlations. The earliest location-function associations were possible through post-mortem lesion analysis of brains from individuals with known deficits. The brain-function associations that could be made using this approach were limited by changes occurring in the brain after the event as a result of healing. Early MRI imaging can allow us to make lesion site- deficit associations before changes occur as a result of brain reorganization or healing. We hypothesized that using diffusion-weighted (DWI) and perfusion-weighted (DWI) MRI in the hyper-acute stage of stoke would allow us to make these associations. Methods: DWI and PWI MRI-based lesion analysis was performed concurrent to instrumental evaluation of swallowing in subjects who sustained a supratentorial ischemic stroke. MRI images were obtained within 48 hours of stroke with instrumental examination of swallowing (videofluoroscopy) within the same timeframe to allow for the identification of brain areas that, if affected, result in specific physiologic deficits that clinically result in dysphagia. Results: Obtaining timely MRI and videofluoroscopic swallowing images was feasible. Analysis of the MRI and vidoefluoroscopic images is possible and preliminary data have allowed for the identification of possible associations in several brain locations such as the premotor cortex and inferior frontal cortex. Conclusions: Lesion analysis using DWI and PWI MRI is a feasible approach to study the brain

networks regulating swallowing. Future studies including diffusion tensor imaging (DTI) can potentially add to the relationships identified using the current approach.

Title: Preclinical oromotor dysfunction and brain pathology in a PINK1 knock-out model of Parkinson Disease

Authors: ***M. R. CIUCCI**, C. A. KELM-NELSON, L. M. GRANT, K. P. CULLEN, E. PAUL; Surgery-Otolaryngolgy, Univ. Wisconsin, MADISON, WI

Abstracts: Parkinson disease (PD) is devastating to oropharyngeal swallowing and the onset, progression and neural correlates of PD-related dysphagia are poorly understood. To address this, we used a genetic rat model of PD and hypothesized that oromotor and swallowing deficits would manifest early in the disease process and be related to pathologies in brain structures associated with cranial sensorimotor function. Data for vocalization and tongue function were reported previously (SfN 2013). This presentation includes new data on biting and oropharyngeal

swallowing, as well as brain pathology.. Rats with homozygous knock-out (KO) of PINK1, and WT controls (n=32) were studied at 4 and 8 months of age. Bite force and timing characteristics were measured during consumption of a 7cm piece of pasta. Videofluoroscopy was used to evaluate swallow function for mastication rate and bolus velocity. Brain tissue was analyzed for insoluble aggregated alpha-synuclein (aSyn), nigrostriatal dopamine content, and serotonergic receptor density in the hypoglossal nucleus. A repeated measures ANOVA and Fishers Least Significant Difference tests were used for the biting data. Planned comparisons between genotypes at ages 4 and 8 months were performed with unpaired t-tests for videofluoroscopy and neurochemistry data (alpha<0.05). For biting/chewing, PINK1 KO rats demonstrated a larger inter-bite interval at 8 months of age [$F(2, 74)=10.12$, $p<0.001$]. For videofluoroscopy, PINK1 KO rats showed a significantly slower mastication rate $t(15)=1.97$, $p=0.034$, and bolus velocity $t(15)=1.84$, $p=0.043$ than WT rats at 8 months.. For the PINK1 KO rats at 8 months of age: 1) aggregated aSyn was found in the substantia nigra, periaqueductal grey and nucleus ambiguus at 8 months 2) decreased pixel area for immunoreactivity for 5HT-1A receptors was found at 8 months of age. There were no significant differences in tyrosine hydroxylase immunoreactivity between WT and PINK1 KO in the substantia nigra or striatum. Overall, results indicate that rats with homozygous KO of PINK1 demonstrate early oromotor and swallowing dysfunction, prior to nigrostriatal dopamine loss. Aggregated aSyn was found in the substantia nigra as well as regions that control or modulate swallowing (periaqueductal grey, nucleus ambiguus), and reduced number of 5HT-1A receptors were found in the hypoglossal nucleus. Findings suggest oromotor/swallowing deficits occur early in the disease process and are related to pathologies outside of the nigrostriatal dopamine depletion framework.

Title: A fast and reliable paradigm for swallowing-related functional magnetic resonance imaging (fMRI)

Authors: *P. SOROS;
Clin. Neurosciences, Univ. of Lübeck, Lübeck, Germany

Abstracts: Purpose: Swallowing-related fMRI is challenging, in particular, in patients with dysphagia. Main obstacles include task-related head motion, multiple attempts to swallow, and fatigue, which limits the time for data acquisition. The objective of this study was to develop a fast and reliable paradigm to evaluate swallowing-related brain function using fMRI. Methods: We studied swallowing-related brain activity in 22 healthy young women, who were cued to swallow their saliva every 44 s. Event-related fMRI was performed on a Siemens Trio Tim scanner at 3T. For this study, we analyzed fMRI data obtained during the first 6 swallows (5 min) of a longer experiment. Data analysis was performed with independent component analysis (ICA) using MELODIC. Results: Swallowing-related brain activity was identified in the bilateral sensorimotor cortex (lateral pre- and postcentral gyrus) and in the bilateral cingulate motor area (anterior cingulate gyrus) in all participants. Conclusions: This study demonstrates that as few as 6 acts of saliva swallowing performed within 5 min are associated with a reliable activation of key areas of the cortical swallowing network in individual participants, when analyzed with a model-free analysis approach (ICA). This analysis does not require monitoring of swallowing events and successfully separates changes in brain activity from head-motion induced artifacts. This approach needs to be validated in healthy seniors and in dysphagic patients and may be particularly useful for the study of patients with severe swallowing deficits, e.g. due to ischemic brain lesions.

Title: Uncoupled dynamics of magnitude and phase of beta oscillations in MIo during feeding behavior

Authors: *K. TAKAHASHI[1], Y. NAKAMURA[2], N. G. HATSOPOULOS[1], C. F. ROSS[1]; [1]Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL; [2]Grad. Sch. of Med. and Dent. Sci., Niigata Univ., Niigata, Japan

Abstracts: Previously we have shown that the β frequency range of local field potentials (LFPs) recorded from the orofacial part of the primary motor cortex (MIo) increased its power prior to the transition from rhythmic chews to swallows. However any dynamics of beta oscillations, particularly during swallow, has never been shown. In order to investigate beta phase dynamics, we used two female were trained to feed with their right hand while restrained. We used a motion capture system to record 3D jaw kinematics and 2D videofluoroscopy to record tongue marker kinematics. Jaw movement cycles were defined by two consecutive maximum gapes. We recorded 96 channels of LFPs from a chronically implanted Utah array in MIo. We then identified the peak of the β oscillation frequency, bandpass filtered each channel of LFP over β peak ± 3 Hz, then computed the amplitude and phase of the Hilbert transform of the filtered LFPs. Then we analyzed swallowing movements and identified 5 commonly used kinematic events to assess swallowing performances: Closing - Start of thyroid cartilage movement, Elevation - Start of thyroid cartilage elevation, Top - Thyroid cartilage reaching the most up-forward position, Descent - Start of thyroid cartilage descent, Return - Return to Closing position. We observed that beta power increased more than one chew cycle prior to the onset of each event of swallowing and attenuated at Closing, Elevation, Top, and Descent. Furthermore, we found that an entrainment of phase locking of beta oscillations took place around 120 ms prior to Top timing and peak phase locking of a few cycle showed consistent frequency with the identified beta oscillation frequency. Our results indicate that the magnitude of β oscillations recorded from MIo can be used to predict the occurrence of transition from a rhythmic chew to a swallow at least one chewing cycle prior to the start of the swallow cycle. Furthermore there is a particular phase alignment prior to Top independent of magnitude of β oscillations.

Title: Functional connectivity of swallowing network areas in children with acquired or congenital hemiplegia: A pilot study

Authors: *G. MALANDRAKI[1], K. FRIEL[2], J. J. SHEPPARD[1], A. GORDON[1];
[1]Biobehavioral Sci., Teachers College, Columbia Univ., New York, NY; [2]Weill Cornell Med. Col., New York, NY

Abstracts: Purpose: To examine the functional connectivity of swallowing network areas in five children with acquired or congenital hemiplegia with and without dysphagia. Methods: Five children with hemiplegia (age range: 6;1-11;1; 3 males) participated in a standardized clinical swallowing assessment and a resting-state fMRI experiment. The swallowing assessment was performed using the Dysphagia Disorder Survey during functional eating and a 4-point Dysphagia Severity Scale. A high-resolution T1-weighted image was acquired for registration of functional images and to obtain lesion information. Additionally, two resting-state fcMRI scans were acquired (TR=2000 ms, TE=35ms, acquisition matrix 64 x 64, FA=75 degrees, slice thickness=4, slices=36, volumes=167) and seed-based connectivity analyses were performed with 5mm radius seed regions in swallowing network areas (primary motor and sensory cortices, insula, and frontal operculum). Results: Dysphagia severity scale scores revealed that one child exhibited no dysphagia, three children exhibited mild dysphagia and one moderate/severe dysphagia. Resting fcMRI analysis showed that for the child without dysphagia all swallowing network areas showed significant and high intensity positive temporal correlations with other swallowing network areas bilaterally (e.g., primary motor and sensory cortices, the anterior cingulate gyrus and the insula) ($t=4.650$, $p<0.001$, uncorrected). Anti-correlations were seen primarily with areas of the prefrontal and visual cortex and the cerebellum bilaterally ($t=4.650$, $p<0.001$, uncorrected). For the three children with mild dysphagia swallowing network areas showed similar patterns of positive correlations but primarily on the unaffected hemisphere (and limited on the affected hemisphere) ($t=4.650$, $p<0.001$, uncorrected); and for the child with moderate/severe dysphagia the analogous positive correlations were seen only ipsilaterally (unaffected side) ($t=4.650$, $p<0.001$, uncorrected). Anticorrelations appeared weaker in the four children with different degrees of dysphagia compared to the child with no dysphagia. Conclusion: These results show preliminary evidence that the functional connectivity of important swallowing areas is altered in children with hemiplegia and dysphagia. Resting-state fcMRI appears to be a useful means for non-invasively investigating swallowing network connectivity and potential neuroplasticity in pediatric patients with dysphagia.

Title: Distinct roles of induced and evoked cortical oscillations for speech motor control

Authors: *R. BEHROOZMAND[1], N. IBRAHIM[2], O. KORZYUKOV[2], C. LARSON[2]; [1]Dept. of Communication Sci. and Disorders, Univ. of South Carolina, Columbia, SC; [2]Dept. of Communication Sci. and Disorders, Northwestern Univ., Evanston, IL

Abstracts: During speaking, the brain has to continuously monitor feedback information in order to correct for unwanted production errors and update the current state of sensory-motor networks for future speech production purposes. This task requires the involvement of short-term and long-term neural processes that facilitate communication between functionally-related areas. In the present work, we studied the electrophysiological correlates of the underlying neural mechanisms of speech motor control in an auditory feedback perturbation paradigm. Electroencephalographic (EEG) responses were recorded from 3 groups of subjects (11 absolute-pitch (AP) musicians, 12 relative-pitch (RP) musicians and 11 non-musicians (NM)) while they maintained steady vocalizations of the vowel sound “a” and received brief (200 ms) pitch shifts (+/- 100 cents) in their auditory feedback. Time-frequency analysis of the EEG signals was performed on a trial-by-trial basis using a complex Morlet wavelet transform and phase-synchronized (evoked) and non-phase-synchronized (induced) neural responses to pitch shifts were extracted for delta (<4 Hz), theta (4-8 Hz), alpha (8-15 Hz), beta (15-30 Hz) and gamma (30-60 Hz) frequency bands. This analysis revealed that the onset of pitch shifts elicited an increase in the power of the evoked responses at frequencies below 10 Hz that peaked at 200 ms

and was significantly larger in AP and RP musicians compared with the NM group. In addition, an increase in the power of the induced neural response components was identified within delta and theta frequency bands that started at latencies around 1000 ms with peaks at 2000 ms following the pitch shift onset. Contrary to the evoked responses, power increases in the induced neural activity was significantly larger in the NM group compared with AP and RP musicians. These findings suggest that the brain utilizes distinct functional mechanisms to process and integrate auditory feedback information during speech motor control. We suggest that the short-latency evoked activities are involved in gating the sensory feedback information to drive compensatory vocal motor behavior. However, long-latency induced oscillations are important for long-range integration and coupling of distinct but functionally-related local neural circuits that are involved in monitoring behavioral performance and updating the state of the sensory-motor networks to accomplish future motor control goals during speaking.

Title: Effect of transcranial direct current stimulation (tDCS) over M1 pharyngeal area on swallowing phase in post-stroke dysphagia

Authors: S. KOGANEMARU[1], F. OSHIMA[2], Y. OHASHI[2], H. FUKUYAMA[3], *T. MIMA[3]; [1]Brain Integrative Sci., Kyoto universtiy, Kyoto, Japan; [2]Japanese red cross kyoto daiichi hospital, Kyoto, Japan; [3]Human Brain Res. Cntr, Kyoto, Japan

Abstracts: Non-invasive brain stimulation has been reported to enhance functional recovery by inducing brain plasticity in post-stroke patients. Recently, some studies revealed that transcranial direct current stimulation (tDCS) given over pharyngeal area of the primary motor cortex (M1) has promoted recovery of swallowing dysfunction in acute and subacute post-stroke patients. However, its detailed mechanism of recovery is still unknown. We investigated which phase of swallowing the tDCS affects in post-stroke dysphagia by using video-fluoroscopy (VF). We had

one chronic post-stroke patient showing intractable dysphagia with nutrition intake through a gastrostomy tube due to the right subcortical infarction and the left subcortical hemorrhage occurred about 20 years ago. He received the bilateral tDCS and sham stimulation each on different day. The anodal tDCS was given over the left M1 pharyngeal area and the cathodal tDCS the right M1 pharyngeal area. Other parameters of tDCS were following; duration of 10 minutes, electrical current of 2mA and the size of the electrodes of 3 cm * 3 cm. During tDCS and sham stimulation, he also received direct swallowing training for 10 minutes by a speech therapist. After the tDCS intervention, VF revealed a shortening of the oral transit time in feeding fluid in the oral phase, of the swallowing reaction time and of pharyngeal transit time in feeding jelly and fluid in the early part of pharyngeal phase, compared to the pre-intervention. There was no apparent change in the late part of pharyngeal phase. After the sham stimulation, there was no change in both of the oral and pharyngeal phase. It suggests that tDCS over the M1 pharyngeal area combining swallowing training might be effective for improvement of coordinated movement of oral and pharyngeal organs in post-stroke dysphagia.

Title: Central processing of masticatory muscle sensation

Authors: T. FUJIO[1], F. SATO[1], A. TOMITA[1], *M. MORITANI[2], A. YOSHIDA[1];
[1]Oral Anat. and Neurobio., Grad. Sch. of Dentistry, Osaka Univ., Suita, Japan; [2]Dept of Physical Therapy, Morinomiya Univ. of Med. Sci., Osaka, Osaka, Japan

Abstracts: Sensations from the masticatory muscles and periodontal ligaments are generally recognized to be transported by the trigeminal mesencephalic nucleus (Vmes) neurons, and to be directly involved in the monosynaptic jaw-closing reflexes. It has been reported in rats that responses to stimulation of the nerves innervating the masticatory muscles can be recorded in the primary somatosensory cortex (S1) and primary somatomotor cortex (M1). Our previous finding that the Vmes neurons receive direct projections from the prefrontal cortex indicated a possibility that sensations from the masticatory muscles or periodontal ligaments are conveyed to the

prefrontal cortex. However, little is known about the central processing of these sensations. To reveal this issue, we examined the central pathways of these sensations to the cerebral cortex in the rat by using neuronal tract tracing and electrophysiological recording techniques. After application of biotinylated dextranamine (BDA) to the masseter nerve, we found BDA-labeled axon terminals mainly in the trigeminal motor nucleus (Vmo) and supratrigeminal nucleus (Vsup). After application of the BDA to the inferior alveolar nerve and the superior alveolar nerve, however, no labeling was found in the Vmes, Vmo and Vsup. Responses to stimulation of the masseter nerve could be recorded in the Vsup. Subsequently, to reveal the thalamic projections of the Vsup neurons, we injected BDA into the Vsup. BDA-labeled axon terminals were found in the medial part of the ventral posteromedial nucleus (VPM) and paracentral nucleus (PC). Responses to stimulation of the masseter nerve could be recorded in the VPM and PC which have been indicated to respectively project to the somatosensory cortex and the prefrontal cortex. Therefore, the present findings suggest that sensation from the masticatory muscles is possibly involved not only in the discriminative aspect but also the autonomic or limbic aspect of the sensory processing.

Title: Neural excitation with positoron emission tomography after tooth mechanical stimulation

Authors: K. OMOTO[1], K. MARUHAMA[2], T. SUGIMOTO[2], *Y. MATSUKA[1];
[1]Stomatognathic Function and Occlusal Reconstruction, The Univ. of Tokushima/ Inst. of Hlth. Biosci., Tokushima, Japan; [2]Oral Function and Anat., Okayama Univ. Grad. Sch. of Med. / Dent. and Pharmaceut. Sci., Okayama, Japan

Abstracts: Dentists often cannot find objective abnormal findings in patients who complain of discomfort or abnormal sensation in their dental occlusion. We hypothesized that abnormal neural transmission from the tooth is related to this occlusal discomfort sensation. Chronic tooth

contact habit may induce neural excitation from the tooth to the central nervous system and it may aggravate the discomfort sensation. However, the details about neural transmission from tooth to the central nervous system are not yet clear. In this study, we stimulated a rat premolar mechanically and observed activated brain sites using positron emission tomography (PET) and ^{18}F-2-fluoro-2-deoxy-D-glucose (^{18}F-FDG). Rats, 5-7 weeks old, were anesthetized using isoflurane inhalation anesthesia and we stimulated the upper right premolar mechanically with an electric von Frey system (Model 1601C, IITC Instruments) by measuring mechanical pressure. Before the tooth mechanical stimulation, we injected ^{18}F-FDG through the rat's caudal vein and used a stimulation intensity of 0g, 100g, 200g or 300g. We recorded ^{18}F-FDG accumulation with PET ten minutes after ^{18}F-FDG administration. At first, the PET brain images were separated into four parts (upper right, upper left, lower right and lower left) for the analysis and the peak value of striatal uptake (SUV) in each part was analyzed. The PET image showed that accumulated ^{18}F-FDG in the lower right part of the brain was higher with 300g tooth stimulation than 100g or 200g. The data showed that tooth stimulation side in the lower right part of the brain was activated with the tooth stimulation by comparing it with the other parts. Since we wanted to know the excitation point in the brain in detail, we measured SUV in the right and left sensory area, motor area, hippocampus, trigeminal ganglia and spinal cord. Unfortunately, we could not find a specific ^{18}F-FDG accumulated point with tooth stimulation. There is a possibility that unknown points in the brain might have been activated after the tooth's mechanical stimulation. Also, we found that spatial resolution of the PET was not enough and we were not able to find the specific activated point. Moreover, ^{18}F-FDG may not be good enough to trace neural activation clearly.

Title: Simplified technique for localizing speech motor cortex implantation targets

Authors: *P. R. KENNEDY[1], A. J. CERVANTES[2], H. MAO[3];
[1]Neural Prosthetics, Neural Signals Inc, Duluth, GA; [2]Belize Healthcare Ctr., Belize City, Belize; [3]Radiology, Emory Univ., Atlanta, GA

Abstracts: Localization of implantation targets using functional MRI was first utilized in our research in 1995 to target implantation of hand motor area in locked-in subjects. Functional MRI utilizing BOLD technique indicated a large and non-specific target area over the left motor / pre-motor cortex. Since that time, identification of discrete targets by Chang and his colleagues (Bouchard et al, Nature 2013) has provided clear demarcation of the somatotopy of lips (medial), jaw, tongue and larynx (most lateral and adjacent to the Sylvian Fissure [SF]). These workers took advantage of electrocorticogram (ECOG) recordings during surgery in seizure patients. Their measurements coincide precisely with functional MRI data taken from one intact human subject in this confirmatory study who used discrete movements of lips, jaw and tongue. To apply this information to surgical implantation of electrodes, standard neurosurgical fiducial data were consulted: These data indicate that a line drawn from the tragus to the vertex passes over or slightly anterior to the central sulcus. CT scan imaging in the same subject confirmed that fiducials placed along the line from tragus to vertex lie over or close to the central sulcus. Future surgical exposure of this motor cortical area should confirm the localization as extending along this line from the SF to 30 mm above the SF (Bouchard et al. 2013). These fiducials markings should simplify targeting of implantable electrodes in individual subjects within the motor speech cortex without the need to perform functional MRI.

Title: Double sealed hermetic implant package for the next generation of a wireless brain-computer interface

Authors: F. KOHLER[1,3], J. ORDONEZ[1,3], T. STIEGLITZ[1,3], *S. CARDOSO DE OLIVEIRA[2,4], J. RICKERT[3,4,5], M. SCHUETTLER[2,3,4,5];
[1]IMTEK, [2]Albert Ludwigs Univ. Freiburg, Freiburg, Germany; [3]Bernstein Ctr. Freiburg,

Freiburg, Germany; [4]Brain Links-BrainTools Excellence Cluster, Freiburg, Germany; [5]CorTec GmbH, Freiburg, Germany

Abstracts: Hermeticity is a crucial technical requirement to avoid failure of moisture sensitive electronics utilized in active implantable medical devices (AIMDs). Our development of a wireless brain-computer interface (BCI) which is intended to stay functional within the human body for decades poses manifold challenges to the technical development. But not only moisture ingress has to be avoided once the device is implanted, process related hazards have to be identified and avoided as well. To allow wireless infrared data communication through our implant packages wall, we decided for a ceramic housing to host the electronics. Ceramic provides excellent hermeticity characteristics and concurrently allows a satisfying amount of infrared light to pass. We developed a solder-sealing concept for the ceramic packages which is reproducible and highly reliable. However, hazardous fumes related to the solder procedure must not enter the package since they could initiate corrosive processes. For that purpose we utilize a two-step sealing concept where we first seal our package from the inside with an epoxy resin followed by the final solder-seal. To achieve a reliable polymeric seal, we utilize a sealing tool, which allows us to align the individual components of our package as well as a heating function to melt the epoxy to form an internal seal and solder fume barrier, respectively. The tool can be utilized for various designs and geometries. It allows variations of the processing temperature as well as the mating force when individual components are joined to form the hermetic enclosure. The process itself works reliably and is easy to handle. Packages with hermeticity values ranging from 10^-10 mbar l s^-1 to 10^-12 mbar l s^-1, depending on the overall size of the package and the length of the sealed joint could be fabricated. The measured hermeticity values predict theoretical lifetimes for the individual packages ranging from 100 to more than 10000 years.

Abstracts: Rationale: Brain-Computer Interface (BCI) technology is a powerful tool for enabling communication between people and the surrounding world by surpassing the muscle activity and utilizing direct brain signal instead. Utilization of invasive BCIs may benefit BCI users. Among several approaches allowing navigation for invasive BCI implantation, the most promicing can be considered the use of magnetoencephalography (MEG). MEG is a non-invasive technology allowing precise temporal and spatial resolution of neuromagnetic signal. The aim of the current study was to evaluate for the first time the possibility for non-invasive navigation of subdural electrode implantation with MEG needed for high accuracy P300 speller performance. Methods: The study was performed in a right-handed female patient (17 yo) with diagnosis of intractable epilepsy, undergoing evaluation for epilepsy surgery. Two main approaches were utilized to select 8 channels for invasive P300 speller: (1) Protocol #1 (MEG-based) used MEG source localization to navigate the choice of electrodes; and (2) Protocol #2 (ECoG-based) utilized statistical ECoG signal analysis. The localized P300 sources obtained from Protocol #1 were overlaid with the 3-D-rendered cortical and grid map. Eight electrodes in a close proximity with localized P300 sources were selected for P300 speller protocol. To choose 8 channels with Protocol #2, a Mann-Whitney U-test was utilized to test if TARGET and NON-TARGET samples originate from the same distribution and led to a p-value for each sample and channel. The channels were selected according to the longest period of significant difference ($p<0.05$) between TARGET and NON-TARGET trials. Results: The accuracy of subdural P300 speller was compared for 8 electrodes identified with MEG (Protocol #1) and for 8 electrodes identified by ECoG data (Protocol #2) after creating a classifier with 10 letter phrases. The accuracy of subdural P300 speller for MEG-identified sites was 80%, whereas for ECoG-identified sites it reached 90%. Conclusions: Our preliminary data suggest that MEG has a potential to serve as a non-invasive tool for navigating electrode implantation of P300 speller-based BCIs.

Title: Mobile closed-loop deep brain stimulation system for ambulatory patient tremor mitigation

Authors: *J. A. HERRON, H. J. CHIZECK;
Electrical Engin., Univ. of Washington, Seattle, WA

Abstracts: Deep brain stimulation (DBS) has become a widely adopted method for treating a variety of neurological and movement disorders. However, current clinically deployed systems are open-loop and do not take into account the potentially intermittent nature of symptoms such as tremor. By closing the loop with wearable sensors to directly sense symptoms, we can determine not only when stimulation may be necessary but also estimate what intensity of stimulation should be used. By limiting stimulation to only the level needed we will increase the battery life of the implanted devices and reduce exposure to unintended side-effects. We have developed a mobile and wireless platform for investigations closed-loop DBS applications in ambulatory patients. This system takes advantage of a personal-area-network to connect sensors and a smartphone to a real-time command link to the implanted device. The system is capable of fusing data from multiple sensor sources including inertial or electromyography data to make control decisions. These control decisions can include enabling or disabling stimulation or modifying individual stimulation parameters (voltage, pulse width, frequency) in response to changes in neurological symptoms. Our platform consists of a set of worn sensors communicating over Bluetooth to a smartphone. The smartphone is capable of performing digital signal processing and sensor data fusion in order to make control decisions. These control decisions are then sent over Bluetooth to a Medtronic Nexus system which relays packets and control decisions to an implanted Activa PC or PC+S Neurostimulator. We will be using this system for investigations into the clinical performance of closed-loop deep brain stimulation. These mobile systems will be useful in expanding our understanding of neurological movement disorders treatable with DBS by providing consistent data collection and monitoring while patients continue their lives outside of the clinic or hospital.

Title: Grasp representations in the human posterior parietal cortex

Authors: ***C. KLAES**[1], S. KELLIS[1], T. AFLALO[1], B. LEE[1,2], Y. SHI[1], K. PEJSA[1], K. SHANFIELD[3], S. HAYES-JACKSON[3], M. AISEN[3], C. HECK[2], C. LIU[2,3], R. A. ANDERSEN[1]; [1]Biol., Caltech, Pasadena, CA; [2]USC, Los Angeles, CA; [3]Rancho Los Amigos Natl. Rehabil. Ctr., Downey, CA

Abstracts: The posterior parietal cortex (PPC) of the Rhesus monkey has been extensively studied electrophysiologically in the past 20 years. It has been shown to be involved in the planning of reaching and grasping movements and decision making amongst other functions. In this current brain machine interface (BMI) study two Utah electrode arrays (UEA) were implanted in the grasp (AIP) and reach (area 5) related areas of a tetraplegic human. While training the participant to brain-control a robotic limb we had the unique opportunity to study the human PPC electrophysiologically. To improve the decoding performance it is important to understand the properties of the neuronal population we are recording from. For grasp related neural responses, we developed a training paradigm based on the widely known 'Rock-Paper-Scissors'-game. The basic version of the task consists of a cue, delay and response phase. In the cue phase a symbol is presented to the participant either in form of an auditory or visual stimulus which is associated with one of the particular hand shapes (rock, paper or scissors) of the game. In the delay phase a blank screen is shown. Finally the participant had to imagine forming the hand shape that was cued and to verbally respond to what he imagined. This basic task was

modified in various ways allowing us to study different aspects of grasp processing. Although only few recorded units stayed stable over many days, we sampled the same cortical area and could therefore statistically compare neuronal tuning properties in different task configurations. Preliminary results suggest that most of the units recorded at a specific electrode site had stable preferences for specific symbols and their corresponding grasp types. The specificity was consistent with the coding of different grasps within a continuous space of grasp features. We found that extending the number of grasp types in the task can change the organization of these features. We could further decode the task required grasp types offline and online, including using the neural activity to control grasps with a robotic hand. Units that were well tuned to the task typically were tuned either in the cue or response phase, although some cells were tuned to both phases of the task. Interestingly we also found units that were tuned when the symbol was cued by auditory or visual stimuli during the cue phase suggesting integration of different modalities into a uniform task relevant encoding prior to or upon entering the PPC. These results provide novel insights into the process of task related neuronal coding in the context of grasp related activity and could help to improve future neuroprostheses.

Title: Non-linear frequency coupling during brain computer interface (BCI) control - an ECoG study

Authors: *J. D. WANDER[1], K. WEAVER[2], R. P. N. RAO[3], J. OJEMANN[4], F. DARVAS[4]; [1]Bioengineering, [2]Radiology, [3]Computer Sci. and Engin., [4]Neurolog. Surgery, Univ. of Washington, Seattle, WA

Abstracts: Activation of large scale brain networks brain-computer interface (BCI) use has been a subject of considerable interest in recent years. Co-activation of separate regions during the operation of a (BCI) has been reported in prior studies, but characterization of direct interactions between these regions has not been widely addressed. Here we present results from a study with 11 subjects using an electrocorticographic (ECoG) BCI where we observe non-linear cross-frequency coupling between the control electrode and distant cortical sites during active modulation of high gamma power (70-200 Hz). We use the bi-phase locking value (bPLV) and short-time windowed correlation (STWC) as measures of interaction in a data-driven approach to identify lower (alpha/mu - beta range) frequency coupling to frequencies in the high gamma range. We find significant bPLV interactions between frequencies ranging from 7 to 25 Hz with a narrow band in the high gamma range (70-87 Hz) in the control electrode to a similarly narrow range (82-104 Hz) at distant electrodes in 10 out of 11 subjects. Further, we find significant STWC interactions between frequencies in the 15 to 31 Hz range at the control electrode to activity in the high gamma range (70-150 Hz) at electrodes in frontal motor networks. These interactions are specific to time periods where the subjects were executing direct BCI control, which suggests that such interactions are directly involved in the execution of the neuroprosthetic skill. Figure caption: Example band-limited power features and interaction metrics for a single subject. (a) Average feature time-series for a frequency band & electrode combination, calculated separately for trials requiring motor imagery and trials requiring rests. (b) Example Beta-to-HG STWC map for up trials at the same electrode pair. All shown STWC values have uncorrected $p < 0.05$. (c) Example plot showing normalized (rel. t=-1 to t=0) bPLV for electrodes from the same subject. In all cases, Black vertical line at t=0 corresponds to onset of the feedback period.

Title: Micro cuff electrodes for very small peripheral nerves

Authors: J. ORDONEZ[1,2], T. STIEGLITZ[1,2,3], *J. RICKERT[4,2,3], M. SCHUETTLER[1,2,3,4]; [1]IMTEK, Albert-Ludwigs Univ., Freiburg, Germany; [2]Bernstein Ctr. Freiburg, Freiburg, Germany; [3]Brain Links-BrainTools Excellence Cluster, Freiburg, Germany; [4]CorTec GmbH, Freiburg, Germany

Abstracts: Cuff electrodes have settled down as the most appropriate method to interface nerves in the animal peripheral nervous system (PNS). However, the prerequisites set on cuffs are very difficult to meet if the dimensions are reduced to match nerve diameters smaller than 500 µm. Even the smallest defect in the seal along the cuff's length can avoid the detection of low amplitude neural activity. Furthermore, it is advantageous to have an inner diameter as close to the nerve diameter as possible in order to prevent current shunting through body fluids within the cuff, which leads to reduced recording amplitude and/or increased stimulation thresholds. At the same time the cuff must not compress the nerve, which results in reduced blood circulation of the small peripheral nerve blood vessels. A large disadvantage in miniaturized interfaces is also the reduced ability to transfer current without triggering toxic corrosion of the electric contacts. Using only medical grade silicone rubber (polydimethylsiloxane, PDMS) and noble platinum metal, we developed a miniaturized bipolar or tripolar electrode to interface nerves sized between 75µm and 300µm in diameter. Different to most other cuff electrode concepts, the device is fabricated in a planar fashion. A nut within the cuff defines the position of the nerve, which is exposed at predefined sites to the metallic contacts. The PDMS body of the electrode contains patterned chambers that expose a larger area of the metal to the electrolyte, reducing the corrosion risk. However, the chambers filled with electrolyte are channeled through the PDMS to allow all current transfer (from contact to contact) to happen across the nerve. This novel approach does not compromise the stimulation ability of the electrode's contact sites allowing higher stimulation amplitudes even when interfacing very small nerves. At the same time, the cuff contains a self-closing flap system to provides a tight seal towards the surrounding electrolytic environment without applying pressure on the delicate nerve. A picosecond laser is used to pattern the planar device. This allows a simple and controlled adaptation of the dimensions to match the targeted nerve's diameter. Furthermore, the contact's surface can be roughened also by laser patterning to increase the charge injection capacity of Pt up to 285 µC/cm^2 (measured by voltage transient detection during pulse testing). The thin and soft

devices (1.5 mm in height) are great in handling, which makes the implantation procedure simple. The initial prototypes are encouraging and we are confident that these can provide a proper tool for interfacing small nerves in the PNS.

Title: A novel neurofeedback paradigm enables the decoupling of LFP high gamma activity from spike rate

Authors: ***M. W. SLUTZKY**[1], Z. A. WRIGHT[2], R. D. FLINT[3], M. R. SCHEID[3]; [1]Neurol., Northwestern Univ., CHICAGO, IL; [3]Neurol., [2]Northwestern Univ., Chicago, IL

Abstracts: The neural substrates generating high gamma (HG) activity (70-300 Hz) in motor cortex are not fully understood. Further, HG power has been postulated to be a close correlate of spiking activity in M1. This postulate is based on the possibility of components of local action potentials leaking into and influencing HG power fluctuation. However, others contest that true HG rhythms are generated by reciprocal interactions of the local pyramidal and interneuron network. Here, we use a novel brain-machine interface paradigm to help determine whether motor cortical high gamma activity and spikes are generated by the same neural substrate. We trained two rhesus macaque monkeys, implanted with 96-channel electrode arrays in M1, to attempt independent modulation of multi-unit spike (MSP) rate and HG power using a novel orthogonal neurofeedback (ONF) paradigm. Monkeys first learned to control a cursor in one-dimension using neurofeedback (1D-NF) of HG power (200-300 Hz) and then MSP rate (using 50 ms time bins) from the same electrode. Monkeys then controlled the cursor using a vector sum of both components (ONF task), with MSP and HG mapped to X and Y components, respectively. The task required the monkey to acquire targets along the X or Y axes and hold there for 100 ms. The degree to which the spike rate and the power in HG band can move the

cursor along orthogonal axes tells us the extent to which these signals can be decorrelated, and thus are generated by different neural substrates. We measured the dependence between the spike rate and HG power using spike-field coherence during the hold time on each electrode for each monkey. We found that both monkeys were able to modulate HG power and MSP rate independently. As the monkeys learned the task, the coherence between MSP and HG significantly decreased over a week of performing the task to a mean of 0.03 ($p < .001$, ANOVA, in both monkeys). Further, coherence was significantly (19% and 75%) lower during ONF than during 1D-NF of HG power ($p < .001$). These results demonstrate for the first time that spikes and high gamma activity on the same electrode can be decoupled and modulated independently. As a consequence, spikes and high gamma may represent two distinct physiological phenomena. The orthogonal neurofeedback paradigm thus provides a way of distinguishing correlated cortical signals.

Title: Identifying selective auditory attention to speech from electrocorticographic signals

Authors: *P. BRUNNER[1,2], K. DIJKSTRA[1,2,3], A. GUNDUZ[4], W. G. COON[1,5], A. L. RITACCIO[2], J. FARQUHAR[3], G. SCHALK[1,2,5];

Brain, Cognition and Behaviour, Nijmegen, Netherlands; [4]Dept. of Biomed. Engin., Univ. of Florida, Gainesville, FL; [5]Dept. of Biomed. Sci., State Univ. of New York at Albany, Albany, NY

Abstracts: People affected by severe neuro-degenerative diseases (e.g., late-stage amyotrophic lateral sclerosis (ALS) or locked-in syndrome) eventually lose all muscular control. Thus, they cannot use traditional assistive communication devices that depend on muscle control, or brain-computer-interfaces (BCIs) that depend on visual stimulation or feedback. For this population, auditory and tactile BCIs are two of only few remaining means of communication. All currently used auditory or tactile BCIs require a relatively artificial mapping between unnatural stimuli and the intended message. Thus, such systems are cumbersome to learn and use. One way to address this issue is to replace unnatural stimuli that require an artificial mapping with natural speech stimuli that do not. In such a system, the user would communicate simply by directing attention to the speech stimulus that matches his/her intent. Recent studies provided the physiological basis for such a BCI by showing that the envelope of attended speech is tracked by electrocorticographic (ECoG) signals in the gamma band (i.e., 70-170 Hz). To what extent this effect may support BCI communication remained to be determined. In this study, we explored this avenue by determining whether it is possible to use brain signals to learn the identity of an attended speech stimulus. Specifically, we recorded electrocorticographic (ECoG) signals from twelve human subjects while they selectively attended to one of two simultaneously and binaurally presented speech stimuli. We recorded 40 trials of 15-23 sec duration (12.5 min total) in which we interleaved and counter-balanced the attended conversation and its aural location. We hypothesized that the envelope of activity in the gamma band would be reflective of the acoustic envelope of the attended conversation. To test this hypothesis, we first calculated, for each trial, each electrode, and each conversation the correlation between the power envelope of the gamma band and the acoustic envelope of the conversation. We then evaluated the potential communication performance of this relationship in a BCI context. Our results show that a single cortical location over superior temporal gyrus or pre-motor cortex can support the identification of the subject's communication intent within 15 sec and with at least 90% accuracy. These results lay the groundwork for future studies that determine the real-time performance of BCIs based on selective auditory attention to speech.

Title: Activation of the human primary motor cortex by sensory inputs in individuals with limb paralysis and implications for brain computer interfaces

Authors: *S. V. HIREMATH[1], A. D. DEGENHART[2], Y. YANG[1], J. L. COLLINGER[1], S. FOLDES[1], E. C. TYLER-KABARA[3,2], D. J. WEBER[2,1], R. GAUNT[1], M. L. BONINGER[1], W. WANG[1];
[1]Physical Med. and Rehabil., [2]Dept. of Bioengineering, [3]Neurolog. Surgery, Univ. of Pittsburgh, Pittsburgh, PA

Abstracts: Introduction and objective: Brain Computer Interface (BCI) technology has the potential to benefit individuals with severe disabilities. One challenge for clinical applications of BCI technology in individuals with paralysis is to train a neural decoder, which maps brain activity to a BCI control command, in the absence of overt movement. Previously, researchers have proposed the action observation paradigm for neural decoder training. In this study, we evaluated the use of somatosensory input to activate the motor cortex for neural decoder training in individuals with largely intact sensory function but minimal motor function. Methods: Testing was performed in two participants with upper limb paralysis (P1 and P2) who had an electrocorticography (ECoG) array (P1) and a penetrating microelectrode array (P2), respectively, over their primary motor cortex. P1 was diagnosed with amyotrophic lateral sclerosis. P2 was diagnosed with spinocerebellar degeneration with no indication of cerebellar involvement. Participants performed two video-cued tasks: attempting hand/arm movement, and passive movement of the paralyzed limb by an experimenter while the participants were blind-folded. P2 also performed a third task of passively observing videos of hand/arm movements. The videos included 13 body movements of shoulder, elbow, wrist and fingers. Neuronal data included high-gamma band features from P1 and P2 (local field potential - LFP), and single/multi-unit activities from P2. The decoding analysis used Naïve Bayes algorithm to predict the thirteen movements. Results and Discussion: Somatosensory and visual input induced motor cortical activity in P2. ECoG data analysis classified attempted and passive movements with an accuracy of 33.8% and 68.2%, respectively. Spatial patterns of high-gamma band activity across all ECoG electrodes over the motor cortex were similar between passive and

attempted movements. In P2, attempted, observed and passive movements were classified using single/multi-unit activity with an accuracy of 59.2%, 28.5%, and 32.3%, respectively. LFP data analysis was able to classify attempted, observed and passive movements with an accuracy of 56.9%, 46.2%, and 47.7%, respectively. Based on the results, we postulate that somatosensory input can potentially be used for neural decoder training.

Title: Understanding the effects of transversal intraneural stimulation in amputee: a combined experimental and computational study

Authors: *S. RASPOPOVIC[1,2], F. PETRINI[1,3,4], M. CAPOGROSSO[1,2], S. MICERA[1,2]; [1]Ecole Polytechnique Federale De Lausanne, Lausanne, Switzerland; [2]Biorobotics Inst., Scuola Superiore Sant'Anna, Pisa, Italy; [3]Lab. of Biomed. Robotics and Biomicrosystems, Campus Bio-Medico di Roma Univ., Rome, Italy; [4]IRCCS S.Raffale-Pisana, Rome, Italy

Abstracts: To achieve a close to natural replacement for the lost hand in case of amputation, the user should be provided with the rich sensations that we naturally perceive when we explore the environment. After the first demonstrations that is possible to induce physiologically plausible sensations in amputees, by electrical stimulation of residual nerves, even years after the amputation, efforts were carried out to make it a viable solution for chronic implantation. However, there is a lack of systematic characterization of stimulation effects and of deep understanding regarding the mechanisms underlying the chronic body response to electrode implanted within the nerves, which would eventually allow for the development of a personalized approach for each patient. For this reason, we performed extensive trials during

which a subject with transradial amputation has been systematically stimulated by means of four transversal intrafascicular electrodes (TIMEs) implanted within his residual median and ulnar nerves. We performed single-site and multi-site stimulations with 56 active sites. He reported a variety of different sensations, such as touch, pressure waves, tingling, proprioceptive, twitch-like and hot. These were located in areas over phantom limb that corresponded to the innervations territories of the implanted nerves. Modulations of the injected current amplitude, frequency and pulse width were performed in order to gain knowledge about the modulability of such sensations. Furthermore, we showed that by combining different active sites in multi-site configurations, even across nerves, it is possible to elicit complex non-linear relationships resulting into a modified position, extension and quality of each perceived sensation with respect to single-site stimulation. These experimental findings were then compared with a hybrid electromagnetic-biophysics model of human nerve that we developed, based on realistic anatomy and histology, with a realistic representation of sensory fibers population, able to statistically reproduce the experimental data. Model results suggest that the fibrosis response developed during the chronic implantation of the electrodes does not induce significant perturbations of the electric potential elicited by the stimulation. Instead fibrosis cells would most probably tend to push away sensory fibers from the electrode (instead of killing them or inhibit their activity) explaining the increase in the threshold necessary to stimulate over time. This model and experimental findings will guide the design of the next generation of optimized implantable devices, for the long-term neuroprosthesis.

Title: Data-driven model comparing the effects of glial scarring and tip metallization loss on chronic neural recordings

Authors: *K. A. MALAGA[1], K. E. SCHROEDER[1], P. R. PATEL[1], Z. T. IRWIN[1], D. E. THOMPSON[1], C. A. CHESTEK[1], P. G. PATIL[1,2];
[1]Biomed. Engin., [2]Neurosurg., Univ. of Michigan, Ann Arbor, MI

Abstracts: The ability to record single-unit activity with chronically implanted microelectrode arrays is hindered by low recording signal-to-noise ratio (SNR). Low SNR can result from glial scarring or materials failures (e.g., loss of tip metallization, degradation of electrode insulation). The objective of this project is to quantify the effects of glial scarring and tip metallization loss on electrode impedance and recording quality using a data-driven model. A finite element method (FEM) electric field model with detailed representation of a single Utah array electrode (Blackrock Microsystems, Salt Lake City, UT) was developed to analyze electrode impedance as a function of encapsulation resistivity, encapsulation thickness, and tip impedance (modeled as a constant phase element [CPE]). Impedance measurements from two Utah arrays implanted in a rhesus macaque for twelve weeks were reconciled with the model. A cable model of a layer V pyramidal cell was then coupled with the FEM model to analyze waveform amplitude as a function of the aforementioned parameters. From the experimental data, mean electrode impedance increased significantly ($p < 0.05$) while mean waveform amplitude remained stable. By week twelve, mean electrode impedance and mean waveform amplitude increased by 81% and 50%, respectively. Histology at four months showed a glial scar thickness of 16 μm around the electrodes. For the default model parameters (ρ_{en} = 600 Ω-cm [Grill, 1994], encapsulation thickness = 20 μm, ρ_{CPE} = 1.92e5 Ω-cm), encapsulation and CPE impedance were 25 kΩ and 369 kΩ, respectively (Z_{tot} = 431 kΩ). CPE impedance was consistent with manufacturer and measured values, and dominated the encapsulation impedance (e.g., ρ_{en} would have to increase by a factor of fifteen for the encapsulation impedance to equal that of the CPE). Electrode impedance increased as a function of encapsulation resistivity, encapsulation thickness, and CPE resistivity. Waveform amplitude decreased as a function of encapsulation resistivity and CPE resistivity, and increased as a function of encapsulation thickness when the neuron model remained stationary and decreased when it moved with respect to the encapsulation boundary (Moffitt, 2005). Thus, to explain the 81% increase in electrode impedance from the experimental data, ρ_{en} or ρ_{CPE} would have to increase by a factor of fourteen or two, respectively. Electrode impedance was mostly insensitive to encapsulation thickness. While glial scarring may still lead to inflammation and neuron displacement, our results suggest that large increases in electrode impedance are more easily explained by tip metallization loss than glial scarring.

Abstracts: One can imagine that an individual permanently connected to a neuroprosthetic will not want to continuously operate their device. Thus, it is critical to know in real time when neural activity of a user is intended for neuroprosthetic control (control state) and when it is not (no-control state). The proposed solution to this problem is to incorporate an asynchronous control mechanism to a brain computer interface (BCI) system as this will enable users to freely control their neuroprosthetic of their own volition. A variety of approaches have been applied to this problem such as using a salient event related potential to switch between the control/no-control states and utilizing the presence of motor planning activity as an indication of an intention to control. None of these approaches, though, have been implemented in a realistic scenario where subjects naturally transition between the control state and the no-control state, which comprises of a sleep state and an idle state where the user is awake but not attempting to engage their BCI. Here we present the design and performance of a cognitive state estimation algorithm that uses the electrocorticographic (ECoG) signal from freely behaving humans to predict the control, idle, and sleep states, and subsequently decide when and when not to control a neuroprosthetic. Data was collected from two human subjects with intractable epilepsy that were implanted with subdural ECoG grids for seizure foci localization. Subjects were implanted with electrodes for approximately one week during which they behaved freely and naturally. In two sessions on separate days subjects were asked to perform trials of a 3D motor reaching task for 1 to 2 hours at a time. Video recordings capturing the behavior of the subjects were acquired and manually examined to identify epochs when the subjects were asleep, performing the reaching task (control state), or awake but not performing the reaching task (idle state). Cognitive state estimation was done hierarchically in two steps using two probabilistic models. The first model learned the features in the ECoG signal that best differentiated the sleep state from the awake state, which encompassed both the control and idle state. The second model learned the features in the ECoG signal that best delineated the control state from the idle state. The models were implemented in succession to predict the three cognitive states and ultimately

decide when to control or not. The algorithm predicted states accurately and with a low false positive rate. The results suggest that this algorithm can be used as a mechanism for asynchronous control in ECoG based BCIs

Title: Comparison of direction information encoded in local field potentials from motor cortex during ipsilateral and contralateral arm movement

Authors: ***Q. ZHANG**[1], D. WANG[2], S. ZHANG[2], Y. LI[2], Y. WANG[2], X. ZHENG[2]; [1]Qiushi Acad. for Advanced Studies, [2]Zhejiang Univ., Qiushi Acad. For Advanced Studies, Hangzhou, China

Abstracts: Brain machine interfaces (BMIs) aims to help people restore their lost motor function. Currently, most of BMIs use the neural signals from contralateral motor cortex associated with the movement of limb. However, these signals are not available in the case that contralateral cortex has physical injury or neurological disease. Thus, many studies explored whether the ipsilateral cortex encoded movement information and they found that individual neurons in motor cortex may encode the direction information of ipsilateral arm movement. However, most previous studies focused on spikes, relatively little researches had directly compared the direction information encoded in multi frequency band of LFPs from motor cortex

during ipsilateral and contralateral arm movement. In this study, three monkeys were trained to perform 2D center-out task using left and right hand respectively. LFPs were collected from primary motor cortex (M1) and dorsal premotor cortex (PMd) of one hemisphere via two 96-channel Blackrock arrays. The results showed that the energy of multi frequency band in LFPs changed significantly during the both ipsilateral and contralateral movement, in which the variation trend was similar. These multi frequency band in LFPs also encoded the ipsilateral movement information through mutual information analysis. Direction tuning analysis showed the same neural signals had significant different prefer directions between ipsilateral and contralateral movement. Furthermore, neural decoding revealed that multi frequency band performed well in decoding ipsilateral kinematics and high frequency bands provided the best decoding performance. These results indicated that LFPs in ipsilateral motor contex, especially high frequency bands, could be a potential control signal source for the patients with unilateral cortex injuries.

Title: Modulation of brain function by transcranial extracellular impedance control (tEIC)

Authors: *A. MATANI[1], M. NAKAYAMA[2], M. WATANABE[1], Y. FURUYAMA[1], A. HOTTA[1], S. HOSHINO[1];
[1]Grad. Sch. of Information Sci. and Technology, the Univ. of Tokyo, Tokyo, Japan; [2]Grad. Sch. of Frontier Sci., the Univ. of Tokyo, Kashiwa, Japan

Abstracts: EEG is a voltage drop of extracellular currents. Each extracellular current is continuously connected to the source current, or the corresponding intracellular dendric current. The voltage sources of these currents are believed to be the membrane potentials of the

pyramidal cells, the EEG-detectable activities of which are spatiotemporally locked. Now, when a shunt resistor is attached to two EEG electrodes, this is a parallel connection to a peripheral branch and hence the impedance seen from the voltage sources decrease. Therefore, this connection can potentially modulate membrane potentials. Although the connection of a positive shunt resistor may only cause slight modulation effects, that of a negative shunt resistor should cause observable modulation effects. The brain circuit seen from the electrode can be modeled with Ho-Thevenin's equivalent circuit, showing that the extracellular current is positively (called Type I setting) and negatively (called Type II setting) amplified. On the other hand, the brain circuit seen from each neuronal voltage source can be modeled with the superposition principle, showing that each source increases with Type I setting (decreases with Type II setting) the current in whose direction it applies. Thus, we call this technique transcranial extracellular impedance control (tEIC). Note that the above-mentioned operating principles are based on the linear electric circuit, which is usually used as EEG forward models and negative resistors for Types I and II were implemented with operational amplifier circuits. We performed a visually selective response task (speed priority) to evaluate tEIC performance. The tEIC resistors were connected to F3 and the right earlobe and the sham, Type I, and Type II conditions randomly switched every 16 trials of the task. The current flowing through the tEIC circuits was of the order of 10 nA, so that EEG recording could be done with tEIC application. The subjects gave written informed consent after they were given a detailed explanation of this study. The study received approval from the Ethics Committee for human and Animal Research of the University of Tokyo. EEG observations implied that tEIC operation was in accordance with Ho-Thevein's theorem and even single channel tEIC application worked as spatial filter (Type I: high-pass, Type II: low-pass). Moreover, Type I significantly improved reaction times. Therefore, tEIC, just a resistor attached to the scalp, can modulate a brain function.

Title: Membrane glucocorticoid receptor activation initiates rapid nuclear localization of cytosolic glucocorticoid receptor in hypothalamic neurons

Authors: *J. R. RAINVILLE[1], V. K. VALSARAJ[1], A. HUGHES[2], J. G. TASKER[3], N. VASUDEVAN[3];

Abstracts: Stress activates signaling through the HPA-axis, which involves negative feedback from adrenal glucocorticoids through receptors in the hypothalamus. Classic glucocorticoid receptor (GR) signaling involves ligand binding, release from chaperone proteins in the cytosol, and translocation into the nucleus where GR dimerizes and acts as a transcription factor to modulate genes downstream of glucocorticoid response elements. Treatment of cells with ligand, such as the synthetic cortisol dexamethasone (Dex), rapidly induces nuclear localization of GR. Although the mechanism of this translocation is not known, there is evidence that ligand binding and participation of the chaperone complex are necessary for entry into the nucleus. However, recent data from a murine hypothalamic cell line (mHypoE-N11), that endogenously expresses GR, demonstrate that Dex conjugated to bovine serum albumin (Dex-BSA) is also able to rapidly induce translocation of the cytoplasmic GR (cGR). Dex-BSA is limited to the plasma membrane by BSA, which is too large and hydrophilic to cross the lipid layers of the membrane. Intensity analysis of the nuclear to cytoplasmic ratio of GR-immunoreactivity is increased by both Dex and Dex-BSA treatment within 10 minutes of treatment, and persists for at least 3 hours. The data suggest that a membrane glucocorticoid receptor (mGR) exists on the cell surface that is able to bind Dex-BSA and relay an intracellular signal that results in translocation of cGR to the nucleus in its unliganded form. MAPK, PKA, and PKC activators and inhibitors were used to identify possible roles of kinase pathways in mGR initiated cGR nuclear localization. Further investigation into alternate pathways, or phosphorylation studies may help elucidate the details of this process.

Title: Novel antidepressant-like activity of Caffeic acid phenethyl ester mediated by enhanced glucocorticoid receptor function in the hippocampus

Authors: *S. HER[1], Y.-H. KIM[1], B.-R. LEE[1], O.-K. PARK[1], K. MORITA[2];

Abstracts: Caffeic acid phenethyl ester (CAPE) is an active component of propolis that has a variety of potential pharmacological effects. Although we have previously demonstrated that propolis potentiated antidepressant-like activity, but the effect of CAPE on the activity remains unknown. The present study assessed whether CAPE treatment (5, 10 and 20 μmol/kg, 21 days) has an antidepressant-like effect on the tail suspension test (TST) and forced swim test (FST) in mice subjected to chronic unpredictable stress. CAPE administration induced antidepressant-like behaviours, evidenced by decreases in immobility time in the TST and FST without affecting serum corticosterone secretion. Western blots conducted after testing the behaviours revealed that CAPE significantly decreased glucocorticoid receptor phosphorylation at S234 (pGR(S234)), thereby resulting in an increased ratio of pGR(S220/S234). We found also negative correlations of the pGR(S220)/(S234) with the p38 mitogen-activated protein kinases (p38MAPK) phosphorylation which was decreased by CAPE treatment. These findings suggest that CAPE treatment has antidepressant-like activity via the down-regulation of p38MAPK phosphorylation contributing to the enhanced GR function.

Title: Hippocampus-synthesized estrogen and androgen rapidly modulate dendritic spines and LTP

Authors: *S. KAWATO[1], Y. HOJO[1], Y. HASEGAWA[2], H. MUKAI[1];
[1]Dept Biophys & Life Sci, Grad Sch. Arts & Sci., [2]Univ. of Tokyo, Tokyo, Japan

Abstracts: We have demonstrated (1) hippocampal synthesis of estrogen, androgen and (2) synaptic modulation by these sex-steroids. [Synthesis] We showed expression as well as neuronal/synaptic localization of essential enzymes (mRNA and protein) in the adult male rat hippocampus. Mass-spectrometric analysis demonstrated that exact levels of estradiol (E2), testosterone (T), dihydrotestosterone (DHT) were 8 nM, 18 nM and 7 nM, respectively, which are much higher than their levels in plasma. Castration significantly decreased T and DHT in the hippocampus, indicating that plasma-derived T is efficiently converted to DHT within the hippocampus. Even after castration to deplete circulating T, the male hippocampal E2 level was not decreased, indicating that E2 is mainly synthesized from hippocampal T. Female hippocampal levels of E2 (0.5-4 nM), and T (1 nM) were less than those of male, and much higher than those in plasma. [Synaptic Modulation] E2-induced rapid modulation (1- 2 h) was demonstrated by analysis of spinogenesis and LTP of adult male rat hippocampal slices (steroid-depleted slices after recovery incubation). LTP analysis showed that 1 nM E2 completely rescued the 1 μM corticosterone-induced suppression of LTP. ERalpha agonist induced the same effect as that of estradiol. These results imply that *in vivo* hippocampal estradiol at 8 nM could rescue acute stress-induced LTP suppression. Spine analysis was performed for pyramidal neurons in hippocampal slices. The density of spines and their head diameters were obtained by mathematical and automated software Spiso-3D which identifies spines by calculating geometrical parameters (Mukai et al., Cerebral Cortex, 2011). E2 at 1 nM rapidly increased the density of small-head (0.2-0.4 μm) spines, in CA1 pyramidal neurons. T and DHT at 10 nM increased the density of middle-head (0.4-0.5 μm) spines and large-head (0.5-1.0 μm) spines, respectively. Signaling pathways are: synaptic ERalpha or AR→ PKA, PKC, MAPK, LIMK → cortactin or coffilin → actin polymerization→ new spine. Title: Pgrmc1/klf4 signaling- triggered glia-neuron crosstalk plays a critical role in progesterone neuroprotection

Authors: *C. SU[1], F. SUN[2], T. NGUYEN[3], X. JIN[3], M. SINGH[2];
[1]UNTHSC at Fort Worth, Fort Worth, TX; [2]Univ. of North Texas - Hlth. Sci. Ctr., Fort Worth, TX; [3]Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstracts: Abundant experimental and preclinical data suggest that progesterone (P4) is a potent neuroprotectant that may exert beneficial effects in a variety of neurodegenerative disorders, including Alzheimer's disease (AD) and stroke, though the mechanism(s) involved are still unclear. Recent findings from our laboratory have demonstrated that 1) P4 induces the expression of BDNF, and 2) BDNF signaling is an essential mediator of P4's protective effects in neuron- and glia-containing organotypic (slice) cultures of the cerebral cortex. Interestingly, P4 did not result in robust cytoprotection in "pure neuronal cultures", suggesting that an indispensable component of the protective program of P4 is glia. We have recently found that Pgrmc1, a novel membrane-associated progesterone receptor unrelated to the classical nuclear progesterone receptors (PR), mediates P4-triggered BDNF release specifically from glia. To date, downstream signaling transduction consequent to Pgrmc1 activation has not been revealed. Here we provide evidence that P4 elicits a Pgrmc1/ERK5/KLF4 (a transcription factor) signaling cascade, which in turn, orchestrates glia-neuron communication via a BDNF (Brain-derived neurotrophic factor)-mediated intercellular crosstalk. Pgrmc1 and KLF4 are abundantly expressed in both glia and neurons, although their functions within the brain are largely unknown. We show that P4 triggered a significant release of mature BDNF from glia, and this effect was abolished by RNAi-mediated knock-down of Pgrmc1 or KLF4. Treatment of neuronal cultures with conditioned media from P4-treated astrocytes (P4-CM) induced a robust increase of synaptic marker expression, while blocking neurotrophin signaling can attenuate this effect, supporting that glia-derived BDNF induced synaptogenesis in neurons. In addition, P4-CM from glia significantly protected neurons against oxidative stress. Interestingly, over-expression of KLF4 in neurons resulted in an increase of TrkB / p75 ratio, supporting that neuronal activation of the KLF4 pathway "prepares" the neurons to interpret the glia-derived mature BDNF signaling as favorable to survival. Finally, we determined that the levels of Pgrmc1, KLF4 and

BDNF expression were decreased in the hippocampi of aged mice, as well as in the 5×FAD mouse model of AD when compared to age-matched controls, suggesting that both "normal" and "pathological" aging (i.e., Alzheimer's disease) may diminish the sensitivity of the brain to the protective effects of P4 through down-regulating the Pgrmc1/KLF4/BDNF signaling system.

Title: Basal and seizure-induced neurosteroid estradiol production in the hippocampus of freely moving rats

Authors: *S. M. SATO, C. S. WOOLLEY;
Neurobio., Northwestern Univ., Evanston, IL

Abstracts: Electrophysiological studies show that 17β-estradiol (E2) acutely modulates synaptic physiology in hippocampal slices from both male and female rats. E2 potentiates excitatory synaptic transmission within minutes in both sexes, and suppresses inhibitory synaptic transmission specifically in females. Furthermore, steroidogenic enzymes required for de novo synthesis of E2 are present in hippocampus, and E2 production in the hippocampus has been demonstrated *in vitro*. While these studies suggest that locally produced E2 could rapidly modulate synaptic function, hippocampal E2 production has not been demonstrated *in vivo*. In the current study, we investigated endogenous E2 synthesis in the hippocampus of awake, freely moving rats. We also evaluated changes in hippocampal E2 concentration during kainic acid (KA)-induced seizures because hyperexcitation observed during limbic seizures resembles the condition used to demonstrate hippocampal E2 synthesis *in vitro*. Adult male and female rats were gonadectomized and implanted with guide cannulae for *in vivo* microdialysis in the dorsal hippocampus. Seven to 10 days later, a dialysis probe was inserted, and Ringer's solution with BSA was perfused through the probe. In a first experiment, androstenedione (4-dione), an E2 precursor, was retrodialyzed for 1 hr after baseline sampling, followed by 2 more hrs of sample collection. Dialysate was assayed using a commercial E2 EIA. We found that 4-dione slowly

increased E2 concentration, reaching ~10 pg/ml above baseline ($F=2.63$, $p=0.041$) after 1 hr, indicating endogenous aromatase activity in the hippocampus. In a second experiment, we injected KA (1.25-5 mg/kg) after baseline sampling and dialysate was collected for 2 hrs while seizure behaviors were recorded on video. Overall, KA-induced seizures more than doubled hippocampal E2 concentration ($F=6.48$, $p<0.001$). Interestingly, the increase in E2 was most pronounced in rats with moderate seizures, in which E2 concentration tripled relative to baseline ($F=6.28$, $p<0.001$), whereas E2 did not increase in animals with the mildest or most severe seizures. Possibly, limbic seizures increase hippocampal E2 production, while extra-limbic seizures may inhibit E2 production. These results parallel our prior demonstration that acute intra-hippocampal administration of an aromatase inhibitor significantly attenuates both electrographic and behavioral KA-induced seizures. Thus, increased local E2 production during seizures likely contributes to seizure progression. These results suggest acute inhibition of hippocampal aromatase activity may be beneficial in preventing seizure progression.

Title: Knocking down expression of PXR in the midbrain ventral tegmental area of female rats attenuates actions of 3α,5α-THP via NMDA and GABA receptors for lordosis

Authors: *C. A. FRYE[1,3], C. J. KOONCE[3,2], J. C. RUSCONI[2], A. A. WALF[3,4,2];
[1]Psychology, [2]Univ. Albany, Albany, NY; [3]Univ. Alaska Fairbanks, Fairbanks, AK; [4]Cognitive Sci. Dept, Rensselaer Polytechnic Inst., Troy, NY

Abstracts: Pregnane xenobiotic receptor (PXR) is traditionally known as a liver factor involved in xenobiotic clearance and cholesterol metabolism, but it is expressed in brain regions, such as the midbrain ventral tegmental area (VTA). Mating induces synthesis of pregnane neurosteroids from cholesterol in the VTA of female rodents. Reducing PXR in the VTA attenuates mating as well as mating-induced biosynthesis of the neurosteroid, 5α-pregnan-3α-ol-20-one (3α,5α-THP). Although these data suggest that PXR is important for the synthesis of 3α,5α-THP in the

midbrain, a related research question is the downstream factors for 3α,5α-THP's actions. 3α,5α-THP has actions in the VTA for lordosis via gamma-aminobutyric (GABAA) and N-methyl-D-aspartate (NMDA) receptor. A question remains about whether PXR may have requisite actions upstream of GABAA and NMDA receptors in the VTA for mating. The hypothesis tested was that, in the midbrain VTA, PXR mediates biosynthesis of 3α,5α-THP, which has subsequent effects at GABAA and/or NMDA receptors for reproductive behavior of rats. Proestrous, ovariectomized (OVX) and estradiol-primed, or OVX and adrenalectomized (OVX/ADX) estradiol-primed rats were compared. Rats were infused to the VTA with saline or PXR antisense oligodeoxynucleotides (AS-ODNs to locally knock down expression of PXR), and then were infused with saline, GABAA receptor (bicuculline), or NMDA receptor (MK-801) to the VTA. Rats were tested in a behavioral battery assessing exploratory (open field), anxiety (elevated plus maze), social (social interaction), and reproductive (paced mating) behavior. Results indicate that knocking down expression of PXR in the midbrain VTA attenuates actions of 3α,5α-THP via NMDA and/or GABAA receptors for lordosis. Few differences were noted in other behavioral tests assessed, suggesting specificity for these effects. There were greater responses among proestrous rats than OVX/ADX rats. This pattern suggests an interactive role of 3α,5α-THP biosynthesis in the brain via PXR and downstream actions at GABAA and NMDA receptors, which is currently being investigated further.

Title: Deletion of estrogen receptor beta is associated with attenuated responses to androgenic neurosteroids to reduce depression-like behavior and lower brain derived neurotrophic factor among mice

Authors: *A. A. WALF[1,2], C. J. KOONCE[2], C. A. FRYE[2];
[1]Cognitive Sci. Dept, Rensselaer Polytechnic Institute,, Troy, NY; [2]Psychology, Univ. Albany, Albany, NY

Abstracts: Differential distribution patterns and whole animal studies investigating activation and knockdown of estrogen receptor (ER) subtypes suggest that ERβ, rather than ERα, may be a target for some of the beneficial trophic effects of estrogens in the brain, without coincidently increasing growth in peripheral steroid-sensitive tissues. How experience, stress, and capacity for neurosteroid synthesis may be factors underlying individual differences in steroids' trophic effects are of interest. The pregnane neurosteroid, 5α-pregnan-3α-ol-20-one (3α,5α-THP), has anti-depressant-like effects and is formed in the brain in response to challenges. Estrogens with activity at ERβ enhance expression of 5α-reductase, which is a rate-limiting steps for 3α,5α-THP formation, and increase levels of 3α,5α-THP coincident with anti-depressant-like effects. Reduced capacity to form 3α,5α-THP is observed in female mice that are ERβ knockout (βERKO). A related question is the role of androstane neurosteroids, such as 5α-androstane,3α,17β-diol (3α-diol), via ERβ, particularly given robust expression of ERβ in the prostate. 3α-diol has rapid actions, which are similar to those of 3α,5α-THP, to modulate stress responses, and may involve actions at ERβ. Effects of a 5α-reductase inhibitor (finasteride), or 3α-diol administration, for depressive behavior in the forced swim test among male mice were assessed. Whether individual differences in responses to androgens may be attributed to current/past exposure to androgens was investigated by comparing mice with typical capacity to produce neurosteroids (C57BL6, wildtype) to those with reduced capacity (5α-reductase knockouts, βERKOs). Results indicate that finasteride increased, and 3α-diol reduced, depression-like behavior of mice, particularly in those that had less prior exposure to androgens. 3α-diol increased brain-derived neurotrophic factor levels in the prefrontal cortex of wildtype, more so than βERKO, mice, without increasing prostate growth. Thus, differences in prior exposure to steroids as well as actions involving ERβ may underlie individual variability in trophic effects in the brain that can be parsed from undesirable growth effects in the prostate.

Title: Androgen-mediated effects on seizure activity among male rats involves pregnane xenobiotic receptors

Authors: *C. J. KOONCE[1,2], A. A. WALF[1,2,3], J. C. RUSCONI[1], C. A. FRYE[1,2];
[1]Univ. Albany, Albany, NY; [2]Univ. Alaska- Fairbanks, Fairbanks, AK; [3]Rensselaer Polytechnic Inst., Troy, NY

Abstracts: Androgens have well-known important physiological functions throughout the lifespan. Testosterone is decreased with aging in male rodents, and seizure activity following a chemoconvulsant is increased coincident with age-related decline in androgens or decline following castration. Furthermore, blocking synthesis of testosterone to its neuroactive metabolite, and neurosteroid, 3α-diol (via pharmacological techniques or in 5α-reductase knockout mice) produces similar increases in seizure activity following chemoconvulsant administration to male rodents, as is observed with aging. The pregnane xenobiotic receptor (PXR) plays a putative role in biosynthesis of neurosteroids through its actions involving cholesterol metabolism. Little is known how PXR mediates androgen synthesis in the male brain and functional effects, such as those involving seizure processes. We hypothesized that genetic knockout of PXR would influence seizure activity and responses to testosterone treatment following chemoconvulsant administration. Adult male Sprague Dawley rats (SD WT) and PXR knockout rats (PXR KO) were injected with vehicle or testosterone prior to pentylenetetrazol (PTZ). Immediately after PTZ administration, seizure behavior (myoclonic twitches, forelimb and hindlimb clonus, tonic clonic, barrel rolls) and mortality of rats was assessed. Results demonstrate that PXR KO rats had increased latencies to intial myoclonic twitch, forelimb, and hindlimb clonus compared to SD WT rats. The latency to, and incidence of, myoclonic twitch, tonic clonic seizures, barrels rolls, and death increased following testosterone administration. There were interactions with testosterone administration and genotype, such that testosterone increased seizure activity among SD WT rats (forelimb clonus and barrel rolls), but decreased it among PXR KO (forelimb and hindlimb clonus). Together, these findings suggest that PXR regulation of androgenic neurosteroids influences ictal activity.

Title: Pregnane xenobiotic receptor deletion among female rats and mice attenuates responses to progestogens for mating

Authors: *J. RUSCONI[1], C. J. KOONCE[1,2], A. A. WALF[1,2,3], C. A. FRYE[1,2];
[1]Univ. Albany, Albany, NY; [2]Univ. Alaska- Fairbanks, Fairbanks, AK; [3]Rensselaer Polytechnic Inst., Troy, NY

Abstracts: Pregnane steroids, such as progesterone (P4) and 5α-pregnan-3α-ol-20-one (3α,5α-THP), have actions in the midbrain ventral tegmental area (VTA) to mediate reproductive behaviors of female rodents. Mating itself promotes production of 3α,5α-THP in the VTA via sequential actions of several well-recognized factors involved in cholesterol metabolism. Pregnane Xenobiotic Receptor (PXR) may be involved in 3α,5α-THP's actions in the VTA. PXR is a nuclear receptor that regulates gene transcription for cytochrome P450 enzymes, which are involved in 3α,5α-THP biosynthesis. PXR has been identified in the midbrain of female rodents. Knocking down PXR in the VTA, with infusions of antisense oligodeoxynucleotides, attenuate lordosis of rats and mating-induced biosynthesis of 3α,5α-THP. An important question is the role of lifelong knock down of PXR, which can be addressed with comparisons of PXR knockout (KO) rats and mice, which are expected to have attenuated responses to progestogens for mating. Experiment 1: wildtype (WT) and PXR KO rats were assessed for lordosis (mating posture) in a mating task when in proestrus (positive control, high endogenous levels of estradiol (E2), P4, and 3α,5α-THP) or following ovariectomy, E2-priming, and administration of vehicle, P4, or 3α,5α-THP. Experiment 2: C57BL6Tac (WT) and PXR KO mice were assessed for lordosis when in proestrus or following ovariectomy, E2-priming, and administration of vehicle, P4, 3α,5α-THP, or other ligands of PXR that do not increase 3α,5α-THP biosynthesis (MPA or RU486). P4 produced similar rates of lordosis as proestrous WT, but not PXR KO, rats; 3α,5α-THP increased lordosis of both WT and PXR KO rats. The same pattern of results was observed among mice, supporting species similarities in this mechanism. Additionally, mice did not respond to MPA or RU486 as they did for P4 or 3α,5α-THP. These results corroborate findings that acute knockdown of PXR reduces lordosis of female rats. These data suggest a specific deficit in synthesis of 3α,5α-THP with PXR deletion, rather than a deficit in binding of 3α,5α-THP to PXR, a promiscuous receptor with many other positive modulators. Thus, PXR may be a novel brain target involved in 3α,5α-THP biosynthesis and action.

Title: Palmitoylation of Caveolin-1 has a role in membrane-initiated estrogen signaling

Authors: *K. R. TONN, P. G. MERMELSTEIN;
Dept. of Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstracts: Through membrane-localized estrogen receptors (ERs), estradiol influences a variety of behaviors including learning and memory, cognition, sensorimotor control, and female sexual receptivity. In most cases, membrane-initiated hormone actions are caused by the activation of a subpopulation of the same receptors known to carry out nuclear activity and regulate gene expression. These membrane receptors transactivate metabotropic glutamate receptors, thus initiating multiple intracellular signaling cascades. In order to traffic to the plasma membrane, ERs undergo posttranslational modification. The entire process behind these alterations remains to be elucidated, but recent studies have demonstrated that palmitoylation is essential for transforming nuclear ERs to membrane proteins. Specifically, palmitoylation of ERα and ERβ is necessary for localization and function of these receptors at the membrane. Mutation of the palmitoylation site eliminates the physical association of surface ERs with caveolin (Cav) proteins required for rapid membrane estrogen signaling. To date, it is unclear if or how the processes of palmitoylation and caveolin association interact to regulate the capability of a cell to respond to estradiol at the membrane. Preliminary findings from our laboratory indicate that caveolin must also be palmitoylated in order for estrogen receptors to be present at the membrane. To further investigate the role of caveolin palmitoylation in rapid estrogen signaling, we mutated the palmitoylation sites on the Cav1 protein and probed the effects on membrane estrogen receptors. Experiments were performed using transient transfection of HEK293 cells followed by protein analysis via membrane fractionation, co-immunoprecipitation, and Western blotting. We found that co-transfection of ERα and non-palmitoylatable Cav1 (Cav1*) resulted in decreased levels of membrane ERα. This was somewhat surprising, as previous reports demonstrate that Cav palmitoylation is not required for the trafficking of this protein to the

membrane. Contrastingly, overexpression of Cav1* did not interfere with the Cav1*-ER association. These data suggest that Cav1 must be palmitoylated for ERα to be present at the membrane, but that palmitoylation is not required for the physical association of ERα and Cav1. We are currently exploring whether or not Cav1 must be palmitoylated in order for ERα to functionally couple to mGluR1.

Title: Inhibition of allopregnanolone synthesis via 5α-reductase type 2 counters sensorimotor gating deficits induced by dopamine D1 receptor agonists in mice

Authors: *L. J. MOSHER, S. C. GODAR, M. BORTOLATO;
Pharmacol. and Toxicology, Kansas Univ., Lawrence, KS

Abstracts: Schizophrenia and other neuropsychiatric disorders feature deficits of sensorimotor gating, the perceptual process that suppresses the execution of motor responses to irrelevant perceptual stimuli. The main operational measure of sensorimotor gating is afforded by the prepulse inhibition (PPI) of the acoustic startle reflex, consisting in the reduction of the startle response by a weak prestimulus immediately preceding the startle-eliciting burst. The neurochemical regulation of this endophenotype is primarily orchestrated by dopamine neurotransmission; accordingly, activation of dopamine D1 receptors induces robust PPI impairments in C57BL/6 mice, which are reversed by antipsychotic agents. We recently showed

that the PPI deficits induced by D1 receptor agonists in mice are countered by pharmacological inhibition of 5α-reductase (5αR), the enzyme catalyzing the key rate-limiting step in neurosteroid synthesis. The functions of 5αR in brain steroidogenesis are primarily served by its isoforms 1 and 2; the specific contributions of these enzymes to the antipsychotic-like properties of finasteride, however, remain unknown. To address this issue, we studied the combined effects of finasteride (50mg/kg, ip) and the potent D1 receptor agonist SKF82958 (0.3mg/kg, sc) on the PPI response in wild-type (WT), 5αR1 knockout (KO) and 5αR2KO mice. While SKF82958 significantly disrupted PPI in all genotypes, these effects were prevented by finasteride in WT and 5αR1KO, but not 5αR2KO mice. Furthermore, we found that the effects of finasteride in WT and 5αR1KO mice were prevented by systemic administration of the neurosteroid allopregnanolone (15mg/kg, ip). Taken together, these data suggest a critical role for both 5αR2 and allopregnanolone in PPI regulation and the antipsychotic-like properties of finasteride. Further studies are warranted to determine the role of allopregnanolone in schizophrenia and other neuropsychiatric disorders characterized by sensorimotor gating perturbations.

Title: Sleep deprivation-induced manic-like behaviors are modulated by 5α-reductase type 1

Authors: *R. PES[1,3], S. C. GODAR[2], L. J. MOSHER[2], M. BORTOLATO[2];
[1]pharmacology and Toxicology, [2]Pharmacol. and Toxicology, Kansas Univ., Lawrence, KS;
[3]Biomed. Sci., Univ. of Cagliari, Cagliari, Italy

Abstracts: Ample evidence shows that sleep deprivation induces manic and psychotic-related behaviors. We previously found that sleep-deprived rats exhibit hyperlocomotion and sensorimotor gating deficits in a dopamine receptor antagonist-sensitive fashion. Dopamine receptor antagonists, however, are suboptimal therapies for mania and psychosis in view of their mixed efficacy and severe side effect profile, highlighting an urgent need for novel therapeutic targets. Our group has previously shown that blockade of the 5α reductase (5AR), the key enzyme for catalyzing the rate-limiting step of neurosteroidogenesis, elicits antidopaminergic properties and attenuates sensorimotor gating deficits without accompanying extrapyramidal symptoms. Moreover, we recently found that 5AR inhibition by finasteride (FIN) countered sleep deprivation-induced sensorimotor gating deficits by blocking the production of the 5-alpha reduced neurosteroid allopregnanolone. Although finasteride blocks 5AR, this enzyme is primarily comprised of two isoforms (type 1 and 2), that differ in substrate affinity and brain distribution. In order to probe the mechanism of finasteride in mediating sleep deprivation-induced mania and psychotic-like phenomena, we investigated the effects of sleep deprivation in 5AR type 1 knockout (5AR1 KO) mice. Our preliminary data show that sleep deprivation significantly enhances exploratory behavior and risk-taking/impulsivity in WT mice. In marked contrast to WT animals, sleep deprivation did not affect either behavioral domain in 5AR1-deficient mice. Studies are currently ongoing to examine sensorimotor gating and anxiety and depression-related behaviors following sleep deprivation in our animal models. In summary, our preliminary data suggest that sleep deprivation may affect manic-related behaviors through alterations in 5AR1 activity.

Title: Chronic GPER1 antagonism improves short term memory in male and female mice

Authors: *K. J. POLLARD, C. GERMANY;
Neurosci., Tulane Univ., New Orleans, LA

Abstracts: In addition to their many roles in organizing the developing brain and activating sexually dimorphic behaviors in adults, sex hormones can also influence day to day asexual cognitive functions such as memory retention. Estrogens in particular act in the brain through an array of specific receptors including the classic nuclear estrogen receptors alpha (ERα) and beta (ERβ) as well as the extra-nuclear G-protein coupled estrogen receptor (GPER1). Using the Y maze task to assay spatial memory, it has recently been demonstrated that administration of the GPER1 selective agonist G-1 to ovarectomized female rats 48 and 24 hours prior to the learning trial can enhance retention of the consolidated memory 48 hours later (Hawley et al. 2014). However, since g-protein signaling can also alter neuronal physiology on a shorter, pre-transcriptional time scale we also hypothesized a role for GPER1 in the retention of short term memories. Therefore we chronically treated gonadectomized male and ovarectomized female mice with G-1 and the GPER1 specific antagonist G-15 and adapted the y-maze and novel objects tasks to a short term memory paradigm with an inter trial delay of only 30 minutes. Surprisingly, G-1 had no effect while the GPER1 antagonist G-15 improved short term memory retention. This data suggests that GPER1 plays opposing roles in retention of short and long term memories and likely engages both post-translational and transcriptional mechanisms to exert differential effects on differential time scales.

Title: Proliferative cells and newborn GnRH3 neurons induced by androgen in female mozambique tilapia

Authors: *Y. NARITA[1], N. OKADA[1], A. TSUTIYA[1], T. KANEKO[2], R. OHTANI-KANEKO[1];
[1]Toyo Univ., Gunma, Japan; [2]The Univ. of Tokyo, Tokyo, Japan

Abstracts: We found sexual dimorphism of gonadotropin-releasing hormone type III (GnRH3) neurons in Mozambique tilapia Oreochromis mossambicus; males have a greater number of

GnRH3 neurons in the terminal nerve than females (Kuramochi et al., 2011). Treatment with androgen (11-ketotestosterone (11-KT) or methyltestosterone (MT)) in females increased the number of GnRH3 neurons to a level similar to that in males, although the mechanism remains unsolved. Since adult neurogenesis has recently been shown to occur in various vertebrate species, we aimed in the present study to examine whether adult neurogenesis is involved in the androgen-induced increase of GnRH3 neurons in female Mozambique tilapia. We first examined whether androgen increased proliferative cells in adult females by detecting cells with the expression of a proliferation-related marker, proliferating cell nuclear antigen (PCNA). Next, we studied the fate of newly generated cells by double labeling with antibodies against 5-bromo-2'-deoxyuridine (BrdU) and one of markers of interest including GnRH3. After adult females were treated with 11-KT, PCNA-positive cells were increased in various regions of the brain, compared to control females injected with oil. We further studied Hu-positive immature neurons and GnRH3-positive cells in combination with BrdU labeling in the brain at the level of the terminal nerve. BrdU- and Hu-positive cells were increased around the midline/ventricular zone, compared to control females. BrdU- and GnRH3-positive neurons were also increased by 11-KT treatment. These results revealed that androgen treatment increased proliferative cells and newborn GnRH3 neurons in females, indicating the androgen-induced increase of GnRH3 neurons in females is mediated partly through adult neurogenesis. Title: Dissociation of androgen effects in different tissues by regulation of androgen receptor genes in a polymorphic fish

Authors: *D. GONÇALVES[1], M. BARUZZO[2], C. POLASTRO[2], R. F. OLIVEIRA[2,3];
[1]USJ, Univ. of St. Joseph, Macau, Macao; [2]ISPA-IU, Lisbon, Portugal; [3]Inst. Gulbenkian de Ciência, Oeiras, Portugal

Abstracts: Across vertebrates, androgens exert a wide range of actions in multiple tissues, including stimulating the development of male secondary sexual characters and promoting sperm development and maturation. Variation in circulating levels of androgens helps to coordinate changes in male-related traits in multiple tissues, including the gonads, the brain and secondary sexual characters. However, in some species, the development of a functional male reproductive system is dissociated from the development of masculine behavioral and morphological traits, either permanently or during certain developmental periods. One possible mechanism allowing for this dissociation is variation in tissue sensitivity to circulating androgens, namely through changes in the expression of androgen receptors genes. We tested this hypothesis in a fish species, the peacock blenny Salaria pavo. Large nesting males of this species have fully developed male morphological traits and display courtship displays towards females to try to attract them towards their nests. However, a second class of smaller males reproduces by mimicking the female morphology and behavior in order to approach the nests of the larger males and parasitically fertilize some of the eggs inside the nest. These males have fully functional testes to allow parasitic fertilization of eggs but do not develop the secondary sexual characters typical of nesting males nor exhibit courtship displays towards females during the parasitic phase. Between the first and second breeding season, parasitic males irreversibly transition to the nesting male morphotype. To understand if variation in androgen-tissue sensitivity could contribute to the apparent dissociation between the effects of androgens in the testes and in other tissues in parasitic males, the expression levels of the two androgen receptors described for the species, ARalpha and ARbeta, were measured by qPCR in the testes, brain macroareas and secondary sexual characters. As predicted, parasitic males had lower androgen receptor expression levels in the brain and in male secondary characters, but not in the testes, when compared with nesting males. The results agree with the hypothesis that, in S. pavo, the observed dissociation in the effects of androgens across tissues is achieved by a differential regulation in the expression of androgen receptor genes.

Title: Comparative expression of GPR30 in the brains of goldfish and zebrafish

Authors: *J. WHITE, T. ADEBANJO, T. SZABO-MAAS;
Delaware State Univ., Dover, DE

Abstracts: Although receptors for steroid hormones are known classically to be nuclear receptors whose major function is regulation of gene expression, recent studies have shown that estrogen receptors (ERs) can be expressed outside of the nucleus in the plasma membrane as well as in the membrane of internal organelles, including the Golgi apparatus and endoplasmic reticulum. Localization of ERs to the membrane strategically positions them to rapidly transduce effects of estrogen. Since expression of ER protein is regulated in a complex manner at multiple time points, including during transcription, translation or splicing of protein isoforms, most studies examining ER expression have focused on ER mRNA. Therefore, little is known about expression and distribution of ER protein in circuits other than a few intensely studied mammalian systems, like the hippocampus. Recent studies have characterized novel estrogen receptors that are not 'classic' nuclear receptors (ERα and ERβ) but are coupled to G proteins, including G protein-coupled receptor 30 (GPR30). To date, few studies have examined expression of GPR30 in the nervous system and none have looked at expression in non-mammalian model systems. We therefore examined expression of GPR30 protein in two well-characterized teleost model systems, the goldfish, Carassius auratus and the zebrafish, Danio rerio. We found that GPR30 is 1) expressed in most brain regions albeit at variable intensities, 2) is highly regulated according to sex and breeding state and 3) is more strongly expressed in peripheral nerves vs. central brain tracts. In the central nervous system, GPR30 labeling appears as discrete puncta that colocalize with neuronal markers, while in the peripheral nervous system, GPR30 appears primarily on myelin. Since this is the first study examining expression of GPR30 protein in a non-mammalian model system, we believe this work will clarify evolutionarily conserved roles of this novel receptor for estrogen.

Title: Multiple distinct estrogen receptor-alpha protein isoforms in the central nervous system of adult teleost

Authors: *T. T. ADEBANJO, J. WHITE, T. SZABO-MAAS;
Delaware State Univ., Dover, DE

Abstracts: Estrogens exert multiple effects on the brain including neuroprotection, and improvements in learning and memory; however, the mechanisms through which they exert their effects are not well understood. Estrogenic effects are transduced via multiple receptor subtypes and isoforms, with estrogen receptor alpha (ERα) being the best characterized. ERα protein expression is known to be regulated at multiple levels, including: 1) during transcription, 2) during translation, 3) by truncation of the full length protein, 4) by its ligand, estradiol and 5) via interactions with other receptor isoforms. As a result, most studies examine distribution and expression of ERα mRNA, while expression of the protein remains unknown. In this study, we examined ERα protein expression in two teleost model systems: 1) the goldfish, Carassius auratus, which exhibits enhanced production of brain aromatase and alterations in sex hormone levels that occur annually in the spring, and 2) the zebrafish, Danio rerio, which does not possess elevated levels of brain aromatase and is an opportunistic breeder that can spawn every 1-2 days. We hypothesized that expression of ERα protein would positively correlate with breeding cycle and estradiol levels for both zebrafish and goldfish. While our results for the full-length ERα dimers and truncated receptor isoforms was more complex. Our study highlights the complexity of steroid hormone receptor expression and its regulation and the importance of examining the mechanism through which estradiol acts at the level of the protein.

Title: Non-nuclear distribution patterns of estrogen receptors in the brains of goldfish

Authors: R. R. THOMPSON[1], *L. A. MANGIAMELE[1,3], T. NICHOLSON[2], D. MICHAUD[2], M. CHEN[2], J. GOMEZ[2], D. DARDEN[2];
[1]Psychology, [2]Bowdoin Col., Brunswick, ME; [3]Dept of Biol. Sci., Smith Col., Northampton, MA

Abstracts: Steroid hormones, most notably estradiol (E2), have rapid, non-genomic effects on physiology and behavior in vertebrates. In order to learn more about the receptors that mediate those effects, we used immunohistochemistry to localize different estrogen receptors (ERs) in the brains of goldfish, particularly those with non-nuclear distribution patterns. GPR30, a membrane-bound G protein-coupled estrogen receptor, extensively co-localized with isotocin in the soma and fibers in the preoptic area. ERbeta immunoreactivity was observed in numerous regions, including those associated with visual processing (the retina and optic tectum), as well as most nodes within the social brain network. There was evidence for nuclear and non-nuclear staining patterns; non-nuclear staining was primarily observed in processes, some of which co-localized with tryrosine hydroxylase (retina), and some of which co-localized with GFAP (telencephalon). Western blots with the ERbeta antibody identified a 62 kD band, the same approximate size as ERbeta that has been identified in other species, in both cytosolic and plasma membrane preparations, suggesting that both cell membrane and nuclear receptor proteins result from expression of a single transcript. We will examine ERalpha distribution patterns in the future. Together, these results suggest that GPR30 likely influences processes associated with isotocin in goldfish, whereas ERbeta may mediate some of E2's rapid effects on sexual behaviors, particularly its ability to modulate responses to female visual stimuli.

Title: Rapid effects of aggressive interactions on DHEA, testosterone, and estradiol levels in the male song sparrow brain: A seasonal comparison

Authors: *S. A. HEIMOVICS[1], N. H. PRIOR[2], C. Q. MA[2], K. K. SOMA[2];
[1]Univ. of St. Thomas, Saint Paul, MN; [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstracts: Across vertebrates, aggression is robustly expressed during the breeding season, when circulating testosterone (T) levels are elevated. T activates aggression during the breeding season either directly or after its local conversion into 17beta-estradiol (E_2) in the brain. In some species, such as the song sparrow, aggressive behavior is also expressed at high levels during the non-breeding season, when circulating T levels are non-detectable. During the non-breeding season, the androgen precursor dehydroepiandrosterone (DHEA) is metabolized within the brain into T and/or E_2 to promote aggression. DHEA can be synthesized in the adrenal glands or in the brain itself. In the present study, we used captive male song sparrows to test the hypothesis that acute agonistic interactions during the non-breeding season, but not during the breeding season, would alter steroid levels in the brain. Non-breeding and breeding subjects were exposed to either a simulated territorial intrusion (STI) or an empty cage (CON) for only 5 min. Immediately afterwards, the brain was rapidly collected and flash frozen. The Palkovits punch technique was used to microdissect specific regions implicated in social behavior. Solid phase extraction followed by radioimmunoassay was used to quantify DHEA, T, and E_2. Overall, brain levels of DHEA, T, and E_2 were higher in brain tissue than in plasma. Local T and E_2 levels in the preoptic area (POA), hypothalamus (Hy), and nucleus taeniae of the amygdala (TnA) were significantly higher in the breeding season than the non-breeding season and were not affected by the STI. As expected, the STI rapidly increased DHEA levels in the POA in the non-breeding season only, suggesting that the POA synthesizes DHEA in response to social cues. Surprisingly, achieving social dominance during the STI was associated with decreased DHEA levels in Hy in both seasons. In addition, social dominance was associated with decreased DHEA levels in TnA in the breeding season only. Taken together, these data suggest that DHEA is involved in the neuroendocrine regulation of aggression throughout the year, but the specific role of DHEA in aggression is season, social status, and brain region-specific.

Title: Evidence for fast, non-genomic-like actions of estrogens in the regulation of birdsong

Authors: *B. A. ALWARD[1], T. T. CHAN[1], J. BALTHAZART[2], C. CORNIL[2], G. F. BALL[1]; [1]Psychological & Brain Sci., The Johns Hopkins Univ., Baltimore, MD; [2]GIGA Neurosciences, Univ. de Liege, Liege, Belgium

Abstracts: Steroid hormones cause long-term changes in behavior by acting at the level of the genome. A plethora of recent evidence, however, has shown that steroids can also have rapid, short-term effects on behavior by acting in a non-genomic manner. Song behavior is well known to be regulated by steroid hormones such as testosterone. Castrated canaries (*Serinus canaria*) substantially reduce song output and treatment with exogenous testosterone restores singing after approximately three days. Moreover, in many songbirds treatment with an inhibitor of aromatase, the enzyme that converts testosterone into estradiol, substantially reduces song output. Interestingly, recent studies in male Japanese quail (*Coturnix japonica*) indicate that brain-derived estradiol acts on a fast time scale (within minutes) to regulate sexual behavior and these effects dissipate within 1-2 hours, suggesting these effects are non-genomic. Here, we investigated the fast-acting, presumably non-genomic influence of estrogens in the regulation of song in male canaries. Male canaries begin singing within approximately 15 minutes after lights on. Five minutes after lights on, each bird was injected intraperitoneally with either fadrozole (30mg/kg), a potent aromatase inhibitor, or its vehicle. Using a within-subjects design, they received the opposite treatment three days later. Results obtained so far indicate that estrogen depletion decreases numbers of songs as well as their loudness, pitch and stereotypy in a rapid manner (in most birds within 45 minutes to 3-4 hours) indicating that estrogens exert an acute control of these aspects of behavior. Importantly, song rate and structure were restored to normal levels by the next day. Hence, estrogens synthesized from testosterone in male canaries regulate song on a rapid time scale in a presumably non-genomic fashion. As both motivational and acoustic measures of song were affected by aromatase inhibition, it is likely that distinct brain regions (e.g., the medial preoptic nucleus and the auditory telencephalon, both of which have dense aromatase expression) play a role in the fast regulation of song by estrogens.

Title: Investigating possible intraspecific variation in testosterone-induced neuroplasticity by comparing two canary breeds

Authors: *F. N. MADISON, B. A. ALWARD, G. F. BALL;
Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstracts: Our previous work has shown that male canaries of the American Singer (AM) strain did not exhibit photoperiodic responses characteristic of wild-type canaries or of other strains such as the Border (BDR) canary. AMs do not regress their gonads when exposed to long days and exhibit photorefractoriness. We also found that castrated males responded to high exogenous testosterone (T) in a variable manner. For example, various doses of T did not consistently induce an increase in the volume of the song nucleus HVC. These findings suggest that domestication of the AM canary, via human selection, perhaps to 'lock in' a certain level of song quality and quantity, has led to a decrease in neuroplasticity associated with changes in photoperiod and hormonal action. In this study, we investigate possible strain differences in response to T on song production and HVC volume in adult male AM and BDR canaries. 15 male AM and 15 male BDR canaries were housed on 8L:16D (light:dark) for at least eight weeks, rendering them photosensitive and were placed into groups of intact control, castrated control, and castrated male implanted subcutaneously with one Silastic implant (12mm) filled with crystalline T. Immediately after implantation, birds were individually housed in sound-attenuated chambers on the 8L:16D light cycle for 3 weeks. After 3 weeks of T treatment, brains were collected. We found that HVC volume was larger in response to T treatment in BDR than in AM. Preliminary data suggest T stimulates castrated AM to sing sooner (1 day post-T treatment) than castrated BDR (3 days post-T treatment). Interestingly, castrated AM treated with T sang as much as their intact counterparts throughout the experiment while castrated BDR treated with T sang more than their intact counterparts from day 9 to day 17 and were indistinguishable from both groups of AM that were exposed to T. Castrated BDR treated with T sang songs with lower entropy (noise or variance) than intact BDR as well as both groups of AM exposed to T. Importantly, castrated AM treated with T sang songs with entropy that was indistinguishable from their intact counterparts. All groups showed a linear increase in the

energy (loudness or amplitude) of their songs. These results suggest T differentially stimulates song features in these two strains of canaries. In AM, song is stimulated relatively quickly, but HVC volume is smaller as compared to male BDR. These findings are consistent with the hypothesis that high rates of singing have been selected for in AM and can occur in the absence of marked T induced neuroplasticity.

Title: Estradiol, synthesized by reactive glia, is a potent anti-inflammatory in the injured vertebrate brain

Authors: *A. L. PEDERSEN, L. H. NELSON, C. J. SALDANHA;
Biology, Psychology, & Ctr. for Behavioral Neurosci., The American Univ., Washington, DC

Abstracts: Neuroinflammation following traumatic brain injury (TBI) may have detrimental and beneficial effects that likely differ between the acute and chronic periods post-trauma. In birds and mammals, traumatic brain injury increases the expression of cytokines in microglia and aromatase (estrogen synthase) in astroglia. In the songbird, TBI-induced synthesis of estrogens by glial aromatization is neuroprotective as aromatase inhibition and replacement with estradiol (E2) exacerbates and mitigates the extent of damage and apoptosis, respectively. The effect of glial estrogens on inflammation, however, remains unstudied. We hypothesized that induced astrocytic aromatization may affect neuroinflammation following TBI, via the synthesis of neural E2 around the site of damage. In three separate experiments on adult zebra finches (Taeniopygia guttata) of both sexes we tested the influence of (a) mechanical TBI, (b) inhibition of induced aromatase expression, and (c) inhibition of induced aromatase with central E2 replacement, on the expression of the pro-inflammatory cytokines TNFα, IL-1β, and IL-6, and aromatase. At 2hr post-injury, in both sexes, TBI increased ($p<0.05$), and tended to elevate, TNFα and IL-1β

respectively. At 24hr post-injury, also in both sexes, cytokines appeared to have returned to baseline, but aromatase is robustly elevated in the lobe that sustained TBI ($p<0.01$). Pharmacological inhibition of induced aromatization resulted in persistent neuroinflammation, as administration of fadrozole increased IL-1β (in females ($p=0.0007$)) and TNFα (in males ($p=0.0003$)) 24hr following MBI. This prolonged neuroinflammation following aromatase inhibition appears to be due to a failure to synthesize E2 locally, since E2 replacement lowered TNFα and IL-1β relative to fadrozole alone ($p<0.01$). IL-6 was not affected by TBI, aromatase inhibition or E2 replacement in either sex. These data suggest that astrocytic E2 synthesis following TBI is a potent and inducible anti-inflammatory signal, with specific modulation of discrete cytokine signaling. Induced neural provision of E2 following damage and compromise of central pathways may protect the brain from the deleterious effects of prolonged neuroinflammation.

Title: Cholinergic regulation of aromatase in brain

Authors: ***J. LI**, D. NELSON, R. GIBBS;
Univ. of Pittsburgh, Sch. of Pharm., Univ. of Pittsburgh Sch. of Pharm., Pittsburgh, PA

Abstracts: Our goal is to understand mechanisms by which estrogens can influence brain function and cognition. Estrogens have been shown to influence neuronal plasticity and cognitive performance. Recent studies suggest that, in some cases, local estrogen synthesis can have a greater impact on neuronal survival and plasticity than systemic estrogen administration. Cholinergic projections also have a significant impact on neuronal plasticity in the brain, and recent studies demonstrate critical links between effects of estrogens and effects mediated by cholinergic inputs. In this project we are investigating whether aromatase expression and activity in specific regions of the adult brain are regulated by cholinergic activity. In one experiment, ovariectomized (OVX) rats were treated with the cholinesterase inhibitors donepezil (3 mg/Kg)

or galantamine (5 mg/Kg) daily for one week prior to tissue collection. In a second experiment, OVX rats received intraseptal infusions of 192IgG-saporin (SAP) to selectively destroy cholinergic inputs to the hippocampus. Tissues were collected two weeks following the infusions. Different groups of rats were used to evaluate effects on aromatase mRNA and aromatase activity. Effects on aromatase mRNA were evaluated using qRT-PCR. Effects on aromatase activity were evaluated using a novel microsomal assay in which brain tissue microsomes were extracted and activity was measured *in vitro* by measuring conversion of testosterone to estradiol. Results show an increase in aromatase mRNA in the preoptic area following treatment with galantamine, but no effect in the hippocampus, frontal cortex, or amygdala. Galantamine also produced an increase in aromatase activity in the amygdala, but no significant effect in other brain regions. Donepezil had no significant effects on either aromatase mRNA or activity. Effects of the cholinergic lesions are still being evaluated; however, preliminary results suggest no significant effect on relative levels of aromatase mRNA in the hippocampus. These results indicate that cholinergic manipulations can affect aromatase expression and activity in specific regions of the brain such as the preoptic area and amygdala, with little or no effect in the hippocampus and frontal cortex. This could have important implications for the effects of cholinergic and anticholinergic medications on local estrogen production in the brain.

Title: Estradiol recruits the cannabinoid system to enhance psychostimulant locomotor sensitization in female rats

Authors: *B. PETERSON, P. G. MERMELSTEIN, R. L. MEISEL;
Neurosci. Dept, Univ. of Minnesota, Minneapolis, MN

Abstracts: Estradiol enhances psychostimulant responses in females, however the neurobiological mechanisms underlying this effect are largely unknown. Recently our lab demonstrated that in ovariectomized female rats, estradiol treatment enhances cocaine-induced locomotor sensitization through an mGluR5-dependent mechanism. These data are in agreement with our model that within the female striatum, estradiol activation of membrane-localized ERα leads to transactivation of mGluR5. Interestingly, previous work has shown that both estradiol treatment and mGluR5 can each independently mobilize endogenous cannabinoids (endoCBs) within the nervous system. Given that the endoCB system is emerging as key mediator of drug related behaviors, we hypothesized that estradiol recruits the endoCB system to enhance psychostimulant responses in female rats via mGluR5. Consistent with previous studies, we found that five days of experimenter-administered cocaine (15mg/kg) induced locomotor sensitization in estradiol-, but not in oil-treated, ovariectomized animals. Consistent with our hypothesis, this locomotor sensitization in estradiol-treated females was attenuated by pretreatment with a cannabinoid receptor type 1 (CB1r) inverse agonist, AM251 (1mg/kg). Unexpectedly, cocaine-induced locomotor sensitization was observed in ovariectomized females that received AM251 treatment in the absence of estradiol. We are currently investigating whether structural plasticity within the striatum following these pharmacological treatments will explain these behavioral data.

Title: Estradiol facilitation of cocaine-induced behaviors in female rats requires activation of mGluR5

Authors: *L. A. MARTINEZ, B. M. PETERSON, R. L. MEISEL, P. G. MERMELSTEIN; Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstracts: In comparison to men, women exhibit enhanced responsiveness to the stimulating and addictive properties of cocaine. A growing body of evidence implicates the steroid hormone estradiol in mediating this sex difference, yet the mechanisms underlying estradiol enhancement of behavioral responses to cocaine specifically in females are not known. Recently, we have found that estrogen receptor alpha (ERα) functionally couples with the metabotropic glutamate receptor 5 (mGluR5) to mediate the effects of estradiol on both cellular activation as well as dendritic spine plasticity in brain regions involved in the behavioral responses to cocaine. Thus, we sought to determine whether mGluR5 activation is required for the facilitative effects of estradiol in females on cocaine-induced behaviors (i.e., locomotor sensitization and self administration). We tested this hypothesis through a series of experiments. In the first experiment, ovariectomized (OVX) female rats were tested for locomotor activity on the first and fifth days of daily systemic injections of cocaine. For the two days prior to each locomotor test, females were injected with the mGluR5 antagonist MPEP (or vehicle) and estradiol (or oil). In the second experiment, OVX females were administered estradiol on a 2 days on, 2 days off schedule during sucrose pellet self-administration training (FR1 schedule). Females were then removed from estradiol treatment, implanted with IV catheters, and trained to self-administer cocaine on an FR1 schedule. At the completion of cocaine training, females were injected with MPEP (or vehicle) and estradiol (or oil) on a 2 days on, 2 days off schedule throughout 21 days of extended access to cocaine self administration (6 hrs per day, FR1 schedule). MPEP treatment blocked the facilitative effects of estradiol on cocaine-induced locomotor sensitization, without affecting acute locomotor responses to cocaine or the inhibitory actions of estradiol on weight gain. The effects of MPEP with estradiol on cocaine self administration are presently under investigation. Thus far, these data indicate that mGluR5 activation is critical for the actions of estradiol on cocaine-induced behaviors in females, and suggest novel therapeutic targets for treating psychostimulant addiction in women.

Title: Interactions between estradiol and group 1 mGluR signaling influence dendritic spine density in the female rat nucleus accumbens

Authors: *K. GROSS, R. L. MEISEL, P. G. MERMELSTEIN;
Univ. of Minnesota, Minneapolis, MN

Abstracts: Estrogen receptors (ERs) can be localized to the cell membrane where their activity can result in alterations in neurotransmission, neural structure, and behavior. These effects are often mediated by group 1 mGluRs associated with surface ERs. Previous research in our lab has found that 17β-estradiol (17βE) influences spine density in the female rat nucleus accumbens (NAc). In the NAc core (NAcC), 17βE decreases dendritic spine density in an mGluR5 dependent mechanism. In contrast, in the NAc shell (NAcSh), 17βE increases spines via mGluR1. Given that these contrasting effects are a result of 17βE-mediated activation of disparate group 1 mGluRs, we wanted to determine if independent activation of individual group 1 mGluRs would bidirectionally change dendritic spine density in the NAc. Ovariectomized female rats were given a systemic injection of an mGluR5 positive allosteric modulator (PAM), CDPPB, at either 5 or 10 mg/kg and sacrificed 24 hours later. Neurons in the NAc were ballistically labeled with DiI, and spine densities were determined. At both doses, CDPPB decreased dendritic spine density throughout the NAc, paralleling the effect of 17βE in the NAcC. Experiments are currently underway to determine if an mGluR1 PAM will increase spine density throughout the NAc, similar to the increase within the NAcSh after 17βE administration. These data would suggest that within the NAc different group 1 mGluRs are functionally coupled to opposing signaling pathways that result in bidirectional effects on dendritic spine density. Furthermore, 17βE produces opposing effects on spine density within subregions of the NAc by activating distinct group 1 mGluRs within the NAcC and NAcSh. The ability of 17βE to differentially regulate plasticity within subregions of the NAc may have consequences for the functional output of this brain region.

Title: Effects of testosterone on stages of neural development in the dentate gyrus of adult male rats

Authors: *M. D. SPRITZER[1], K. M. K. CALHOUN[1], E. A. ROY[1], Z. E. SCHNEIDER-LYNCH[1], J. M. BARKER[2], L. A. M. GALEA[2];
[1]Dept. of Biol. and Program in Neurosci., Middlebury Col., Middlebury, VT; [2]Dept. of Psychology and Grad. Program in Neurosci., Univ. of British Columbia, Vancouver, BC, Canada

Abstracts: Within the mammalian brain, neurogenesis occurs throughout adulthood along the subgranular zone of the dentate gyrus. We previously showed that castrating a male rat causes a decrease in hippocampal neurogenesis and injections with testosterone restore normal neurogenesis levels. However, some studies have found no effects of testosterone replacement on adult neurogenesis. Discrepancies among studies may be partly due to the timing of hormone injections relative to the stages of cell development. Another key variable is testosterone dose, as we have found that some doses of testosterone do not consistently improve neurogenesis. Therefore, the present experiment tested the effects of two testosterone doses given during three different stages of neural development. Adult male Sprague Dawley rats (N=8/group) were bilaterally castrated and give a one week recovery period. All subjects were given a single injection of bromodeoxyuridine (BrdU; 200 mg/kg) on the first day of the experiment to label actively dividing cells, and animals were euthanized sixteen days later to assess BrdU labeling. Subjects were assigned to three groups based on injection doses of testosterone propionate: oil-injected control group, 0.250 mg/rat, or 0.500 mg/rat. All subjects received five consecutive days of injections during one of three stages of neural development: Days 1-5 (cell proliferation and migration), Days 6-10 (neurite growth), or Days 11-15 (neuron maturation). Rats were transcardially perfused, brains sectioned (40 μm), and peroxidase immunohistochemistry was used to visualize BrdU-labeled cells. Light microscopy (1000x) was used to count all labeled cells in every 10th section throughout the dentate gyrus. Testosterone injections had a significant effect on the number of BrdU-labeled cells ($P = 0.022$), with the 0.500 mg/rat dose causing a significant increase in the number of BrdU-labeled cells compared to the 0.250 mg/rat dose and the control group. There was no difference in the number of BrdU-labeled cells between the 0.250 mg/rat group and the control group. The timing of injections had no significant effect on BrdU labeling. The effects of testosterone did seem to be strongest for the later stage (11-15 days) of neural development, but there was no statistically significant interaction between time and dose. Additionally, the effect of dose was found to be stronger for the ventral portion of the dentate gyrus ($P = 0.024$) than for the dorsal portion ($P = 0.13$). These results add to past

evidence that high physiological doses of testosterone increase adult neurogenesis, and suggest that only a short-term surge (5 days) of testosterone is necessary to see this effect.

Title: GPR30 activation stimulates mTOR-dependent protein synthesis in hippocampal slices through BDNF release

Authors: *V. BRIZ, M. BAUDRY;
Western Univ. of Hlth. Sci., Pomona, CA

Abstracts: Estrogen is an important modulator of hippocampal synaptic plasticity through its rapid action on membrane-associated receptors. Stimulation of mammalian target of rapamycin (mTOR)-dependent protein synthesis is a key event required for consolidation of hippocampal long-term potentiation and hippocampus-dependent learning and memory. We recently showed that estradiol stimulates mTOR phosphorylation in hippocampal neurons through activation of G-protein coupled receptor 30 (GPR30), but the underlying molecular mechanisms are not yet fully understood. In the present work, we used acute rat hippocampal slices to analyze the mechanisms underlying the rapid changes in mTOR signaling elicited by estradiol and the GPR30 agonist G1. Both estradiol- and G1-induced mTOR phosphorylation were blocked by the novel and specific tropomyosin related kinase B (TrkB) receptor antagonist ANA-12. Similarly, estradiol- and G1-induced phosphatase and tensin homolog (PTEN) degradation, Akt activation and increase in calcium/calmodulin-dependent protein kinase II levels were prevented by ANA-12. Furthermore, the effects of G1 on PTEN/Akt/mTOR signaling pathway were also abolished by pre-incubating slices with recombinant TrkB-Fc chimera, suggesting that GPR30-mediated stimulation of mTOR signaling involves brain-derived neurotrophic factor (BDNF) release.

Immunohistochemistry studies revealed that G1 rapidly enhanced dendritic Arc protein synthesis in the CA3 area of hippocampus, an effect that was suppressed both by ANA-12 and TrkB-Fc. Overall, the present study indicates that estrogen exerts some of its effects on synaptic function and plasticity through the release of BDNF as a result of GPR30 activation.

Title: Right or left hemiovariectomy effects on dendritic length of CA1 and CA3 neurons of ventral hippocampus

Authors: D. A. BRAVO[1], *A. B. SILVA[2];
[1]Escuela de Biología, BUAP, Puebla, Mexico; [2]Escuela de Biología, Benemérita Univ. Autónoma de Puebla, Puebla, Mexico

Abstracts: Hemiovariectomy is an experimental paradigm recently used to study neural connections between the ovaries and the central nervous system. Due to this procedure it has been suggested that sensorial innervation has an important role in the biosynthesis of steroids which is different between ovaries. The aim of the present study was to determine the effects of hemiovariectomy (Hovx) on the morphology of CA1 and CA3 pyramidal neurons of ventral hippocampus, regarding the *in situ* ovary and the cerebral hemisphere analyzed. A total of 48 female rats of CIIZ-V strain with at least three regular estrous cycle monitored by cytological examination of daily vaginal smears were used. All rats were housed in light-dark cycle (12:12 h) with access to food and water ad libitum. We performed the surgery during the estrus phase of the estrous cycle in all the rats. Twenty four animals were anesthetized, laparotomized and underwent hemiovariectomy (Right Hovx= 12, Left Hovx=12), the remaining rats were used with Sham surgical treatment (Right Sham=12, Left Sham= 12) as control group. After surgery, the estrous cycle was monitored and after presenting three consecutive 4-d cycles, the animals were sacrificed. The brains were collected and processed by Golgi-Cox method. Twenty neurons of CA1 and twenty of CA3 regions (Right Hemisphere = 10, Left Hemisphere = 10) were drawn with camera lucida. Using Sholl analysis the total dendritic length was calculated. Also dendritic spine density was determinated. In Left Hovx animals a decrease in basolateral and apical

dendritic length of CA1 neurons in left hippocampus (LH) was observed, while CA1 neurons of Right Hovx rats showed a decrease in the basolateral dendritic length in LH. Neither Left Hovx nor Right Hovx group showed changes on spine density of CA1 neurons. On the other hand, Left Hovx rats showed an increase in basolateral total dendritic length of CA3 neurons in LH. In Right Hovx animal a decrease in basolateral dendritic length of CA3 neurons in both LH and right hippocampus (RH) was observed. Spine density showed an increase in apical trees of CA3 neurons in LH. It has been described that gonadal steroids have an important activity in pyramidal cells of hippocampus, since a depletion of estradiol after an ovariectomy promotes a decrease in spine density mainly in CA1 pyramidal neurons. These results support previous data about the different neural innervation between ovaries and the central nervous system and suggest that left hemiovariectomy produces neural changes mainly in basolateral and apical tress of CA1 neurons in LH; meanwhile right hemiovariectomy affects basolateral tress of CA3 neurons.

Title: Evidence for an acute estradiol-induced increase in postsynaptic sensitivity to glutamate at synapses in the hippocampus

Authors: *J. G. OBERLANDER, C. S. WOOLLEY;
Neurobio., Northwestern Univ., Evanston, IL

Abstracts: Estradiol (E2) is well-known to acutely potentiate excitatory synaptic transmission in the hippocampus of both males and females. In ovariectomized E2-primed adult female rats, paired-pulse ratio decreases in parallel with E2-induced synaptic potentiation, suggesting that potentiation occurs at least partly through increased glutamate release probability (Smejkalova and Woolley, 2010). Whether E2 also acutely increases postsynaptic sensitivity to glutamate is unknown. To investigate this, we used 2-photon laser uncaging of glutamate at individual CA1 pyramidal cell dendritic spines combined with whole-cell voltage clamp recording before,

during, and after 10 minute application of 100 nM E2 to hippocampal slices. We tested the effects of E2 in 5 groups of rats: juvenile females and adult males and females that were either gonadectomized or gonadally intact. We found that E2 significantly increased the amplitude of uncaging-evoked EPSCs (uEPSCs) in approximately 20% of spines (t test, within spine) with similar prevalence in all groups; no spines showed a significant decrease in uEPSC amplitude. The magnitude of E2-induced uEPSC amplitude potentiation ranged from 25-65%, and spines on the same cell (in some cases even the same dendritic branch) typically showed differential responsiveness to E2. These results indicate that E2 acutely potentiates the postsynaptic response to glutamate at a subset of synapses. Between uncaging pulses, we also recorded miniature EPSCs (mEPSCs) and measured their amplitude and frequency in each cell. Similar to the E2-induced increase in uEPSC amplitude, E2 also increased the amplitude of mEPSCs, in approximately 31% of cells, by 30-80%; this E2-related increase occurred with a similar prevalence in cells from all groups. In fewer than 5% of cells, and all from females, mEPSC amplitude decreased after E2, by 30% or less. In addition, and consistent with our previous results, the frequency of mEPSCs, which is an indirect measure of presynaptic glutamate release probability, was significantly increased after E2. E2 increased mEPSC frequency in more than 50% of cells, by 25-100%. As with EPSC amplitude increases, the E2-induced increase in mEPSC frequency occurred in all groups with similar prevalence. Importantly, increases in mEPSC amplitude and frequency after E2 rarely occurred in the same cells, fewer than 10%, indicating that higher mEPSC frequency measured after E2 is not likely to be an artifact of larger mEPSCs. Together, these results demonstrate that E2 acutely potentiates synapses in the hippocampus of males and females through both pre- and postsynaptic mechanisms that are likely to be independent.

Title: Pregnenolone sulfate as a modulator of synaptic plasticity

Authors: *K. SUGUNAN[1], J. I. LUEBKE[2], V. KUMARESAN[1], D. H. FARB[1];
[1]Pharmacol., [2]Anat. and Neurobio., Boston Univ. Sch. of Med., Boston, MA

Abstracts: Neurosteroids such as pregnenolone have been implicated in the pathophysiology of neuropsychiatric disorders such as schizophrenia and cannabinoid addiction (1, 2). Our laboratory discovered that the unique negatively charged steroid pregnenolone sulfate (PregS), the product of pregnenolone metabolism via a single sulfation step, modulates fast excitatory synaptic transmission by potentiating NMDA receptor activity in a fashion that is balanced by AMPA receptor inhibition at micromolar concentrations. We recently reported finding a novel high affinity response to PregS (EC50 = 2 pM), that increases intracellular [Ca2+] and CREB activation in cultured rat cortical neurons. Here, we report that PregS increases glutamate receptor and PSD95 colocalized puncta, presumably on dendritic spines of hippocampal neurons, suggesting that PregS increases surface-postsynaptic AMPARs and NMDARs. Whole cell recordings of primary rat hippocampal neurons revealed that PregS increases the frequency of spontaneous excitatory postsynaptic currents, suggesting an increase in glutamate release from presynaptic terminals or an increase in the number of activatable synapses. The results indicate that PregS acts within the physiological range of endogenous concentrations (3) to recruit AMPA receptors to postsynaptic sites, thereby altering synaptic plasticity. This mechanism may well underlie the cognitive enhancing pharmacological properties of PregS first reported 20 years ago (4). (1)Marx et al. Adiposity Diseases, Univ. of Leipzig, Leipzig, Germany; [5]Berlin Sch. of Mind and Brain, Mind and Brain Inst., Berlin, Germany

Abstracts: Introduction: Several lines of evidence from animal models and human studies suggest sex hormones to be important modulators of neuroplasticity. The menstrual cycle offers a unique natural setup to study whether physiological sex hormone fluctuation can influence brain morphology. However, data on the potential impact of the menstrual cycle phase on female brain architecture are sparse, especially regarding white matter microstructural organization. Here, we utilize diffusion weighted imaging (DWI) to investigate the impact of fluctuating hormone levels during the menstrual cycle on fractional anisotropy (FA). Methods: DW-images were acquired during 30 scanning sessions across four menstrual cycles with a 3-Tesla Magnetom Verio scanner (Siemens, Erlangen, Germany). Diffusion imaging data were processed with the FMRIB's software library (www.FMRIb.ox.ac.uk/fsl). Based on previous work that links the menstrual cycle to gray matter changes and to changes in functional connectivity in the hippocampus, we chose this structure as our Region-of-Interest (ROI). Hand drawn ROIs were derived from the thresholded (FA > 0.2) mean FA image. Mean FA values of mask regions were extracted, correlated with hormone levels and fed into partial correlation analysis (scan acquisition time) using SPSS Statistics 22 ($p < 0.05$). To investigate correlations between estrogen and progesterone levels in plasma and FA on a whole brain level, voxel-wise statistical analysis of the diffusion imaging data was carried out using tract-based spatial statistics (TBSS) and whole-brain smoothed FA. Results: In the ROI analyses, the extracted mean FA values of the left hippocampus showed a positive correlation with estrogen ($r = 0.504$, $p = 0.005$). No significant FA changes were mediated by progesterone in the mask regions. No regions in the TBSS and voxel-wise whole-brain approach reached significance after correction. Conclusion: Our findings suggest that estrogen-fluctuations across the menstrual cycle modulate FA in the hippocampus. Our results are in line with well-established evidence from rodents demonstrating hippocampal-plasticity to be mediated by sex steroids and reports in humans that suggest estrogen replacement therapy to be associated with changes in hippocampal volume. To our knowledge, this exploratory single-subject study is the first to link the subtle hormonal fluctuations that occur during the menstrual cycle to changes in FA. Our study demonstrates the feasibility of such a longitudinal DWI design and represents a step towards creating a personalized map of the human brain by integrating potential mediators of brain states, such as menstrual cycle phase.

Title: Pre- and post-wean early life social environments interact to shape socio-spatial memory in prairie voles

Authors: *G. S. PROUNIS[1,2], L. FOLEY[2], A. REHMAN[2], A. OPHIR[1,2];
[1]Cornell Univ., Ithaca, NY; [2]Zoology, Oklahoma State Univ., Stillwater, OK

Abstracts: Several studies have demonstrated that the dynamic influence of pre-weaning social environments shape behavioral and neural development across taxa. For example, maternal interactions influence oxytocin-mediated social behavior. It is important to consider how socio-environmental influences may interact during pre- and post-weaning development to finely shape the neurobehavioral phenotype. The social world in which an animal is raised conveys both the identity of conspecifics, and where they are in space. These two forms of socio-spatial information can have important implications on the reproductive decisions that an animal will make as an adult. Prairie voles provide an opportunity to understand the influence of social environments on neurobehavioral development. They are a bi-parental, socially monogamous species in which complex early-life manipulations are possible. They also demonstrate a large degree of intraspecific variation in both the social brain and behavior. Here we aim to determine if pre- and post-weaning early life social environments influence social and spatial memory. Male prairie voles were reared in a bi-parental or fatherless pre-weaning environment, and then weaned into isolated or group housing until reaching sexual maturity. Males were then tested in a modified social discrimination test, which allowed us to measure social and spatial memory simultaneously. Whereas the presence or absence of the father had no effect on social recognition of group housed males, isolated males raised without fathers did not demonstrate social recognition but isolated males raised with fathers did. Additionally, unlike the males raised with fathers or those that were group housed, males that were both fatherless and then isolated appeared to exhibit an overdependence on spatial rather than social information. Our results indicate that post-wean social isolation interferes with how animals use socio-spatial information, but the presence of a father buffers this effect. The expression of oxytocin (OTR) and vasopressin (V1aR) receptor in the social brain network suggests that in some cases, early life social environment can have profound effects on the behavioral and neural phenotype. We

speculate that the changes in brain and behavior induced by an interaction between pre- and post-weaning development may predispose animals to adopt different strategies in life.

Title: Social status affects metabolic activity patterns of the social decision making network

Authors: *S. MAGUIRE, H. A. HOFMANN;
Univ. of Texas At Austin, Austin, TX

Abstracts: Animals continuously evaluate external cues from a stimulus in relation to internal information such as their past experience, current condition, and hormonal state. In the context of social behavior, decision-making is governed by a network of twelve evolutionarily conserved brain areas, the Social Decision-Making (SDM) network. Behavioral decisions vary across physiological contexts. For example, an animal may approach other individuals during the breeding season but may avoid the same stimulus in the non-breeding season. We hypothesized that this variation in response is regulated by changes in the patterns of activity across the SDM network that co-vary with behavioral phenotype. The African cichlid fish Astatotilapia burtoni is a model system in social neuroscience and ideally suited to study the mechanisms underlying social decision-making. Males of this species display several distinct phenotypes: dominant, subordinate, and intermediate. These phenotypes are associated with differences in behavior, hormone levels and brain gene expression patterns. We quantified the behavior of males in a social transition paradigm and found that transitioning males showed marked increases in aggression, sexual behavior, gonad size and coloration. We then measured metabolic activity in the SDM network using histochemistry of cytochrome oxidase (COX), an enzyme critical for energy metabolism whose activity correlates with neuronal activity. We used linear models to identify the brain areas where COX activity co-varied with social status and behavioral patterns. Furthermore, we constructed co-variance networks across the nodes of the SDM network and used the quadratic assignment procedure to assess how these patterns relate to social status. Ongoing studies are testing how these status-dependent activity patterns influence neural activity and behavior induced by social stimuli.

Title: Decreased number and mean frequency of ultrasonic vocalizations in juvenile Brattleboro rats

Authors: ***M. J. PAUL**[1], N. V. PETERS[2], J. WHYLINGS[2], C. BADEAU[2], G. DE VRIES[2]; [1]Psychology, Univ. at Buffalo, SUNY, Buffalo, NY; [2]Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstracts: Many neurodevelopmental disorders are characterized by deficits in social behaviors. For example, children with Autism Spectrum Disorders exhibit deficits in social interactions (including social play) and social communication. The neurobiological basis for these deficits in social development is not known. Recently, the neuropeptide arginine vasopressin (AVP) has been implicated in the development of social behaviors (e.g., social play and social recognition). Here we ask whether AVP also contributes to the development of social communication using Brattleboro rats, which contain a single base pair deletion in the vasopressin gene that disrupts the production of AVP in homozygous mutants. Male and female pairs of juvenile wild type, heterozygous, and homozygous Brattleboro rats (34±1 and 44±1 days of age) were single-housed then reunited 24 h later in a social behavior test, during which ultrasonic vocalizations (USVs) were recorded. All genotypes predominantly produced ~50 kHz USVs when reunited in the social behavior test. Preliminary data, however, indicate that the absence of a functional vasopressin gene in male and female homozygous pairs reduced the number and mean frequency of USVs. These data indicate that AVP is necessary for the expression of typical levels and call quality of USVs in male and female juvenile rats. They further indicate that AVP plays a broad role in social development, impacting several juvenile social behaviors including social communication.

Title: Investigation of sex differences in wheel running and social behavior in pre-pubertal mice

Authors: *E. A. GORDON, S. F. BAMJI, K. N. BENCKER, D. N. PATEL, C. CORBITT; Dept. of Biol., Univ. of Louisville, Louisville, KY

Abstracts: The idea that sex differences in social behaviors exist in mammals during adulthood is well accepted, and further evidence suggests that sex differences in behavior are present even before sexual maturity (e.g., play behaviors). In order to model behavioral disorders in animals, it is important to assess baseline sex-related behavioral differences, especially when studying disorders for which sex-related behavioral effects are expected, such as autism. We undertook a study to measure potential sex-related behavioral differences in C57BL/6 and CFW mice (P27-P33), investigating the effect of sex on distinct behaviors in pre-pubertal males and females using a series of wheel running assays developed to evaluate autism-like behaviors. Specifically, we examined the animals' ability to gain and maintain a routine, cognitive rigidity and social interactions. We found no significant differences in latency to run on the wheel or total duration of wheel interaction between males and females. We also evaluated stereotypical behaviors, such as burrowing and grooming. During the social interaction test, there were no differences between the sexes in latency or total duration of contact or following between a subject and novel mouse. In addition, no play behavior was noted, but brief mutual grooming was displayed between mice. Both sexes showed characteristic wheel running behavior, spending the majority of their time interacting with the wheel when it was free and more time performing other activities (e.g., stereotypical behaviors, general locomotion) when it was jammed. Given that pre-pubertal sex differences were not detected in this assay, the results suggest that baseline pre-pubertal sex-related differences are not strong enough to influence behavior in wheel running studies. We conclude that sex-related behavioral differences can be discounted when designing future experiments to measure the effects of developmental insults on this assay in juvenile mice.

Title: The development of play fighting: Do interactions with siblings before weaning matter?

Authors: *B. T. HIMMLER[1], R. STRYJEK[2], K. MODLINSKA[2], S. M. HIMMLER[1], B. KOLB[1], W. PISULA[2], S. M. PELLIS[1];
[1]Univ. of Lethbridge, Lethbridge, AB, Canada; [2]Polish Acad. of Sci., Warsaw, Poland

Abstracts: Play fighting behavior begins to develop in the week preceding weaning, but is incomplete at this stage, not attaining its completed form until the week after weaning. What is unknown is whether experiencing immature patterns play fighting is necessary for the development of the fully mature form. Previous literature has shown that if rats or cats are weaned early, they exhibit heightened levels of play, suggesting the earlier experiences with play may be important. The objective of the present experiment was to evaluate the contributions of the siblings to the development of play behavior in a wild strain of rat--Warsaw Wild Captive Pisula Stryjek rats (WWCPS). On postnatal day 15, both male and female rats were randomly selected to be reared in one of three conditions, (1) Mother-only rearing, (2) Sibling-Only rearing, or (3) Mother and Sibling-reared. It must be noted that in the sibling-only condition, the rats received adequate nutrition. It was predicted that the rats reared in the mother-only condition would show the biggest deviation in juvenile typical play, because with the mother, the animals receive little-to-no playful experiences. Surprisingly, our results show that in all conditions, the rats developed juvenile typical play, suggesting that peer-peer interactions at this age are not necessary for the development of normal play fighting. Indeed, the only group that showed some inadequacies in the sensory-motor coordination of playful movements was the sibling-only rats, suggesting that even though the mother does not engage in play with the pups, she must be providing some experiences which contribute to the development of some important brain mechanisms that are engaged during play.

Title: Reduced social anxiety and elevated fear expression in mice lacking NMDA function in CRF neurons

Authors: *J. DAMERT, T. GILMAN, J. D. MEDURI, A. M. JASNOW;
Dept. of Psychological Sci., Kent State Univ., Kent, OH

Abstracts: Corticotropin-releasing factor (CRF) is a neurohormone involved in mediating behavioral and neuroendocrine responses to various stressors. Here, we employed a cross of two transgenic mouse lines to better understand the regulation of the CRF system and how its activation influences stress-related behaviors. Mice expressing Cre recombinase (Cre) specifically driven by the CRF promoter (CRF-Cre mice) were crossed with floxed NR1 (fNR1) mice allowing for selective ablation of NMDA receptor function only in CRF-expressing neurons. Male fNR1xCRF-Cre mice positive for Cre (fCC+) were first trained along with their Cre negative littermates (fCC-) in cued fear conditioning. Though both groups of mice acquired training similarly, fCC+ mice displayed increased fear retention as well as impaired fear extinction. These fear traits have been observed previously in C57BL/6 mice characterized as resilient following social defeat stress (i.e., displaying unperturbed social investigation following defeats). Consequently, a cohort of these fCC mice was exposed to social defeat stress involving 8 total defeats (4/day) by different male CD-1 aggressor mice. A social interaction assessment was performed 24 h after the last defeat. Though we hypothesized fCC+ mice would display greater resilience, we observed no genotype-dependent differences in social investigation by resilient or susceptible (i.e., displaying reduced social investigation following defeats) fCC mice. Surprisingly, only in the control group was any indication of a genotype difference observed, with fCC+ mice showing a trend for increased social investigation. Indeed, this was confirmed by examining baseline sociability and social novelty behavior in defeat naïve fCC+ mice and comparing to their fCC- littermates. Due to this enhanced social propensity of fCC+ mice, we then hypothesized that the 8 defeats may have masked any genotype-related differences in social stress responsiveness. Therefore, social investigation was examined 24 h after a single defeat

stress. Interestingly, all fCC+ mice displayed a resilient phenotype, while fCC- mice were more likely to be characterized as susceptible. These data support previous literature indicating a behavioral link between defeat resilience and enhanced fear expression/impaired extinction. Furthermore, they suggest activation of CRF neurons via NMDA receptors modulate behavioral susceptibility to social stress and the ability to adequately attenuate fear responses over time.

Title: Effect of stress on the anxiety-like behavior in an animal model of perimenopause

Authors: *P. D. BARROS[1], N. PESTANA-OLIVEIRA[1], C. LEITE-PANISSI[2], J. A. ANSELMO-FRANCI[2];
[1]Physiol., [2]Morphology, Physiol. and Basic Pathology, Univ. of São Paulo, Ribeirão Preto, Brazil

Abstracts: Introduction: It is known that during perimenopause, a period of transition from reproductive to non-reproductive life several hormone and behavioral alterations arise. During this time, the rates of mood disorders, such as depression and anxiety, are highest when compared to any other phase in woman life. A suitable animal model of perimenopause can be produced by the administration of the chemical 4-vinylcyclohexene diepoxide (VCD) which lead to ovarian failure through gradual depletion of primordial and primary follicles, allowing studies on this transition period of reproductive life. Preliminary data of our laboratory show that this perimenopause animal model exhibit anxiety-like behavior. Since is well established that previous stresses can intensify the anxiety behavior of male rats, we aimed at investigating if previous stresses applied in this animal model could also increase this behavior, evaluated in the elevate plus maze (EPM). Material and Methods: 28-day old female rats were treated subcutaneously with VCD (160 mg/Kg) or corn oil during 15 days. Around 80 days after the beginning of VCD/oil administration, on metestrus, rats were submitted to restraint stress during one hour and then isolated from the other animals for 24 hours before the EPM test, performed on diestrus. The unstressed rats were not submitted to restraint or isolation stress. The number of

entries in open and closed arms as well as the time spent in open arms were counted. Moreover, risk assessment behaviors, such as stretched attend posture, rearing and end-arm exploration were also analyzed. Results: VCD-treated rats exhibited an increased anxiety-like behavior expressed by a lower number of entries as well as time spent (in percent) in the open arms when compared to the control rats (1.2±0.7 vs 3.4±1.2 and 4.2±2.6% vs 16.4±6.9% respectively), while the number of entries in closed arms was unchanged. There was no difference between control and VCD-treated rats regarding the risk assessment behaviors analyzed. Previous and associated stress did not modify any of the parameters studied. Conclusion: Although VCD-induced ovarian failure has led to increased anxiety-like behavior in female rats, previous stresses were not able to intensify this behavior.

Title: Organizational and behavioral effects of the early cultural environment in the highly social prairie vole

Authors: *B. S. CUSHING, L. STETZIK;
Biol. and Integrated Biosci. Program, Univ. Akron, Akron, OH

Abstracts: The expression of high levels of prosocial behavior is the product of the interplay of underlying neural mechanisms, which include the neuropeptides, oxytocin (OT) and arginine vasopressin (AVP) and steroids, especially estrogen. Here we report of the effects of the early social/cultural environment on the organization of the brain and expression of social behavior using two populations of prairie voles (*Microtus ochrogaster*). While both populations Illinois (IL) and Kansas (KS) are socially monogamous they are behavioral, physiologically and neuroanatomically distinct, with IL prairie voles displaying much higher levels of prosocial behavior than KS. To separate genomic effects from cultural effects litters IL and KS breeding pairs were established and their litters were then in-fostered to a pair form the same population or

cross-fostered to pairs from the other population on postnatal day 1-2. Litters were reared using standard vole animal husbandry and then tested as adults for the expression of prosocial behavior using a partner preference test, as pair bond formation is a critical aspect of social monogamy. Test animals were cohabitated for six hours with an unrelated sexually naïve member of the opposite sex IL conspecific and then participated in a 3 hr test to determine social interaction with the familiar or sex- and age-matched novel individual. Brains were then collected and analyzed, using immunocytochemistry, for OT and AVP expression in the PVN and tyrosine hydroxylase and estrogen receptor alpha in the hypothalamus. The effects of fostering were populational and sexually dimorphic. As predicted there were significant differences in the levels of prosocial behavior between KS and IL, with in-fostered IL voles displaying higher level of social interaction than KS and with in-fostered males showing higher levels than females. The largest effects of cross-fostering were observed in KS males, who were the only group to form a partner preference, spending significantly less time exploring the novel female and significantly more time ($p < 0.05$) in the cage of and in physical, side-by-side, contact the familiar female than the novel female. We also report on significant differences in arginine vasopressin and oxytocin immunoreactive cells in the PVN and estrogen receptor expression and tyrosine hydroxylase in the hypothalamus by population and associated with cross-fostering and expression of differential social behavior.

Title: Endocannabinoid Regulation of Sociability

Authors: *D. WEI[1], C. MURRAY[1], D. LEE[1], A. ANGUREN[1], D. DINH[1], K.-M. JUNG[2], D. PIOMELLI[2];
[2]Anat. & Neurobio., [1]UC Irvine, Irvine, CA

Abstracts: Social behavior is a hallmark of diverse species from invertebrates to humans and is essential to health and group survival. The neural systems that underlie the expression of sociability and encode the reward of social interactions remain largely unknown. Clues indicate that the endogenous cannabinoid ('endocannabinoid') system might be involved: (a) users of marijuana, a drug in which the psychoactive principle chemically resembles the endocannabinoids, report changes in sociability, and (b) endocannabinoids regulate mood and cognition through the activation of cannabinoid type-I (CB1) receptors, which are richly expressed in areas of the brain involved in social behavior. However, how the endocannabinoids system might regulate sociability and its possible dysregulation in social impairment are unknown. Initial studies suggest that enhancement of the endocannabinoid anandamide, through pharmacological blockade or genetic removal of the anandamide-hydrolyzing enzyme fatty acid amide hydrolase, promotes socially-conditioned place preference, while CB1 blockade decreases this preference. We also found that anandamide signaling is low in BTBR mice, a well-established model of social impairment. Anandamide enhancement in this model restores normal social approach, as evaluated using the three-chamber test. These studies suggest that anandamide is important for the regulation of social reward and its signaling can be targeted to correct social impairment. We hypothesized that anandamide might exert these effects through an interaction with oxytocin, a neuropeptide known to be crucial for social behavior. We found that oxytocin receptor antagonism attenuated both the andandamide-mediated enhancement in socially-conditioned place preference as well as social stimulation-induced increases in anandamide. Consistent with the expectations suggested by these findings, anandamide enhancement corrects aberrant oxytocin transcription in the socially-impaired BTBR mice. Together, these studies suggest that anandamide is important for the regulation of sociability through an interaction with oxytocin. This provides implications for the understanding of the neurobiology of sociability and social impairment, a cardinal feature of many neuropsychiatric disorders.

Title: Behavioral response and functional neuroanatomy of male golden hamsters during social eavesdropping

Authors: *C.-Y. LIU[1], W.-C. YU[1], C.-Y. CHANG[1], W.-S. LAI[1,2,3];
[1]Psychology, [2]Grad. Inst. of Brain and Mind Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan

Abstracts: Social eavesdropping is a special type of social learning and it is defined as the act of extracting information about the relative or absolute quality of signalers from social interactions between conspecifics. Social eavesdropping has advantage in information gathering and has attracted increasing attention. However, this behavioral phenomenon and its underlying neural mechanisms remain much unclear. Taking advantage of agonistic behaviors in male golden hamsters, we developed a new laboratory method to study social eavesdropping. After 3-day social learning, naïve male bystanders were attracted to the winning demonstrators whereas bystanders with defeated experience avoided approaching to the winning demonstrators in a U-maze. To further identify brain areas and related neural activity underlying social eavesdropping in hamsters with defeated experience, 3 groups of hamsters that exposed to either a fighting interaction, a neutral encounter, or an empty arena were tested. In experiment 1, compared with the arena controls, male bystanders in the other two groups displayed more time in the information gathering behaviors during the 3-day social learning. Using c-Fos immunohistochemistry to map neuronal activities in the brain, males in the fighting interaction group had more c-Fos labeled neurons in the piriform cortex and sub-regions of cingulate cortex compared with males in the other two groups. But no significant difference was found in the hippocampus and amygdala. In experiment 2, local field potential was recorded in the cingulate cortex of behaving hamsters to reveal neural activity during social eavesdropping. Data collection and analyses are still in progress. Collectively, our data suggest that hamsters are capable of social eavesdropping and cingulate cortex plays an important role in the information gathering and extracting process.

Title: Dose-Response study of di-(2ethylhexyl) phthalate (dehp): Androgenic and anti-androgenic actions

Authors: *K. M. QUINNIES[1], E. P. HARRIS[1], E. F. RISSMAN[2];
[1]Neurosci. Grad. Program, [2]Biochem. and Mol. Genet., Univ. of Virginia, Charlottesville, VA

Abstracts: Di-(2ethylhexyl) phthalate (DEHP) is a man made endocrine disrupting compound (EDC) used in production of flexible plastics. The mechanism of action for this EDC is complex acting on both steroid receptors and steroidogenic enzymes. Much of the work on this compound has focused on the effects that high doses have on androgen-target tissues. However, in addition to gonadal hormones, effects of DEHP may be caused by its actions on lipid and cholesterol, the hypothalamic-pituitary-adrenal axis, and/or retinoic acid. Epidemiological studies have demonstrated correlations between metabolites in urine and a variety of behaviors in children, including higher urinary levels of DEHP in autistic as compared with control children. Here we use several doses of DEHP given orally to mice (5ug, 40ug, 400ug and of 200mg/kg body weight/day) during pregnancy and the first ten days of lactation. These doses represent a range from low (within levels found in humans) to rather high and others have suggested the low doses are androgenic while the highest dose is anti-androgenic. Preliminary data indicates that PN1 male offspring have a shorter anogenital distances than control males, suggesting an anti-androgenic effect. Furthermore, dams exposed to low doses of DEHP tend to display less maternal care than dams not consuming DEHP. This research has important implications for human social behaviors; and may be relevant to disorders with known sex differences, such as Autism Spectrum Disorders. Due to the interaction of DEHP with genes and steroid hormone pathways integral to neurodevelopment, as well as social behavior effects in human studies, we predict that animals exposed to DEHP *in utero* will have dose-related changes in behavior.

Title: Stress inhibits partner preference in same-sex pairs of female meadow voles

Authors: *A. M. ANACKER, K. M. REITZ, E. R. GUNZEL, A. K. BEERY;
Neurosci., Smith Col., Northampton, MA

Abstracts: Meadow voles (Microtus pennsylvanicus) provide an excellent model of social relationships between same-sex peers. While females of this species are territorial and solitary in the summer breeding season, they live in groups and nest communally in the winter. In the laboratory, they form partner preferences for other specific females under winter-like light conditions (10 hours of light : 14 hours of dark). Here we tested whether stress hormone levels differ under winter- and summer-like conditions, and whether stress inhibits partner preferences, in order to understand the factors that can mediate same-sex relationship formation. Adult female meadow voles housed under winter-like light conditions had lower levels of free serum corticosterone than those housed under summer-like light conditions. Previous studies in monogamous female prairie voles found that a forced swim stressor or an injection of the stress hormone corticosterone inhibited formation of a preference for a male partner (DeVries et al. 1996, 1997). We exposed adult female meadow voles housed under winter-like light conditions to a three-minute swim stress in room temperature water, and then paired the test subject with another female previously unknown to the subject (the partner). Following 24-hour cohabitation, we measured the amount of time the subject spent huddling with the partner or a stranger in a 3-hour partner preference test. We found that swim stress exposure decreased the amount of time spent with the partner in comparison to controls and decreased the likelihood that voles would exhibit a preference for the partner over a stranger. In a separate test we demonstrated that the three minute swim stress significantly increased corticosterone levels. Further studies will demonstrate whether corticosterone is necessary and/or sufficient to inhibit partner preference formation. These findings demonstrate that stress inhibits same-sex social bonding in female meadow voles, which may relate to their seasonal changes in social behavior.

Title: Infection threat elicits assortative sociality in female mice

Authors: *M. KAVALIERS[1], C. J. CLOUTIER[2], K.-P. OSSENKOPP[3], E. CHOLERIS[4]; [1]Univ. Western Ontario, London, ON, Canada; [2]Psychology, [3]Univ. of Western Ontario, London, ON, Canada; [4]Psychology, Univ. of Guelph, Guelph, ON, Canada

Abstracts: There is mounting evidence that pathogen threat affects social and sexual responses and underlies the evolution of disgust. In humans the reverse is also true with the presence of strangers heightening sensitivity to pathogen threat, promoting "in-group" bias and "out-group" avoidance. Whether or not a similar effect of social context on pathogen threat occurs in non-human animals is unclear. The present study shows that the responses of female mice to males are also rapidly affected by the presence of either unfamiliar or infected males in a manner consistent with the expression of disgust. In female mice, where odor cues determine the appetitive aspects of social responses and preferences, brief (1 min) exposure to the urinary odors of an unfamiliar male led to females subsequently discriminating more strongly against the odors of males subclinically infected with the nematode parasite, *Heligiomides polygyrus*. In a parallel fashion, brief exposure to the odors of infected, males attenuated the responses of females to the odors of the normally preferred unfamiliar males and enhanced their preferences for familiar males. These findings are consistent with the concept of "assortative sociality", whereby the presence of infection threat and unfamiliar individuals biases female preferences for uninfected and familiar individuals ("in-group" preference and in human terms "ethnocentrism") and leads to the avoidance of unfamiliar individuals ("out-group" avoidance and "xenophobia"). Hence, as in humans infection associated social information can rapidly bias the social preferences and elicit assortative sociality in female mice.

Title: Intrasexual dimorphism of the serotonergic system in a vocal fish with alternative reproductive tactics

Authors: *M. TIMOTHY[1], Z. N. GHAHRAMANI[2], A. CHERNENKO[1], M. GORBONOSOV[1], P. M. FORLANO[1,2,3];
[1]Biol., Brooklyn College, City Univ. of New York (CUNY), Brooklyn, NY; [2]Ecology, Evolutionary Biol. and Behavior, [3]Behavioral and Cognitive Neurosci., CUNY Grad. Ctr., New York, NY

Abstracts: The plainfin midshipman, *Porichtys notatus*, is a seasonally breeding marine teleost that produces vocal signals for intraspecific communication. There are two different male reproductive morphs: Type I males establish nests and vocally court females while type II males neither build nests nor produce a mating call but instead sneak-spawn in competition with type I males. The morph phenotype is fixed once an individual is mature. Type I males are consequently the territorial, and aggressive morph, possessing a distinct vocal motor and hormonal profile relative to type II males. Circulating cortisol as well as CNS glucocorticoid receptor expression is greater in type II males. The highly conserved serotonergic (5-HT) system is known to modulate a range of socially motivated behaviors across taxa, including mating-related vocalization and audition, stress, and aggression. 5-HT reciprocally interacts with the hypothalamic-pituitary interrenal axis in teleosts; agonist binding at toadfish 5-HT1A receptors elevates circulating cortisol. Subsequent decrease in 5-HT1A expression indicates a negative feedback organization. The nuclei of the mammalian superior raphe (SRa) are functionally distinct as a result of specific projection patterns, receptor associations, and electrophysiological profiles, as well as distinctive axonal morphology. Similarly, recent studies in zebrafish demonstrate specialization of SRa nuclei in teleosts. In midshipman, ascending serotonergic fibers innervate the auditory thalamus, parvocellular preoptic area, and limbic homologs in the telencephalon. Intrasexual differences in the anatomy of the teleostean SRa may underlie morph-specific behavioral profiles, with the expectation of a more robust ascending serotonergic system in non-aggressive type II males. Reproductive adult males were collected from intertidal nests and processed for 5-HT immunofluorescence histochemistry. Midshipman SRa 5-HT-ir somata were quantified and assigned to one of three groups delineated strictly by anatomical landmarks: a dorsomedial, ventromedial, or ventrolateral group. Our results demonstrate that type II males have significantly greater total numbers of SRa 5-HT-ir neurons compared to type I males. We

also provide evidence (in both morphs) for heterogeneity between the proposed raphe groups, specifically the morphometric confirmation of a distinct 5-HT-ir ventromedial SRa group exhibiting significantly smaller somata. Our findings support the hypothesis of a divergent ascending 5-HT phenotype inversely related to aggressive territorial phenotype in a teleost model with fixed male alternative reproductive morphs.

Title: Association of smoking-induced variations on hypothalamic pituitary adrenal axis activity and mental health stress in African Americans

Authors: ***P. A. ABRAHAM**, J. KAZMAN, S. ZENO, K. DENNIS, P. DEUSTER; Military and Emergency Med., Uniformed Services Univ., Bethesda, MD

Abstracts: Objective: Ample evidence suggests cigarette smoking causes neuroendocrine changes in humans. We investigated the possible influence of smoking on changes in cortisol and DHEAS and self-reported psychological status in adult African Americans (AA). Methods: AA aged 18 to 60 years were recruited from the community. Morning saliva samples were obtained to measure cortisol and DHEAS. Additionally, questionnaires were administered to assess self-reported depression, daily hassles and anxiety. Participants were classified into two groups based on smoking status: Smokers (S: n= 40) and Non-Smokers (NS: n=80). The p value was set at ≤0.01. Results: DHEAS levels did not differ by smoking status (S: 22.9±2.3 vs. NS: 20.2±1.6; p =0.4), but cortisol was slightly lower in smokers (S: 11.6± 2.4 vs. NS: 14.7± 1.7; p=0.3). Additionally, smokers had significantly higher scores on depression (S: 8.9±1.0 vs. NS: 5.5±0.7; p≤0.01), trait anxiety (S: 42.0±1.6 vs. NS: 35.8±1.1; p≤0.01), and state anxiety (S: 40.5±1.7 vs. NS: 30.7±1.2; p≤0.001) but not on daily hassles (S: 45.2± 4.2 vs. NS: 35.9± 3.0; p = 0.08). Conclusion: Although no significant differences in cortisol or DHEAS were noted as a function of smoking status, symptoms of anxiety and depression were significantly higher in

smokers than non-smokers in AA. The modulation of psycho-social-neurobiological variables must be considered when providing smoking cessation education programs. Whether other neuroendocrine markers contribute to the association between mood and smoking needs to be further investigated.

Title: Validation of a partner preference test in coppery titi monkeys (Callicebus cupreus)

Authors: *E. ROTHWELL[1], S. CARP[3], S. FREEMAN[2], E. FERRER[1], K. BALES[1,2];
[1]Psychology, [2]California Natl. Primate Res. Ctr., Univ. of California- Davis, Davis, CA;
[3]Psychology Dept., Univ. of Nebraska-Omaha, Omaha, NE

Abstracts: The partner preference test is a behavioral paradigm that has been used extensively in rodents to quantify social preference in a variety of species. The development and validation of this behavioral task has given researchers the ability to study the factors that influence the formation of social attachments in monogamous species as well as social memory and mate choice in non-monogamous rodent species. However, an analogous partner preference testing paradigm for use in nonhuman primates has not yet been developed and validated. Thus, the goal of the current study was to establish an adapted partner preference test for nonhuman primates using the socially monogamous coppery titi monkey (*Callicebus cupreus*). Twelve established pairs of monkeys were tested in a three-chambered apparatus for three hours. Analogous to the paradigm used in rodents, the test subject was placed in the middle chamber, with its pair-mate

on one side and an opposite sex stranger on the other. The test animal was separated from the two stimulus animals by grated windows, and we recorded the duration of time that the test animal spent in proximity with and touching each window. All monkeys spent significantly more time near the partner's window compared to the stranger [$t = 3.88$; $p < .001$], but the time touching either window did not differ [$W = 335$; n.s.]. A dyadic mixed model analysis revealed partner preference did not change during the test. We found that females, but not males, spent significantly more time near the stranger's window as the test progressed [$t = 2.43$; $p = 0.017$]. This validated partner preference test can now be used as a standardized measurement for social preference in a variety of primate species to quantitatively study the formation and maintenance of pair bonding and to determine what factors influence the expression of social preference.

Title: Excitatory and inhibitory reciprocal connections between the anterodorsal and posterodorsal medial amygdala in the adult male Syrian hamster

Authors: *J. WHYLINGS[1], A. BURNS[2], P. BEHNIA[1], A. PETRULIS[1], B. M. COOKE[1]; [1]Neurosci. Inst., [2]Biol. Dept., Georgia State Univ., Atlanta, GA

Abstracts: The medial amygdala (MeA) is important for processing social odor cues and is critical for reproductive behavior in rodents. The MeA can be subdivided into anterior and posterior subdivisions; in male Syrian hamsters (Mesocricetus auratus), communication between these subdivisions is necessary for processing sexually relevant odor cues. Disconnecting the anterior MeA from the posterodorsal medial amygdala (MePD) abolishes opposite sex odor preference, and lesioning the anterior MeA reduces MePD Fos labeling in response to opposite-sex odors. In contrast, if the MePD is lesioned, anterior MeA Fos expression in response to

opposite-sex odors is unchanged. This suggests that the anterior MeA provides a stronger excitatory input to the MePD during odor processing than the MePD provides to the anterior MeA. Thus, we predicted that projections from the anterodorsal medial amygdala (MeAD) would be predominantly glutamatergic, and that projections from the MePD would be mainly GABAergic due to the large number of GABAergic neurons in the MePD. To test this, we quantified the excitatory and inhibitory connections between these areas in male Syrian hamsters. We injected the anterograde tracer biotinylated dextran amine (BDA) into either the MeAD or MePD, and then visualized BDA-labeled axons in sections immunolabled for either vGlut2 or GAD65, which are markers of glutamatergic and GABAergic presynaptic terminals, respectively. Confocal z-stack images were sampled from throughout both regions. We selected well-defined axons and determined the linear density of terminal bouton-like varicosities, defined as any enlargement greater than 1.5x the axon diameter, on ~16 axon segments per hamster (mean length 58 μm ± 31 μm). We then determined each bouton's colocalization with the presynaptic marker. Contrary to our expectation, preliminary results suggest that the MeAD and MePD project roughly equivalent numbers of excitatory and inhibitory efferents to each other. However, the extent of co-localization with either presynaptic marker is greater in MeAD efferents than in MePD efferents. It is unclear whether the disparity in colocalization is due to differences in terminal characteristics such as size, or likelihood to express vGlut2 or GAD65. More exploration will be needed to distinguish between these and other possibilities, as well as to determine the peptidergic content in these projections.

Title: Gene co-expression network analysis in a free-living, behaviorally polymorphic species

Authors: *W. M. ZINZOW-KRAMER[1], B. M. HORTON[1], G. K. THARP[2], D. L. MANEY[1]; [1]Psychology, [2]Yerkes Div. of Developmental and Cognitive Neurosci., Emory Univ., Atlanta, GA

Abstracts: Individuals of all species must balance parental investment and competitive behavior to successfully produce viable offspring. In this context, aggression is associated with prioritizing short-term goals (maximizing mating opportunities) over long-term goals (successfully rearing young). Our research takes advantage of a unique model species, the white-throated sparrow, to study the genetic underpinnings of individual differences in aggressive and parental behavior. This species exhibits a plumage polymorphism that correlates with alternative reproductive strategies. Individuals of the white stripe (WS) morph are more aggressive and adopt a more competitive, less parental strategy than individuals of the tan stripe (TS) morph. The plumage polymorphism is linked to a chromosomal rearrangement, presenting a unique opportunity to study the relationship between genes and social behavior. In this study, we employed genome-wide transcriptome analysis to identify clusters of genes associated with social behavior in a free-living population. At our study site, a higher song rate in WS males represents the greatest behavioral difference between the morphs. We therefore prioritized male song as the main behavioral focus. In order to correlate this behavior with gene expression, we measured song rate in response to simulated territorial intrusions during the breeding season. We then collected brains from those males and isolated RNA from two regions: the medial amygdala and the hypothalamus. We used RNA-sequencing to generate transcriptome data for each region, which we then used to identify genes that vary in expression with relation to both plumage morph and vocal aggression. Because social constructs such as aggressive behavior are mediated by many genes, we are ultimately interested in identifying genetic pathways associated with behavior. Therefore, we used weighted gene co-expression network analysis (WGCNA) to conduct a systems-level analysis of the gene networks that differed according to morph. Gene modules identified by WGCNA consist of groups of genes with expression profiles that are related across samples. Thus, we identified groups of genes with expression profiles that are associated with plumage morph and behavior. Because genes and pathways that regulate social behavior are highly conserved, our findings are likely relevant to the mechanisms underlying social strategies in all vertebrates.

Abstracts: The adult brain of teleost fish is distinguished by a high degree of structural plasticity with extensive brain neurogenesis and gliogenesis persisting throughout life span. Fish are also the vertebrate class with the highest degree of behavioral plasticity and in many species individuals undergo major behavioral transitions during their lifetime, including changing sex or adopting alternative modes of reproduction. We hypothesized that these extreme behavioral changes in the adult stage rely on a significant capacity for structural rearrangements of neuronal networks that include the integration of new neurons. This idea was tested in a species with a high level of behavioral plasticity, the peacock blenny Salaria pavo. In this species, young males reproduce by mimicking female behavior and appearance in order to approach nests defended by larger males, deceive the males, enter the nests, and parasitically fertilize part of the eggs inside the nest. The small "sneaker" males transition to the nesting male phenotype, suffering extreme morphological and behavioral changes. An experiment was conducted to test if the behavioral transition was associated with an increase in cell proliferation levels. One outdoor pool was set up with 12 nesting males and respective nests, 24 females and 24 sneaker males. The 24 sneaker males were provided with 12 potential nests to induce the transition in approximately half of the sneaker males. In fact, at the end of the experimental period (10 days), some of the sneakers had occupied the available nests and started the morphological and behavioral transition while others had remained sneakers. To compare cell proliferation levels in the brains of nesting males, sneakers and transitional males, fish were injected with the mitotic marker BrdU and sacrificed 2h later. Animals were perfused, the brains extracted, sliced in a cryostat at 15µm and a BrdU immunohistochemistry protocol with DAPI counterstain was applied for detecting new cells. Cells were manually counted under a fluorescence microscope. A detailed map of the brain proliferation areas for this species was generated. For the most significant nuclei, differences in the number of proliferating cells between the male morphotypes were analyzed. The results are discussed in light of the hypothesis that periods of extreme behavioral transition are associated with an increase in cell proliferation levels. In conclusion, extensive adult neurogenesis may be a condition for extreme behavioral plasticity and may explain why, throughout vertebrates, adult behavioral plasticity seems to be associated with the capacity for adult neuroplasticity.

Title: Neonatal maternal separation impairs osmotic stress coping in adult rat: Mapping brain metabolic activity by [18F]-FGD positron emission tomography and c-Fos expression

Authors: *C. L. IRLES[1], V. M. LARA[2], M. C. AVILA[2], H. BARRIO[1,3], E. RAMOS[4], T. MORALES[4], M. A. AVILA-RODRIGUEZ[2], L. ZHANG[1];
[1]Fisiología, Dept. de Fisiología, Facultad de Medicina, Univ. Nacional Autónoma, Mexico City, Mexico; [2]Unidad PET, Facultad de Medicina, UNAM, Mexico City, Mexico; [3]Facultad de Ciencias, Univ. Nacional Autónoma de México, Mexico City, Mexico; [4]Inst. de Neurobiologia, UNAM, Queretaro, Mexico

Abstracts: Hypothalamic AVP-containing osmosensitive neurosecretary neurons serve as important sources for AVP intracerebral innervation (1-5). We have previously demonstrated that neonatal maternal separation (MS, 3 hr daily, from postnatal day 2 to 15) potentiates hypothalamic vasopressin (AVP) system. Under the experimental conditions in which the AVP system was particularly up-regulated (e.g. hypertonicity), the adult MS rats exhibit high anxiety and spatial learning impairments. In light of these previous observations, we herein hypothesized that up-regulation of the VP system by an osmotic stimulus in MS rats would result in differences in brain metabolism in the neuropeptide hypothetical downstream regions. Hence, we used high resolution positron emission tomography for rodents (microPET) with [18F] 2-fluoro-2-deoxy-D-glucose (18F-FDG) to *in vivo* image the regional brain glucose metabolism, as an indicator of neuronal activities. Adult (postnatal day 90) male Wistar animal facility reared (AFR) and MS rats were injected with 18F-FDG under isoflurane anaesthesia. Dynamic scans of

90 min were acquired in the microPET. Hypertonic saline (900mM saline, 2% of body weight) was injected i. p. at min 20 post-injection of the tracer. The averaged values from the min 15-20 served as the baseline of the metabolic activity for each region/subject. Dynamic images were analysed post-hoc using the ASIPro VM software. Dynamic changes of 12 brain regions were plotted (time vs standardized uptake value). MS rats showed an increased metabolism in hypothalamus, locus coeruleus (LC), periaqueductal gray (PAG), dorsal raphe (DR), lateral septum (LS), striatum, amygdala, infralimbic prefrontal cortex (IL), motor cortex 1, cerebellum and ventral hippocampus (vHi). Using immunohistochemistry against the immediate early gene c-Fos, we found increased neuronal activation in some of the regions with increased metabolism, especially CeA, vHi, LS, LC, PAG and DR. These results suggest than MS modifies the stress-related neurocircuitry of the VP system downstream regions crucially involved in anxiety modulation, spatial learning and fight-of-flight response. 1. Title: Over-expression of TRH and/or a TRH-like peptide in the limbic system and adrenals of a spontaneous rat mutant

Authors: *A. SATTIN[1], A. E. PEKARY[2];
[2]Res., [1]VA Greater Los Angeles Hlth., LOS ANGELES, CA

Abstracts: Thyrotropin-releasing hormone (TRH, pGlu-His-Pro-NH2) and TRH-like peptides (X-TRH, pGlu-X-Pro-NH2), where “X” can be any amino acid residue, are endogenous neuroprotective, antidepressant, anti-epileptic, analeptic, and anxiolytic peptides. During studies of the effects of ketamine on TRH and TRH-like peptide turnover in commercially sourced male

Sprague-Dawley rats, very high levels of TRH or a TRH-like peptide, eluting right after TRH during reverse phase HPLC, was observed in limbic brain regions, even in untreated animals. All animals were hyperglycemic (serum glucose: 213 ±44 mg/dl) but euthyroid (fT4: 1.67 ±0.04 ng/ml); T3: 71.4 ±1.6 ng/ml). The TRH-like peptide being over-expressed is likely to be Thr-TRH, but mixing synthetic TRH, Thr-TRH and tissues extracts from various brain and peripheral tissues resulted in coelution of the synthetic and endogenous TRH and Thr-TRH. The ratio (mutant/normal) of the TRH-immunoreactivity (TRH-IR) derived from various brain regions eluting in the region of TRH and Thr-TRH were: hippocampus (285), periform cortex (63), posterior cingulated (57), entorhinal cortex (46), adrenals (13), frontal cortex (11), nucleus accumbens (11), striatum (11), anterior cingulate (10), cerebellum (9), amygdala (3), medulla oblongata (2), and hypothalamus (0.6). Because the mutants were euthyroid, it is unlikely that TRH is the peptide being over-expressed in the limbic system, though feedback inhibition of hypothalamic TRH biosynthesis is suggested by the reduced hypothalamic TRH levels. The dams for these males are being used to establish a breeding colony for the purpose of: (1) studying the effects of TRH-like peptide over-expression on behavioral tests for depression (Porsolt forced swim test), anxiety (elevated plus maze), and reward seeking (running wheel), (2) identifying the progenitor protein for the over-expressed TRH-like peptide and the enzymes involved in its processing to the bioactive tripeptide, and (3) determining the therapeutic potential for TRH-like peptide over-expression in the treatment of neuropsychiatric disorders such as major depression, bipolar disorder, anxiety, Alzheimer's and Parkinson's diseases.

Title: Effect of neonatal maternal separation and adolescent ethanol exposure on adult preference for ethanol

Authors: *A. T. NAVA KOPP[1], C. IRLES[1], H. BARRIO[2], L. ZHANG[1];
[1]Dept. of Physiology, Fac. of Medicine, Natl. Autonomous Univ. of, Mexico City, Mexico; [2]Fac. of Sciences, UNAM, Mexico City, Mexico

Abstracts: Mechanisms underlying physiological actions of ethanol are not fully understood. However, the involvement of different types of neurotransmitter systems, such as GABA and opioids is clear. For instance, alcohol is known to increase GABAa ionotropic receptor (GABAaR) activation, but its precise molecular mechanism remains unclear. On the other hand, there are evidences suggesting 1) adolescent exposure to ethanol (AEE) increases drinking in adulthood; 2) adverse environmental conditions during development, such as neonatal maternal separation (MS) potentiate ethanol preference. A down-regulation of GABAergic transmission via GABAaR in determined brain regions has been suggested to underlie the latter phenomenon. The potentiation of the intracerebral vasopressinergic (AVP) transmission has been associated to elevated ethanol consumption, since administration of V1bR specific antagonist has been demonstrated to decrease anxious- and depressive-like behaviors, as well as ethanol consumption in alcohol preferring rats. We have previously demonstrated that MS up-regulates the AVP hypothalamic system. Hence, it is interesting to test whether the exposition to alcohol in the MS subjects can cause permanent adaptational modifications inducing up-regulation or down regulation of V1bR in the brain. The objective of the present study is to evaluate the possible role of MS and AEE in the development of alcohol preference during adult life, and to elucidate if one of the underlying mechanisms involves AVP transmission. For this purpose, alcohol intake of male Wistar rats exposed to 4 different developmental environments was quantified, experimental groups comprised (i) different rearing conditions: animal facility reared (AFR) vs. MS, and (ii) differences in ethanol exposure during adolescence: naïve (n) vs. experienced (e). Alcohol preference was measured during adulthood using a 2-bottle free choice paradigm. MS and AEE increased ethanol intake, observed in AFRe and MSn groups; however, rats from the MSe group had a significant higher average alcohol intake compared to all other groups. These results suggest that MS and AEE provoke a higher preference for ethanol in adults. Protein signaling pathways underlying this phenomenon is being carried out.

Title: Maximum load exercise induced increases in neuropeptide Y and allopregnanolone correlate with fitness and increases in pain threshold and tolerance

Authors: *A. RASMUSSON[1], E. R. SCIOLI-SALTER[2], J. D. OTIS[2], K. ALLSUP[3], D. E. FORMAN[4];
[1]NC-PTSD/WHSD, VA Boston Healthcare System/116B-3, Boston, MA; [2]Psychiatry, Boston Univ. Sch. of Med., Boston, MA; [3]VA Boston Healthcare Syst., Boston, MA; [4]Cardiol., Harvard Med. Sch., Boston, MA

Abstracts: The high comorbidity between chronic pain and posttraumatic stress disorder (PTSD) may be explained in part by a shared underlying molecular pathophysiology. Neuropeptide Y (NPY) and the GABAergic neuroactive steroid allopregnanolone (ALLO) play critical roles in pain gating at the spinal and supra-spinal levels, are lower in the blood and cerebrospinal fluid in PTSD, and correlate negatively with PTSD symptoms. Exercise in humans and rodents increases plasma NPY and ALLO. This pilot study assessed the effects of acute exercise on NPY and ALLO levels and their relationship to pain threshold and tolerance measured by the cold pressor test in two groups: a) healthy trauma-exposed male and female Veterans, and b) Veterans with PTSD comorbid with chronic pain. A symptom-limited maximum load cardiopulmonary exercise test was performed in accordance with guidelines of the American College of Cardiology. During exercise, rates of oxygen (O2) consumption and carbon dioxide (CO2) production were calculated from continuous recordings of ventilation rate and expired fractions of O2 and CO2. Blood sampling from an IV line was performed prior to exercise, during the last minute of each exercise workload, and at 5' and 30' after exercise for measurement of NPY, ALLO, and other hormones of interest. Pain threshold and tolerance were measured via the cold pressor test 30 minutes before and 30 minutes after testing. The pilot sample (N=12) was 58.3% male (n=7), 41.7% female (n=5) with mean age of 38 years; 42% identified themselves as Black, 33% White, 8% Asian and 16.7 as "other. Half of the participants had PTSD and comorbid

chronic pain; the rest were trauma-exposed but healthy. Across all participants, peak VO2 correlated with change from baseline in ALLO ($r=0.77$, $p<.01$), NPY measured at the anaerobic threshold ($r=.61$, $p<.05$), and NPY measured 5' post-exercise ($r=.81$, $p<.01$). Pain threshold measured after exercise by the cold pressor test correlated with changes in ALLO ($r=.61$, $p<.05$) and NPY ($r=.81$, $p<.01$), but not cortisol or DHEA. A regression model in which NPY and ALLO changes predicted post exercise pain threshold was significant: $F(2,9) = 13.38$, $p<.01$. Exercise-induced changes in NPY and pain tolerance were also correlated ($r=.64$, $p<.05$). This is the first study of exercise-associated increases in the anti-stress, anti-nociceptive compounds NPY and ALLO in healthy trauma-exposed participants compared to persons with comorbid PTSD and chronic pain. As exercise training increases VO2max, we are now investigating whether it will also increase the capacity for release of these protective anti-nociceptive molecules_with possible resultant reductions in pain in CP/PTSD.

Title: Gender differences in the effect of perinatal high sugar diet on spatial cognitive behavior of adolescent rats

Authors: *I. ZARCO DE CORONADO, S. MOSSO-MENDOZA;
Fisiologia, UNAM, Mexico DF, Mexico

Abstracts: We described that individuals perinatally exposed to high sucrose diet have an increased risk of obesity and dyslipidemia. This study was undertaken to determine whether the perinatal administration of high sugar diet would affect spatial learning/memory behavior. Also, we would like to know if the coffee can improve this cognitive function. Mothers and the after weaning tested offspring were exposed to water (controls) or 20% sucrose diets since gestation day 14 to the 34 postnatal (PN) day. From PN28 day the offspring were tested 3 days in a maze (8 arms) and the latency to go out was determined. After the second test, coffee (25mg/dl) was added for 24 hrs to the drinking solution. Male control and experimental rats did not show significant differences in the latency the first test day but the female experimental rats showed

significant (P= 0.03) increased latency in the maze solution. Second test day males and females showed similar significant (P= 0.01) decreased latency to go out (learning). After coffee both groups presented no significant increase in latency. Thus our results indicate that high sugar diet affects not just metabolic but also cognitive functions in rats in a sex dependent action.

Title: Hypertonicity increases arousal and anxiety following predator exposure: The direct and indirect modulation of hypothalamic vasopressin containing magnocellular neurosecretory neurons on Fos expression in limbic regions in rat

Authors: *E. VAZQUEZ-JUAREZ[1], F. JÁUREGUI-HUERTA[2], V. S. HERNÁNDEZ[1], L. ZHANG[1];
[1]Fac. of Medicine, Physiol., Univ. Nacional Autonoma De Mexico, Mexico City, Mexico; [2]Dept. de Neurociencias, Ctr. Universitario de Ciencias de la Salud, Univ. de Guadalajara, Guadalajara, Mexico

Abstracts: Hypothalamic vasopressin containing magnocellular neurosecretory neurons (VP-MNNs) are potently upregulated by hypertonicity. Traditionally, it has been considered that this population of neurons almost exclusively projects to the posterior pituitary. However, recent results from our group, together with other few groups, have challenged this notion. We have found by *in vivo* juxtacellular labeling, retrograde tracing and anatomical analysis that a subpopulation of MNNs possess important axonal branches from/near MNN-somata projecting intracerebrally, especially to the limbic regions, such as ventral hippocampus (1), amygdala (2),

locus coeruleus (3) and lateral habenula (4). However, the functional implications of these intracerebral projections remain elusive. In order to assess whether a potent upregulation of this VP-MNN population modulates predator-fear processing and the neuronal activation weights in different nodes of the so called "survival circuit", we used a live-predator (cat) exposure test in rats the assess the changes in behavior and the neuronal activation weights in hypothalamus, amygdala, locus coeruleus, hippocampus, striatum and thalamus, under two conditions: basal and hypertonicity, i.e. 900mM saline, 2% b.w., injected under sevoflurane-inhalation as transient anesthesia, 30min before the behavioral test. Ethological analysis showed significant behavioral modifications in "hypertonicity" group, including a four-fold increase of freezing behaviour. Immunohistochemical assessment of C-Fos expression showed generally sharpened patterns in amygdala, thalamus and hypothalamus. The Fos expression in the basolateral (BLA) and corticomedial (CoMA) nuclei of the amygdala were significantly attenuated, while the expression of central and medial nucleus (the postero-dorsal division (MeApd)) were increased. Remarkable increase of Fos+ nucleus counts was also observed in the locus coeruleus (LC). Immunohistochemical analysis with light and electronic microscopy has showed increased VP immunopositve fibers in MeApd, CeA and LC, where VP containing type I synapse were found. Our data, together with recent findings reported in the literature, suggest that the up-regulation of the VP-MNNs exert strong modulatory effects on fear processing. 1. Zhang L.& Hernandez VS. Title: Does maternal ghrelin drive transgenerational change in emotional processing and stress responsivity?

Authors: *G. LEE[1], K. A. GOOSENS[2];
[1]PsyRING, McGovern Inst. For Brain Res., Cambridge, MA; [2]McGovern Inst. for Brain Res., Massachusetts Inst. of rtechnology, Cambridge, MA

Abstracts: Stress during pregnancy can have a profound impact on the emotional state of both the mother and offspring. A tremendous amount of work has focused on stress hormones of the hypothalamic-pituitary-adrenal (HPA) stress axis as the primary cause of such changes. However, the Goosens lab has recently identified a critical role for ghrelin and growth hormone in affective dysregulation following chronic stress, acting independently of the HPA axis. Because hunger, a stress state that elevates ghrelin in humans, has been closely linked to transgenerational changes in stress responsivity and health, we hypothesize that elevated maternal ghrelin signaling during pregnancy may give rise to depressive behaviors in the mother, and also alter aversive processing and stress responsivity in the offspring. Here, we exposed rat dams to an agonist of the ghrelin receptor (growth hormone secretagogue receptor, or GHSR), during pregnancy, mimicking the prolonged enhancement of ghrelin that is observed in chronically stressed animals. In the dams and adult offspring, we found behavioral deficits including anhedonia (sucrose preference), dysfunctional exploratory behavior in the open field and elevated plus maze, and deficits in fear learning (auditory Pavlovian fear conditioning). We are currently exploring changes in endogenous ghrelin-growth hormone signaling that may account for the dysfunction in neural circuits involved in emotional processing. These data indicate a role for circulating ghrelin in the emotional state of both mothers and their offspring. Ghrelin-growth hormone signaling in the brain is a potential developmental risk factor for emotional processing disorders, and provides a potential therapeutic target that may improve the quality of life of people that suffer with poor stress coping.

Title: Activation of glucocorticoid and NMDA receptors in the prelimbic prefrontal cortex decreases the expression of contextual conditioned fear in rats

Authors: *F. M. REIS[1,2], R. C. ALMADA[3], M. V. FOGAÇA[3], M. L. BRANDÃO[1];
[2]Psychology, [3]Pharmacol., [1]Univ. of São Paulo, Ribeirao Preto, Brazil

Abstracts: Glutamatergic abnormalities and functional alterations of the medial prefrontal cortex (mPFC) have been associated to several psychiatric disorders such as anxiety. Decreased NMDA receptor activity and potentiation of glutamatergic neurotransmission at non-NMDA receptors in the mPFC have been linked to behavioral maladjustment. It is also recognized that stress and changes on circulating glucocorticoids concentrations induce changes in glutamate synapses and circuitry, and this in turn can modify mental states. Although it is known that glucocorticoids can influence glutamate release in the mPFC, the role of mineralocorticoid (MR) or glucocorticoid receptors (GR) and the interaction between corticosteroid effects and glutamatergic activity in the mPFC on the expression of conditioned fear remain to be elucidated. The present study investigated the role MR and GR located in the prelimbic cortex (PrL) on the expression of freezing response of rats subjected to contextual fear conditioning. The effects of enhanced glutamatergic transmission at NMDA receptors on fear expression were also evaluated. Wistar male rats received vehicle or different doses of MR or GR antagonists bilaterally into the PrL and were exposed to a context previously paired with footshocks. The results showed that administration of the MR antagonist reduced freezing expression while the GR antagonist produced no effects. Previous administration of GR antagonist into the PrL abolished the anxiolytic effects induced by MR antagonist in this region. Additionally, corticosterone administration in the PrL reduced the expression of conditioned fear, an effect abolished by previous GR antagonist administration. Administration of NMDA in the PrL prior to the test also decreased conditioned fear expression. Thus, these findings suggest that the modulation of conditioned fear in the PrL is partly influenced by GR activation highlighting the importance of this mechanism in behavioral adaptation. The results concerning NMDA effects in the PrL will be useful in future experiments to explore possible interactions between glucocorticoids effects and the glutamatergic system as an underlying mechanism involved in the non-genomic effects induced by GR activation.

Title: Límbic-Region projections of vasopressin containing mangocellular neurosecretory neurons revealed by *in vivo* juxtacellular recording and anatomical analysis: its rhythmic changes under osmotic stress and implications on predator fear processing

Authors: *L. ZHANG, E. VAZQUEZ-JUAREZ, V. S. HERNÁNDEZ;
Facultad de Medicina, Physiology, Medicine, Natl. Autonomous Univ. of Mexico, Mexico City, Mexico

Abstracts: Hypothalamic vasopressinergic mangocellular neurosecretory neurons (VP-MNNs) are well known to release their peptidergic contents from neurohypophyseal axonal terminals into the circulation as well as to release VP locally from their dendrites serving as powerful autocrine and paracrine signals to their neighboring neuronal populations. However, the possible crosstalk between these MNNs population and distant neuronal populations has not yet been explored. In order to assess whether this subcortical neuropeptidergic system also exerts fast/precise influence to the limbic regions, we used a combination of electrophysiological approaches, including *in vivo* juxtacellular recording, labeling and frequency analysis, *in vitro* acute slices patch-clamp recording and pharmacological tools, fluorogold retrograde tracing, immunohistochemistry, confocal imaging, electron microscopy and behavioral tests as our study strategy. We show an *in vivo* labelled PVN VP-MNN possessing multiple axons and other axons branching very near the soma. Beside of the neurohypophyseal axon, neurobiotin labelled axon segments/terminals were found in the preoptical area, anterior hypothalamic area (AHA), suprachiasmatic nucleus, in the thalamus and the lateral habenula (LHb). Frequency analysis of LFP recorded in the PVN showed clear theta rhythms (7-9 HZ) in the region and the osmotic stressor increased the theta power and shifted the frequency band to 8-10 Hz. To evaluate the functional consequence of those intracerebral projections of the MNNs, we used predator fear behavioural test and c-Fos expression to assess the neural circuits involved in fear processing under osmotic stress. Our data showed a four-fold increase of freezing behaviour and modified Fos expression patterns in lateral septum, AHA, ventromedial hypothalamus, amygdala (MeApd, CeC and BLA), locus coeruleus and LHb. These findings clearly indicate a regulatory role of VP-MNNs in stress coping.

Title: Testosterone replacement restores spatial working memory in castrated adult male rats

Authors: *B. CULLEN[1], C. G. BATSON[2], S. C. SPILLANE[2], B. A. WAGNER[2], M. D. SPRITZER[2];
[2]Dept. of Biol. and Program in Neurosci., [1]Middlebury Col., Middlebury, VT

Abstracts: Testosterone declines among men with increasing age, and some evidence indicates that low testosterone levels lead to an increased risk of dementia. Therefore, testosterone replacement may be useful for the treatment of age-related memory loss, but the role of testosterone in regulating memory remains controversial. We previously demonstrated that a high physiological dose of testosterone (0.500 mg/rat) improved spatial working memory among castrated male rats relative to a castrated control group. Using the water maze, we found that only a relatively low dose of testosterone was needed to restore spatial memory. It remained to be determined whether testosterone had dose-dependent effects on spatial working memory. Therefore, the current study involved testing a wide range of testosterone doses for their effects on the performance in a working-reference memory version of the 8-arm radial maze. Castrated adult male Sprague-Dawley rats (N = 13-15/group) were either given daily s.c. injections of drug vehicle (castrated control and sham-castrated control) or one of five doses of testosterone propionate (0.0625, 0.125, 0.250, 0.500, and 1.00 mg/rat). Injections started 7 days before the first day of maze testing and continued through the 25 days of acquisition trials on the maze. Four arms of the maze, chosen at random for each rat, were consistently baited on each day of testing. Testing proceeded until all food rewards were retrieved or 10 min had elapsed. Working memory errors were defined as repeated visits to the same arm within a day of testing, and reference memory errors were defined as first visits to arms that were never baited. Rats showed significant reductions in working memory errors and reference memory errors over the course of testing (both $P < 0.005$), indicating that all groups were able to learn the task. We found that testosterone had a significant effect on working memory errors ($P = 0.041$), with all groups except the 0.250 and 1.000 mg/rat doses performing significantly better than the castrated control

group. In contrast, there was no significant effect of testosterone on spatial reference memory. There were also no significant day x treatment interaction effects for either working memory or reference memory errors. These results indicate that testosterone replacement can restore spatial working memory among castrated male rats, but these effects showed complex dose-dependent effects which may explain some discrepancies among past studies. Importantly, the one supra-physiological dose of testosterone that we used (1.00 mg/rat) did not restore spatial memory function, suggesting that physiological doses may have the most therapeutic value.

Title: Neuroendocrine response to extreme challenge

Authors: *V. J. MEYER, Y. LEE, E. SHIRTCLIFF;
Univ. of New Orleans, New Orleans, LA

Abstracts: Skydiving is an extreme challenge which activates stress-responsive biomarkers. Our aim was to broadly characterize the neuroendocrine response to skydiving, and to examine how reactivity may be moderated by previous experience or gender. Prior research on laboratory stressors has shown evidence for habituation to a stressor with repeated exposure. Sex differences also emerge, with males demonstrating greater cortisol reactivity to laboratory stressors than females. We hypothesized that participants would show reactivity to the challenge by demonstrating increases in cortisol, DHEA, and testosterone. We further hypothesized that males would have greater responses to the jump across these three stress-responsive biomarkers. We collected five saliva samples from 44 skydiving participants. Saliva was assayed using enzyme immunoassays. Hierarchical linear modeling was utilized to model the hormone response. Cortisol (β=.42, $p<.001$), testosterone (β=.17, $p<.001$), and DHEA (β=.32, $p<.001$) all demonstrated reactivity to the jump. Experienced jumpers showed less cortisol reactivity (β=-0.41, $p<.05$) and faster recovery (β=-0.37, p0.05). Sex differences emerged in testosterone levels

(β=-1.38, p<.001), but not reactivity or recovery (p's<0.05). There were no sex differences in cortisol or DHEA levels or responses (p's>0.05). Our findings of hormonal reactivity to skydiving show that, across several biomarkers, the body mounts a neuroendocrine response to deal with the stressor. This is in line with previous research which demonstrates the utility of skydiving as a model of an extreme challenge. Contrary to hypotheses, we did not find sex difference in cortisol response to the jump. The similarity of hormone response profiles in males and females may indicate that skydiving activates the HPA and HPG axes in a non-sex-specific manner. The slightly different profile among experienced jumpers indicates that skydiving is a reliable activator of the HPA and HPG axes, even with repeated exposures; however, experience may modulate the response.

Title: Blocking luteinizing hormone but not gonadotropin-releasing hormone in the dorsal hippocampus rescues spatial memory deficits in ovariectomized female rats

Authors: V. L. BURNHAM, A. GOLDBERG, *J. E. THORNTON;
Neurosci. Dept, Oberlin Col., OBERLIN, OH

Abstracts: Recent work has implicated the activity of luteinizing hormone (LH) in post-menopausal memory decline. In rodents, increasing physiological levels of LH has been shown to significantly decrease performance on spatial memory tasks. Previous research has also indicated that blockage of gonadotropin releasing hormone (GnRH) activity, which decreases LH levels, can cause amelioration of spatial memory deficits. However, it is unclear whether directly reducing activity of LH in the brain is able to rescue spatial memory deficits in individuals with high LH. To further investigate the role of hippocampal LH receptors in spatial memory deficits, female Sprague-Dawley rats were ovariectomized (ovx) and implanted with either an estradiol (E) or blank (blk) capsule. Bilateral cannulae were implanted into the dorsal hippocampus (DH). Animals received infusions of 0.9% saline (vehicle), the LH homologue hCG (human chorionic

gonadotropin), or deglycosylated-hCG (dg-hCG; an LH receptor antagonist), 3-5 hours prior to behavioral testing via Object Location Test (OLT). Consistent with previous results, estradiol enhanced spatial memory (ovx + E compared to ovx) and ovx + E animals receiving hCG infusions into the dorsal hippocampus showed a significant decrease in spatial memory compared to vehicle infusions. Importantly, infusion of the LH receptor antagonist dg-hCG into the dorsal hippocampus of ovx + blk animals caused a rescue of spatial memory deficits induced by ovariectomy. These data indicate that LH acts on the hippocampus to modulate spatial memory. Whether GnRH antagonism exerts its effects on spatial memory via its effects on LH or thru some more direct action on the dorsal hippocampus was also assessed. In the present experiments infusion of Antide via bilateral cannulae into the DH of ovx + E and ovx + blk animals 4-6 hours prior to administration of behavioral tests did not result in any significant alteration of OLT performance, when compared to vehicle infusion. These results support the hypothesis that the GnRH antagonist Antide affects spatial memory via regulation of LH levels. Together these data provide strong evidence that LH acts at the hippocampus as a key modulator of hippocampal-dependent spatial memory.

Title: Toxoplasma-gondii infection shifts balance between approach-avoidance decisions towards impulsivity

Authors: *D. TAN, A. VYAS;
Nanyang Technological Univ., Singapore, Singapore

Abstracts: Foraging theories predict that foraging animals maximize their rate of energy intake per unit of time. In contrast, several empirical observations suggest that foraging behavior does not reach the adaptive perfection. Decisions made by animals are rather subject to probabilistic and reciprocal trade-offs between foraging, reproduction and predation. Interestingly, each of these trade-offs are essentially intertemporal decision problems. In this backdrop, we report our

observations about effects of a shift in trade-offs on intertemporal discounting or delay discounting. Male rats infected with a parasite *Toxoplasma gondii* are known to manifest a hyper-androgenic metabolism. This metabolic change is believed to institute behavioral changes in the host that are likely beneficial for the parasite transmission. This model has been previously used in context of parasitic behavioral changes in host. We posit that *Toxoplasma gondii* provides a serendipitous perturbation model to study effects of higher testosterone and concomitant shift to reproductive state on decision making process. We report that *Toxoplasma gondii* infection enhances preference for sooner but smaller rewards in comparison to larger but later available food. This represents a change in impulsivity of choice, but neither to hedonic value of food itself and nor in motor impulsivity. Moreover, this represents a coordinated and organized biological change, as demonstrated by specific structural change in neuronal arbors of nucleus accumbens core, but not in other brain regions important for decision making processes. Our observations provide support to the notion that life history choices and hormonal changes adaptively modulate decision making, constraining the decisions from adaptive perfection. These observations also provide putative biological substrates for modulation of economic decision making under uncertainty and delay.

Title: Investigation of the roles of the hippocampus and basolateral amygdala in rapid estrogenic enhancement of social learning

Authors: *K. S. ERVIN[1], P. PALETTA[1], M. SAWULA[1], A. MOORE[1], K. SINCLAIR[1], A. PHAN[2], E. CHOLERIS[1];
[1]Univ. of Guelph, Guelph, ON, Canada; [2]Scripps Res. Inst., Jupiter, FL

Abstracts: Social learning is a strategy by which animals acquire information from others in their social group rather than through potentially costly trial and error learning. The social transmission of food preferences (STFP) is a natural form of social learning, common in rodents,

including mice. In the STFP, a naïve observer interacts with a demonstrator that has recently fed on a novel flavoured food. The observer then tends to prefer the food it smelled on the demonstrator's breath over other novel foods. Estrogens modulate performance on this task via both genomic mechanisms (i.e. 48h after hormone manipulation) (Clipperton et al 2008, Neuropsychopharmacology: 2362-75) and rapid mechanisms. We previously found that systemic treatment with 17β-estradiol (E2) rapidly facilitated social learning within 45 min. However the brain regions involved in the rapid estrogenic enhancement of social learning in the STFP are currently unknown. The hippocampus is a likely candidate as systemic E2 rapidly enhances dendritic spine density in the CA1 hippocampus (Phan et al 2012, Neuropsychopharm: 2299), intrahippocampal E2 rapidly enhances learning in nonsocial learning tasks (Phan et al 2012, SfN abstracts: 92.12), and hippocampal lesions impair acquisition of the STFP (Alvarez et al 2001, Learn Mem: 79). Hence, we implanted female ovariectomized CD1 observer mice with bilateral guide cannulae aimed at the dorsal hippocampus. Observers were infused with 0.5µl per side of vehicle, 25, 50, or 100nM E2 15 min prior to a brief social interaction with a same sex demonstrator. Observers were immediately tested for a food preference and measurements were taken at the 30 min, 2h, 4h, 6h, and 8h intervals. The first measurement was therefore 45 min after treatment to focus on the rapid E2 effects. The STFP task was also modified to be difficult, such that vehicle treated observers typically show no social learning, in order to see any enhancing effects. Our results show that the hippocampus is likely not the site of rapid estrogen facilitation of social learning. Thus estrogens may enhance social and nonsocial learning by acting in different brain regions. Therefore in ongoing experiments, we are investigating the role of the basolateral amygdala, which has also been implicated in the STFP (Wang et al 2006, Learn Mem: 794) and other social behaviours. Using the same procedures described above, we are infusing E2 bilaterally into the basolateral amygdalae of female ovariectomized observer mice. Our aim is to further elucidate how estrogens act in the brain to facilitate social learning, as it is an adaptive and ubiquitous learning strategy. Supported by NSERC.

Title: Patch clamp recording in hypocretin/orexin neurons in larval zebrafish (Danio rerio) *in vivo*: sensory responses

Authors: *X.-B. GAO[1], J.-L. DU[2];
[1]Yale Univ. Sch. Med., New Haven, CT; [2]Inst. of neuroscience, Chinese Acad. of Sci., Shanghai, China

Abstracts: The zebrafish, Danio rerio, has long been a model organism widely used in the study of early development in animals. In recent years, zebrafish has emerged as a powerful model organism in the study of basic behaviors in animals highly conserved across the species from fish to mammals. The neuropeptide hypocretin/orexin (Hcrt), which was originally discovered in mammals, plays crucial roles in the regulation of homeostatic and cognitive functions in the brain. It is now clear that Hcrt expresses in the zebrafish and exerts functions relevant to what have been observed in mammals. Although ample studies have been performed to investigate the changes in activity and morphology in the Hcrt system in behaving larval zebrafish with molecular, structural and imaging approaches, the direct evidence is required to verify and understand these changes in Hcrt neurons *in vivo*. In this study, we performed whole-cell patch clamp recording in Hcrt neurons in larval zebrafish (3-7 days post-fertilization) *in vivo* and the electrophysiological responses of Hcrt neurons to sensory (light flash and sound) stimuli were examined. In larval zebrafish exclusively expressing GFP in Hcrt neurons driven by a selective Hcrt promoter (a gift from Dr. A. F. Schier at Harvard), whole-cell patch clamp recording of membrane potential, action potential and spontaneous excitatory postsynaptic currents was performed as reported by Mu et al (2012). The exposure to a light flash induced a significant inhibition in Hcrt neurons while the exposure to a sound stimulus excited these cells. The inhibition of Hcrt neurons by a light flash was due to a significant decrease in excitatory inputs onto Hcrt neurons as examined under voltage clamp mode. The responses to light and sound stimuli were not detected in a neighboring neuron without the expression of GFP, suggesting the specificity of the responses in Hcrt cells. In summary, our preliminary results indicate that the patch clamp recording in intact larval zebrafish is capable of providing an unparalleled insight into neural circuits centered on Hcrt neurons.

Title: Vasopressin modulates lateral habenula network activity via both V1a and V1b receptors: Dual electrophysiological mechanisms revealed by *in vitro* whole-cell patch clamp recording

Authors: *V. S. HERNANDEZ, F. CHAY, C. IRLES, L. ZHANG;
Dept. of Physiology, Fac. of Medicine, Natl. Autonomous Univ. of Mexico, Mexico City, Mexico

Abstracts: The lateral habenula (LHb) is an important epithalamic structure within the dorsal diencephalic conduction system, which controls the exchange of information between forebrain and midbrain structures. Its involvement is implicated in a variety of biological functions, including a strikingly powerful role in the regulation of midbrain monoamine release. Glutamatergic projections from the lateral hypothalamus targeting VTA-projecting neurons in the lateral habenula have recently been reported (Poller WC et al, 2013). We have also recently reported (Hernandez and Zhang, SfN, 2013) that vasopressin (VP) containing fibers from the hypothalamic paraventricular nucleus, specifically the medial magnocellular division (PVNmmd), strongly project to the medial division of the LHb. However, little is known about the vasopressin (VP) signaling pathway or the electrophysiological response in the LHb. Using whole cell patch clamp recording in an acute slice preparation of the rat LHb, we demonstrate that the application of VP (10nM) to the recording chamber induces a differential electrophysiological respons. 50% of recorded neurons increased their firing rate [post-hoc identification revealed some of these neurons to contain vesicular GABA transporter (vGAT)], 30% decreased their firing rate, and 20% had no evident response. Western blot analysis on fresh microdissected habenula revealed a remarkable expression of V1a protein (protein bands: ≈ 47 KDa as well as ≈ 70 KDa, Alomone Avr-010) and the presence of V1b protein as well (protein bands: ≈ 47 KDa as well as ≈ 70 KDa Enzo ADI-905-750), although the latter one was near the limit of detection. The ≈ 70 KDa protein band has been attributed to the glycosylation of the receptors these receptors. These data support the previously reported presence of vasopressin

receptors V1a and V1b mRNA in the habenula by *in situ* hybridization. Moreover, at the electron microscopic level, we found AVP containing fibers establishing asymmetric synapses with lateral habenular neurons (synapse n=10, 100% type I). Our data strongly suggests that the PVN VP population is an upstream element for a function of the LHb that mainly plays an activation role implicated in the promotion of negative rewards

Title: Igf-1 regulates neuronal structure and function via rhoa/rock signaling

Authors: *N. ASHPOLE, J. E. LANDOLL, E. L. HODGES, M. C. MITSCHELEN, H. YAN, J. FARLEY, W. E. SONNTAG;
Reynolds Oklahoma Ctr. on Aging, Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK

Abstracts: Neuroendocrine regulated hormones such as insulin-like growth factor-1 (IGF-1) have an important role in learning and memory since they influence neuronal differentiation, enhance axonal path finding, and promote dendritic growth. It is generally accepted that IGF-1 exerts these actions via downstream activation of growth-stimulating signaling pathways, mainly Phosphoinositide 3-kinase/Akt. We hypothesize that in addition to the classical role of upregulating growth-stimulating pathways, IGF-1 also downregulates growth-limiting pathways such as the RhoA/Rho-associated coiled-coil containing protein kinase (ROCK) pathway. RhoA/ROCK signaling is associated with spine retraction, synapse elimination, decreased neuronal excitability, and impaired learning and memory. Thus, if IGF-1 serves as a negative regulator of RhoA/ROCK signaling, it may further promote learning and memory by preventing neurite retraction. To test this hypothesis, IGF-1 was inhibited in both cultured murine hippocampal neurons as well as in the hippocampus of IGF-1f/f mice. Following treatment,

Western blots, GTP-binding assays, and *in vitro* phosphorylation assays were used to assess RhoA/ROCK activity. Sholl analysis was employed to measure neuronal complexity following co-administration of IGF-1 modulators with pharmacological antagonists of ROCK. Spatial learning and memory was assessed using the Barnes maze and the TSE intellicage behavior testing system. Our results indicate that IGF-1 regulates the RhoA/ROCK signaling cascade. Our *in vitro* studies indicate that a reduction in IGF-1 resulted in the upregulation of RhoA/ROCK activity. No change in RhoA/ROCK protein expression was identified; however, antagonism of ROCK signaling restored neuronal growth to control levels even when IGF-1 signaling was impaired. Together, these results are consistent with a model suggesting that IGF-1 can influence neuronal structure by negatively regulating the RhoA/ROCK signaling pathway. To determine the influence this regulation may have on learning and memory, we knocked out circulating and hippocampal IGF-1 in our IGF-1f/f. This resulted in a significant decrease in spatial learning and memory. We are now examining the regulation of RhoA/ROCK in our *in vivo* mouse model.

Title: Sex differences in the response to intermittent hypoxia, a model for obstructive sleep apnea

Authors: *T. G. AUBRECHT, R. D. JENKINS, R. J. NELSON;
The Ohio State Univ., Columbus, OH

Abstracts: Obstructive sleep apnea (OSA) results from upper airway obstruction during sleep, causing repeated brief periods of low oxygen termed hypoxia. In addition to increased health risks, individuals with OSA experience impaired cognitive functions and ~50% of people presenting with OSA are also diagnosed with depression and anxiety. OSA is more prevalent in men than premenstrual women, but the mechanism for this sex difference remains unspecified. Gonadal hormones are one obvious mechanism underlying sex differences in OSA. Sleep apnea

is more frequently reported in postmenopausal women than premenopausal women, and both prevalence and severity of OSA increase after menopause, even after correcting for body mass index. Additionally, exogenous testosterone treatment has been associated with exacerbating OSA in men. Considered together, these data suggest a role for gonadal hormones in the development of OSA that could also affect OSA associated symptoms. OSA can be modeled in mice using intermittent hypoxia (IH). Such research indicates sex differences in the cellular response to IH, especially protection from IH in intact females that is negated by ovariectomy. Therefore, we hypothesize that female gonadal hormones may protect mice from IH induced behavioral and hippocampal morphological changes. To test this hypothesis we exposed intact or gonadectomized male and female mice to IH (15 cycles/h, 8 h/day, FIO2 nadir of 5%) for a total of 30 days. During the final four days of IH mice were tested for anxiety- and depressive-like behaviors during the dark phase. After cessation of IH exposure mice were also tested on the Barnes maze and passive avoidance tests to asses learning and memory. Ovariectomy in female mice paired with IH treatment impaired spatial learning and memory compared to all other female groups. Intact male mice in IH treatment also displayed significantly impaired learning and memory compared to intact or castrated male mice exposed to room air. These data suggest that female sex hormones provide protection against IH induced deficits, whereas male sex hormones partially exacerbate IH induced deficits. Spatial learning and memory deficits should be mirrored by changes in cornu ammonis (CA) 1 hippocampal morphology. Work is currently underway to assess the benefits of estrogen replacement in protecting against IH-induced cognitive deficits. Understanding the role of sex hormones in the development of OSA or the worsening of OSA symptoms could provide support for hormone treatment in a clinical setting.

Title: Sex-differences in hippocampal ca1 intrinsic excitability and peripheral responses in a high-energy diet-induced prediabetic rat model

Authors: *E. UNDERWOOD, L. THOMPSON;
Sch. of Behavior and Brain Sci., The Univ. of Texas At Dallas, Richardson, TX

Abstracts: Alarming increases in fat intake and rising obesity/insulin-resistance/type-II diabetes necessitate focusing on dietary effects on brain and cognitive function. Diabetes affects over 10% of the adult U.S. population, with an additional 35% considered prediabetic (50% when > age 65). Rats exhibit enhanced memory retention when intrahippocampal insulin is administered immediately post-acquisition (Babri et al., 2007). Acquisition and consolidation of many memory tasks reduces Ca2+ dependent afterhyperpolarizations (AHPs) of hippocampal pyramidal neurons (see Farmer & Thompson, 2012), increasing intrinsic excitability. Here we investigated the effects of a high-energy (HE) diet in a prediabetic state on measures of CA1 hippocampal neuron intrinsic excitability, on performance in a novel object recognition (NOR) task, and on peripheral blood chemistry measures associated with diabetes. Male and female adult Long-Evans rats (3-4 mo) were fed from weaning either a control (14% fat, 64.8% carbohydrate, 21.2% protein) or a HE diet (57.6% fat, 26.8% carbohydrate, 15.6% protein) for 6-10 wk prior to experimentation. The control diet was augmented with casein and coconut oil to achieve the desired HE ratios without altering other nutrients. Episodic memory was assessed in a NOR task, serum samples were collected for biochemical analyses, and vaginal cytology was performed on female subjects to assess estrus. *In vitro* current-clamp recordings were made to assess post-burst AHPs, accommodation, and passive membrane properties. After baseline recordings, slices were perfused with 12.5 nM insulin and all measures repeated to directly assess insulin-sensitivity of CA1 pyramidal neurons. Baseline sex-dependent differences were observed in weight gain and other measures, in NOR, and in hippocampal excitability. Females had reduced AHPs compared to males. After 6 wk on the HE diet, this sex-dependent intrinsic excitability profile reversed, with AHPs of CA1 neurons from both sexes significantly enhanced. HE diet female neurons had significantly larger mAHPs and longer duration sAHPs than those from males, which were also less excitable after 6 wk or more on the HE diet. Insulin-sensitivity was significantly reduced by the HE diet before traditional peripheral measures indicative of diabetes were altered. Since there is an increased prevalence of Alzheimer's in the diabetic population, these sex-dependent neurophysiological changes in hippocampus, occurring early in the pre-diabetic state may have significant consequences in brain development, brain aging and cognitive decline, which are being longitudinally followed in the next phase of our studies.

Title: Low-to-severe neurotoxicity and thyroxine deficits in the absence of behavioral changes in rats with developmental hypothyroxinemia

Authors: *P. R. MOUTON[1], G. S. TRAVLOS[2], C. J. PRICE[4], J. HARRY[3];
[1]Pathology & Cell Biol., Univ. of South Florida Col. of Med., Tampa, FL; [2]Clin. Pathology, NIEHS, Research Triangle Park, NC; [3]NIEHS, Research Park, NC; [4]Discovery-Science-Technology, RTI Intl., Research Triangle Park, NC

Abstracts: Thyroid hormones (TH) regulate biological processes that are implicated in neurodevelopmental disorders and behavioral aberrations, yet animal models with less than 50% disruption in TH levels rarely manifest behavioral changes. To compare neuroanatomical and behavioral effects associated with tetrachloroazobenzene (TCAB)-induced developmental hypothyroxinemia, male rats were exposed to TCAB (0.1, 1.0, or 10.0 mg/kg/day) or vehicle (corn oil) from gestation day 6 to postnatal-day (PND) 21. Endpoints included serum TH levels in dams (PND 4) and offspring and a standard behavioral battery between ages PND 21 and 150. The left cerebrum was sectioned in the parasagittal plane and stained with histochemical and immunologic-based methods for qualitative and stereological evidence of neuropathology at PND 21 and 150 and the right cerebellum was Golgi-stained for morphological analysis of Purkinje cells (PC) at PND 21. TCAB significantly reduced serum thyroxine (T4) in dams and offspring in a dose-dependent manner at PND 21 with normalization by PND 150, and no changes in 3,5,3'- triiodothyronine (T3) or thyroid stimulating hormone (TSH) at either time point. Standard qualitative examination of the left cerebrum showed no TCAB-related neurodegeneration or neurogliosis for any TCAB dose at PND 21 and PND 150 while more rigorous qualitative examination at PND 21 revealed glial cell disturbances in hippocampus and frontal lobe, including thinner astrocytes processes with reduced density at the two higher doses and reduced complexity of microglia processes at the highest dose. Golgi-stained sections at PND 21 suggested about a 15% reduction in dendritic branching area of PCs at the highest TCAB dose (10 mg/kg/day). Blinded computerized stereology confirmed significant reductions in total numbers of neurons in hippocampus at both PND 21 and 150. Despite evidence of neurodegeneration and glial cell disturbances there were no behavioral changes related to TCAB exposure between PND 21 and 150. Reduced complexity of process morphology of astrocytes

and microglia indicate TCAB-mediated developmental delay, while adult deficits in total number of hippocampal neurons at PND 21 and 150 show developmentally initiated changes not mitigated by a return to normal T4 levels. These findings suggest that standard neurobehavioral and neuropathological assessments lack sensitivity to detect long-term changes induced by developmental T4 deficits in TCAB-exposed male offspring. The demonstrated sensitivity of hippocampal neurons and glial cells to TH-disrupting chemicals support inclusion of these endpoints in future assessments of developmental neurotoxicity.

Title: Genetic deletion of SNAP-25b: A new mouse model of genetic diabesity

Authors: *I. V. ACEBES[1,2], T. DARAIO[4], K. BRISMAR[5], S. ÖGREN[3], H. TOMAS[2], C. BARK[6];
[1]Dept. of Neurosci., Stocholm, Sweden; [2]Dept. of Neurosci., Karolinska Institutet, Stockholm, Sweden; [3]Dept. of Neurosci., Karolinska Institutet, Stockolm, Sweden; [4]Mol. Med. and Surgery (MMK), [5]Dept. of Mol. Med. and Surgery (MMK), [6]The Rolf Luft Centrum for Diabetes and Endocrinol., Karolinska Institutet, Sweden

Abstracts: BACKGROUND: The relationship between the release machinery of neuroendocrine messengers and the development of diabesity has been poorly explored. The SNARE complex is conceived as a master regulator of exocytosis of neurotransmitters and other signaling molecules involved in the regulation of body weight, energy expenditure and glucose homeostasis. AIM: We therefore hypothesize that a genetic predisposition for an imbalance in the release machinery controlling the release of signalling molecules triggers cognitive and/or emotional disorders secondary to the onset of diabese phenotypes. METHODS: Five-week-old male and female SNAP-25b-deficient mice and C57Bl6 controls were assigned either to a high-fat/high-sucrose diet or to a control chow diet for 7 weeks. We monitored: 1) Body weight, food intake, and water intake; 2) Lipid homeostasis and the serum levels of adipokines released; 3) Glucose tolerance and the release pattern of insulin; 4) Leptin receptor content, AMPK-alpha1/2 and ERK1/2 phosphorylation in brain areas involved in the regulation of energy balance (hypothalamus) and in emotional aspects of eating behavior (hippocampus and frontal cortex); 5) Depression and anxiety processes linked to genetic- and/or diet-induced obesity. RESULTS: SNAP-25b deletion elicits vulnerability to develop early-onset diabesity with associated deranged lipid homeostasis, adipocyte hypertrophy, glucose intolerance, hepatic steatosis and hypothalamic dysfunction; all primary features of the human metabolic syndrome. The lipotoxic diabese phenotype, the consequence of SNAP-25b-deficiency, was associated with depression-like behavior and an anxiety-related phenotype. CONCLUSION: An intact release of signalling molecules involving SNAP-25b is essential to prevent major metabolic abnormalities related to eating habits as well as ensuing depression and anxiety disorders. These findings open up for novel therapeutic strategies to prevent development of major metabolic abnormalities and their secondary consequences, such as mood disorders.

Institute, Univ. of Cambridge, Cambridge, United Kingdom; [9]Dept. of Clin. Biochem., Addenbrooke's Hosp., Cambridge, United Kingdom; [10]Dept. of Fetal Med., Rosie Maternity Hosp., Cambridge, United Kingdom

Abstracts: Testosterone is known to have organizational effects on brain structure and function in non-human species. Our previous research shows that variation in fetal testosterone (fT) predicts regional gray and white matter (GM; WM) volume in pre-pubertal boys (♂). In a follow-up study we investigate how variation in fT predicts regional WM volume in ♂ and girls (♀) aged 13-17 years old. We hypothesized that volume of areas associated with fT level overlap with regions showing sex differences (SD) in a congruent direction as found in the child WM volume study, higher fT in boys overlaps with SD regions larger in girls in an independent group of adolescents of the same age-range. T1-weighted scans were acquired of 21 ♂ and 17 ♀ (mean (M) age in years ♂ 15, ♀ 15) part of the Cambridge Child Development Project. FT was measured using radioimmunoassay from amniotic fluid samples collected between 13-20 weeks of gestation (fT range: ♂ 0.40-2.05 nmol/L; ♀ 0.15-0.40 nmol/L). Measures of handedness (H) and self-report puberty development stage (PDS) were also taken (right-H: ♂ 16; ♀ 15; PDS: ♂ 3.02, ♀ 3.51). Data from the NIH Pediatric Repository of adolescents (♂ 88; ♀ 98) between 13-

17 years (M age in years ♂ 15, ♀ 15; right-H: ♂ 75, ♀ 90; PDS: ♂ 2.74, ♀ 3.28) were used as an age-matched group to identify normative SD. The Template-O-Matic Toolbox was used to create sex- and age-specific tissue prior templates. SPM8 New Segment and DARTEL were run and statistical analysis was done using general linear model. Total WM volume effect was adjusted at an individual level. FT, PDS, age, and H were regressors for the separate fT regressions and sex, PDS, age, H and scanning sites in the NIHPR SD regression. Results were thresholded at a cluster-wise topological FDR $q < 0.05$, with voxel-level threshold set at $p < 0.01$. Overlap with WM tracts was identified using standard-space diffusion-based white matter tract atlas (Thiebaut-de Schotten, 2011). Areas overlapping with anterior corpus callosum, bilateral and inferior fronto-occipital fasciculi were larger in ♂ and areas overlapping with the medial fornix, internal capsule (IC), left and right medial arcuate fasciculi (AF), ILF, cortico-ponto cerebellar (CPC) and cortico-spinal (CS) tracts were larger in ♀. In ♀, no correlations between fT and WM were found. In ♂, fT positively predicted WM volume in a cluster encompassing the left IC, CS and CPC tracts, and the AF. These results (i.e., areas positively correlating with fT in ♂ overlap with an SD region larger in ♀) confirm the hypothesis. These findings provide more evidence that fT may act differently as an organizing mechanism in WM than in GM in brain development in ♂, but not in ♀.

Title: Distinct membrane excitability control of Ca2+ handling in identified synaptic terminals in *Drosophila* neuromuscular junctions

Authors: *X. XING[1], C.-F. WU[2];
[1]Dept. of Biol., [2]Univ. of Iowa, Iowa City, IA

Abstracts: The *Drosophila* larval neuromuscular junction (NMJ) is ideal for investigating the genetic mechanisms for synaptic terminal excitability control and Ca2+ handling. By expressing the Ca2+ indicator GCaMPs in motor neurons, we performed genetic dissections to investigate how ion channels regulate synaptic Ca2+ dynamics. Our results demonstrate striking effects of several well-established Na+ and K+ channel mutations on synaptic Ca2+ accumulation. We found that Na+ channel mutations of the paralytic gene and K+ channel mutations of the Shaker locus exerted preferential effects on the tonic and phasic motor synaptic terminals. The hyperexcitable allele of paralytic (bss) as well as several alleles of Shaker enhanced the rise, but not the decay, kinetics of the Ca2+ transients. However, the decay time was impeded by inhibition of Ca2+ extrusion with high pH saline, confirming that ion channels control Ca2+ influx rather than clearance. At low external Ca2+ levels (0.1 and 0.5 mM), both types of mutations markedly enhanced the Ca2+ transients in phasic synaptic terminals at lower frequency stimulation (2 - 20 Hz), whereas the enhancement in tonic synapses were detected at higher frequency (20 - 40 Hz). Applications of available GCaMP variants (GCaMP1, GCaMP6 and myrGCaMP5) confirmed the distinct properties of tonic and phasic motor terminals, regardless of their subcellular localization and sensitivity to cytosolic Ca2+. Our findings reveal basic differences in Ca2+accumulation and frequency dependence of different *Drosophila* NMJ synapses, reflecting their distinct frequency domains of operation. These findings provide baseline information for inferences of GCaMP signals during *in vivo* studies of neuronal activity.

Title: BDNF's role in the excitatory-inhibitory imbalance within the solitary tract nucleus during the critical period of postnatal development in the rat

Authors: *X.-P. GAO, M. T. WONG-RILEY;
Cell Biology, Neurobio. and Anat., Med. Col. of Wisconsin, Milwaukee, WI

Abstracts: Previously, we found a transient imbalance between suppressed excitatory postsynaptic currents (EPSCs) and enhanced inhibitory postsynaptic currents (IPSCs) on postnatal days (P) 12-13 in hypoglossal motorneurons of rats. This is a critical period when abrupt neurochemical, metabolic, ventilatory, and physiological changes occur in multiple respiratory-related nuclei of the rat's brain stem, but its mechanism is poorly understood. Interestingly, a reduced expression of brain-derived neurotrophic factor (BDNF) and its high affinity tyrosine kinase B (TrkB) receptors also occurred in the same nuclei during the critical period. As BDNF normally enhances excitatory and suppresses inhibitory synaptic transmission, we wished to test our hypothesis that *in vivo* application of a TrkB agonist (7,8-DHF) will partially reverse the imbalance during the critical period. Using whole-cell patch-clamp recordings, we studied nucleus tractus solitarius (NTS) neurons in brain slices of normal rats and those that received 7,8-DHF *in vivo*. Results indicate that: 1) the amplitude and frequency of spontaneous EPSCs (sEPSCs) in normal NTS neurons were significantly reduced at P12-13; 2) the amplitude and frequency of spontaneous IPSCs (sIPSCs) in normal NTS neurons were significantly increased at P12-13; 3) after 7,8-DHF application *in vivo* (5 mg/kg, i.p. once a day at P10 and P11), the amplitude and frequency of sEPSCs were increased by 35.22% and 44.71%, respectively, during the critical period (P12-P13); and 4) the amplitude and frequency of sIPSCs were decreased by 43.66% and 25.26%, respectively, during the critical period. Thus, our results documented the existence of an excitatory-inhibitory synaptic imbalance within the NTS of normal rats during the critical period. They also substantiated BDNF's role in the synaptic imbalance within respiratory-related nuclei during this time. This may have significant implication for Sudden Infant Death Syndrome (SIDS).

Abstracts: The three phases of mammalian respiration, inspiration (I), post-inspiration (PI), and active expiration (AE), are thought to be generated by interacting neuronal populations along the ventral respiratory column (VRC) that extend bilaterally along the ventral lateral medulla. Computational models based on *in vivo* and *in situ* studies propose that the three phases of breathing are generated by a ring of inhibitory neurons located in the Bötzinger complex and preBötzinger complex (preBötC). This ring requires excitation from the pons. Indeed transverse medullary slices containing only the preBötC fail to generate PI and AE and continue to generate only inspiration. Here we introduce two novel mouse (p5-p10) brainstem slice preparations: a transverse slice containing the BötC, and a horizontal slice that keeps the entire VRC intact bilaterally and maintains phrenic activity to define inspiratory motor output (Fig. 1). Using these *in vitro* approaches we demonstrate that the preBötC forms a contiguous excitatory rhythmogenic column with the BötC. A confined region within the BötC spontaneously generates a PI population rhythm, which can be stimulated with 2μM norepinephrine suggesting that under more intact conditions, noradrenergic input from the pons may excite the PI population. Similar to the preBötC, the BötC can burst rhythmically in an isolated transverse slice indicating that the BötC can function as an independent oscillator. We also demonstrate that 1) blocking glycinergic inhibition in the horizontal slice results in a decreased inspiratory burst duration, while 2) completely eliminating inhibition by the additional application of gabazine results in the synchronization of the two rhythms. Thus, we propose that inhibition is responsible for establishing phase relationships between the preBötC and the BötC, but not the underlying rhythmicity. We conclude that the preBötC is not the only excitatory kernel, but instead forms an excitatory column containing the preBötC and BötC and that similar rhythm generating mechanisms determine rhythm generation along this column.

Title: Optogenetic activation of Glycinergic neurons of the rostral Ventral Respiratory Column inhibits inspiration and affects respiratory phase transition

Authors: *M. G. FORTUNA[1], A.-M. BISCHOFF[1], S. KÜGLER[2], S. HÜLSMANN[1,3];
[1]Neuro- und Sinnesphysiologie, [2]Neurology, Viral Vectors Lab., [3]Anesthesiol., Universitätsmedizin Göttingen, Goettingen, Germany

Abstracts: Neural circuitry controlling breathing in mammals is organized within brainstem compartments, which regulate its own activity by feedback loops, and extend from the pons to the lower medulla. The core network which generates the respiratory rhythm is distributed among adjacent, functional structures of the ventral respiratory column (VRC) in the medulla. We sought to investigate the role of a genetically defined population of Glycinergic neurons of this network, located in the Bötzinger complex (BötC) and the pre-Bötzinger complex (pre-BötC), by combining optogenetics with an *in situ* working heart-brainstem preparation (WHBP). Selective expressions of the Channelrhodopsin-2 (ChR2) in a anatomically defined population of glycinergic neurons was achieved by combining GlyT2-Cre mice (where Cre recombinase is expressed under glycinergic GlyT2 promoter) with Cre-inducible Adeno-Associated Virus (AAV-DIO) vectors. AAV6 virus was stereotactically injected into the rostral part of VRC of adult mice (Tg(Slc6a5-icre)121Veul). After at least 2 weeks of incubation, the effect of blue light stimulation on the inspiratory motor output was assessed in the WHBP by monitoring Phrenic Nerve Discharge (PND). We report here that selective, tonic (30-45s, 33Hz pulses, 50% duty cycle) stimulation of glycinergic neurons of the BötC and pre-BötC resulted in depression of inspiratory frequency of about 40%, independent of the level of baseline activity. The effect on the PND amplitude was much more variable with tendency for potentiation, depended on the level of baseline rhythm with the most pronounced effect on fast, low amplitude respiratory

activity. Burst stimulation (0.9s, 33Hz, at fixed interval) had the capacity to alter, reset and pace the rhythm. This work shows that glycinergic neurons located in the BötC /preBötC area of the VRC are important components of the circuitry controlling breathing; activity of these cells seems to be especially vital for the control of the duration of the expiratory period, transition from inspiration to expiration and the timing of the inspiratory output.

Abstracts: Non-clinical studies in juvenile animal models show that exposure to some anesthetics and sedatives is associated with memory and learning deficits and other neurodegenerative changes in the central nervous system. We examined changes in brain activity in response to breathing 5% CO2 or foot shock in sham operated and stroke rats looking at vascular reactivity and functional coupling at different times following insult. Studies were performed using BOLD imaging on awake animals at 7 Tesla on days 3, 7 and 14 post surgery. Stoke was induced by right medial cerebral arterial occlusion in a 90 min surgical procedure using 5% isoflurane anesthesia. The reduced BOLD signal change in response to foot shock was not unexpected given the severity of the stroke although it was noted that the diminished activity was bilateral and not just confined to the side of the stroke. Most surprising was an unexpected absence in vascular responsivity to CO2 challenge. Data from day 3 indicated both sham and

stroke animals were unresponsive to 5% CO2 challenge that persisted through day 7. On day 14 the changes in brain activity to response to 5% CO2 and foot shock appeared comparable for sham and stroke animals. Raising questions about unanticipated effects of prolonged isoflurane anesthesia during surgery and possible cognitive impairment.

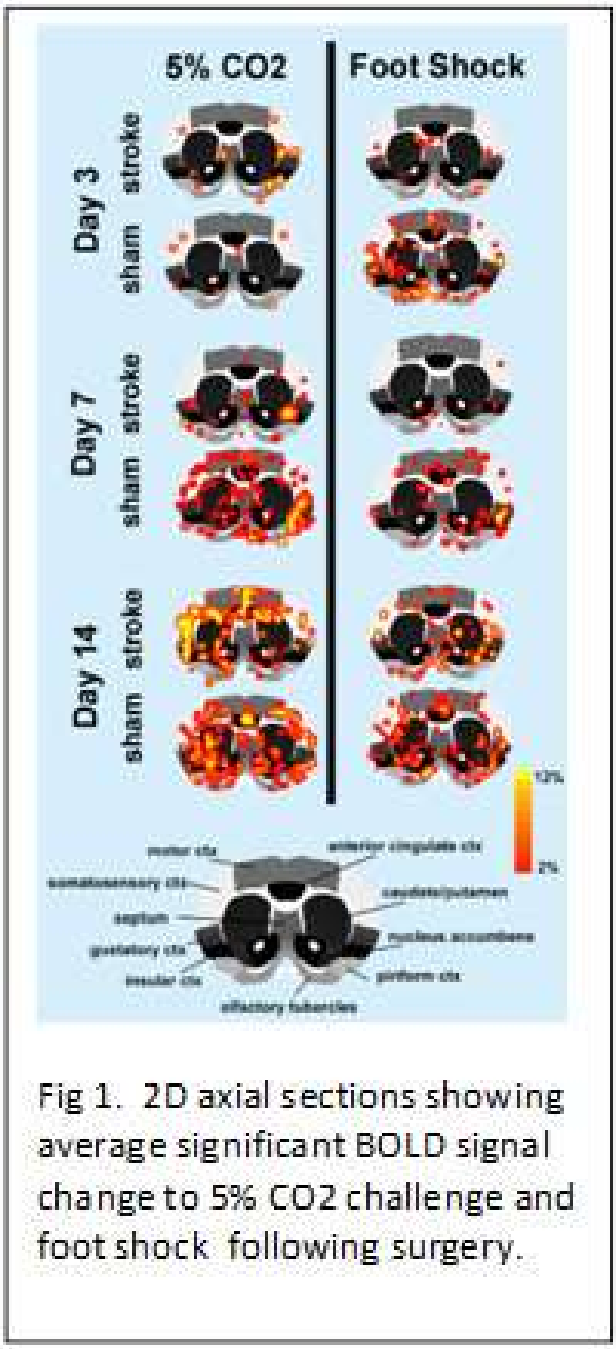

Fig 1. 2D axial sections showing average significant BOLD signal change to 5% CO2 challenge and foot shock following surgery.

Title: The anticipation of respiratory threat impairs performance in a subsequent visual recognition memory task

Authors: *G. JURAVLE[1], P. REICHERTS[2], M. L. WEINSTEIN-RIECHMANN[1], M. J. WIESER[2], A. VON LEUPOLDT[3,1];
[1]Systems Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [2]Univ. of Würzburg, Würzburg, Germany; [3]Univ. of Leuven, Leuven, Belgium

Abstracts: It is well known that cognitive and emotional processes impact the anticipation and perception of bodily threat sensations, such as breathlessness. However, little is known about the reverse influence of breathlessness on cognitive and emotional processes. Here, we investigated how recognition memory (RM) is affected by the perception versus the anticipation of a respiratory threat (resistive-load-induced breathlessness, RLIB). For this, 35 participants were presented with 180 pictures of positive/neutral/negative content under conditions of either constant moderate RLIB, temporally unpredictable highly aversive RLIB anticipation, or an unloaded baseline. Participants were unaware of the subsequent RM test, to which they were subjected approximately 90 minutes later. For the RM test, participants were presented with 180 OLD and 180 NEW pictures of matched emotional content. For each of the pictures, participants indicated by means of button presses whether they have already seen the pictures before (a 'YES' response for the OLD photos) or not (a 'NO' response for the NEW photos). We analyzed RTs, percentages of correct responses, as well as measures of signal detection theory (d prime and criterion c). As expected, both percentages of correct responses and d prime data indicated

that participants' recollection was significantly better for the OLD emotional pictures, as compared to the OLD neutral ones. Furthermore, the same dependent measures indicated that participants remembered significantly fewer pictures that they have previously seen while anticipating the unpredictable respiratory threat, as compared to the conditions of constant RLIB and baseline, with no difference between the latter. Importantly, during the anticipatory condition participants were also significantly more conservative in giving a 'YES' response, as indicated by the criterion c data. Our results thus highlight that the anticipation, and not the perception, of respiratory threat leads to significant decrements in RM for picture stimuli, as well as to a conservative decisional criterion shift. Results such as these suggest that the brain automatizes its response to a perceived respiratory threat. On the other hand, this automatic process is absent for the anticipation of respiratory threat, thus suggesting that the available cognitive processing resources are diminished. These findings are relevant in the light of cognitive deficits in patient groups who frequently anticipate and/or perceive respiratory threat, such as patients with anxiety or severe respiratory disorders (e.g., COPD).

Title: The role of synaptic inhibition in respiratory rhythm and pattern generation in brainstem *in situ*

Authors: *N. KOSHIYA[1], H. KOIZUMI[1], R. ZHANG[1], B. P. MOSHER[1], M. F. TARIQ[1], V. MARCHENKO[2], I. RYBAK[2], J. C. SMITH[1];
[1]Cell. & Systems Neurobio. Section, NIH - NINDS, BETHESDA, MD; [2]Dept. of Neurobio. and Anat., Drexel Univ., Philadelphia, PA

Abstracts: Inhibitory circuit interactions within the pre-Bötzinger (pre-BötC) and Bötzinger (BötC) complexes of the mammalian brainstem have been proposed to play an important role in generating respiratory rhythm and the normal three-phase respiratory pattern, but the exact role of inhibitory interactions in these processes has not been resolved. In this study we tested the role of synaptic inhibition by pharmacologically blocking endogenous GABAergic and glycinergic receptor-mediated inhibition within the active pre-BötC/BötC circuits of arterially perfused brainstem-spinal cord *in situ* preparations from Sprague-Dawley juvenile rats (3-5 wks old). Activities of phrenic and vagus nerves as well as extracellular unit and/or neural population activities in pre-BötC or BötC circuits were recorded and analyzed. The specific blockers of $GABA_A$ (gabazine, 25 μM) and glycine (strychnine, 25 μM) receptors were microinfused together bilaterally into the pre-BötC or BötC regions through glass micropipettes (inner diameter ~15 μm, at ~30 mmHg infusion pressure) for up to 2 min to determine perturbations of respiratory circuit activity. Microinfusion sites were marked and confirmed by *post hoc* histological analyses. Microinfusion of the inhibitory receptor blockers into the BötC or pre-BötC disrupted rhythm generation with site-specific patterns of respiratory activity perturbations. Block of inhibition in the BötC caused a reduction in the amplitude of inspiratory motor activity of all recorded nerves and bradypnea with accompanying prolongation of the expiratory phase (n=9/9) and in many cases cessation of respiratory motor output (apnea, n=5/9). Microinfusion of the inhibitory receptor antagonists into the pre-BötC always elicited progressive tachypnea and decline of inspiratory discharge amplitude (n=9/9), which in some cases led to loss of respiratory motor output. Before loss of inspiratory nerve activity and during recovery from the apnea, the normal three-phase respiratory pattern was disrupted with a loss of post-inspiratory activity in recorded vagus nerve motor output and/or BötC neural activities, and integrated phrenic inspiratory discharge was transformed from a normal ramping pattern to a low amplitude square-wave discharge pattern. These results agree with those obtained in rats *in vivo* (see Marchenko *et al*., this volume). We conclude that GABAergic and glycinergic receptor-mediated inhibition in pre-BötC and BötC circuits plays a major role in the generation of respiratory rhythm and the normal three-phase respiratory pattern in the brainstem respiratory network *in situ.*

Title: The role of synaptic inhibition in respiratory rhythm and pattern generation *in vivo*

Authors: *V. MARCHENKO[1], N. KOSHIYA[2], T. BEZDUDNAYA[1], H. KOIZUMI[2], R. ZHANG[2], I. A. RYBAK[1], J. C. SMITH[2];
[1]Dept Neurobiology/Anatomy, Drexel Univ. Col. of Med., Philadelphia, PA; [2]Cell. and Systems Neurobio. Section, NINDS, NIH, Bethesda, MD

Abstracts: A current model of the respiratory central pattern generator (Smith et al. 2007, 2013) suggests an important role of inhibitory circuit interactions within and between the pre-Bötzinger (pre-BötC) and Bötzinger (BötC) complexes in generating respiratory rhythm and the normal three-phase respiratory pattern. Janczewski et al. (2013) have challenged this suggestion, and the exact role of inhibitory interactions in respiratory rhythm and pattern generation *in vivo* remains unclear. In this study, we tested the role of synaptic inhibition within pre-BötC/BötC circuits for respiratory rhythm and pattern generation *in vivo* by imposing pharmacological blockade of endogenous GABAergic and glycinergic receptor-mediated inhibition within these regions. We used anaesthetized (1.75-2% isoflurane in O2), paralyzed, vagotomized, chemo-/baro-denervated, and artificially ventilated adult male Sprague-Dawley rats. Activities of hypoglossal, vagus, and phrenic nerves were recorded and analyzed. By a ventral surface approach, the specific blockers of GABAA (gabazine) and glycine (strychnine) receptors were bilaterally microinfused in mixed solutions (250 μM of each, 110 nl total volume infused) into the pre-BötC (n=9 rats) and BötC (n=12 rats). Microinfusion sites were marked with yellow-green beads and confirmed by post hoc histological analyses. Bilateral microinfusion (1-2 min.) of gabazine and strychnine into the BötC or preBötC disrupted rhythm generation with site-specific patterns of respiratory activity perturbations. Block of inhibition in the BötC caused either severe bradypnea (mean inspiratory frequency=25.32% of control, n=2/12 rats) or in most cases bradypnea followed by apnea (n = 10/12 rats), whereas microinfusion of the antagonists into the pre-BötC elicited a transient tachypnea (90.82±53% increase of inspiratory frequency, n=9 rats) with a progressive decline of inspiratory discharge amplitude in all recorded nerves and complete suppression of respiratory motor output in 6/9 rats. Prior to the loss of inspiratory nerve activity and during recovery, the normal three-phase respiratory pattern was also disrupted with a loss of post-inspiratory activity on the vagus nerve and change in pattern of integrated inspiratory discharge from a ramping pattern to a low amplitude square-wave pattern. These results agree with those obtained in perfused brainstem preparations *in situ* (see Koshiya et al., this volume). We conclude that GABAergic and glycinergic receptor-mediated inhibition within and between

pre-BötC and BötC circuits plays a major role in the generation of respiratory rhythm and the three-phase respiratory pattern *in vivo*.

Title: Involvement of P2Y purinergic receptors in the nucleus of the solitary tract on the respiratory responses induced by hypoxia

Authors: *N. MARQUES, J. V. MENANI, P. M. DE PAULA;
Dept of Physiol. and Pathology, Dent. School, UNESP, Araraquara, Brazil

Abstracts: Cardiorespiratory responses to hypoxia are controlled by brainstem areas including the nucleus of the solitary tract (NTS). Bilateral injections of suramin (non-selective purinergic receptor antagonist) into the NTS reduced hypoxia-induced hyperventilation, whereas bilateral injections of PPADS (P2 purinergic receptor antagonist) into the NTS did not change cardiorespiratory responses to hypoxia. Nevertheless, the participation of P2Y purinergic receptors of the NTS on the cardiorespiratory responses induced by hypoxia is still unknown. Therefore, in the present study, we investigated the involvement of P2Y purinergic receptors of the NTS on cardiorespiratory responses induced by hypoxia in awake rats, using injections of MRS 2179 (selective P2Y purinergic receptor antagonist). Male Holtzman rats (290-310 g, n=4-6/group) with stainless steel cannulas implanted into the NTS were used. A polyethylene tubing (PE-10 connected to a PE-50) was inserted into abdominal aorta through femoral artery to record mean arterial pressure (MAP) and heart rate (HR) in awake rats. Respiratory frequency (fR), tidal volume (VT) and VE were recorded by whole-body plethysmography. VE, fR, VT, MAP and HR were recorded before and after bilateral injections of saline or MRS 2179 (1 nmol/100 nl) into the NTS during hypoxia (7% O2 for 35 min). Hypoxia reduced MAP (100 ± 3 mmHg,

vs. normoxia: 117 ± 4 mmHg, p <0.05) and HR (382 ± 14 bpm, vs. normoxia: 441 ± 15 bpm, p<0.05) and increased VE (992 ± 44 ml/min/kg, vs. normoxia: 488 ± 28 ml/min/kg, p<0.05). Bilateral injections of MRS 2179 into the NTS reduced VT during hypoxia (6.6 ± 0.4 mL/kg, vs. saline: 7.8 ± 0.2 mL/kg, p=0.028) and hypoxia-induced hyperventilation (804 ± 77 ml/min/kg, vs. saline: 992 ± 44 ml/min/kg, p=0.04), without changing tachypnea (122 ± 7cpm, vs. saline: 128 ± 4 cpm), MAP (99 ± 2 mmHg, vs. saline: 100 ± 3 mmHg) or HR (446 ± 23 bpm, vs. saline: 441 ± 15 bpm) during hypoxia. The present data show that P2Y purinergic receptors in the NTS are involved in the respiratory responses induced by hypoxia.

Title: Medullary catecholaminergic (CA) neurons modulate hypoxic ventilatory response in neonatal rats (P7-8)

Authors: ***L. A. PATRONE**, V. BIANCARDI, K. C. BÍCEGO, L. H. GARGAGLIONI; SAO PAULO STATE UNIVERSITY, JABOTICABAL, Brazil

Abstracts: It is known that catecholaminergic (CA) neurons are involved in autonomic and respiratory regulation during low O_2 conditions in adult mammals. We evaluated the participation of medullary CA neurons of male and female neonatal rats (P7-8) in mediating the hypoxic ventilatory response (HVR) by specifically lesioning them with antidopamine beta-hydroxylase-saporin (DBH-SAP, 42ng / 100nL) injected into the 4th ventricle. We also quantified rates of O_2 consumption (VO_2) of control and lesioned neonates (P7-8) exposed to hypoxia. Minute ventilation (VE) of neonates was recorded by pressure-plethysmography from the body chamber during normoxia and hypoxia (10% O_2), and the VO_2 measurement by open flow respirometry. The mammalian HVR typically results in increased VE upon exposure to acute hypoxia. HVR was significantly reduced in male and female lesioned neonatal rats by

about 23 and 15%, respectively, (male- control group: 137.3±7.9 (% of baseline) vs. lesioned group: 105.3±2.4 (% of baseline), $p<0.01$; female- control group: 127.0±3.0 (% of baseline) vs. lesioned group: 108.6±1.7 (% of baseline) $p<0.02$). The VO_2 was decreased in the lesioned newborns, but only the lesioned male group was significantly lower (control group: 76.8±12.14 (% of baseline) vs. lesioned group: 45.3±13.3 (% of baseline) $p<0.03$). These results suggest that catecholaminergic neurons, specifically from medullary nuclei, exert an excitatory modulation of O_2 chemosensitivity in neonatal rats.

Title: HCN channels contribute to serotonergic modulation of ventral surface chemosensitive neurons and respiratory activity

Authors: *V. E. HAWKINS[1], J. M. HAWRYLUK[1], A. C. TAKAKURA[2], T. S. MOREIRA[3], A. V. TZINGOUNIS[1], D. K. MULKEY[1];
[1]Physiol. and Neurobio., Univ. of Connecticut, Storrs, CT; [2]Dept. of Pharmacol., Univ. of Sao Paulo, Sao Paulo, Brazil; [3]Dept. of Physiol. and Biophysics, Univ. of Sao Paulo, Sao Paolo, Brazil

Abstracts: Chemosensitive neurons in the retrotrapezoid nucleus (RTN) provide a CO_2/H^+-dependent drive to breathe. They also function as an integration center for multiple brain regions involved in respiration, including serotonergic medullary raphe neurons. We recently showed that serotonergic modulation of RTN chemoreceptors involved inhibition of KCNQ channels and activation of an unknown inward current. HCN channels are the molecular correlate of the hyperpolarization-activated inward current (Ih) and have a high propensity for modulation by

neurotransmitters including serotonin. Therefore, we hypothesize that HCN channels contribute to serotonergic modulation of RTN chemosensitive neurons. To investigate this possibility, we characterized effects of serotonin on activity of RTN chemoreceptors *in vitro*, and on respiratory motor output of both anesthetized and awake rats, under control conditions and in the presence of a specific KCNQ channel blocker (XE991) and/or a specific HCN channel blocker (ZD7288). *In vivo*, phrenic nerve recordings show that unilateral RTN injection of XE991 alone blunted the ventilatory response to serotonin by ~50%, and XE991 plus ZD7288 together eliminated the serotonin responsive. In the brainstem slice preparation, cell-attached current-clamp recordings from chemosensitive RTN neurons show that bath application of XE991 decreased excitatory effects of serotonin by ~50%, and residual serotonin-sensitivity in XE991 was eliminated by blocking HCN channels with ZD7288 or CsCl, or by inhibition of adenylate cyclase with SQ22536. In the whole-cell voltage-clamp configuration (Ihold = -60 mV; TTX) chemosensitive RTN neurons exposed to serotonin showed a depolarizing shift in the voltage-dependent activation of Ih, as expected for cAMP-mediated activation of HCN channels. Further, a 5-HT_7 receptor agonist (5-carboxamidotryptamine; 5-CT) mimicked serotonin-mediated activation of RTN chemoreceptors and the 5-CT response was blocked by a selective 5-HT_7 receptor antagonist (SB258719). Together, these results suggest that serotonin modulates respiratory drive at the level of the RTN in part by activation of HCN channels.

Title: Muscarinic cholinergic mechanisms within the retrotrapezoid nucleus modulate breathing without changing CO2 chemosensitivity

Authors: *C. R. SOBRINHO[1], A. C. TAKAKURA[2], I. C. WENKER[3], T. S. MOREIRA[5], D. K. MULKEY[4];

[1]Dept. of Physiol. and Biophysics, Univ. of Sao Paulo, Sao Paulo, Brazil; [2]Inst. of Biomed. Science, Univ. of Sao Paulo, Pharmacol., Sao Paulo, Brazil; [3]Physiol. and Neurobio., [4]Physiol. and Neurobiology,, Univ. of Connecticut, Storrs, CT; [5]Physiol. and Biophysics, Inst. of Biomed. Science, Univ. of São Paulo, São Paulo, SP, Sao Paulo, Brazil

Abstracts: The retrotrapezoid nucleus (RTN) contains neurons that regulate breathing in response to changes in tissue CO_2/H^+ (central chemoreceptors). Previous evidence suggests that cholinergic transmission within the RTN contributes to the chemoreflex; however, cellular and molecular mechanisms underlying cholinergic-modulation of breathing are still unknown. Here, we used *in vivo* and *in vitro* experiments to evaluate effects of exogenous administration of acetylcholine (Ach) on baseline activity and CO_2-sensitivity of RTN chemoreceptors, and to dissect the signaling pathway by which Ach activates these neurons. *In vivo* non-anesthetized adult Wistar rats, unilateral injection of Ach into the RTN increased ventilation and MAP under control conditions but not after pre-treatment with the muscarinic antagonist atropine. *In vitro*, cell-attached recordings of membrane potential show that Ach directly activates CO_2/H+-sensitive RTN neurons, and this response could be substantially attenuated by various specific and nonspecific muscarinic antagonists (atropine, 4DAMP and pirezenpine). The effects of Ach on RTN chemoreceptor activity was also blunted by inhibition of IP3-receptors with 2APB and by a casein kinase 2 inhibitor (TBB), but not by a PKC inhibitor (SKF-96365) or a cation channel blocker (flufenamic acid). Finally, both *in vivo* and *in vitro* experiments show that the muscarinic antagonist does not change CO_2 responses. These results suggest that Ach stimulates RTN chemoreceptors by activation of M1 and/or M3-receptors and an IP3-mediated activation of CK2 without directly influence on chemosensitivity. The ion channel targets of Ach have yet to be determined.

Title: Slow oscillations require a balance between the linear negative-slope conductance region of a regenerative inward current and persistent outward currents

Authors: *Y. GUAN[1], A. BOSE[2], J. GOLOWASCH[3], F. NADIM[3];
[1]Rutgers Univ., Newark, NJ; [2]New Jersey Inst. of Technol., Newark, NJ; [3]Rutgers Univ. and NJIT, Newark, NJ

Abstracts: Slow oscillations underlying neuronal bursting commonly involve a regenerative inward ionic current with a nonlinear inverted bell-shape IV curve. In the crab pyloric central pattern generator, multiple peptidergic modulatory inputs activate the regenerative inward current IMI in several pyloric neurons, which is critical for the generation of neuronal oscillations. Our recent work suggests that the contribution of such regenerative currents to the production of oscillations is limited to the region of the IV curve in which the current exhibits a linear negative-slope conductance (INL). When INL is introduced with dynamic clamp in the pyloric pacemaker PD neurons, it can recover oscillations, even when the neuron is isolated by TTX (Bose et al, 2014). However, it is unknown whether other pyloric neurons can produce oscillations in the presence of INL and, if not, what factors determine the ability of INL to produce them. We examined whether, in the presence of TTX, INL is sufficient for producing slow oscillations in synaptically-isolated pyloric neurons. We found that the PD neuron can produce INL-induced oscillations in a range of gNL (40-300 nS) and ENL (-15 to +15 rel. to Vrest) values. The oscillation frequency (1.1-1.8 Hz) in PD increased, and its amplitude (30-10 mV) decreased with |gNL|, but both frequency and amplitude had a non-monotonic dependence on ENL `(13/13 cases). In contrast to the PD neuron, even when gNL and ENL were varied in a large range, none of the follower pyloric neuron types PY (0/6), LP (1/8), IC (0/3), VD (0/3), LPG (0/3) could produce slow oscillations with INL. We explored what factors may oppose the expression of oscillations in LP neurons in the presence of INL. Our previous modeling work suggests that INL-induced oscillations depend on a balance between INL and the voltage-gated outward currents (Bose et al, 2014). We therefore compared the outward currents in the PD and LP neurons. We found that the LP neuron has a significantly larger high-threshold K current (IHTK: delayed rectifier + Ca-dep. K currents) than PD (20% larger at 0 mV), and that PD has a larger IA than LP (45% larger at 0 mV). However, the kinetics of IHTK and IA were statistically identical in PD and LP. We thus examined whether changing the levels of IHTK and IA would affect the ability of PD or LP to oscillate with INL. We found that LP can oscillate with INL by reducing IHTK using TEA (N=4). However, preliminary results using the blocker 4AP indicate that IA does not contribute to PD oscillation in INL (N=2). We conclude that slow oscillations in a neuron require a balance of the negative-slope conductance region of the regenerative inward current with the high threshold outward currents.

Title: Neonatal mortality in CPEB2 knockout mice reveals its physiological function in respiratory regulation

Authors: Y.-T. LAI[1,2], *Y.-S. HUANG[1];
[1]Academia Sinica/Institute of Biomed. Sci., Taipei, Taiwan; [2]Grad. Inst. of Microbiology, Natl. Taiwan Univ., Taipei, Taiwan

Abstracts: Cytolasmic polyadenylation element binding protein (CPEB2) is an RNA-binding protein and translational regulator. To understand the physiological function of CPEB2, we generated CPEB2 knockout (KO) mice and found most of the KO animals died within three days after birth. CPEB2 is highly expressed in the brainstem which controls vital life functions such as breathing and heartbeat. Using the ultrasound and whole body plethymography, we found the KO pups had normal heart rate but abnormal respiration with increased apnea. Nevertheless, the anatomical morphology of the respiratory center (i.e. pre-Botzinger complex and parafacial respiratory group) and the respiratory-like activity electro-recorded from C4 ventral roots *in vitro* are comparable between WT and KO littermates, indicating the apnea episodes in the KO neonates are unlikely caused by rhythm-generating failure. Immunohistochemical analyses only identified up-expressed choline acetyltransferase (ChAT) in the dorsal motor nucleus of vagus (DMNV) of the KO neonates. Many abnormalities have been found in the DMNV of SIDS (sudden infant death syndrome) infants. Because neurons in DMNV control bronchoconstriction via acetylcholine release, these SIDS infants are likely died of DMNV-related airway obstruction. Intriguingly, characterization of respiratory patterns recorded under hypercapnia also reveals the KO neonates have increased airway resistance. Therefore, the elevated cholinergic transmission-induced airway obstruction in the KO neonates likely accounts for their respiratory defect and mortality.

Title: Topical application of D-serine on raphe nuclei and ventral respiratory column increases fictive respiration in slices from mouse neonates

Authors: *S. BELTRAN-CASTILLO, I. LLONA, J. EUGENIN;
Biología, Univ. De Santiago De Chile, Santiago, Chile

Abstracts: We have reported that D-serine, an endogenous co-agonist for NMDAr in CNS, modulates fictive respiration in *in vitro* preparations from mouse neonates. Superfusion with D-serine increases the frequency of fictive respiration in a concentration-dependent way, reaching up to 150% of basal frequency in en bloc and in medullary slices. We have also showed that pre-incubation with D-aminoacid oxidase reduces slightly the effect of hypercarbia upon the respiratory rhythm, suggesting a role of D-serine as a mediator of respiratory response to hypercarbia. Now we have tested the effect of local application of D-serine on different brainstem nuclei to define possible sites of D-serine action. Spontaneous activity from the ventral respiratory column (VRC) was recorded with glass suction electrodes from medullary slices obtained from neonatal CF1 mice (P0-P4).Superfusion was done with artificial cerebrospinal fluid (aCSF) equilibrated with O2:CO2 = 95%: 5%, (pH 7.4, 29 ±1°C). D-serine or vehicle (aCSF) was applied locally into the brainstem nuclei using a borosilicate glass capillary (0.75 mm inside diameter and tip diameter of 3.75 µm) filled with D-serine 100 µM using pulse pressure generated with a pneumatic picopump (3 psi, 10 s). D-serine applied into raphe nuclei (RN) and VRC increased the frequency of fictive respiration up to 127% of basal frequency (n=5) and up to 131% (n=4), respectively. Microinjection with vehicle did not alter the basal frequency of fictive respiration. Our preliminary results indicate that D-serine can increase the frequency of fictive respiration acting directly on VRG or RN. Since both nuclei are chemosensitive, these results support the idea that D-serine may be a mediator of the respiratory response to hypercarbia

Title: Assessing the role for murine KCNQ5 in opioid suppression of respiratory drive: KCNQ5 genomic editing by CRISPR/Cas9

Authors: *A. D. WEI, P. WAKENIGHT, T. ZWINGMAN, K. J. MILLEN, J.-M. RAMIREZ; Ctr. for Integrative Brain Res., Seattle Children's Res. Inst., Seattle, WA

Abstracts: Reduced respiratory drive is a major cause of morbidity from opioid-based medications and drugs of abuse. Clinically, respiratory failure during post-operative surgical recovery can be a significant risk factor, limiting therapeutic options with existing opioid analgesics. Identifying molecular mechanisms that modulate opioid-mediated suppression of respiratory drive may provide novel targets for pharmaceutically augmenting respiratory drive and reversing opioid-mediated respiratory suppression (ORS), without compromising analgesic efficacy. We combined electrophysiological and genetic approaches to dissect the mechanism of ORS in mice. Contrary to expectation, we observed no significant contribution to respiratory suppression from opioid-mediated activation of GIRK potassium channels, nor from blocking large-conductance calcium-activated BK potassium channels. Instead, using selective pharmacology and electrophysiological recordings of fictive respiration from medullary slices containing the preBötzinger Complex (pBötC), we identified a subclass of non-canonical KCNQ potassium channels (KCNQ5), as a major target for modulating ORS by mu-opioid receptor activation. Genetic removal of CaV2.1 (CACNA1) which likely mimics mu-opioid-mediated suppression of P/Q calcium channel function compromised respiratory rhythm generation, consistent with a predominantly presynaptic locus for opioid-mediated suppression of central respiratory drive. We hypothesize that KCNQ5 serves to set basal neuronal excitability within pBötC respiratory circuits, and that blockers of KCNQ5 may override ORS due to opioid-mediated suppression of presynaptic function. To further test this hypothesis, we used CRISPR/Cas9 technology to target the murine KCNQ5 locus for genomic editing. Cas9/sgRNA constructs targeting exon 5 of KCNQ5 were transfected into Black Swiss/C57BL6 ES cells, and 19 clones were selected for molecular analysis. 89% (17/19) of these clones yielded deletions of the targeted exon detectable by T7 endonuclease assays. Sequence analysis of 7 selected clones revealed biallelic deletions in 6/7 clones ranging from 1 to 459 bps (mode=~20 bps), biased

towards the 5' side the targeted PAM site. Animals derived from these ES cells, with expected loss-of-function have been generated. We anticipate generating additional gain-of-function and GFP-fusion alleles of KCNQ5 by using similar CRISPR/Cas9 techniques. Analysis of these strains for opioid-mediated respiratory suppression will complement our pharmacological studies, and provide genetic evidence of our hypothesis of opioid suppression of pBötC circuit function.

Title: Opioidergic modulation of breathing revealed by naloxone application in the sagittaly sectioned rat hindbrain preparation

Authors: ***N. M. MELLEN**[1], B. GOURÉVITCH[2];
[1]Kosair Children's Hosp Res. Inst., Univ. Louisville, LOUISVILLE, KY; [2]UMR CNRS 8195, Université Paris-Sud, Orsay, France

Abstracts: Opioid receptors are broadly distributed along the respiratory column in ventrolateral medulla, and exogenous opioids have a profound effect on breathing. Less is known about how endongenous opioids interact with other neuropeptides and neurotransmitters to modulate breathing. Here, recordings were carried out from isolated, parasagittally sectioned medulla-spinal cord preparations (P0-P2, n=10) before and during bath administration of the opioid receptor antagonist naloxone (NAL; 10 μM). At the system level, NAL significantly shortened inspiratory duration and significantly increased inspiratory variability. In parallel with system-level recording, network activity was recorded optically using the medium affinity Ca2+ indicator fluo 8L (Kd=1.86 μM; AAT Bioquest), which permitted recording with single neuron resolution from local networks along the respiratory column at 45.5 Hz. Coupling between neuron pairs was inferred from changes in spike rate, estimated by deconvolving Ca2+ traces. A total of 309 neurons were recorded (control n=249, NAL n=201, match n= 142). Neurons were divided into 3 groups based on the effect of NAL on coupling relations: neurons whose (generally weak) coupling was unchanged by NAL (group 1); neurons with strong driver

coupling under control conditions that were transformed into weak followers under NAL (group 2); and neurons with weak follower coupling that were transformed into strong drivers under NAL (group 3). This consistent NAL-induced reconfiguration across preparations suggests that coupling relations between respiratory network constituents along the VRG are state-dependent, and are in part determined by endogenous opioid modulation.

Title: Control of the hypercapnic chemoreflex by Locus coeruleus noradrenergic neurons in female rats

Authors: ***M. B. DIAS**[1], D. C. DOURADO[2], J. ANSELMO-FRANCI[3], R. E. SZAWKA[4], K. C. BÍCEGO[2], L. H. GARGAGLIONI[2];
[1]Dept. of Physiol., UNESP, Botucatu, Brazil; [2]Dept. of Animal Morphology and Physiol., UNESP-FCAV, Jaboticabal, Brazil; [3]Dept. of Morphology, Physiol. and Pathology, Univ. of Sao Paulo, Ribeirao Preto, Brazil; [4]Dept. of Physiol. and Biophysics, Inst. of Biol. Sciences, Federal Univ. of Minas Gerais, Belo Horizonte, Brazil

Abstracts: The Locus coeruleus (LC) has been suggested as a CO2 chemoreceptor site. However, most of the studies involving the role of LC in hypercapnic ventilatory response have been performed in males. Ovarian steroids modulate the activity of LC neurons and females have a different respiratory response to CO2 comparing to males. Thus, we evaluated the c-Fos expression of LC noradrenergic neurons during normocapnia and hypercapnia in diestrus ovariectomized (OVX) and estradiol-treated ovariectomized (OVX+E2) female rats, and in intact orchidectomized (ORX), testosterone-treated orchidectomized (ORX+T) and estradiol-treated orchidectomized (ORX+E2) male rats. Double-staining was performed to show the presence of

tyrosine hydroxylase. In addition, we investigated the effect of noradrenergic LC neurons lesions in OVX and OVX+E2 females, by using 6-hydroxydopamine, in the hypercapnic chemoreflex. Hypercapnia (7%CO2) increased the double-staining in LC neurons in all groups comparing to air. In the OVX+E2 group there was attenuation in the c-FOs expression in normocapnia and hypercapnia. The hypercapnic ventilatory response was significantly decreased in 6-OHDA-lesioned rats compared with sham group (29.4% in OVX group and 28.7% in OVX+E2 group). Thus, we can conclude that noradrenergic neurons in the LC of female and male rats are activated by CO2 and play a role in the hypercapnic ventilatory response. Further, our results suggest that estradiol inhibits the activation of LC noradrenergic neurons during hypercapnia but does not change the hypercapnic ventilatory response probably due to compensatory mechanisms from other chemosensitive sites.

Title: Gender differences in hypoxic acclimatization in cyclooxygenase-2 deficient mouse

Authors: ***K. XU**[1], X. SUN[2], C. P. TSIPIS[2], G. F. BENDERRO[2], J. C. LAMANNA[2];
[1]Dept Neurol., [2]Dept Physiol. & Biophysics, Case Western Reserve Univ., CLEVELAND, OH

Abstracts: Cyclooxygenase-2 (COX-2) is the inducible isoform of cyclooxygenase, the key rate-limiting enzyme in the prostaglandin biosynthesis pathway, which is known to be involved in many physiological and pathological processes including inflammation and angiogenesis. In this study we used COX-2 deficient mouse to investigate the role of COX-2 in acclimatization responses to prolonged hypobaric hypoxia. Age-matched wide-type (WT) and COX-2 knockout (KO) mice including both sexes were exposed to the equivalent of 8% O2 at sea level for up to 21 days in a hypobaric chamber at a pressure of 300 mmHg (0.4 ATM); littermate controls were kept normoxic in the same location to ensure identical ambient condition. Capillary density were determined in brains at 21 days of exposure; in separated groups of animals, blood and tissue

samples were collected at different time points of exposure for measurement of hematocrit and Western blot analysis for hypoxic inducible factor -1α (HIF-1α), vascular endothelial growth factor (VEGF) and erythropoietin (EPO). Results showed that there was no gender difference in hypoxic acclimatization in the WT mice; however, male COX-2 KO mice exhibited increased vulnerability to prolonged hypoxia; the female COX-2 KO mice had similar adaptive responses compared to the WT mice. At 21 days of exposure, the survival rate in the male KO group was 58% (8/14), which was significantly lower than that of the male WT group (100%, 21/21); the survival rate in the female KO group was similar to that of the WT mice (94%, 15/16 vs. 100%, 21/21). Compared to the WT and female COX-2 KO mice, during hypoxia, the erythropoietic response in kidney and polycythemic response were decreased in the male COX-2 KO mice. Cerebral vascular remodeling through angiogenesis is the major CNS acclimatization response to prolonged hypoxia. We observed that the baseline capillary density was similar in the WT and the COX-2 KO mice. The capillary density in brain cortex was increased about 20% after 21 days of hypoxia in the WT mice and female COX-2 KO mice; however, there was no hypoxia-induced angiogenesis in the male COX-2 KO mice. In addition, absence of COX-2 resulted in attenuated HIF-1α accumulation during hypoxia, which correlated a response deficit in downstream gene expressions of EPO and VEGF. Our data suggest that there is gender difference in hypoxic acclimatization in the COX-2 deficient mice, absence of an adaptive response in the male COX-2 deficient mice highlights the importance of COX-2 signaling pathway as a requirement for adaptive response to oxygen limiting environments in the males.

Title: Effects of isoflurane and caffeine on breathing in mice during the neonatal period

Authors: *C. A. MASSEY[1], Y. WU[1], K. R. CHIRCO[2], S. M. HARMAN[1], G. B. RICHERSON[1];

[1]Neurol., Univ. of Iowa Hosp. and Clinics, Iowa City, IA; [2]Biosci. Grad. Program, Univ. of Iowa, Iowa City, IA

Abstracts: Isoflurane is a commonly used anesthetic in both research and clinical settings. Isoflurane-induced breathing depression in infants, especially premature infants, has been well documented. In fact, anesthesia-induced apneas are a common problem in the neonatal intensive care unit and frequently require intubation. Previously, our laboratory has shown that isoflurane severely depresses CO_2 chemoreception due in part to inhibition of serotonin (5-HT) neurons. It is important to understand the underlying mechanisms for why this depression of baseline breathing is seen in neonates, but not adults. We used whole animal plethysmography to study the effects of isoflurane (1%) on breathing in mice at two different ages – postnatal day 1 (P1) and postnatal day 8 (P8). Experiments were performed in a chamber held at an ambient temperature of 30 °C. Relative minute ventilation (VE) was expressed in arbitrary units since body temperature was not measured from animals this young. We found that *Lmx1b*$^{f/f/p}$ mice, in which 5-HT neurons have been genetically deleted, at the age of P1 had decreased relative VE (0.85 ± 0.36; n=23) in 21% O_2/Balance N_2 compared to wild type (WT) littermates (2.33 ± 0.56; n=21). Isoflurane (1%) depressed relative VE in both WT (0.63 ± 0.12; n=21) and *Lmx1b*$^{f/f/p}$ (0.49 ± 0.10; n=23) mice. However, isoflurane had a more potent effect on WT mice as their relative VE decreased 71.97 ± 6.12% (n=21) compared to only 37.47 ± 15.34% in *Lmx1b*$^{f/f/p}$ mice (n=23). After washout of the drug, relative VE in WT mice increased but did not return to baseline (1.24 ± 0.46; n=21). *Lmx1b*$^{f/f/p}$ mice did not recover from isoflurane (0.60 ± 0.19; n=23). We then tested the same mice one week later at P8, and found that isoflurane had less of an effect on baseline breathing in both WT and *Lmx1b*$^{f/f/p}$ mice than it did at P1. In WT mice at P8, relative VE was reduced in isoflurane by 38.62 ± 18.26% compared to 71.97 ± 6.12% at P1. Furthermore, after washout the relative VE of these mice returned to baseline at P8. These data indicate that isoflurane induces hypoventilation at baseline in the early neonatal period, but this effect decreases as mice age. Furthermore, these results suggest that 5-HT neurons play a role in isoflurane-induced hypoventilation. Caffeine is used to treat neonatal apnea and hypoventilation, so we are now investigating whether it has similar effects in mice. Preliminary data (n=2) indicate that neonatal exposure to caffeine increases breathing and may counteract isoflurane-induced hypoventilation.

Title: Impact of chronic intermittent hypoxia on hippocampal neuronal function: An *in vivo* recording study

Authors: ***L. XU**[1], Q. LI[1], Y. KE[2], W. YUNG[2];
[1]The Chinese Univ. of Hong Kong, Hong Kong, China; [2]The Chinese Univ. of Hong Kong, Hong Kong, Hong Kong

Abstracts: Chronic intermittent hypoxia (IH) occurs in obstructive sleep apnea (OSA), a very common sleep and breathing disorders that is associated with central nervous system dysfunction, including learning and memory impairment. Despite the obvious importance, the question of exactly what happens to neuronal activities in different brain regions during intermittent hypoxia has never been addressed. We envision that long-term recording of the firing activities of neurons and brain rhythms *in vivo* during and after the IH will provide direct information to address this question and thus considerable insight into the cause of cognitive dysfunctions in OSA. Based on a well-established OSA model in which the rats were subject to daily 8-hr cycling of oxygen between 21% and 10% every 90s, the firing activities of neurons in the CA1 region of the hippocampus were followed for 14 days by chronically implanted multi-electrode arrays. We found that both CA1 principal neurons and interneurons tended to increase their firing activities during the first week of IH treatment, particularly apparent at the late hours (at 8 h) but not early hours (at 5 min and 3 h) of daily IH paradigm. The hyper-excitability, however, was followed by gradual suppression of firing in the second week. At Day 14, the firing rates of principal neurons and interneurons were typically less than 60% and 25%, respectively of those at Day 1. These profiles paralleled the increase in long-term potentiation magnitude at Day 2 and its suppression in the second week of IH treatment measured from acutely prepared hippocampal slices. Partial recovery of the neuronal activities was found after 1-week recovery in normoxia but confined to principal neurons only. Interestingly, analysis of the field potential revealed that the hippocampal theta rhythm (4-8 Hz) was diminished by chronic IH with no sign of recovery 1 week after the IH treatment. Together, these data suggest that hippocampal neurons respond to short-term hypoxia treatment by boosting their activities. However, long term IH impairs the firing activities, suppresses synaptic plasticity and related theta rhythm, which is more likely contributed by impaired functions of interneurons than pyramidal neurons. These results provide the cellular function correlates of the memory deficit observed in OSA subjects.

Title: Perinatal exposure to fluoxetine diminishes the respiratory response to hypercarbia *in vivo* and *in vitro* in mouse neonates

Authors: *K. A. BRAVO, J. EUGENÍN, I. LLONA;
Univ. De Santiago De Chile, Santiago, Chile

Abstracts: Serotonin (5HT) is known to play a principal role during development of SNC in mice (Gaspar et al., 2003, Nat. Rev. Neurosci. 4: 1003). We have reported that ventilatory response to hypercarbia at P8 (postnatal age) is reduced in mouse neonates exposed to fluoxetine (specific 5HT reuptake inhibitor) during pregnancy and early postnatal age (Bravo et al., 8th FENS Forum Neuroscience, 2012). Serotoninergic neurons of raphe nucleus are chemosensitive i.e. stimulated by hypercapnia *in vivo* and by acidosis *in vitro*. In the present work we investigated the effect of fluoxetine treatment on a) the CO2-induced activation of raphe neurons *in vivo* and b) the changes in fictive respiration induced by acidosis using the medullary slice preparation. Three experimental groups were used: neonates born from CF-1 dams to which were implanted with osmotic minipumps delivering fluoxetine (7mg Kg-1 day-1) or saline from the fifth day of gestation up to day 14 postnatal A third group consisted of neonates born from dams not receiving any minipump. We used c-Fos immunocytochemistry to assess neuronal activation by hypercapnia (20 minutes of inhalation air enriched with 10% CO2). Fictive respiratory activity was recorded from the ventral respiratory group in medullary slices at P8. Acidosis was obtained by switching the artificial cerebrospinal fluid equilibration from 5 to 10% CO2 (pH 7.4 to 7.2). Fluoxetine decreased the number of c-Fos positive neurons induced by hypercapnia in the raphe and tractus solitarius nuclei, but not in the hypoglossal nucleus. In slices from P8

neonates, fluoxetine reduced the increase in the frequency of fictive respiration induced by acidosis. In contrast, in sham operated and intact mice no detrimental effects were observed. Our results suggest that fluoxetine treatment during perinatal period alter central chemosensory responses of raphe nucleus during the postnatal life.

Title: Altered insular resting-state functional connectivity in patients with obstructive sleep apnea

Authors: *B. PARK[1], N. TOMA[2], P. M. MACEY[3,4], M. A. WOO[3], F. L. YAN-GO[5], R. M. HARPER[2,4], R. KUMAR[1,4,6];
[1]Anesthesiol., [2]Neurobio., [3]Sch. of Nursing, [4]Brain Res. Inst., [5]Neurol., [6]Radiological Sci., Univ. of California at Los Angeles, Los Angeles, CA

Abstracts: Obstructive sleep apnea (OSA) is accompanied by brain tissue injury and dysfunction in regions that regulate autonomic and motor actions. Brain injury appears in various sites, including insular cortices, which may play important roles in serving these deficient functions through altered functional connections with other brain regions; however, integrity of insular functional connectivity in OSA remains unclear. Our aim was to assess the resting-state functional connectivity (FC) of insular cortices to other brain areas in newly-diagnosed, treatment-naïve OSA compared to control subjects. We acquired resting-state functional MRI data from 47 OSA (age, 46.9±9.0 years; Females, 11; BMI, 30.4±5.2 kg/m2; AHI, 31.8±21.1 events/hr), and 59 control subjects (46.18±8.13 years; 18; 24.8±3.8kg/m2), using a 3.0 Tesla MRI scanner. Data were processed using SPM8 with standard procedures, canonical nuisance signals were removed by regression, and data band-pass filtered. Using left and right insula seed regions, we calculated individual correlation maps between each seed area and whole-brain voxels, and converted those maps into z-scored maps with Fisher's r-to-z transformation. We compared z-scored maps voxel-by-voxel between OSA and control subjects using analysis of

covariance (covariates; age and gender; $P<0.05$; cluster-corrected). The left insula showed decreased FC in OSA with the left inferior occipital, caudate, anterior cingulate cortex, orbitofrontal cortex, and rolandic operculum, and both left and right cerebellum and supplementary motor area. However, increased FC appeared with the left postcentral gyrus, left middle occipital gyrus, right hippocampus, right putamen, right supramarginal, and left and right inferior frontal regions. The right insula in OSA showed decreased FC with the left and right calcarine and cerebellum, left caudate, left thalamus, anterior cingulate cortex, and orbitofrontal gyrus, and increased FC in the right putamen, left and right postcentral gyrus, and posterior cingulate cortex. These findings suggest that recently-diagnosed treatment-naïve OSA subjects show complex aberrant FC between the insular cortices and several other brain regions regulating autonomic and motor actions. The altered FC may affect both parasympathetic and sympathetic interactions, as well as sensorimotor integration, all of which are affected in OSA. The functional changes likely result from the prominent structural changes with the condition in these regions. Supported by National Institutes of Health R01 HL-113251.

Title: Association of axonal and myelin changes with obstructive sleep apnea severity

Authors: *R. KUMAR[1,2,3], S. K. YADAV[1], B. PARK[1], J. A. PALOMARES[1], M. A. WOO[4], D. W. KANG[5], R. M. HARPER[6,3];
[1]Anesthesiol., [2]Radiological Sci., [3]Brain Res. Inst., [4]Sch. of Nursing, [5]Med., [6]Neurobio., Univ. of California at Los Angeles, Los Angeles, CA

Abstracts: Obstructive sleep apnea (OSA) patients show axonal and myelin changes in several brain sites that regulate autonomic, cognitive, and neuropsychologic functions, all of which are deficient in the condition. Brain axonal and myelin changes may vary with disease severity; however, the extent of such associations is unknown, and we examined those relationships using

the apnea-hypopnea-index (AHI), as an index of disease severity. We collected diffusion tensor imaging (DTI) data (two series; 64 diffusion directions and 7 b0 images) from 17 OSA subjects (age, 49.8±9.5 years; 4, females; AHI, 40.8±23.4 events/hour; body mass index, 29.4±8.9 kg/m2), using a 3.0 Tesla MRI scanner. Using each DTI series, we calculated axial diffusivity (reflecting axonal changes) and radial diffusivity (indicating myelin alterations) maps; both maps were realigned, averaged, normalized to common space, and smoothed. The smoothed axial and radial diffusivity maps were used to examine relationships between regional axial and radial values and AHI scores using linear regression analyses with ANCOVA (covariates; age and gender; uncorrected threshold; $p = 0.005$). Multiple brain sites with axial and radial diffusion changes showed negative and positive relations with AHI scores, indicating acute and chronic axonal and myelin changes, respectively. Brain regions with negative associations between axial diffusivity and AHI scores appeared in the putamen, internal capsule, anterior and posterior thalamus, middle cerebellar peduncle, cerebellar cortex, and occipital cortex, and positive relations emerged in the prefrontal, medial frontal, and ventral prefrontal cortices, extending to white matter, insular cortices, posterior cingulum bundle, caudal pons, ventral temporal cortices and white matter, and parietal and occipital cortices. Brain sites with negative relations between radial diffusivity and AHI scores appeared in the putamen, occipital cortex, and cerebellar peduncles and cerebellar cortices, and positive association emerged in the insular cortices, ventral medial prefrontal cortex, dorsal temporal cortex, posterior cingulum bundle, caudal pons, and frontal and parietal cortices. Both positive and negative correlations appeared between axial and radial diffusivity and AHI scores, indicating acute and chronic axonal and myelin changes, in various brain sites that regulate autonomic, cognitive, and neuropsychologic functions. The findings indicate that disease severity plays a significant role in axonal and myelin changes in OSA. Supported by National Institutes of Health R01 HL-113251.

Title: Alterations in caudate nuclei resting-state functional connectivity in obstructive sleep apnea patients

Authors: *R. M. HARPER[1,2], T. IBRAHIM[1], B. PARK[3], P. M. MACEY[4,2], M. A. WOO[4], F. L. YAN-GO[5], R. K. HARPER[1], R. KUMAR[3,6,2];

Abstracts: Obstructive sleep apnea (OSA) patients show cognitive, autonomic and neuropsychologic deficits, likely resulting from brain injury which appears in the caudate nuclei, among other sites. However, the integrity of functional connections from the caudate nuclei to other brain sites in OSA subjects is unknown. We aimed to examine the resting-state functional connectivity from both left and right caudate nuclei to other brain areas in untreated, newly-diagnosed OSA over control subjects. We performed, using a 3.0 Tesla MRI scanner, resting-state functional MRI in 47 OSA (age, 46.9±9.0 years; Females, 11) and 59 controls (46.18±8.13 years; Females, 18). Functional MRI data were processed using SPM8 with standard procedures and MATLAB-based custom software. Using left and right caudate seed areas, we derived individual correlation maps between each seed site and whole-brain voxels, and converted those data into z-scored maps with Fisher's r-to-z transformation. We compared z-scored maps voxel-by-voxel between OSA and control groups using analysis of covariance, with age and gender included as covariates ($P<0.05$, cluster-corrected). The left caudate showed decreased functional connectivity in OSA with the right superior frontal gyrus and right superior parietal gyrus, while the right caudate showed decreased functional connectivity with the left medial superior frontal gyrus. However, increased functional connectivity with the right caudate appeared in the left insula, left superior temporal gyrus, left precuneus, right temporal pole, and right postcentral gyrus, and the left caudate showed increased functional connectivity in the left parietal cortex. Untreated, recently-diagnosed OSA subjects have altered functional connectivity between the caudate nuclei and various other brain areas that regulate cognitive function, with connectivity in the condition enhanced to some regions but reduced to others, possibly reflecting altered perseverative and decision-making behaviors, among other neuropsychological deficits in the syndrome. Title: Nicotinamide mononucleotide adenylyltransferases in a mouse model of term equivalent birth asphyxia

Authors: *R. GALINDO, M. GREENBERG, D. M. HOLTZMAN;
Neurol., Washington Univ. In St. Louis, Saint Louis, MO

Abstracts: Neonatal hypoxia-ischemia (H-I) is an important and often devastating neurological disorder and it is the major cause of newborn death. Despite its high prevalence, there are only limited therapies available for its prevention and treatment. Furthermore, we still know little about the neurobiological processes that regulate neuronal cell fate in the injured and healthy developing brain. The family of nicotinamide adenine dinucleotide (NAD+) metabolizing enzymes known as Nicotinamide Mononucleotide Adenylyltransferases (NMNATs) have been shown to be importantly involved in the survival of axons following peripheral nerve injury. Utilizing quantitative PCR methods, we found that term equivalent neonatal cerebral hypoxia and/or ischemia results in a time-dependent 1.5 to 7 fold up regulation in the endogenous expression of the three NMNAT isoforms during the first 72 hours after injury in the mouse cerebral cortex and hippocampus, two brain regions significantly affected after neonatal H-I. Injury-associated NMNAT induction is seen as early as 8 hours post H-I and returns to baseline levels by 7 days after injury. Utilizing immunohistochemical methods we confirm that the observed increases in NMNAT mRNA directly translate into temporally-associated increases in NMNAT1 immunoreactivity. These data suggest that cerebral injury in the immature brain triggers endogenous mechanisms that enhance NMNAT expression during the acute phase of neonatal H-I. Given the putative role of these molecules in neuroprotection, we asked whether the endogenous NMNAT up regulation seen after injury is related to the selected survival or death of the affected neurons. To begin answering this question and to further understand the role of endogenous and exogenous NMNATs in immature neuronal survival, we developed and characterized an *in vitro* and *in vivo* NMNAT knockdown and NMNAT overexpression model utilizing serotype 8 Adeno-associated viral (AAV) vectors containing small hairpin RNAs targeting or each of the three NMNAT genes. We find that intraventricular injection of AAV8-shNMNAT vectors at postnatal day 0 results in effective gene knockdown and wide spread and stable infection throughout the brain. Utilizing this method, we then investigate whether NMNAT2 knockdown, the NMNAT isoform most highly expressed in neurons, results in increases in the amount of neuronal degeneration and apoptosis following neonatal H-I. Understanding the function of NMNATs in neuronal survival may offer new potential targets for

the effective treatment and prevention of the immediate and long-term neurological consequences that affect neonates exposed perinatal asphyxia.

Title: TRPA1 agonist, cinnamaldehyde induced long-lasting facilitation of respiratory rhythm in the brainstem-spinal cord preparation isolated from newborn rat and in the *in situ* perfused-preparation from juvenile rat

Authors: ***H. ONIMARU**[1], S. LIN[1], M. TANI[1], I. YAZAWA[2], K. IKEDA[3], K. KAWAKAMI[4]; [1]Dept Physiol, [2]Dept Anat., Showa Univ. Sch. of Med., Tokyo, Japan; [3]Div. Biol., Hyogo Col. Med., Nishinomiya, Hyogo, Japan; [4]Div. Biol., Jichi Med. Univ., Shimotsuke, Tochigi, Japan

Abstracts: It is not well understood whether chemicals that are known as transient receptor potential (TRP) channel agonists or antagonists exert any effects on the medullary respiratory center. In the present study, we examined effects of TRPA1 agonist (cinnamaldehyde or ally isothiocyanate) on respiratory rhythm generation in the brainstem-spinal cord preparation from newborn rat (P0-P3) and in the *in situ* perfused- preparation from juvenile rat (P11-13). The experimental protocols used in this study were approved by the Institutional Animal Care and Use Committee of Showa University. The preparations were superfused by modified Krebs solution at 25-26oC, and inspiratory C4 ventral root (or phrenic nerve) activity was monitored. In the newborn rat *in vitro* preparation, cinnamaldehyde (0.5 mM) induced typically biphasic responses in C4 rate; initial short increase (0.5-2 min) and subsequent decrease followed by gradual recovery of the rhythm during 15 min bath application. After washed out, the rate of respiratory rhythm further increased and has been kept higher than that of control (200% of control) for more than 2 hrs (i.e. long-term facilitation). Ally isothiocyanate induced effects similar to cinnamaldehyde. The long-lasting facilitation of respiratory rhythm was partially antagonized by TRPA1 antagonist, HC-030031 (10 μM). We have obtained similar results of a long-lasting facilitation in the *in situ* perfused- preparation from P11-13 rats. On the basis of

results from cutting experiments of the medulla and whole-cell recordings from pre-inspiratory neurons in the parafacial respiratory group (pFRG), we suggest that the rostral medulla including the pFRG was important in the induction of long-lasting facilitation. The histochemical analysis demonstrated a wide distribution of TRPA1 channel positive cells in the reticular formation of medulla including the pFRG, with strong expression in the motor neuron pools. Similar distribution was also confirmed by *in situ* hybridization of mRNA for TRPA1 channel protein. Our findings suggest that activation of TRPA1 channels could induce a long-lasting facilitation of the respiratory rhythm.

Title: Morphometric properties of Dbx1 pre-Bötzinger complex (preBötC) neurons that contribute to respiratory rhythm and pattern generation in neonatal mice slice preparations *in vitro*

Authors: *V. AKINS, C. DEL NEGRO;
Applied Sci., Col. of William and Mary, Williamsburg, VA

Abstracts: The inspiratory phase of the respiratory rhythm is generated by the preBötzinger complex (preBötC), a bilaterally distributed site located in the ventral medullary brainstem. Putatively rhythmogenic neurons in the preBötC are derived from a single genetic line, whose precursors express homeodomain transcription factor Dbx1. We performed electrophysiological experiments in slice preparations that retain the preBötC and generate spontaneous inspiratory motor output, which revealed a suite of intrinsic properties that could contribute to rhythm generation but did not provide a complete understanding of the role of Dbx1 neurons in respiratory rhythm generation. An analysis of the morphological features of Dbx1 neurons, independent of their intrinsic membrane properties, provided further insight into how they communicate and contribute to network behavior. Dbx1 neurons have smooth un-branched

dendrites that remain largely within the plane of the soma (~37 μm). Most Dbx1 neurons showed commissural axon projections, but some also showed premotor-like projections to the XII motor nucleus. These morphological features facilitate signal transduction, provide additional evidence supporting bilateral synchronization the preBötC through Dbx1 neurons, and demonstrate that Dbx1 preBötC neuron connectivity includes recurrent interconnections, as well as premotor projections. These findings through morphometric analyses show that Dbx1 preBötC neurons influence respiratory rhythm and pattern.

Title: Multielectrode recording of brainstem neurons: Swallow control of the respiratory neural network

Authors: H.-W. TSAI[1], G. ZHOU[2], K. F. MORRIS[3], C. GESTREAU[3], S. C. NUDING[3], L. S. SEGERS[3], B. G. LINDSEY[3], *P. W. DAVENPORT[4];

Abstracts: The pharyngeal phase of swallow requires a modulation of respiratory patterns to inhibit inspiration (i.e. swallow apnea). We hypothesized that swallow and respiration have shared components in the brainstem and generate specific swallow patterns by the reconfiguration of the respiratory neural network. We stimulated the superior laryngeal nerve (SLN) or applied fluid to the pharynx of paralyzed, decerebrate cats to elicit swallow. We used multiple electrodes placed into the nucleus of solitary tract (NTS) and ventral respiratory column (VRC) to simultaneously record spike trains during fictive swallow and breathing. SLN elicited swallow recruited non-respiratory modulated (NRM) neurons in the NTS while fluid elicited different groups of NRM swallow NTS neurons. However, expiratory (E) neurons in the VRC responded similarly to both SLN and fluid stimuli. Although most E neurons in the VRC were

inhibited by SLN and fluid stimuli, a few were facilitated by both perturbations. The results suggest that SLN afferents are processed by NTS neurons that are different from NTS neurons processing fluid elicited swallow. Once swallow is elicited, VRC E neurons have the same swallow related pattern reconfiguration. The results also suggest that NTS neurons differentiate between swallow stimuli and participate in the control of VRC respiratory neural network modulation to produce swallow apnea.

Title: Operantly conditioned slow breathing in the rat modifies baseline respiration and engages behavioral changes consistent with the relaxation response

Authors: *D. NOBLE[1], M. L. MCKINNON[1], T. I. NEBLETT[1], W. N. GOOLSBY[2], S. HOCHMAN[1];
[1]Physiol., [2]Cell Biol., Emory Univ., Atlanta, GA

Abstracts: In humans, exercises involving slowed respiratory rate/deep breathing (SRR) have been found to counter autonomic sympathetic bias and engage the relaxation response. This state of deep rest reduces responses to stressors, including in individuals with various degrees of autonomic dysfunction. We sought to develop an animal model of the SRR-induced relaxation response to better understand the neurophysiology of stress reduction. We previously reported preliminary operant conditioning studies of SRR in a small cohort of animals. Here, we successfully replicate pilot work and show that animals conditioned to slow their breathing display a maintained reduction in respiratory rate following the final session of training, as well as reduced behavioral stress responses. We used electric field sensors (Plessey Semiconductors) to non-invasively monitor respiratory rate and motor activity in response to stress. For

conditioning, respiratory rate was continuously monitored during 20 two-hour sessions using whole body plethysmography, with feedback provided via a customized interface in LabVIEW. Experimental (SRR) animals, but not yoked controls, were able to turn off aversive visual stimulation (intermittent bright light) by slowing their breathing. Only SRR rats displayed an increasing incidence of breaths below the target respiratory rate over training, with average respiratory rate decreasing by 20 breaths/minute. Following training, baseline respiratory rate was recorded in the absence of visual reinforcement for one hour to monitor the persistence of observed changes into the post-training period, while subsequent testing addressed the impact of conditioned slow breathing on stress reactivity: i) anxiety-like behavior in an open field, and ii) respiratory rate and overall activity levels in confined, stress-inducing restraint chambers. We observed that the reduction in respiratory rate during training was maintained in SRR animals, and corresponded to increased periods of calm inactivity under pseudo-restraint and increased exploration in an open field (4.5 vs. 2.25 center-field visits). In conclusion, rats could be trained to reduce their respiratory rate, rate reductions were maintained following training, and additional behavioral changes seen following conditioning were consistent with the development of an animal model of the relaxation response focused on respiration as a triggering stimulus.

Abstracts: Clarifying the mechanisms that underlie stress-induced alterations of learning and memory may lend important insight into susceptibility factors governing the development of stress-related psychological disorders, such as post-traumatic stress disorder (PTSD). Previous work has shown that carriers of the ADRA2B Glu^{301}-Glu^{303} deletion variant exhibit enhanced emotional memory, greater amygdala responses to emotional stimuli and greater intrusiveness of traumatic memories. We speculated that carriers of this deletion variant might also be more vulnerable to stress-induced enhancements of long-term memory, which would implicate the variant as a possible susceptibility factor for traumatic memory formation. Participants submerged their hand in ice cold (stress) or warm (no stress) water for 3 min. Immediately afterwards, they studied a list of 42 words varying in emotional valence and arousal and then completed an immediate free recall test. Twenty-four hours later, participants' memory for the word list was examined via free recall and recognition assessments. Stressed participants exhibiting greater heart rate responses to the stressor had enhanced recall on the 24-hr assessment. More importantly, stressed female ADRA2B deletion carriers, particularly those exhibiting greater heart rate responses to the stressor, demonstrated greater recognition memory than all other groups. These findings support our hypothesis that the ADRA2B deletion variant is associated with increased susceptibility to stress-induced enhancements of learning. Furthermore, they extend this speculation by revealing that females are selectively influenced by the genetic variant, which could lend insight into sex-dependent susceptibility to traumatic memory formation and PTSD.

Title: Selective deficits in object recognition memory are part of the depressive phenotype produced by repeated corticosterone in rats

Authors: *K. BRYMER[1], E. Y. FENTON[2], J. SIMPSON[1], J. G. HOWLAND[3], L. E. KALYNCHUK[4];
[2]Pharm. and Nutr., [3]Physiol., [4]Med., [1]Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstracts: Exposure to life stressors frequently precedes the onset of depression in human patients. Accordingly, many preclinical rodent models of depression make use of chronic exposure to stress or glucocorticoids to induce a depressive phenotype. We and others have found that repeated corticosterone injections induce a depressive phenotype in rodents, characterized by increased immobility in a forced swim test (FST), decreased sucrose preference, and decreased sexual behavior. However, little is known about the effects of corticosterone on object recognition memory and sensorimotor gating. In this experiment, we examined the effect of repeated corticosterone treatment on three object recognition memory tests, prepulse inhibition (PPI), and FST behavior. Rats received either 21 days of daily corticosterone injections (40 mg/kg) or vehicle injections, with behavioral testing commencing on day 22. Corticosterone-treated rats weighed significantly less than vehicle-treated rats by the end of the study and they also showed increased immobility time in the FST, thus replicating previous findings. Interestingly, corticosterone had differential effects on the three object recognition tasks used in this experiment. That is, the corticosterone-treated rats showed deficits in object-location recognition and object-in-place recognition, but not novel object-recognition. They also displayed less prepulse facilitation than vehicle-treated rats. These results suggest that impaired object recognition memory is part of the depressive phenotype seen in corticosterone-treated rats. They also suggest that corticosterone affects the hippocampus-prefrontal cortex circuit to a greater degree than the perirhinal cortex, as it is known that object-location and object-in-place recognition tasks are hippocampal-prefrontal dependent tasks whereas novel-object recognition is a perirhinal-cortex dependent task. These dissociations are consistent with previous work showing that the hippocampus and prefrontal cortex are particularly susceptible to the deleterious effects of chronic stress.

Title: A matter of time: Post stress enhancement of rule based category learning performance

Authors: *S. B. HUTCHINSON[1], L. HAWTHORNE[1], L. SZYMULA[1], S. K. MCCOY[1], S. W. ELL[1,2];
[1]Psychology, Univ. of Maine - Psychology Dept., Orono, ME; [2]Univ. of Maine - Grad. Sch. of Biomed. Sci. & Engin., Orono, ME

Abstracts: Stressful situations result in the activation of multiple physiological responses. Recent research suggests that the time varying nature of these physiological responses has important implications for cognitive function, particularly processes dependent upon prefrontal cortical function. Presently we consider the temporal impact of this response in relation to rule-based categorization - a task thought to depend on working memory and cognitive control processes. Rule-based category learning performance was tested after completion of a social-evaluative stressor (modified version of the Trier Social Stress Test) at varying time delays relative to cessation of the stressor (no delay, short delay, and long delay conditions) or after a no stress, comparison condition. As expected, participants in the three stress conditions, but not the no stress condition, were physiologically and psychologically stressed. Participants in the long delay condition performed better on the rule-based category learning task than participants in the no delay, short delay, and no stress conditions. These data are consistent with a literature suggesting that cognitive processes dependent upon working memory may be enhanced after physiological recovery from acute stress.

Title: Shipping stress in rats permanently alters stress response, gestational duration and epigenetic signatures

Authors: *F. C. ZUCCHI[1,2], Y. YAO[2,3], I. KOVALCHUK[3], G. METZ[2];
[1]Dept. de Ciencias Fisiologicas, Univ. of Brasilia (unb), Brasilia, Brazil; [2]Neuroscience, Canadian Ctr. for Behavioural Neurosci., [3]Biol. Sci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstracts: Transport of laboratory animals between facilities can cause shipping stress which may significantly affect experimental outcomes. It may represent a traumatic event with potentially long-term consequences for hypothalamic-pituitary-adrenal (HPA) axis function, behavioural and health outcomes. Thus, shipment of animals may represent a significant confound in the comparison of results between laboratories. Here we investigated if shipment of laboratory rats between facilities has lasting effects on basal HPA axis activity, stress response, and standard measurements of simple and complex behaviours. We hypothesized that the shipment of laboratory rats would result in permanent changes in stress responsiveness, behaviour, gestational length and potentially heritable epigenetic alterations of gene expression, which are potentially heritable to subsequent generations. Stress responses and behavioural phenotypes were measured in adult male and female Long-Evans rats shipped from an external breeder (EB; Charles River, ON) and given one month of acclimatization in the new housing facility. Outcomes in EB rats were compared with age-matched Long-Evans rats raised in a local breeding colony (LB). Animals were trained and tested in skilled reaching and assessed in standard open field task as measurements of behavioural performance and emotional state. A subset of rats was assigned to one week of daily sessions of 20 min restraint to investigate their response to acute stress. Another group of rats underwent timed pregnancy to determine gestational length as an indicator of physiological integrity. Furthermore, global DNA methylation status of prefrontal cortex and hippocampus was measured by cytosine extension assay as an indication of epigenetic status associated with the shipping experience. Naïve male and female EB rats displayed significant alterations in skilled and non-skilled motor behavior when compared to LB rats. EB female rats showed shorter gestational lengths and greater risk of poor birth outcomes. Notably, EB rats were resistant to restraint stress effects. Furthermore, shipping experience in EB rats was associated with significant epigenetic modifcations, including hippocampus global hypermethylation and prefrontal cortex global hypomethylation. Shipment experience may represent a significant stressor to laboratory rats that interferes with physiological mechanisms and epigenetic regulation. Long-term alteration of HPA axis response, behaviour and poor pregnancy outcomes associated with shipping stress may significantly challenge attempts to standardize and compare models and techniques between laboratories.

Title: Corticotropin releasing factor (CRF) impairs sustained attention in male and female rats

Authors: ***Y. KAWASUMI**, R. COLE, G. VAN BUSKIRK, V. PARIKH, D. BANGASSER; Dept. of Psychology, Temple Univ., Philadelphia, PA

Abstracts: Stress can disrupt a variety of cognitive processes, including attention. Moreover, patients with stress-related psychiatric disorders, such as depression, often report difficulty sustaining attention. Despite these well-documented effects, the neurobiological basis for stress regulation of sustained attention systems remains underexplored. During a stressful event, corticotropin releasing factor (CRF) is released centrally to modulate cognitive and behavioral stress responses. Previous research identified sex differences in the CRF1 receptor that increase neuronal sensitivity to CRF in female compared to male rats. The present study was designed to examine whether CRF alters sustained attention and if so, whether there are sex differences in this effect. To this end, male and female Sprague-Dawley rats were trained on an operant Sustained Attention Task (SAT) in which they had to discriminate visual signals from non-signaled events. After attaining criterion (70% correct responses on signal and non-signal trials), one of three doses of CRF (100ng, 500ng, and 1μg) or vehicle (artificial cerebral spinal fluid) were administered intracerebroventricularly 20-min prior to the task onset. The doses were administered in a counterbalanced fashion using a within-subjects design (successive infusions were separated by at least a week). In both male and female rats, CRF significantly reduced average response accuracies and vigilance index (a measure of overall attentional performance) in a dose-dependent fashion, with the highest dose of CRF causing the largest deficit. Interestingly, the ability to sustain vigilance throughout the session declined in female rats at the 500 ng dose, while the performance of male rats remained stable across the session at this dose. Although the number of omissions increased with the CRF dose in both males and females, female rats omitted more trials, presumably reflecting a lower motivation to perform under stressful conditions than males. Together, the results reveal that intracranial CRF administration

disrupts sustained attention in both male and female rats. However, on some measures, attention deficits are greater in females than in males, an effect that may be linked to sex differences in CRF receptors. Clinically, these findings suggest that CRF antagonists represent a viable therapeutic option to treat attentional deficits that characterize certain stress-related psychiatric disorders.

Title: Post-learning stress facilitates long-term memory consolidation and differentially influences emotional memory in females depending on stage of menstrual cycle

Authors: *C. E. CADLE[1], A. E. KALCHIK[1], D. M. PETERS[1], C. M. BROWN[1], A. R. SCHARF[1], A. M. DAILEY[1], M. B. EARLEY[1], C. L. KNIPPEN[1], E. D. SCHOLL[1], B. R. RORABAUGH[2], P. R. ZOLADZ[1];

Abstracts: Stress-induced alterations of learning and memory underlie the formation of traumatic memories and, thus, one of the most debilitating and costly psychological disorders that society faces, post-traumatic stress disorder (PTSD). However, the effects of stress on learning and memory are complex and still poorly understood. One relatively consistent finding in this area has been that post-learning stress enhances long-term memory; however, recent work has challenged this view with contradictory findings. Therefore, we examined the influence of post-learning stress on 24-hr declarative memory. Fifty-two participants learned a list of words varying in emotional valence and arousal and were then given an immediate free recall test. Participants then submerged their dominant hand in a bath of ice cold (stress) or warm (no stress) water for 3 min. Twenty-four hours later, participants returned to the laboratory and completed free recall and recognition assessments. Results indicated that stress enhanced participants' long-term free recall, while having no effect on recognition memory. Also, females in the follicular phase of the menstrual cycle recalled more arousing than non-arousing words following stress

exposure. These findings corroborate a significant portion of the stress-memory literature by revealing that stress enhances consolidation. They also suggest that post-learning stress exerts effects on memory that depend on female hormone levels.

Title: Functional significance of mobile genetic elements

Authors: *T. A. BEDROSIAN, C. QUAYLE, F. H. GAGE;
Salk Inst. for Biol. Studies, La Jolla, CA

Abstracts: Environmental experience causes profound changes in brain structure and function. One mechanism contributing to these changes may be the mobilization of active retrotransposons in the genome. For example, during neuronal differentiation LINE-1 retrotransposons can insert into genes, leading to changes in gene expression and putatively neuronal function. We have developed an approach to investigate the effects of experience on active retrotransposable elements, with the hypothesis that changes in the frequency or location of genomic insertions may alter neuronal function and behavioral phenotypes. First, we designed primers targeted to active retrotransposon families in the mouse genome. Then we developed an assay using droplet digital PCR as a highly sensitive method of detection for mobile elements. Using contrasting environmental experiences, including chronic stress and environmental enrichment, we are measuring the frequency of insertions in various brain regions using our droplet digital PCR approach. In addition, we are developing a targeted sequencing method to identify where new insertions occur within the genome. Furthermore, to determine the effect of retrotransposition on neuronal and behavioral phenotypes, we have developed a pharmacological approach to attenuate retrotransposon activity in mice. Studies are being conducted to examine neuronal and behavioral phenotypes under conditions of limited retrotransposition. Retroelements were once

considered ‘junk DNA’ but accumulating evidence suggests they can actively reshape the genome. These experiments will contribute to our understanding of the functional relevance of retrotransposons to behavioral and neuronal phenotypes.

Title: Chronic stress effects on spatial learning and hippocampal citogenesis of senile male rats

Authors: T. MORALES-SALCEDO[1], G. YAÑEZ-DELGADILLO[1], P. HERNANDEZ-CARRILLO[1], G. CHIPRES-TINAJERO[1], F. JÁUREGUI-HUERTA[1,2], Y. RUVALCABA-DELGADILLO[2], J. GARCÍA-ESTRADA[2], *M. S. LUQUIN DE ANDA[1];
[1]Univ. Guadalajara, Guadalajara, Mexico; [2]Neurosci., Inst. Mexicano del Seguro Social, Guadalajara, Mexico

Abstracts: The hippocampal formation and its cognitive functions have been the most explored targets for the deleterious effects of stress. The hippocampus is considered the main structure in the study of brain aging. Proliferative changes have also been proposed at the basis of volumetric changes seen in chronically stressed subjects. It is no clear however whether proliferative changes may affect senile subjects suffering stressing conditions. There is also controversy about the direction of changes produced by stress over spatial learning in aged subjects. The aim of this study was then to evaluate the effects of chronic exposure to stress on spatial learning and hippocampal proliferation on senile male rats. A group of aged male rats (18 month old) were exposed for 15 days to a chronic variate stress model. At the end of the exposure, the rats were assessed on the MWM paradigm. All the subjects were also injected with the cellular proliferation marker 5'bromodeoxiuridine(BrdU), and their brains were processed for immunohistochemical analysis. Coronal sections were immunolabeled with anti--BrdU antibodies to identify newborn cells in dentate gyrus (DG), cornu amonis areas CA1 and CA3. We found an improving effect of stress over spatial learning abilities of senile rats as showed by MWM execution. We also found region specific changes on the proliferative rate of hippocampal

cells. These findings sustain the idea that senile subjects may be affected by chronic stress in ways different from young or mature subjects.

Title: The relationship between oxytocin and cortisol during acute psychosocial stress in a non-clinical undergraduate sample

Authors: *K. MONDE[1], M. PANERO[2], J. KIM[3], D. SIMEON[4], V. LUINE[1];
[1]CUNY Hunter Col., New York, NY; [2]Boston Col., Boston, MA; [3]Michigan State Univ., East Lansing, MI; [4]Mount Sinai Sch. of Med., New York, NY

Abstracts: Increased levels of stress and chronic stress is known to negatively affect both physical and mental health. Cortisol, a steroid hormone, is released as part of the hypothalamic pituitary-adrenal axis of humans and is associated with both physical and emotional stress. Oxytocin (OT), a neurohypophysial hormone, is also related to stress and emotionality. Studies have indicated that cortisol administration facilitates the production of OT, and OT administration attenuates the stress response. Additionally, two studies have demonstrated a positive relationship between basal levels of endogenous OT and Cortisol (Taylor et al., 2006; Altemus et al., 2001), and one study found an inverse relationship between OT and cortisol levels during psychosocial stress (Pierrehumbert et al., 2010). In the current study, 55 undergraduates underwent the Stressful Event Speech task (SES) in which they described a stressful interpersonal event. Salivary OT and cortisol levels were assessed before, directly following, and after a 20 minute recovery period. Cortisol increased in response to the SES and returned to baseline post-recovery. OT decreased during recovery. We also found a positive relationship between post-SES cortisol levels and OT decrease during recovery ($r=.445$, $p<.05$) and a positive correlation between cortisol stress reactivity (post-SES cortisol - basal cortisol

levels) total OT decrease at the level of a trend ($r = .364$, $p = .06$). Thus, higher cortisol levels were associated with more decrease in OT. The temporal relationship between increased cortisol and decreased oxytocin demonstrates not only the responsiveness of OT system to stress, but that under stress, heightened cortisol may trigger changes in OT system function that lead to decreases in endogenous OT concentrations. Associations between OT and emotion suggest that decreased OT levels may aid individuals in feeling less stressed.

Title: Odor-induced stress effects on first responder medical decision-making

Authors: ***B. D. WINSLOW**, N. NGUYEN, E. GOODRICH, S. DUFF, V. LUGO, D. JONES; Design Interactive, Inc., Oviedo, FL

Abstracts: Exposure to stress has the potential to significantly affect human cognitive performance processes such as reaction time, decision making, and memory. Odorant exposure can cause initiation of a stress response, activating the sympathetic division of the autonomic nervous system (ANS) and the hypothalamic-pituitary-adrenal cortex axis (HPA), resulting in neurotransmitter and corticosteroid release and subsequent downstream physiological effects. The coding of pleasant and negative odors is computed in distinct brain areas, including the orbitofrontal cortex and anterior cingulate, respectively. Building resilience - the human ability to adapt in the face of tragedy, trauma, adversity, hardship, and ongoing stressors - to odors is beneficial to first responders who are presented with novel odors during the treatment of trauma, and are expected to maintain high cognitive performance. Here we report a model of human resilience to odor by measuring and classifying HPA and ANS activation from physiological sensors during odor exposure. Novice participants were trained in medical triage, and performed either in the presence or absence of medically relevant odors. The rate of learning to perform triage classifications and retention of that knowledge were the primary measures of cognitive

function. Measurements of HPA and ANS activity including heart rate variability, respiratory sinus arrhythmia, and electrodermal activity were quantified using ECG, respiration, and electrodermal sensors. Fine motor performance was assessed following odor exposure using the Purdue Pegboard Test. Medically-relevant odors were presented during training and retention evaluation via a custom scent-delivery system. Odor exposure significantly increased the time/trials needed to attain proficiency in triage task performance, and significantly increased sympathetic and corticosteroid activity in early triage trials, but approximated the performance and physiology of the control group after several trials. Retention was assessed two weeks later. In addition, the generalizability of the odor-induced stress response was assessed using a second medically-relevant odor. An analysis of the physiological and behavioral data showed evidence for the cross-odor transfer of resilience to a novel odor after learning in the presence of odor. Strategies aimed at increasing resilience through pre-exposure and providing stress management techniques prior to task performance reduced sympathetic activity and increased performance in the odor condition, suggesting that the integration of stress training and odor exposure may improve first responder performance.

Title: Bidirectional effects of stress on decision-making and its neural correlates in a dynamic environment

Authors: *J. CHEY[1,2], H. PARK[1], D. LEE[3], N. DAW[4];
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Neurol., Columbia Univ. Med. Sch., New York City, NY; [3]Neurobio., Yale Univ. Med. Sch., New Haven, CT; [4]Psychology, New York Univ., New York City, NY

Abstracts: Although too much stress impairs performance in a variety of tasks, it can also improve cognitive performance when a certain level of arousal is beneficial, as often referred to as the Yerkes-Dodson law (inverted U). In addition, previous studies have reported that stress increases habits while decreasing goal-directed behaviors. However, whether and how such bidirectional effects of stress manifest as a potentially shifting balance between habit versus goal-directed systems has not been investigated. In this study, we examined the dose-dependent effects of stress on model-free and model-based reinforcement learning at both behavioral and neural levels, using computational models and functional magnetic resonance imaging. Participants were randomly assigned to one of the three conditions, no-stress, single-stress-treatment, and double-stress-treatment. Two types of psychological stress protocol were employed in the study, which was immediately followed by a two-stage Markov decision-making task in which the reward probabilities for the choices in the second stage underwent reversals without notice. Analogous to the Yerkes-Dodson hypothesis, goal-directed behaviors increased in a single-stress-treatment condition but decreased in a double-stress-treatment condition. Similarly, BOLD activity in the frontal and parietal cortex was higher during decision making in the single-stress-treatment condition than in the no-stress and the double-stress-treatment conditions. These results suggest that stress can play a critical role in arbitrating the two controllers (habit and goal-directed) of decision-making in opposite directions depending on the level of stress currently experienced by the decision-maker, and further confirm the role of prefrontal cortex and superior parietal cortex in goal-directed actions.

Title: Multiple effects of stress on decision making in a changing environment

Authors: *P. HEYEON[1], D. LEE[2], J. CHEY[3];
[1]Dep. of psychology, Seoul Natl. Univsersity, Seoul / Gwanak-Gu, Korea, Republic of; [2]Dept. of

Neurobio., Yale university, New Haven, CT; [3]Dept. of Psychology, Seoul Natl. Universiy, Seoul, Korea, Republic of

Abstracts: Previous computational and lesion studies suggested that behaviors might be controlled by at least two partially separate neuroanatomical systems. Habit or model-free reinforcement learning incrementally shapes behaviors by trial and error, whereas goal-directed behaviors or model-based reinforcement learning rely on the internal model of the decision maker's environment and motivation. Here, we examined how stress influences human decision-making in a changing environment by testing whether it biases the contribution of model-free and model-based reinforcement learning processes and alters the rate of incorporating new information from the environment. Participants were randomly assigned to stress and control conditions, and performed a two-stage Markov decision-making task in which the reward probabilities underwent reversals without notice. We found that stress increased the contributions of model-free reinforcement learning while diminishing the influence of model-based reinforcement learning. It also decreased the rate at which the decision making strategy is updated by new experience. These results have implications for the underlying neural mechanism mediating the effects of stress on the formation of maladaptive habits, such as addictive behavior, as well as dysfunctional behaviors associated with stress-related disorders.

Title: Rescuing inhibitory tone following chronic stress reverses stress-induced hippocampal-dependent deficits on object placement

Authors: *J. B. ORTIZ, S. TAYLOR, P. PAODE, C. D. CONRAD;
Dept. of Psychology, Arizona State Univ., Tempe, AZ

Abstracts: Chronic stress leads to hippocampal-dependent spatial learning and memory deficits and the simplification of hippocampal CA3 dendrites. Past studies report that chronic stress skews the inhibitory (gamma-aminobutyric acid, GABA) and excitatory (glutamate) hippocampal neurotransmitter systems toward hyperexcitability. Correcting the inhibitory tone

through pharmacological manipulations to reduce hyperexcitability or to enhance inhibition can prevent stress-induced CA3 dendritic retraction. Consequently, we hypothesized that the dysregulated inhibitory tone following chronic stress might also contribute to the deficits in spatial learning and memory. Since blocking the GABAergic system or facilitating the glutamatergic system can potentiate hippocampal-dependent spatial learning and memory in non-stressed animals, we predicted that higher doses of a GABAA antagonist or glutamatergic agonist would be needed to improve spatial memory in chronically stressed rats than would be needed in nonstressed controls. Young male Sprague-Dawley rats were chronically stressed (STR, wire mesh restraint, 6h/d/21d) or not (CON). The day after chronic stress ended, all rats were injected i.p., with either Bicuculline (BIC, 0.0 mg/kg, 0.25 mg/kg, 0.50 mg/kg, a GABAA antagonist) or D-Cycloserine (DCS, 0.0 mg/kg, 3 mg/kg, or 15 mg/kg, a partial NMDA receptor agonist). Thirty min later, rats were tested for spatial memory using a 2-trial object placement task designed to be challenging to animals without pharmacological treatment. During training, rats were allowed to explore two identical objects in an open field. After a 3-hour inter-trial interval, one object was moved to a new location and time spent exploring both objects was recorded. BIC produced dose-dependent effects; BIC facilitated spatial memory in CON rats at both 0.25 and 0.50 mg/kg doses, whereas BIC facilitated spatial memory in STR at the highest dose only (0.50 mg/kg). DCS also led to dose-dependent effects with both doses (3, 15 mg/kg) facilitating spatial memory in CON rats, but only the 3 mg/kg dose improving spatial memory in STR rats. Consequently, STR rats required a higher dose of a GABAA antagonist to rescue spatial memory than was needed in CON rats. In contrast, the amount of DCS needed to rescue spatial memory in STR rats may follow an inverted U-shaped function. Thus, dose-dependently rescuing the inhibitory tone through GABAA antagonism reverses the impairing effects of chronic stress on spatial ability, whereas rescuing the inhibitory tone via the NMDA receptor is more complex than observed for the GABAergic system.

Title: D-serine prevents acute stress-induced cognitive deficits in mice

Authors: G. D. GUERCIO[1], L. E. BEVICTORI[1], C. M. MADEIRA[1], C. VARGAS-LOPES[1], J. D'ÁVILA[2], V. F. CARVALHO[2], *R. A. PANIZZUTTI[1];
[1]Biomed. Sci. Inst., Federal Univ. of Rio De Janeiro, Rio de Janeiro, Brazil; [2]Fiocruz, Rio de Janeiro, Brazil

Abstracts: Increasing evidence indicates that acute stress can disrupt cognitive functions mediated by the N-methyl-D-aspartate receptor (NMDAR), although the mechanisms are not fully understood. D-serine is the major endogenous co-agonist of the NMDAR, and is produced in the brain exclusively by serine racemase. Importantly, serine racemase is inhibited by phosphorylation on serine residues, resulting in lower D-serine levels. D-serine is crucial to long term potentiation induction and it also contributes to learning and memory. Also, D-serine is involved in sensorimotor gating, a filtering mechanism that is thought to prevent sensory overload. However, regulation of D-serine by acute stress remains to be investigated. Here we examined whether the D-serine pathway is regulated by acute stress in C57BL/6 male mice. To this end, we euthanized the mice after the stress protocol and dissected the prefrontal cortex and the hippocampus. We used high performance liquid chromatography to study D-serine levels and we performed an immunopreciptation followed by immunoblotting of the brain homogenates to study serine racemase phosphorylation. Interestingly, acute restraint stress decreased D-serine levels ($p<0.01$, $t=3.071$) and increased serine racemase phosphorylation on serine residues ($p<0.0001$, $t=5.393$) in the prefrontal cortex. In the hippocampus, neither D-serine levels nor serine racemase phosphorylation were altered by acute restraint stress. To study whether D-serine could prevent the effect of stress on memory, we performed an object recognition task. We tested the effect of acute restraint stress immediately after memory acquisition, during the memory consolidation phase. Recognition memory was impaired by acute restraint stress, which was prevented by peripheral administration of D-serine (1g/kg) 30 minutes before acquisition ($p<0.05$) or immediately after acquisition, before the stress procedure ($p<0.05$). However, D-serine had no effect on the memory impairment caused by stress when given one hour before memory retrieval. To investigate the impact of stress on sensorimotor gating, we measured the prepulse inhibition of the startle response (PPI). Acute restraint stress impaired PPI ($p<0.01$), which was prevented by D-serine administration 20 minutes before stress ($p<0.01$). Taken together, our results show for the first time the interplay between acute stress and D-serine. We demonstrated acute restrain stress lowered normal levels of D-serine, and that exogenous D-serine injections were efficient at restoring normal cognitive performance.

Title: Corticotropin-releasing factor acts within the prefrontal cortex to impair cognitive function

Authors: *S. HUPALO[1,2], R. C. SPENCER[2], C. W. BERRIDGE[2];
[1]Neurosci. Training Program, [2]Psychology, Univ. of Wisconsin - Madison, Madison, WI

Abstracts: The prefrontal cortex (PFC) regulates a variety of 'executive' cognitive processes critical for goal-directed behavior, particularly under distracting and/or ambiguous conditions. Stress impairs PFC-dependent cognitive function in humans, primates, and rodents. Stress-related impairment in PFC-dependent function is posited to contribute to a variety of psychopathologies. Yet, our understanding of the neural mechanisms responsible for stress-related impairment in PFC function is currently limited. The majority of research on this topic has focused on the actions of PFC catecholamines, demonstrating an important role of dopamine and norepinephrine in the cognition-impairing effects of stress. However, additional stress-related neurotransmitters are present in the PFC, including corticotropin-releasing factor (CRF). To date, the degree to which CRF acts within the PFC to modulate PFC-dependent cognition is not known. Given the prominent role of CRF in stress, we hypothesized that CRF signaling in the PFC elicits a stress-like impairment in PFC-dependent cognition. To test this hypothesis, we examined the effects of bilateral infusions of varying doses of CRF (25, 50, 100, 250 ng/hemisphere) into the medial PFC of rats on performance in a delayed response task of spatial working memory (T-maze). We observed that CRF exerts a regionally-specific and dose-dependent impairment in working memory. Specifically, CRF infusion into the dorsocaudal region of the medial PFC elicited robust impairment in working memory performance. In contrast, CRF infusion into the ventrocaudal or rostral PFC (both ventral and dorsal subfields) had no impact on performance. This is in contrast to what is seen with catecholamines, which modulate working memory via actions in the rostral medial PFC. These results provide the first evidence that CRF signaling in the PFC modulates higher cognitive function in a stress-like manner and suggest that CRF signaling within the PFC may contribute to stress-related

dysregulation of cognition. Ongoing studies are investigating the degree to which endogenous CRF signaling in the PFC modulates working memory in the absence and presence of stress. Finally, these findings provide further evidence for a topographic organization of medial PFC function that exists across both rostrocaudal and dorsoventral axes. This research lends new insight into the neurobiology of PFC-dependent function and may have relevance for treating psychopathologies associated with PFC dysfunction, including stress-related disorders.

Title: Computations of uncertainty predict acute stress responses in humans

Authors: *A. O. DE BERKER[1,2], R. RUTLEDGE[2], R. J. DOLAN[2], S. BESTMANN[1]; [1]Sobell Dept. for Motor Neurosci., Univ. Col. London, London, United Kingdom; [2]Wellcome Trust Ctr. for Neuroimaging, Univ. Col. London, London, United Kingdom

Abstracts: Indirect evidence suggests that uncertainty is an important contributor to stress, with one striking suggestion being that predictable events should not be described as stressful (Koolhaas et al., 2011). Building on this idea, we formalised stress as an adaptive reaction to uncertainty about threat. In this framework, stress responses function to reduce uncertainty by focusing attention and improving mnemonic function, with uncertainty providing a key parameter by which the amplitude of stress responses are controlled. We therefore hypothesised that physiological and subjective stress responses in human participants would scale with the current level of uncertainty about threat. To test this, we used a learning paradigm in which participants earned money by learning a probabilistic mapping between stimuli and shocks. On each trial, subjects were presented with one of two stimuli and asked to predict whether they were about to receive a shock. For each correct prediction, they earned a small amount of money.

Shocks were delivered irrespective of predictive accuracy, so that all participants received the same number of shocks (160). Crucially, the contingencies between stimuli and shocks shifted unpredictably over time, introducing uncertainty and requiring subjects to constantly update their estimates of threat for each stimulus. We dynamically assessed subjective stress using a visual analogue scale presented every 4-5 trials, and continuously monitored heart rate, breathing rate, and skin conductance. We used a computational model of learning under uncertainty (Hierarchical Gaussian Filter; Mathys et al., 2011) to characterise expectations, uncertainty, and prediction errors experienced by each subject throughout the course of the experiment. We used these quantities to construct a predictive model of task-elicited stress responses. We found that surprising events, including the surprising omission of a shock, are strong contributors to emotional and physiological stress responses, and that individuals' emotional stress dynamics are predictive of their physiological sensitivity to shock and uncertainty. This study provides empirical support for a theory of stress as an adaptive response to uncertainty.

Title: Arousal modulates short-term emotional memory in women on hormonal contraception

Authors: *S. E. NIELSEN, S. J. BARBER, M. MATHER;
USC, Los Angeles, CA

Abstracts: To date, few studies have investigated whether sex hormones and arousal interact to modulate short-term memory. Thus, the present study tested whether arousal at encoding differentially modulates short-term memory for emotional and neutral images in naturally cycling women (NC women) and women on hormonal contraception (HC women). Based on arousal-biased-competition theory (Mather & Sutherland, 2011), we predicted that arousal at encoding would enhance short-term memory for negative images (i.e., high priority images) and suppress memory for neutral images (i.e., low priority images). Given that long-term emotional memory is modulated by contraceptive status (Nielsen, et al., 2011), we also tested whether the effects of arousal on short-term memory also depended on contraceptive status. This study had a

2 (Arousal vs. No arousal at encoding) X 2 (NC vs. HC women) X 3 (Negative vs. Positive vs. Neutral pictures) design. To induce arousal at encoding, at the beginning of the experiment some women were administered an isometric handgrip protocol, which has reliably increased endogenous norepinephrine levels in previous studies. For the control condition, the handgrip task was replaced with a relaxed water bottle hold. Immediately after this, all participants saw a slideshow containing negative, positive, and neutral pictures. Later, all women completed a free recall test for the images. We used eye-tracking technology to assess pupil diameter changes (index of arousal) in response to the handgrip v. control tasks, and we collected salivary samples to assess changes in salivary alpha-amylase (a biomarker for norepinephrine) and levels of 17β-estradiol and progesterone. We tested whether increases in arousal would enhance the tendency to preferentially recall the negative rather than the neutral images, and whether this would vary as a function of contraceptive status. A preliminary ANOVA revealed a significant three-way interaction between picture valence (negative v. neutral), arousal condition (handgrip v. control) and contraceptive status (HC v. NC women). Follow-up analyses suggest that in HC women only, arousal enhanced short-term memory for negative images while suppressing short-term memory for neutral images. NC women exhibited no differences in short-term recall of negative or neutral images, regardless of arousal condition. These preliminary results suggest that physiological arousal at encoding modulates short-term emotional memory differently depending on contraceptive status. In women, sex hormones and contraceptive status appear to modulate both immediate and long-term memory consolidation processes for emotional stimuli.

Title: L. reuteri induced anxiety behavior and fear related memory change in C57BL/6J mice

Authors: ***M. J. EIMERBRINK**[1], J. D. WHITE[1], M. J. CHUMLEY[2], G. W. BOEHM[1]; [1]Psychology, [2]Biol., Texas Christian Univ., Fort Worth, TX

Abstracts: This research utilized the bacteria Lactobacillus reuteri to induce behavioral changes in C57BL/6J. Specifically, we were interested in the how chronic treatment with L. reuteri can alter anxiety behaviors and fear related memory. To assess anxiety, we utilized an elevated zero

maze and an open field test. Behavioral data from both measures support the hypothesis that treatment with L. reuteri can effectively reduce anxiety related behaviors. To assess fear related memory, we used both contextual and delay conditioning paradigms. Again, we found evidence to support fear related memory alterations such that L. reuteri treated animals display less freezing behavior during testing compared to control animals. To explore potential biological mediators of behavior, we analyzed both corticosterone levels 30 minutes after behavior data collection and GABA receptor expression in the hippocampus and amygdala. Additionally, we evaluated whether L. reuteri can protect against exaggerated anxiety behaviors induced by fear conditioning.

Title: Blood chromatin as a protein biosensor: Morphometrics, cognition and behavior

Authors: B. M. FEINER, K. A. CHASE, *R. P. SHARMA;
Dept Psychiatry, Univ. of Illinois at Chicago, CHICAGO, IL

Abstracts: Introduction: Histone modifications in peripheral mononuclear blood cells (PBMCs) from living patients can be conceptualized as analogous to blood glycated hemoglobin (HbA1c) levels in diabetic patients in that both serve as a proxy for the degree of their respective modifications in the entire body. Across the genome, epigenetic regulation of chromatin can be seen as an organizing principle by which central and peripheral compartments are interlinked by virtue of commensurable gene network entrainment. Chromatin deposition along these networks is imposed by the totality of epigenetic influences, including significant contributions from biochemicals that readily traverse the blood-brain barrier. Utilizing PBMCs allows us to generate a hypothesis connecting the epigenetic influence on gene networks and clinical outcomes of aberrant histone modification levels in real-time. Method: 30 subjects were recruited from the community at the University of Illinois at Chicago, Illinois. Clinical measurements included

morphometric measurements (waist circumference and BMI), the MATRICS cognitive battery, and the Heinrichs-Carpenter Quality of Life Scale (QLS). Acid extraction of PBMC extracts was performed and protein levels were quantified by the Bradford assay (n=30). Three histone modifications were measured via Elisa assays from Active Motif (H3K9acetyl-#53114, H3K9me2-#53109, H3K4me3-53109, Total H3-#53110). All histone modifications were first normalized to an internal standard curve, followed by a plate-control standard, and finally to the total histone H3 protein. Results: a) Increases in H3K9me2 levels were correlated with increases in attention and vigilance (MATRICS; $\rho=0.46$; $p<0.03$), decreases in both intelligence (WAIS-III score: $\rho=-0.42$; $p<0.039$) and sociosexual relationship functioning (QLS; $\rho=-0.46$; $p<0.01$). In addition, H3K9me2 levels were increased in overweight participants, as measured by both waist circumference ($\rho=0.44$; $p<0.016$) and BMI ($\rho=0.35$; $p<0.002$), and in participants with a history of hyperlipidemia ($t=2.76$; $p<0.01$). H3K9acetyl modifications were correlated with increases in a sense of purpose (QLS; $\rho=0.47$; $p<0.014$). H3K4me3 modifications were significant decreased in overweight participants, ($t=-2.12$; $p<0.035$), but were increased in participants with a history of diabetes ($t=3.98$; $p<0.001$). Discussion: Real time blood levels of chromatin modifications in living patients have the capacity to integrate all ambient epigenetic inputs. In this preliminary study, we can report that specific modifications are enriched in certain physiological and cognitive phenotypes.

Title: Decreased sensitivity of female rat locus coeruleus neurons to μ-opiate agonists: Electrophysiological, protein and behavioral studies

Authors: *H. M. GUAJARDO[1,2], A. HO[2], X.-Y. ZHANG[3], R. VALENTINO[3,2];
[1]Neurosci. Grad. Group, [2]Univ. of Pennsylvania, Philadelphia, PA; [3]Stress Neurobio., Children's Hosp. of Philadelphia, Philadelphia, PA

Abstracts: Females are more likely than males to have depression and anxiety disorders. It has been hypothesized that this sex difference results from differences in stress response systems. The locus coeruleus (LC)-norepinephrine (NE) system, is a major stress response system that is thought to be dysregulated in stress-related psychiatric disorders. During stress, the LC-NE system is activated by corticotropin releasing factor (CRF), a primary mediator of the stress response. At the same time, endogenous opioid neuropeptides provide an inhibitory influence on LC activity that restrains CRF activation and facilitates a return to baseline activity when the stressor ends. An imbalance in the opposing regulation of the LC-NE system by CRF and opioids could influence stress-sensitivity and enhance stress vulnerability. Sex differences could be expressed through differences in sensitivity to either CRF or to endogenous opioids. The goals of this study were to determine whether there are sex-differences in 1) LC neuronal responses to μ-opiate receptor (MOR) agonists; 2) LC-MOR expression levels; or 3) cognitive/behavioral correlates of MOR activation in the LC. We generated dose response curves for the MOR-agonist, DAMGO, on LC discharge rates. Extracellular single-unit LC activity was recorded in anesthetized male and female Sprague Dawley rats using double barrel micropipettes and DAMGO was simultaneously microinfused. Notably, the highest dose [10 pg] completely suppressed LC firing in males (n=7) but not in females (n=7). A two way repeated measures ANOVA, revealed sex differences in the response to DAMGO such that females were less sensitive ($F(1, 12) = 15.281$, $p<0.002$). Western blot analysis revealed decreased MOR levels in LC punches from female (n=11) compared to male (n=11) rats ($t(20) = 2.142$, $p< 0.05$). Finally, the ability of DAMGO in the LC to affect behavior in an attentional set-shifting task (AST), an animal model of cognitive flexibility were assessed. In male rats DAMGO (3 pg, intra-LC) increased the number of errors in performance of a strategy shifting task compared to vehicle control ($F(2, 23) = 3.6$, $p<0.05$, n=7-9). Preliminary data in females (n=3-5/group) suggest that unlike males, DAMGO does not impair strategy shifting behavior in females. Together, the data suggest that LC neurons of females are less sensitive to MOR agonists as a result of decreased MOR in the LC. Given the protective effects of MOR activation in the LC during stress, this could be a mechanism underlying enhanced stress sensitivity of females.

Title: Is enhanced retrieval of fear memories part of the depressive phenotype produced by repeated corticosterone treatment in rats?

Authors: *L. E. KALYNCHUK[1], W. N. MARKS[1], E. Y. FENTON[1], N. M. FOURNIER[2], B. D. KULYK[1];
[1]Univ. of Saskatchewan, Saskatoon, SK, Canada; [2]Yale, New Haven, CT

Abstracts: Repeated exposure to corticosterone (CORT) is often used as a preclinical model of depression in rats as it produces robust increases in depressive-like behaviour. However, although a bias towards maladaptive thinking patterns and emotional responses is a cardinal symptom of depression, these symptoms have been rarely considered in preclinical models. One way to investigate maladaptive thinking is through the use of fear conditioning paradigms. Typically fear conditioning tasks are used to model post traumatic stress disorder and anxiety in rodents. However, fear conditioning tasks also demonstrate more general alterations in emotion-associated memories, a symptom of depression in humans. We propose that fear conditioning also be used as a measure of depressive-like behaviour in rodents. In a series of experiments, we systematically investigated the effects of repeated injections of CORT on two variations of fear conditioning, delay fear conditioning and trace fear conditioning, as well as whether the antidepressant fluoxetine reverses changes in fear-related behaviour produced by CORT. In the first experiment, male Long-Evans rats received either vehicle or 40 mg/kg of CORT injections for 21 consecutive days followed by forced swim testing to demonstrate a depressive phenotype using traditional measures of depressive-like behaviour. Results revealed a significant increase in helplessness behaviour in CORT rats during the forced swim test. In the second experiment, rats received similar treatment as experiment one with the addition of a 5mg/kg CORT group to examine dose dependent effects of CORT on learning and memory of delay conditioned cues. We found that 40mg/kg of CORT significantly enhances freezing behaviour during retrieval of both contextual and tone cued fear, whereas only tone cues are responsive to the effects of 5mg/kg of CORT. A third experiment examined the effects of repeated injections of 40 mg/kg of CORT on trace conditioning. Interestingly, we found that CORT enhanced freezing behaviour both during acquisition and retrieval of trace conditioning. In a final experiment, we provide preliminary evidence that fluoxetine administered concurrently with 40mgk/kg CORT significantly reduces freezing during retrieval of tone cues. Collectively, these experiments demonstrate that enhanced freezing during retrieval of conditioned fear cues is reliably produced by repeated exposure to CORT, effects that are partially reversed by fluoxetine. Overall, this suggests that fear conditioning is a potential tool for exploring the circuits that mediate pathological alterations in emotion-associated memory associated with depression.

Title: Effect of a metformin-derived small molecule on circadian clock phase-resetting

Authors: *H. S. ROW[1], S. KIM[3], K. KIM[2];
[2]Deparment of Brain & Cognitive Science, Col. of Natural Sci., [1]Seoul Natl. Univ., Seoul, Korea, Republic of; [3]Hanall Biopharm., Seoul, Korea, Republic of

Abstracts: Circadian rhythm governs daily physiology and behavior in mammals. Disruption of circadian clock molecule(s) has been known to cause metabolic disorders such as obesity and diabetes. Metformin is the first line of antidiabetic drug in the biguanide class. We investigated the effect of a metformin derivative (designated as HL156A) on circadian clock regulation. HL156A phosphorylated 5'-AMP activated kinase (AMPK), a key energy sensor at much lower dosage as compared to Metformin. HL156A shortened pulse period and dampened amplitude of Period2 oscillation in a dose-related manner in the mouse embryonic fibroblast cells cultured *in vitro*. In a jet lag *in vivo* model, administration of HL156A enhanced duration of re-entrainment after 6-h phase advance in LD cycle, while it did not affect the free running locomotor activity in a constant dark condition. HL156A degraded circadian clock proteins such as PER2 and CRY1 in the presence of cyclohexamide, much faster than that of metformin, indicating that Metformin-drived small molecule may affect phase resetting. Taken together, it appears that a novel metformin derivative, HL156A may hold a potential as a chronomodulator to treat desynchronous syndrome such as jet lag.

Abstracts: Mitogen-activated protein kinase (MAPK) is a protein involved in several neurobiological functions, including sleep modulation. However, no evidence is available regarding the circadian fluctuation of this protein in sleep-related brain areas such as hypothalamus (HYP) or pons (PONS). Thus, the aim of the experiment was to describe the circadian pattern of MAP-K in HYP and PONS. For this purpose, male Wistar rats were sacrificed by decapitation at different times during 24h: Zeitgeber hour 4 [ZT1], ZT8, ZT12, ZT16, ZT20, ZT24. Brain samples were collected for MAP-K analysis using Western blot techniques. It was found that MAP-K expression was higher in HYP and PONS during the lights-on period, especially at ZT4, whereas a diminution was observed across time, specifically during the lights-off period (ZT16). Importantly, we found that MAP-K expression was higher in PONS compared to HYP in the time points studied across time points. Preliminary data suggest that MAP-K expression is under a circadian influence and changes in its expression depends upon the lights/dark period. Further studies are needed to elucidate the mechanism of action of circadian fluctuation of MAP-K in sleep-related brain areas such as HYP and PONS.

Title: Identification and characterization of a novel agonist modulating circadian nuclear receptor, REV-ERBα

Authors: *J. J. LEE[1], Y. SUH[2], K. KIM[3];
[1]Sch. o biological science, [2]Sch. o Col. of Pharm., [3]Sch. of biological science and Departments of Brain & Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstracts: Rev-erba (NR1D1) belongs to the nuclear receptor superfamily of transcription factors which regulate a wide range of biological processes including circadian rhythm and metabolism. We attempted to identify small synthetic molecules that modulate Rev-erba by cell-based screening with 1200 drug-like compounds based on 2x RORE (Rev-erba/Ror response element)-mediated transcriptional activity. One of compounds (designated as KK-S6) repressed RORE- but not mutant RORE-mediated transcriptional activity. KK-S6 compound dramatically altered amplitude, but not period of circadian oscillation of BMal1 in a dose-related manner. We also evaluated Rev-erba dependency in mouse embryonic fibroblast cells from Rev-erba KO mouse. In Hepg2 cells, KK-S6 repressed endogenous expression levels of Rev-erba-regulated genes including hBMal1, hPlasminogen-activator inhibitor (type 1) and hCitrate synthase, which values are comparable to GSK4112, a known Rev-erba agonist as a reference. Further optimization and subsequent functional studies may lead to development of potential therapeutic agents of Rev-erba involved in circadian rhythm and metabolism. ***Key words: Circadian clock, Rev-erba, synthetic compound, RORE***

Title: An integrative study of the circadian rhythmicity of electric behavior: From the field to the dish

Authors: *A. SILVA[1], A. MIGLIARO[1], P. MARCHAL[2,3];
[1]Inst. De Investigaciones Biológicas Clemente Estable - Facultad De Ciencias, Montevideo, Uruguay; [2]Univ. Claude Bernard, Lyon, France; [3]Inst. De Investigaciones Biológicas Clemente Estable, Montevideo, Uruguay

Abstracts: Keeping an adequate timing among physiological and behavioral processes is a key point for survival, hence, endogenous biological rhythms are synchronized with external cues, mainly photoperiod, which vary in circadian and circa annual fashion. Gymnotus omarorum, a nocturnal South American weakly electric fish, displays electric behaviors consisting on modulations of the electric organ discharge (EOD). The EOD is driven by a medullary pacemaker nucleus (PN) whose activity is modulated by environmental, sensory, and social cues. The basal rate of the EOD is an indicator of social hierarchy, and shows a transient small-amplitude melatonin-dependent nocturnal rise (NR) in coincidence with general arousal and the increase in locomotor activity. With the aim of characterizing the NR as a circadian rhythm, we continuously recorded the EOD and locomotor activity of isolated non-sexually mature adults (n=6) for 10 days at constant water temperature and conductivity (22°C, 150µS/cm), both with a light-dark cycle 12:12 and in constant darkness. A robust rhythm of EOD rate and locomotor activity was confirmed in the light-dark regime, which did not persist in all the individuals during the dark-dark regime. However, the characterization of circadian rhythms in wild animals using exclusively laboratory settings is currently questioned as it might limit the detection of behavioral patterns that only emerge in nature. We therefore recorded circadian changes in EOD basal rate in the wild for 72 h (isolated individuals in restricted areas, Laguna del Sauce, Maldonado Uruguay, 34°51'S, 55°07'W, n=6); and EOD basal rate and sheltering behavior in semi-natural conditions (400L outdoor tanks with equally-sized EOD-recording shelters, n=10). To test if the main circadian messenger, melatonin, is directly involved in the modulation of EOD rate, we are currently testing its effect on the spontaneous activity of the PN recorded from brainstem slices.

Title: LD-stress alters circadian expressions of GAD in mice

Authors: *A. MUTO, K. OSADA, T. WATANABE, A. TAGUCHI, T. HAGA, Y. OGAWA, M. NAKANO, Y. SASUGA, N. YAMAGUCHI;
Neuropsychiatry, St.Marianna Univ. Sch. of Med., Kawasaki, Japan

Abstracts: Amino acids [glutamate and γ-aminobutyric acid (GABA)] are the most abundant neurotransmitters and are largely responsible for the excitation/inhibition balance in the brain. These studies have suggested that GABA levels may be decreased in animal models of depression, and clinical studies reported low plasma and CSF GABA levels in depression. Living matter are known to have 24 h circadian rhythm. It is considered as one factor of major depressive disorder (MDD), this circadian rhythm is the disturbance because a lot of depressed patients is sleeplessness. A circadian rhythm is subject to influence of light. Preclinical study had suggest that 3.5-h light and 3.5-h dark (LD-stress mice) increased depression-like behaviors by forced swimming test and sucrose preference (Tara A et al, Nature, 2012). Administration of the antidepressant drugs to LD-stress mice improved depression-like behaviors, then LD-stress mice was considered to model animal of depression. We used this animal models, determined the mRNA clock gene and Gad1, Gad2 from hypothalamus and salivary glands cells, and investigated how circadian oscillation of clock gene and Gad1, Gad2 expression changed in the LD-stress mice. In addition, we examined the effect of fluoxetine. The hypothalamus contain the primary mammalian circadian clock that regulates rhythmic physiology and behavior. GABA is an important neurotransmitter in the hypothalamus cells. This study investigated whether the circadian rhythm to GABA existed in the mouse hypothalamus and salivary glands cells by real-time PCR. Total RNA was extracted using a protocol combining the Oragene RNA Self-Collection Kit (DNA Genotek) and the RNeasy Micro Kit (QIAGEN). To quantify the amount of mRNA in hypothalamus, we performed real-time PCR by using TaqMan Fast Universal PCR Master Mix (life technologies).

Title: Circadian rhythms in differentiating adult neural stem cells from the dentate gyrus of the hippocampus

Authors: *A. MALIK, R. J. JAMASBI, M. E. GEUSZ;
Biological Sciences, Bowling Green State University, Bowling Green, OH

Abstracts: Embryonic stem cells appear to lack circadian rhythms. It is unclear whether neural stem cells contain an endogenous clock and express circadian rhythms. Our previous work indicated that neural stem cells from the mouse subventricular zone lack a circadian rhythm until they differentiate. Reports have shown *mPer2* expression in the dentate gyrus but did not detect a circadian rhythm in the activity of this circadian clock gene. Studies have shown a daily rhythm in hippocampal adult neurogenesis. It is possible that circadian control of neurogenesis produces nascent neurons at a time of day when fine discrimination of sensory information is most critical. To determine whether hippocampal adult neural stem progenitor cells can generate circadian rhythms, neural stem cell cultures (neurospheres) were prepared from the dentate gyrus of 4 to 5-month-old transgenic mice expressing firefly luciferase under control by the *mPer1* promoter. Presence of stem cell markers nestin and musashi-1 was confirmed by immunocytochemistry. Neurospheres were imaged after they were treated with forskolin to synchronize any circadian pacemaker cells present and then placed in medium that induces differentiation into neurons and glial cells (10% fetal bovine serum) or medium that maintains the stem cell state (containing fibroblast growth factor-2 and epidermal growth factor). Only the neurospheres in serum medium produced circadian rhythms, suggesting that differentiation allows circadian timing to be detected. Average period for the first and second cycles was 23.71 hours (±2.16 S.D., n=7). Because circadian rhythms were present before the neurospheres differentiated completely, it appears that transit-amplifying cells derived from the stem cells contain a circadian clock before they form mature neurons.

Title: Circadian and subregional gene expression in the suprachiasmatic nucleus

Authors: *J. L. LENSIE[1], E. M. MINTZ[1,2];
[1]Biol. Sci., [2]Biomed. Sci., Kent State Univ., Kent, OH

Abstracts: The suprachiasmatic nucleus (SCN) of the hypothalamus acts as an endogenous circadian clock. Individual neurons of the SCN are capable of acting as independent circadian oscillators, but the SCN exhibits a specific structural organization, with subregions that can be defined by a variety of criteria, including neuropeptide expression and cellular responses to stimuli. Individual subsets of cells can show different rhythms of gene expression. Individual genes have been identified that are differentially expressed in three specific SCN subregions. In mice, these include 1) The ventral SCN, characterized by expression of vasoactive intestinal polypeptide (VIP), 2) the central SCN, characterized by expression of gastrin-releasing peptide (GRP), and 3) the dorsomedial SCN, characterized by expression of arginine vasopressin (AVP). There is some overlap among all of these regions. In this study we hypothesized that these 3 regions were not only defined by their neuropeptide expression, but other circadian and non-circadian gene expression, thus revealing previously unknown details of the organization of the neuronal components of the SCN. Thirty-seven adult, male, C57BL/6J mice were housed in constant dark for two weeks in cages equipped with running wheels to assess circadian time (CT). Animals were sacrificed at 2-hr time points across the circadian cycle, and brains removed and flash frozen. Cells from SCN subregions were extracted using laser capture microdissection. RNA was purified from the extracts, amplified and labeled, and hybridized to Affymetrix mouse ST 1.0 whole genome expression arrays. The most pronounced region-specific differences in expression occurred in genes for known SCN neuropeptides, with few other genes showing large regional variations with the exception of a set of genes presumably expression in oligodendrocytes in the ventral SCN relating to myelin production. Regional and circadian expression of clock and neuropeptide genes was confirmed by qPCR analysis of a separate set of samples. We have identified numerous transcripts that show very robust circadian cycling across all three subregions. Known genes among these all have important roles in the circadian clock or circadian output. Some genes have not been identified as important in the clock, but represent good targets for further investigation. These data suggest that functional variation across SCN subregions are largely a function of neuropeptide expression, spatial location, and network connectivity, and not to fundamental differences in neuronal function.

Title: Light effects on circadian clock modulation of metabolism

Authors: ***Y.-F. ZOU**, C.-C. LEE, S.-K. CHEN;
Life Sci., Natl. Taiwan Univ., Taipei, Taiwan

Abstracts: Abstract: The disrupted circadian rhythm is related to higher risks of getting metabolic disorders such as insulin resistance, obesity and hyperlipidemia, which could further develop severe diseases related to cardiovascular, gastrointestinal and metabolic function, including type II diabetes. It was revealed in previous research that light signals would influence non-image forming physiological functions through intrinsically photosensitive retina ganglion cells (ipRGCs). Althought recent studies have shown that circadian rhythm is involved in modulation of physiological regeneration and storage of energy , whether the light signal can manipulate key pathways of the metabolism remains unknown. Thus, we want to exame how light signal transduction from the retina affects the metabolic status. We housed several ipRGC mutant mouse lines, inclulding *melanopsin* knockout (Cre/Cre) strain and Brn3b positive ipRGCs eliminated strain (3bDTA/+), under dim light at night and evaluated the metabolic conditions of these mice. Our preliminary data showed that the body weight gain, final body weight, as well as the composition of the intestinal microbiota of these mice were altered in different light-dark conditions. It suggests that light signals regulates the mammalian metabolic status through ipRGCs integration without shifting the central clock at SCN.

[1]Neurosci. and Brain Technologies, Inst. Italiano Di Tecnologia (IIT), Genova, Italy;
[2]Epigenetics Programme, The Babraham Inst., Cambridge, United Kingdom

Abstracts: Independent molecular clocks are integrated across various cell types, enabling the synchronization of circadian rhythms within an organism. These molecular regulatory processes include transcriptional and translational positive/negative feedback loops of core clock genes. To date, very little is known about the role of specific epigenetic mechanisms regulating the circadian clock. In this study we address specific questions about the interplay between circadian clock alterations and DNA methylation. Traditionally, DNA methylation has been considered a permanent silencing mechanism for gene expression. However, a few recent studies have shown dynamic methylation changes in the brain which depend on environmental variations and neuronal activity. Here we have conducted a CpG island (CGIs) methylation genome-wide screen in the mouse After-hours (Afh) mutant, expressing an extreme lengthening of the circadian period, and wild-type littermate controls. We have used a reduced representation bisulphite sequencing (RRBS) approach and we have identified significant changes of DNA methylation in a small number of specific targets. Preliminary results indicate that 20 CGIs regions were differentially methylated between Afh homozygous mutants and wild-type controls in the suprachiasmatic nucleus (SCN) of the hypothalamus. A cutoff of 5 sequencing reads for each CpG site was used to identify significant methylation changes between mutants and controls. We have observed a range of changes between Afh mutants and controls, which oscillate from 5% to 20% according to specific genes. Among the targets we have identified we report here NKx2-2 (homeobox protein Nkx-2.2), Brd4 (bromodomain-containing protein 4), Kcnh3 (potassium voltage-gated channel subfamily H member 3), Opn4 (opsin 4) and Sfn (stratifin). Moreover, 15 regions presented a hypermethylation in the mutants SCN compared to the wild type, which suggest a possible involvement of Afh mutation in hypermethylation of specific CpGs intragenic sequences. Overall, our study revealed that a genetically determined alteration of the circadian clock (due to the Afh mutation) can alter the DNA methylation profile of genes involved in different functions such as cell signaling, synaptic plasticity and transcriptional activity.

Title: Metabolic feedback to the hypothalamic circadian clock by adiponectin

Authors: *A. TSANG[1,2,3], H. OSTER[1,3];
[1]Med. Dept. I, Univ. of Luebeck, Luebeck, Germany; [2]The Göttingen Grad. Sch. for Neurosciences, Biophysics, and Mol. Biosci., Univ. of Goettingen, Goettingen, Germany; [3]Circadian Rhythm Group, Max Planck Inst. for Biophysical Chem., Goettingen, Germany

Abstracts: There is a growing body of evidence suggesting an extensive crosstalk between circadian clocks and energy metabolism. Peripheral metabolic state can feed back on central clock function, but the mechanism of this link is still poorly understood. In this study, we engineered a hypothalamic neuronal cell line to stably express a circadian reporter and used it as a model to screen for metabolic signals that are capable of resetting neuronal clocks. With this methodology, we identified an adipokine hormone, adiponectin, as a potential modulator of hypothalamic circadian circuits. Adiponectin deficient mice show dampened 24-h feeding rhythms associated with altered diurnal profiles of clock and appetite-regulating gene expression in the mediobasal hypothalamus. Further analysis revealed that adiponectin acts via adiponectin receptor 1 (ADIPOR1) and PGC1a-mediated activation of the core clock gene Bmal1 to reset the molecular oscillations of hypothalamic neurons. Together, these data reveal a novel metabolic feedback mechanism to the central circadian clock.

Title: Rhythmic control of mrna stability is essential for circadian amplitude of mouse period3 mrna

Authors: *J. CHOI[1], S.-H. KIM[2];
[1]Life science, [2]school of interdisciplinary bioscience and bioengineering, POSTECH, POHANG, Korea, Republic of

Abstracts: The daily oscillations observed in most living organisms are endogenously generated with a period of 24 hours, and their fundamental structure is an autoregulatory transcription-translation feedback loop. In addition to transcriptional and post-translational regulation, mechanisms of untranslated region (UTR)-mediated post-transcriptional regulation (i.e., mRNA degradation and internal ribosomal entry site (IRES)-mediated translation) have been suggested to fine tune clock gene expression. Mouse Period3 (mPer3) is one of the Period paralogs and its functions are important in peripheral clocks and a sleep physiology. mPer3 mRNA displays a circadian oscillation and a circadian phase-dependent stability, while the stability regulators still remain unknown. In this study, we identify three proteins - heterogeneous nucleus ribonucleoprotein (hnRNP) K, polypyrimidine tract-binding protein (PTB), and hnRNP D - that associate with the cis-acting element suggested from the previous study. Two of these proteins contribute to mRNA stability. Both experiments and mathematical modeling describe their roles in the cytoplasm for mRNA stability regulation and circadian amplitude formation. Moreover, our mathematical model suggests a mechanism of how post-transcriptional mPer3 mRNA stability modulation provides the flexibility of oscillation amplitude, as well as the robustness of the period and the phase, for its circadian expression.

Title: Honey bees exhibit shift work in foraging and fanning behavior

Authors: *M. A. GIANNONI GUZMAN, T. GIRAY, J. L. AGOSTO-RIVERA;
Dept. of Biol., Univ. of Puerto Rico Rio Piedras Campus, San Juan, PR

Abstracts: Although shift work is an essential component of human society, for example in areas such as healthcare and security, it is associated with circadian misalignment and increased susceptibility to a number of diseases. Studying these processes in humans has proven difficult and limited by lack of experimental manipulations. Honey bees for a long time have been used as a model for social interactions, learning and memory and addiction among many others. A recent study investigating if pollen foragers captured during the morning were genetically different from those captured in the afternoon, found that there are paternal lineages that are only observed either in the morning or the afternoon suggesting that that shift work may occur in pollen foragers. Based on these findings, we hypothesized that honey bee foragers exhibit shift work in their foraging tasks. To test this hypothesis we number tagged 1-day-old workers and made direct behavioral observations of entry, exit, pollen load and fanning behavior for 14 days. Our results revealed that about 18% of foragers only made trips during the morning, while approximately 26% only foraged in the afternoon and the remaining bees foraged during both morning and afternoon. By evaluating the foraging pattern of individuals throughout the observation period we found that some individuals change shifts as they age, while others remain in the same shift (morning or afternoon). Analysis of the foraging trips of individual foragers revealed that individuals with no shift work perform more foraging trips. In addition, we looked at fanning behavior at the entrance of the colony and found that fanning behavior is also performed in shifts. Understanding the underlying mechanisms of shift work in honey bees will open the door for a better understanding of how individual differences in chronotype result in increased disease susceptibility.

Title: Application of wavelet analysis to zebrafish circadian and behavioral data

Authors: *E. A. MOSSER, C. N. CHIU, D. A. PROBER;
California Inst. Technol., PASADENA, CA

Abstracts: A commonly used method for analyzing circadian physiological and behavioral oscillations is sinusoidal curve fitting. This approach allows for the characterization of circadian oscillatory parameters such as period, phase, and amplitude but assumes a constant rhythm in which these parameters do not vary over time. However, conditions that alter circadian oscillations can have effects that change over time. Wavelet analysis of biological rhythms provides a means to capture time-varying changes in circadian oscillations that more standard methods cannot obtain. An advantage to using larval zebrafish for circadian studies is that both molecular clock oscillations and circadian locomotor behavior can be monitored in the same organism. We have applied wavelet transforms to *in vivo* zebrafish molecular and behavioral circadian oscillations to examine the kinetics of rhythms in fish treated with known small molecule circadian clock effectors. We have found that several compounds known to lengthen circadian periods via different molecular targets yielded distinct kinetics. For example, the period lengthening effect of a casein kinase 1 (CK1) inhibitor decreased over the time course of the experiment, while the period lengthening effect of a cyclin-dependent kinase (CDK) inhibitor increased over the time course of the experiment. We have also compared the kinetics of CK1 inhibitor induced period lengthening of molecular rhythms to the kinetics of the period lengthening of behavioral rhythms and found that while the period lengthening effects on the molecular clock decreased over the time course of the experiment, the period lengthening effects on behavioral rhythms remained constant over time. These results highlight the potential of using wavelet analysis to capture dynamic changes in rhythms. We expect this approach will lead to a deeper understanding of circadian clock regulation and function in physiology and behavior.

Title: Short-circuit: A circadian mutant in a novel suprachiasmatic nucleus transcription factor

Authors: ***M. J. PARSONS**[1], M. BRANCACCIO[2], L. MAYWOOD[2], J. K. EDWARDS[1], M. SIMON[1], S. SETHI[1], J. E. CHESHAM[2], A.-M. MALLON[1], M. HASTINGS[2], P. M. NOLAN[1]; [1]MRC Harwell, Harwell, Oxfordshire, United Kingdom; [2]Div. of Neurobio., MRC Lab. of Mol. Biol., Cambridge, United Kingdom

Abstracts: Short circuit (Sci) is a semi-dominant homozygous lethal mutant found in an N-ethyl-N-nitrosourea (ENU) mutagenesis screen for circadian phenotypes. Heterozygotes (Sci/wt) have a shortened tau in constant darkness τDD=23.0. The gene containing the Sci mutation, zinc finger homeobox 3 (Zfhx3), encodes for a highly pleiotropic transcription factor that has been implicated in neuronal differentiation and development. Moreover, the gene is highly expressed in the adult suprachiasmatic nucleus (SCN). We found that mutant ZFHX3 results in less effective transcriptional activation of a conserved promoter motif *in vitro* compared to wildtype protein. The same motif is activated in a circadian fashion in *ex vivo* SCN cultures. We also found a diminished activation in *ex vivo* SCN of heterozygotes, in line with the *in vitro* findings. Together these data suggest that Zfhx3's role as a transcription factor may underlie the circadian phenotype. In order to investigate transcriptional changes in the SCN of Sci/wt animals, we conducted RNA sequencing experiments using RNA from the SCN of both Sci/wt and wt/wt animals. We found 27 high confidence differentially expressed genes ($q < 0.05$). Clustering and enrichment analysis revealed a functional gene module in which the heterozygotes have decreased SCN specific expression of a number of neuropeptides and neuropeptide receptors (including Vip, Vipr2, Grp and Avp) that have been shown to be important for normal SCN firing. We have now verified the decreased expression of a number of these genes using RT-PCR and immunofluorescence. Interestingly, many of these contain the conserved motif within their promoters. Using luciferase specific reporter gene assays we found that mutant ZFHX3 is less effective at transcriptional activation. In summary, this suggests that the decreased ability of mutant ZFHX3 to transcriptionally activate the novel circadian motif in the promoters of genes may underlie its circadian phenotype and further suggests a wider role for Zfhx3 in circadian transcriptional regulation.

Title: A novel protein, CHRONO, functions as a core component of the mammalian circadian clock

Authors: *F. HATANAKA[1,2], A. GORIKI[1,2], J. MYUNG[1,2], J. K. KIM[3,4], K. FUJIMOTO[2], Y. KATO[2], A. MATSUBARA[2], D. FORGER[3], T. TAKUMI[1,2];

Abstracts: Circadian rhythms are controlled by a system of negative and positive genetic feedback loops composed of clock genes. Although many genes have been implicated in these feedback loops, it is unclear whether our current list of clock genes is exhaustive. We have recently identified Chrono as a robustly cycling transcript through genome-wide profiling of BMAL1 binding on the E-box. Here, we explore the role of Chrono in cellular timekeeping. Remarkably, endogenous CHRONO occupancy around E-boxes shows a circadian oscillation antiphasic to BMAL1. Overexpression of Chrono leads to suppression of BMAL1-CLOCK activity in a histone deacetylase (HDAC) -dependent manner. *In vivo* loss-of-function studies of Chrono including Avp neuron-specific knockout (KO) mice display a longer circadian period of

locomotor activity. Chrono KO also alters the expression of core clock genes and impairs the response of the circadian clock to stress. CHRONO forms a complex with the glucocorticoid receptor and mediates glucocorticoid response. Our comprehensive study spotlights a previously unrecognized clock component of an unsuspected negative circadian feedback loop that is independent of another negative regulator, Cry2, and that integrates behavioral stress and epigenetic control for efficient metabolic integration of the clock.

Title: Continuous theta-burst TMS to the right inferior frontal gyrus increases local EEG theta power and memory for contextual and non-contextual objects

Authors: *W. LEGON[1], R. MORAN[2,3,1];
[2]Electrical and Computer Engin., [1]Virginia Tech. Carilion Res. Inst., Roanoke, VA; [3]Dept. of Psychiatry and Behavioral Med., Virginia Tech. Sch. of Med., Roanoke, VA

Abstracts: Previous research has demonstrated significant changes in inferior frontal gyrus (IFG) in response to change in contextual information provided during episodic memory encoding. Here, we tested the effect of delivering low intensity (20% max. stimulator output) continuous theta burst stimulation (cTBS) to the right IFG upon broad spectrum (4 - 30 Hz) EEG dynamics and recall behavior. Participants were randomly assigned to either the real cTBS group or the sham stimulation group. Stimulation was performed 5 minutes prior to the encoding task. 64 channel EEG was collected while participants performed a simple two-choice visual encoding task. Two household items were presented on a screen with a question below asking if either of the objects is 1) colored Red (low contextual information) or 2) belongs in a Kitchen (high contextual information). A total of 28 pairs of objects were shown, repeated 10 times. A one hour retention period followed and participants were then tested whether they had seen particular pairs of objects. Behavior was quantified as response time to either Red or Kitchen questions during encoding as well as percent items pairs recalled correctly after the retention period. EEG epochs around visual stimulus onset (-380 - 1345 msec) were convolved with a 3 cycle complex

Morlet wavelet at 4Hz increasing linearly with frequency up to 30Hz. Spectra were grouped into established frequency bins including theta (4 - 8 Hz), alpha (9-13 Hz) and beta (14 - 30 Hz) bands. Preliminary behavioral analysis indicates participants responded slower to Kitchen questions compared to Red questions - stimulation had no effect upon response rate. There was a main effect for stimulation where cTBS retention rates were higher for both Kitchen and Red trials though no interaction as Red trial recall was higher compared to Kitchen trials for both cTBS and Sham stimulation. This second main effect of context is commensurate with our previous fMRI study and challenges the notion that "deep" encoding strategies are more efficacious. EEG data indicate cTBS to increase the power of theta frequency in right frontal areas beginning at ~100 msec after stimulus continuing to ~ 1000 msec for both Red and Kitchen trials. cTBS induced a non-spatially specific increase in alpha power for both Red and Kitchen trials. Beta power displayed non-specific power increases starting at ~ 350 msec for Kitchen trials to cTBS stimulation and no differences for sham stimulation. These data indicate that cTBS to the right inferior frontal cortex specifically increases local theta power in IFG and that this may be associated with an increase in general memory retention for objects regardless of contextual framework.

Title: Memory representations of context guides visual search in an immersive virtual environment

Authors: *C.-L. LI[1], M. P. AIVAR[2], D. M. KIT[3], M. H. TONG[4], M. M. HAYHOE[4];
[1]Inst. of Neurosci., The Univ. of Texas At Austin, Austin, TX; [2]Facultad de Psicología, Univ. Autónoma de Madrid, Madrid, Spain; [3]Dept. of Computer Sci., Univ. of Bath, Bath, United Kingdom; [4]Ctr. for Perceptual Systems, The Univ. of Texas at Austin, Austin, TX

Abstracts: Despite limited attentional resources, humans reliably allocate gaze to appropriate regions in the visual environment to guide daily behavior. It is likely that this ability depends on the existence of memory representations or learned priors that govern attentional allocation. With simple stimulus displays it has been demonstrated that familiar contexts aid visual search. It has also been demonstrated that the preview of an image of a natural scene facilitates subsequent search. However, experiments attempting to characterize the role of memory in gaze allocation almost all use two-dimensional (2D) images, and it is not clear how the results from 2D studies generalize to behaviors in immersive, interactive three-dimensional (3D) environments, given the drastically different nature of the stimulus exposure, both spatially and temporally. In this study, we developed an immersive virtual environment to determine (i) to what extent does pre-exposure to the global scene context and target location benefit subsequent visual search, and (ii) what aspect of local context guides visual search. Eye movements of human subjects were recorded while they were immersed in a virtual apartment using a head-mounted display with a large field-of-view. The apartment was composed of two rooms; one room was explored for 1 minute before the search trials while the other was not. Early search targets were geometric objects, while later targets were realistic apartment objects that were part of the context during early searches. The search time and number of fixations spent to locate targets were indicators of search efficiency. We found that 1 minute of pre-exposure to one of the rooms led to a small benefit during early searches of geometric targets, whether the targets were present during exploration or not. Search time and number of fixations drop rapidly during the first five search trials in the environment, even though each trial was for a different target, suggesting that there is a significant benefit from learning the context through active experience. There was an added benefit on the second search trial for a given object. Targets were located rapidly after only one previous search trial, suggesting that search is driven by memory for target location, as well as memory for the context itself. Interestingly, search time was not dependent on the number of previous incidental fixations on the object. Together the results provide the insight into the time course of developing memory representations in an immersive 3D environment, and demonstrate the importance of memory for object location, memory for context, and task relevance in visual search in natural immersive environments.

Title: The effects of the amount of binding information on the recognition and retrieval of episodic memory

Authors: *F. E. TORRES TREJO, S. CANSINO;
Lab. of NeuroCognition, UNAM, México City, Mexico

Abstracts: The aim of the present study was to examine the effects of binding two and three items on recognition and retrieval. Thirty participants were asked at encoding to determine whether the two- and three-item stimuli comprised natural, artificial or both types of common objects. During recognition, the participants indicated whether the stimuli were equal to those presented at encoding, were modified through the exchange of one of the two-item stimuli for one of the three-item stimuli or represented a new stimulus. The correctly identified modified item pairs and triads were included in a subsequent cued-recall task in which participants verbally reported the missing item. Recognition diminished as the number of bound items increased for both old and modified stimuli; whereas the retrieval of the missing item was unaffected by the number of bound items. The results suggest that both familiarity and recollection processes took place in the recognition task and both were influenced by the number of items. Bindings based on recollection allowed the retrieval of the individual elements independent of the complexity of the episodic event.

Title: Memory for sequences of events shows bilateral hippocampal and medial prefrontal cortical activity in humans

Authors: *V. K. BOUCQUEY[1,2], T. A. ALLEN[1,2], N. J. FORTIN[1,2], C. E. L. STARK[1,2]; [1]Neurobio. and Behavior, [2]Ctr. for the Neurobio. of Learning and Memory, Univ. of California, Irvine, CA

Abstracts: Memory for the sequence of events is a critical component of episodic memory. However, the neurobiological substrates of this type of memory are not well understood, especially in humans. To address this, we acquired BOLD fMRI data in humans while preforming our cross-species sequence memory task. Importantly, this task tests memory for non-spatial sequences of events and shows cognitive parallels in rats and humans (Allen et al., 2014), allowing for multidisciplinary research. Subjects were first presented with four different sequences of six distinct kaleidoscopic images in succession (e.g., Sequence "ABCDEF"). Subsequently, BOLD fMRI was acquired while subjects were presented images with all items in sequence (e.g., "ABCDEF"), or with one item out of sequence (e.g., "ABC**F**EF"). Subjects initiated image presentations by pressing and holding down a button. Images disappeared when the button was released, or after the decision threshold (1sec) was reached. If an image was "in sequence" the subjects were instructed to hold down the button for 1sec, if the image was "out of sequence" they were instructed to release the button before 1sec. Successful sequence memory was demonstrated if subjects responded accurately to both "in sequence" and "out of sequence" items. All subjects completed 240 probe sequences (1440 images). Each subject accurately indicated items as "in sequence" and "out of sequence" at levels significantly greater than chance. We then completed a whole-brain analysis contrasting "in sequence" with "out of sequence" presentations, corrected for multiple comparisons at a brain-wise $\alpha<0.05$. We found that the sequence task showed strong bilateral activation of the hippocampus and the medial prefrontal cortex (dorsal and ventral). These results are consistent with previous research in rats that used a temporary inactivation approach to show the cross-species sequence task relies on the hippocampus and medial prefrontal cortex. Further, single-unit recordings in rats from the CA1 region of the hippocampus and prelimbic region of the medial prefrontal cortex show a dynamic and complementary series of changing representations that can solve the sequence task. The current results extend this work to humans and strongly suggest homologous underlying neural substrates in memory for sequences of events. These results encourage the use of the cross-

species sequence memory task in understanding the neural underpinnings of this aspect of episodic memory as it normally functions, as it changes with healthy aging in which episodic memories decline, and in disorders such as Alzheimer's disease where the declines in episodic memories are more deleterious.

Title: Manipulating mental context in a memory task using real-time fMRI

Authors: *M. T. DEBETTENCOURT[1], N. B. TURK-BROWNE[1,2], K. A. NORMAN[1,2]; [1]Princeton Neurosci. Inst., Princeton, NJ; [2]Dept. of Psychology, Princeton, NJ

Abstracts: Context has a powerful effect on memory: we are much more likely to recall information when the external environment and our internal state match what was present when that information was encoded. Recent developments in fMRI acquisition and analysis make it possible to identify brain states in real-time, potentially allowing us to detect when particular contexts are active in the brain. Here we not only detect such contexts, but also provide this information as neurofeedback to participants, to manipulate their current context. Specifically, we hypothesized that inducing the same context in a participant during study and test by providing neurofeedback would boost recall of the studied information, relative to a condition in which a different context was induced. We defined two arbitrary contexts by training a classifier to distinguish between multivoxel patterns associated with different perceptual categories. Then, participants were trained to modulate the degree to which one of these contexts was active. Finally, we incorporated this learned control of context into a standard memory retrieval paradigm. During the study phase, participants were induced into a particular context with

neurofeedback, and when they succeeded in activating the target context to a predetermined threshold, the presentation of the study item was triggered. During the test phase, participants were again given neurofeedback to induce a context that, across runs, either matched or mismatched the study-phase context, and then were instructed to recall the study items. Initial results suggest that participants were able to successfully activate the desired context during study and retrieval, and that the ability to activate contexts improved with practice and concurrent neurofeedback. Moreover, we compared activity patterns at retrieval for items that were encoded in different contexts and observed that the study-phase context was reactivated at retrieval. This provides preliminary evidence of contextual reinstatement in this paradigm. Other analyses (e.g., looking at how context match affects recall behavior) are ongoing. Using real-time fMRI to induce contexts provides a way to conduct more causal manipulations of how contextual reinstatement and context change impact memory. More broadly, this approach could become a powerful way to probe theories of memory retrieval.

Title: An ERP study of memory differences between musicians versus non-musicians

Authors: ***J. SCHAEFFER**, R. MEAHL, H. PARK;
Psychology, Univ. of Texas At Arlington, Arlington, TX

Abstracts: Previous research has suggested that music training is related to improvements in working memory performance and verbal processing. However, little research has been conducted to investigate the relationship between music training and long-term memory beyond working memory. It is also unknown whether the effect of music training on memory is content-specific (e.g., verbal vs. nonverbal). In this study, we employed event-related potentials (ERPs) to investigate both behavioral and neural differences in memory between professional musicians and non-musicians using both words and pictures. Behaviorally, musicians outperformed non-musicians on working memory tasks for both words and pictures; however, musicians showed a memorial advantage on long-term memory only with pictures. These differences were associated with electrophysiological activity of increased discriminability to target words and pictures on

working memory tasks and enhanced sensitivity to studied pictures on long-term memory tasks. ERPs differed between musicians versus non-musicians in mid-frontal (300-500ms) and parietal old/new (400-800ms) regions. These findings extend previous studies of music training and indicate the influence of long-term music training on memory with both behavioral and ERP measures.

Abstracts: Convergent evidence shows that learning is supported by two systems with different cerebral correlates (Knowlton et al. 1996). The first system allows acquisition of declarative knowledge during initial stages and is supported by structures in the medial temporal lobe, and attention-related regions such as lateral prefrontal and medial frontal cortex (Chein et al., 2005). A second system is the procedural system that works independently of executive control and involves the basal ganglia. While there is agreement with regards to the neural bases of declarative memory across domains, neuroimaging and neuropsychological research suggest that procedural learning engages different brain regions dependent on task (Poldrack, 2000). In the present study, we put forward the concept of "re-learning" to account for learning situations that cannot be fully explained by traditional learning distinctions. We investigated the neural bases of re-learning in the acquisition of a second language. We assume that re-learning is based on the re-arrangement of associative connections within an established network and, most likely, a change in representations that belong to the native language of second language learners. To address this question, we presented picture-words pairs to be learnt. We manipulated Number of Repetitions and Relatedness of picture and words. Stimuli included high, low, and non-related

pairs. Using mixed-design fMRI and rs-fMRI, we replicated previous results of the language-acquisition literature that show early activation of the IFG (Ye et al. 2011) and activation of regions involved in executive control in non-related trials such as the ACC, SMA (Wible et al. 2006) bilaterally. However, we failed to find greater activation as repetitions increased. Comparison of pre- and post-learning resting state showed connectivity changes associated with a conflict score (as measured with the multi-source interference task), but not with the learning slope. A mechanism similar to that found in other language-acquisition studies might be involved at least in early learning phases. Further, the resting state connectivity analyses together with increased activation in ACC and SMA, bilaterally, suggest that executive control is a crucial mechanism involved in re-learning. As these areas did not show any increase during repetitions, further research is needed to fully describe this phenomenon. By means of this, we can reach a deeper understanding of re-learning processes in specific populations and use it to improve its training. Additionally, future studies will have to focus on the consequences of re-learning on previously acquired representations.

Title: Intracranial evidence of parietal cortex involvement in the encoding of episodic memories

Authors: *A. GONZALEZ-BARBOSA[1,2], J. HUTCHINSON[6], K. F. LAROCQUE[3,2], J. CHEN[6], B. L. FOSTER[4], V. RANGARAJAN[4], J. PARVIZI[4,5,2], A. D. WAGNER[3,5,2]; [1]Electrical Engin., [2]Stanford Human Intracranial Cognitive Electrophysiology Program, [3]Psychology, [4]Neurol. and Neurolog. Sci., [5]Neurosciences Program, Stanford Univ., Stanford, CA; [6]Psychology, Princeton Univ., Princeton, NJ

Abstracts: Functional MRI has shown that activity in lateral posterior parietal cortex during the encoding of episodic memories predicts later memory outcomes. In particular, superior parietal lobe (SPL) shows greater activity during events that are subsequently remember vs. forgotten, which is thought to reflect the role of top-down attention at encoding. In this experiment, we

used electrocorticography (ECoG) to investigate the temporal dynamics of SPL activity during encoding. Four epilepsy patients, with grids of electrodes covering the left intraparietal sulcus (IPS, #elec=29) and the SPL (#elec=30), performed multiple encoding-retrieval blocks. At encoding, subjects viewed words (20 per block, 2-4 blocks), deciding whether each was abstract or concrete. During retrieval, 20 new words were randomly intermixed with the studied words, and subjects indicated whether they recognized each word as 'old' or 'new'. As a proxy for subsequent memory strength we used the response time for correct trials at retrieval to label the encoding trials as 'subsequently-remembered fast-response' (strongMem), and 'subsequently-remembered slow-response' (weakMem). Given the relationship between fMRI BOLD signal and high-gamma power, we examined the relationship between high frequency power (80-180Hz) at encoding in individual electrodes and subsequent memory strength. Left SPL electrodes showed greater power for strongMem than weakMem from 400-to-600ms, and from 1200ms-to-1400ms post-word presentation. By contrast, left IPS electrodes showed greater power for weakMem than strongMem at a similar late temporal window (1100-1400ms). Together, these results suggest that greater neural activity in SPL during event encoding contributes to the building of strong memories for the event.

Title: Dopamine improves overnight consolidation of episodic memory: Recall, not recognition

Authors: ***J. P. GROGAN**[1], R. BOGACZ[2], D. TSIVOS[3], A. WHONE[3], E. COULTHARD[1,3]; [1]Univ. of Bristol, Bristol, United Kingdom; [2]Univ. of Oxford, Oxford, United Kingdom; [3]North Bristol Trust, NHS, Bristol, United Kingdom

Abstracts: Previous work has established an important role of dopamine in memory, however it is not known to what extent its effects are due to encoding, consolidation or retrieval in humans.

This study aimed to separate the effects of dopamine on learning and testing on an episodic memory test. Fifteen Parkinson's Disease (PD) patients and 13 healthy age-matched controls completed the Hopkins Verbal Learning Test, which has 3 immediate recall trials, and 30 minute and 24 hour delayed recall and recognition tasks. PD patients were tested on and off their dopaminergic medication for each of the two days, giving four conditions tested in a within subjects design (on-on, on-off, off-on, off-off). Controls were tested once. PD patients show large impairments on every aspect of this task, with lower recall accuracy on the immediate and delayed recall trials, and a decrease over the delays that controls do not show. Dopaminergic medication during learning had a significant detrimental effect on 30 minute and 24 hour delayed recall with lower word retention when patients were on medication on day 1. Dopamine on day 2, however, had a positive effect with patients having higher 24 hour retention when on medication at time of testing. As retrieval takes place at both 30 minute and 24 hour recalls but the positive effect of dopamine is only seen after the longer delay, this suggests a role of dopamine in consolidation. Patients are also impaired on the recognition task, compared to controls, and again show a decrease in recognition discrimination accuracy on the delayed tasks which the controls do not show, which was unaffected by medication state. However, day 1 dopaminergic state did affect response bias (from signal detection analysis) on the day 2 recognition test. Patients that were on medication on day 1 had a more negative response bias on day 2, meaning more "yes" responses to the question "Was this word on the list you heard yesterday?" Patients that were off medication on day 1 had the opposite effect, with a more positive response bias on day 2, so more "no" responses. This suggests that although dopamine does not affect recognition accuracy, dopamine levels at the time of learning (or soon thereafter) do affect the amount of evidence needed for a word to be accepted as a memory when tested 24 hours later. In conclusion, PD patients were impaired on delayed recall and recognition compared to controls, and dopamine overnight and at testing 24 hours after learning improves recall, but without improving recognition of those words. This suggests that consolidation of episodic memories for later recall and recognition use different mechanisms, only the former of which is dopamine dependent.

Title: Naturalistic and laboratory encoding contexts dissociate subjective and objective measures of episodic memory in older adults

Authors: *N. DIAMOND[1,2], B. LEVINE[1,2];
[1]Rotman Res. Institute, Baycrest Hosp., Toronto, Canada, ON, Canada; [2]Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstracts: Introduction Laboratory-based studies of episodic memory (EM), which are typically highly controlled but use relatively artificial stimuli, are assumed to tap into the same core processes that support memory for past experiences from outside the laboratory. However, compared to lab-based measures of EM, autobiographical episodes involve a greater range of factors that affect encoding and subsequent recollection. Accordingly, there is evidence for important differences in the neural substrates of EM across lab-based and naturalistic paradigms. We addressed this disparity by probing memory for a rich and interactive yet homogeneous and controlled event, using aging as a model for EM decline. We also manipulated event properties by testing memory for the same content encoded in a naturalistic (real-life walking tour) vs. laboratory (photo-slideshow of same tour) context in order to investigate how aging interacts with the encoding context to produce differences in EM quality and accuracy. **Methods** Younger and older healthy adults were randomly assigned to the naturalistic tour (NT) or the lab tour (LT). Participants in both conditions listened to the same audio tour guide that controlled item sequence and viewing time. After a 48 hour delay, all participants completed the same novel recognition memory test comprising 86 true/false statements and a subjective rating (remember/know/guess) for each statement. **Results** Overall, the NT condition evoked greater recognition accuracy than the LT condition, $f(1,36) = 8.966$, $p = .005$, but this difference was only significant in the younger group. The NT condition elicited significantly more remember responses overall $f(1,36) = 7.279$, $p=.011$). In the older group only, we observed a significant interaction between event condition and subjective rating ($f(2,44) = 6.575$, $p = .003$) with NT eliciting more remember responses and fewer guesses than LT despite no accompanying advantage in objective recognition accuracy. **Conclusions** These results suggest that subjective re-experiencing and high-fidelity retrieval of event details are behaviorally dissociable. The richer spatiotemporal context of the naturalistic encoding context elicited greater subjective recollection in older adults despite no significant difference in objective recognition memory accuracy across conditions. Age-related brain changes may affect retrieval of fine-grained details while sparing the felt vividness of mnemonic representations. We were able to detect this finding by designing a naturalistic experimental event approximating the complexity and scale of autobiographical episodes and the control and homogeneity of the laboratory.

Title: Transcranial direct current stimulation improves audioverbal memory in patients with stroke

Authors: *T. KAZUTA[1], R. OSU[2], K. TAKEDA[3], S. TANAKA[4], A. OISHI[1], K. KONDO[1], M. LIU[5];
[1]Tokyo Bay Rehabil. Hosp., Narashino-shi/Chiba, Japan; [2]ATR Computat. Neurosci. Labs., Kyoto, Japan; [3]Fujita Mem. Nanakuri Institute, Fujita Hlth. Univ., Mie, Japan; [4]Lab. of Psychology, Hamamatsu Univ. Sch. of Med., Shizuoka, Japan; [5]Dept. of Rehabil. Medicine, Keio Univ. Sch. of Med., Tokyo, Japan

Abstracts: Objectives: We investigated whether anodal transcranial direct current stimulation (tDCS) over the left temporoparietal area improved the audioverbal memory in patients with stroke. **Mehods**: 12 patients (mean age 71.8 yrs) with mild to moderate cognitive deficits after a stroke participated in this single-masked, crossover, and sham-controlled experiment. All participants performed the Rey Auditory Verbal Learning Test (RAVLT). In the RAVLT, we presented the participants aurally a list of 15 common words one-by-one (encoding procedure). After the presentation of the 15 words, the participants were asked to repeat as many words as they could (recall procedure). This encoding-recall procedure was repeated five times. Each participant underwent two tDCS conditions: 10 min anodal and 15 s sham stimulation over the left temporoparietal cortex within 7 days of a washout period. The order of the two conditions was randomly assigned for all participants. The stimulation was applied from the second encoding procedure until the end of the session. We measured the number of recalled words in each recall procedure (1-5). The results were analyzed with two-tailed paired-samples t tests for within-subjects using the Bonferroni correction for multiple comparisons. **Results**: The mean number of recalled words was larger in anodal compared with that in sham conditions on the second, third and fifth procedure. Especially, the mean number of recalled words positioned at the beginning of the list was larger in anodal stimulation than in sham control (primacy effect). In addition, anodal tDCS increased the amount of recalled words on the fifth procedure compared with the first procedure, and the improvement was greater than that with the sham, suggesting improvement in verbal learning ability. **Conclusion**: Our results imply that anodal tDCS over the left temporoparietal cortex induced short-term modulation and the primary effect

in learning aurally presented words in patients after a stroke. tDCS could be a promising tool for improving memory performance.

Title: Contributions from memory competition on intentional forgetting

Authors: *J. A. LEWIS-PEACOCK[1,2], K. PLACEK[1];
[1]Dept. of Psychology, [2]Imaging Res. Ctr., Univ. of Texas at Austin, Austin, TX

Abstracts: Forgetting is often viewed as a failure of memory; however, forgetting can be understood as an adaptive process that prunes unneeded memories to increase our cognitive efficiency. How do we forget? According to the nonmonotonic plasticity hypothesis (Newman & Norman, 2010), neural competition leads to forgetting, such that moderate activation of a neural representation will lead to weakening of that representation. This hypothesis has been used to explain incidental forgetting in a variety of behavioral paradigms (e.g., in paired-associate retrieval, visual statistical learning, and working memory switching; e.g., Norman, Turk-Browne, Lewis-Peacock, and colleagues). Does competition also underlie the deliberate scrubbing of memories? Intentional forgetting of information has been described an active, effortful cognitive process (Fawcett & Taylor, 2008). We hypothesized that neural competition between lingering memory items contributes to the cognitive effort observed during intentional forgetting. Specifically, we predicted that lingering activation of a to-be-forgotten item will thrust that item into a losing competition with other, more strongly activated to-be-remembered items, thus leading to weakening of that item. To test this prediction, we designed a fMRI study to assess whether the degree of activation of memory items that are cued for deletion correlates with subsequent forgetting of those items. We used an item-method directed forgetting procedure: on each trial, participants were shown a single picture, followed by a brief delay period. They were asked to make a subcategory judgment about each picture and to focus on remembering the picture during the subsequent memory delay. On a random one-third of the trials, however, a cue during the delay period indicated that the preceding item should instead be forgotten. At the end

of the experiment, participants performed recognition judgments on the studied pictures with novel pictures as foils. Behavioral piloting replicated the standard directed-forgetting effect: items cued to be forgotten were less well remembered. Preliminary fMRI data collection has begun, and we are performing multi-voxel pattern analysis on brain data from the learning phase of the experiment and correlating these activation levels with subsequent memory performance on an item-by-item basis. We hypothesize that an item will more likely be forgotten if, following the forget instruction, its neural representation is moderately active relative to the preceding to-be-remembered items. Results of these analyses will be discussed in the context of the neural mechanisms underlying deliberate forgetting.

Title: Long term memory influences the deployment of auditory attention as revealed by neuromagnetic recordings

Authors: *J. ZIMMERMANN[1], M. MOSCOVITCH[2], C. ALAIN[2];
[1]Rotman Res. Inst., Oakville, ON, Canada; [2]Rotman Res. Inst., Toronto, ON, Canada

Abstracts: Numerous studies have shown that long term memory (LTM) can influence the deployment of visuo-spatial attention (Patai et al., 2012). Here, we tested whether LTM can also bias the deployment of auditory attention. Participants completed a learning and a test phase, which were separated by a one hour retention interval. During the learning phase, participants were presented with 2.5 second audio clips (e.g. bar sound scene, birds chirping, etc.). Half of the audio clips, referred to as valid scenes, contained a brief (200 ms) and slightly louder pure tone target. The target was presented to the left or right ear at 2000 ms after sound sound clip onset. The pairing between an audio clip and a target location was kept constant during the learning and test phases. The other half of the stimuli did not include a target (neutral scenes).

During the learning phase, participants were asked to press a button indicating the location of the target. Immediately following the learning phase, a memory test was administered to determine for which audio clips the association between the clips and the target location was formed. During the memory task, participants heard the audio clips from the learning phase (but with no pure tone in any of the clips), and were asked to indicate where they remember the tone being presented with a keypress response (right side, left side, or none). Results of the memory test indicated that participants formed memory contingencies between audio clips and location of embedded target for a large proportion of trials (M = .71, SD = .15), significantly more than the proportion expected by chance (M = .33). Following an hour retention interval, event related fields were measured using magnetoencephalography during the subsequent testing phase, where participants were cued with valid or neutral sound scenes from the learning phase (i.e., all previously heard), and pressed a button indicating the location of a pure tone target, which appeared either at a previously learnt target location (for valid scenes) or at an unlearned location (neutral scenes). Participants were faster and more accurate in judging the location of a target sound when they had previously learned the target location within that scene (valid scenes) than when no contextual memory existed (neutral scenes). This gain in performance was accompanied by specific changes in neuroelectric activity associated with allocation of attention to expected target locations, which differed from responses to unlearned target locations. The study shows that auditory LTM facilitates the deployment of attention toward the location of an incoming target.

Title: Dominant elements are powerful memory cues for entire episodes

Authors: *D. J. BRIDGE[1], J. L. VOSS[2];
[1]Med. Social Sci., [2]Med. Social Sci. and Ken and Ruth Davee Dept. of Neurol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstracts: Episodic memories are composed of various elements encountered within a given spatial and temporal context. Out of the many elements, are any more likely than others to later serve as the strongest cues for retrieval of the entire episode? We have previously demonstrated that the hippocampus selectively binds dominant memory elements with relatively novel contextual information. Building on these findings, we hypothesized that dominant elements of an event would provide the strongest cues for retrieving the associated elements, because dominant features may be preferentially bound to the other information. In contrast, we predicted that nondominant elements would provide relatively weak cues for episodic retrieval. To test this hypothesis, we collected EEG and eye-movement data while subjects completed a spatial association task. During the study phase, subjects studied three objects in unique spatial locations on a grid. In order to manipulate element dominance, we prompted subjects to either actively recall one object's associated location or passively move one object back to its associated position on a grid. Thus, for each trial, one object and its location (i.e., an element) was made relatively dominant, while the other two objects remained equally non-dominant. During the test phase, subjects were cued with one location on the grid: either the dominant object or a nondominant object, and were required to recall the identity and location of another nondominant element. Memory of nondominant elements was enhanced when given a dominant cue relative to a nondominant cue. These results suggest that dominant event elements serve as powerful retrieval cues, potentially due to their ability to preferentially support pattern completion for the various elements comprising an episode. ERP and eye-movement correlates of these effects of element dominance will also be discussed.

Title: Different modes of contextual association learning modulate the neural correlates memory

Authors: *D. R. O'YOUNG, J. L. VOSS;
Northwestern Univ., Chicago, IL

Abstracts: Associative learning occurs in specific contexts that govern the appropriate behavioral expression of memory (e.g. remembering to dress formally for a wedding, but not the gym). Human and animal research implicates differential involvement of hippocampus/prefrontal cortex versus striatum during associative learning, with the former involved in relatively flexible, rule-based memory and the latter in inflexible, habit-based memory. We studied the effects of contextual association learning under conditions designed to promote flexible versus habitual expression of memory. Trials were presented in one of four quadrants (e.g. contexts). Given a Cue object, subjects indicated if a subsequent Target object was associated or not (e.g. yes or no). Cue-Target associations were varied by context such that Targets could be classified as Associated, Conflicting (e.g. associated in other contexts), or Non-associated. Each subject performed the task during two sessions, including either: (i) repetitive, predictable trial sequences to promote learning associations in series and habitual responding, or (ii) pseudo-randomized trial sequences to promote learning associations in parallel rule-based responding. Learning was based on feedback to subject responses. A subsequent test phase, which did not contain feedback, was used to examine memory of the learned associations. Accuracy was high and did not vary by session (N=10), indicating successful learning and expression of memory across conditions. ERP findings during the test phase indicate enhanced late positive potentials in response to Cues after repetitive, predictable learning, suggesting greater cued recall in this condition. Pseudo-randomized learning, on the other hand, lead to an enhanced late positivity during the test phase in response to Conflicting targets but not Associated or Non-associated targets, suggesting greater utilization of contextual information in memory to resolve such conflicts. Together, these results suggest that different modes of learning distinguished only by the order and predictability of trials can engage different brain systems during subsequent expression of memory. Results are interpreted with regards to distinctions between human and animal memory research, which often differ in consistency and predictability of training, potentially promoting involvement of different brain systems.

Title: Gamma-band oscillations in the human hippocampus during memory retrieval

Authors: *O. A. ARBIV[1], M. C. DRAGAN[1], T. K. LEONARD[1], R. MONTEFUSCO-SIEGMUND[1], T. A. VALIANTE[2], K. L. HOFFMAN[1];
[1]York Univ., Toronto, ON, Canada; [2]Toronto Western Res. Inst., Toronto, ON, Canada

Abstracts: Gamma-band (30-100 Hz) synchrony is thought to facilitate the communication, integration, and selection of information in the brain. In the hippocampus of rodents, gamma-band synchrony is a correlate of both encoding and retrieval of memories, with fast gamma band (60-100 Hz) hypothesized to facilitate encoding of memories through plasticity across adjacent phases of the gamma oscillations, whereas slower gamma oscillations (30-60 Hz) could support memory retrieval by allowing for communication amongst neurons that is too slow for LTP to take place, thereby maintaining the connection strengths across the assembly of cells supporting the memory trace (Bragin et al., 1995; Colgin & Moser, 2010). In humans, gamma oscillations are stronger during successful encoding (Sederberg et al., 2007), but little is known about whether or not hippocampal gamma oscillations are involved in memory retrieval. We addressed this question using a memory-guided visual search task that requires hippocampal integrity (Chau et al., 2011). In Experiment 1, 6 patients with intractable epilepsy, implanted with hippocampal depth electrodes for clinical purposes, performed a flicker target-detection task. The task involves visual exploration of a flickering scene that alternates presentation of one object in the scene (‘target’). Target detection (fixation) was faster on repeated trials that were remembered than on novel or forgotten trials, an effect that requires an intact hippocampus (Chau et al., 2011). In the time leading up to target detection, we observed an increase in oscillatory power in the gamma-band (60-100 Hz) in remembered trials, compared to the same time period in novel trials, $t(5) = 3.40$, $p = .02$. In Experiment 2, 3 of the aforementioned patients performed an uncued (non-flicker) target detection task. In this task, participants viewed naturalistic scenes for 5 seconds, after which a target object was revealed in the image. In repeated viewings of the scenes, participants were asked to fixate upon the remembered (but otherwise uncued) location of the target object. We observed a similar memory-related increase in the gamma-band spectral power (limited to 50-80 Hz) in the 1-second period preceding

successful recall compared to fixations balanced for time or location during novel trials. These results suggest that gamma-band synchrony may indeed be related to memory retrieval. In contrast with the putative role of fast gamma in encoding, we observed fast-gamma oscillations during successful recall, perhaps indicating a different role than previously suggested (Colgin & Moser, 2010).

Title: Neurofeedback training of large-scale brain networks

Authors: *R. LORENZ[1,2], A. A. FAISAL[2], M. DINOV[1], I. R. VIOLANTE[1], R. LEECH[1]; [1]Med., [2]Bioengineering, Imperial Col. London, London, United Kingdom

Abstracts: Recently, the focus in cognitive neuroscience has shifted in support of the view that cognition results from an interaction between large-scale brain networks rather than is attributable to isolated brain areas (Bressler & Menon, 2010). The active modulation of such intrinsic brain networks by means of real-time (rt-) fMRI neurofeedback has great therapeutic potential in improving impairments in high-level cognitive functions such as attention and memory. In our pilot study, we investigate the feasibility of such an rt-fMRI neurofeedback approach for voluntarily controlling activity of the default mode network (DMN). A subject-specific map of the DMN was derived from a standard template independent component (Smith et al., 2009) using a dual regression approach on a four minute resting state scan prior to the experiment. The subject-specific map was used to calculate an estimate of DMN function for each repetition time (TR). Real-time fMRI motion correction, preprocessing, registration as well as feedback calculation and display were performed within the open-source FSL-integrated toolbox FRIEND (Sato et al., 2013). Offline fMRI analyses were performed in FSL. Subjects reported a perceived neurofeedback control and how this varied across fMRI runs. Offline fMRI analyses indeed showed a significant relationship between subjective assessment of control and activation within the DMN, indicating network activity modulation. Although the vast majority of rt-fMRI research focused on the volitional control of activity in well-circumscribed brain

regions, the field is now mature enough to incorporate rt-feedback of large-scale brain networks and their connectivity. In the future we are interested in modulating functional connectivity between the DMN and executive control networks in healthy subjects and traumatic brain injured patients.

Title: Selective attention in a dynamic auditory scene

Authors: *I. CHOI, H. GOLDBERG, H. BHARADWAJ, B. SHINN-CUNNINGHAM; Boston Univ., Boston, MA

Abstracts: To communicate in social settings, we focus selective attention on one voice while simultaneously monitoring novel voices that unexpectedly arise from other locations. This study investigates the behavioral and neural consequences of "social monitoring" during selective auditory attention. We hypothesized that when a specific location is the focus of attention, sensory inputs from other locations are strongly inhibited, but that when listeners anticipate having to reorient to unexpected events, inhibition is weaker, degrading the ability to focus on the original target. Listeners heard either two or three spatially separated sequences of syllables spoken by the same talker. Both a center stream and a concurrent distractor stream on the left (-700 μs interaural time difference or ITD) were always played. In 2/3 of trials, a stream on the right (+700 μs ITD) started at a random time after the second syllable of the center stream. On

each trial, a visual cue 2s before the auditory stimulus denoted whether the trial was "Fix" or "Switch." On “Fix” trials, listeners had to report the syllables from the center stream. On “Switch” trials, listeners had to report the syllables from the delayed, right steam if it occurred (2/3 of trials), but report the center stream on other trials (1/3). Throughout, scalp potentials were measured using 64-channel electroencephalography. Inter-channel pairwise phase consistency (PPC) of alpha (8-14Hz) oscillations was analyzed from the preparatory period (after the visual cue but before auditory stimulus). We compared behavioral performance for Fix and Switch conditions in the trials where no right stream was present (i.e., physically identical trials with only center and left streams, report center). Performance was significantly better in the Fix condition, revealing the behavioral cost of social monitoring. Moreover, alpha-oscillation PPC over parieto-occipital electrodes was larger for the Fix condition than the Switch condition. Our results are consistent with previous studies associating alpha oscillations with inhibition of sensory inputs. In addition, we find that listeners pay a cost to enable dynamic switching of attention to new events, a result of reducing the inhibition that focuses selective attention.

Title: Failure of the default mode network to deactivate precedes attentional lapses: An intracranial EEG study

Authors: *A. D. MEHTA[1], P. MEGEVAND[2], Z. YANG[4], D. M. GROPPE[3], C.-G. YAN[5], F. CASTELLANOS[6], M. P. MILHAM[4];

Sch. of Med., New York, NY

Abstracts: “Everyone knows what attention is”, wrote W. James over a century ago, and yet its neuroanatomical and neurophysiological underpinnings remain uncertain. Recent evidence has begun to link attention with the default mode network (DMN), a set of brain regions whose

activity is generally greater at rest than during task performance. Specifically, functional MRI studies suggest that failure of the DMN to deactivate during task execution might underlie attentional lapses. Intracranial EEG (iEEG), with its millisecond level temporal resolution and centimeter scale spatial resolution, offers a unique opportunity to test whether activity in the DMN causally determines attentional capabilities. In this preliminary iEEG study, we report on the correlation between trial-to-trial DMN activity and behavioral performance. iEEG was recorded with subdural electrodes over multiple brain regions within and outside the DMN in patients with drug-resistant epilepsy who performed a warned four-choice reaction time (RT) task. The iEEG electrodes' anatomical location was determined by co-registering pre- and post-implant CT and MRI scans. High-gamma amplitude (HGA, an index of local neuronal firing) was extracted using the Hilbert transform on the bandpass-filtered iEEG (4-order Butterworth filters with 10-Hz passband incrementally from 65 to 175 Hz), demeaned over the complete recording session (96 trials, ~20 min). We looked for changes in HGA power in the second following the appearance of the target stimulus. We also correlated single-trial RT with slow HGA fluctuations (<= 1 Hz) in the 1-s period immediately preceding stimulus appearance. The motor strip, supplementary motor area (SMA), and middle frontal gyrus (MFG) showed stimulus- and response-related HGA increases, whereas decreases were seen in the orbitalis portion of the inferior frontal gyrus (IFG) and the superior frontal gyrus (SFG), especially its medial and anterior part. Importantly, these areas with task-related HGA decreases are known nodes of the DMN. Crucially, we found positive correlations between longer RT and pre-stimulus high HGA in the same DMN areas. These preliminary findings support the notion that higher DMN activity precedes attentional lapses.

Title: The functional neuroanatomy of sustained non-selective attention

Authors: C. P. COSTE[1], *A. KLEINSCHMIDT[2];
[1]Clin. Neurosciences, UNIGE - Geneva Univ. Hosp., Genève, Switzerland; [2]NeuroSpin, Hôpitaux Universitaires de Genève, Service de Neurologie, Genève, Switzerland

Abstracts: Paradigms investigating the neural basis of tonic alertness or vigilance have usually employed single targets and often been conducted in sleep-deprived subjects, thereby collapsing over effects from arousal, alertness, and selective attention. Here, we sought to selectively target tonic alertness by a task requiring merely sustained non-selective attention. We used functional magnetic resonance imaging and a sparse event-related design with many randomly appearing and interleaved auditory and visual trials, all of them targets. Moreover, to fully avoid signal contributions from selective attention once a given stimulus was presented, we focused on the influence of variations of ongoing brain activity prior to task appearance on reaction times. We analyzed effects in several intrinsic functional connectivity networks and early sensory cortices and compared pre-stimulus activity for quickly and slowly reported targets. We found higher pre-stimulus activity in a cingulo-insular network but also the default mode network to result in faster response speed, although only the former activated in response to the paradigm. Conversely, dorsal attention network activity was overall irrelevant and on auditory trials even detrimental to performance. Effects in sensory cortices suggested non-significant contributions from randomly switching selective attention: they were confined to the respective modality or, for visual trials, most pronounced in the relevant retinotopic representation. In a paradigm where no information predicted timing, modality or properties of a subsequent stimulus, our results hence establish the central role of the cingulo-insular network for sustained alertness and demonstrate a neural dissociation, both anatomically and functionally, between non-selective and selective attention.

Title: Humans expressing a subcapacity choline transporter variant: Attenuated right prefrontal activation during challenges to attention

Authors: *M. SARTER[1], A. S. BERRY[1], R. D. BLAKELY[2], C. LUSTIG[1];
[1]Psychol, Univ. Michigan, ANN ARBOR, MI; [2]Vanderbilt Univ., Nashville, TN

Abstracts: Studies in rodent models indicate elevated cholinergic neurotransmission in right prefrontal cortex (PFC) is essential for maintaining attentional performance, especially in challenging conditions. Conceptually paralleling the right PFC cholinergic increases in rodents, fMRI studies in humans reveal right PFC activation increases in response to elevated attentional demand. Enhanced activation in right Brodmann Area (BA) 9, associated with cognitive control, is thought to scale with greater attentional effort during distractor challenge. In the present study we examined the possible role of human cholinergic function in modulating BA 9's response to distraction consisting of a rapidly-changing background during signal detection. Specifically, we tested participants with a polymorphism thought to limit choline transport capacity (Ile89Val variant of the choline transporter gene SLC5A7, rs1013940) and matched controls. We previously showed that Ile89Val heterozygotes were more vulnerable to external distraction; here we assessed whether this polymorphism is associated with attenuation of the typically robust right BA 9 response to attentional demands. Relative to controls, Ile89Val participants showed blunted enhancement of right BA 9 activation in response to increased attentional demand. Further, pattern classification analyses of activation within this region significantly predicted participant genotype. These analyses also suggested Ile89Val may have differentially recruited orbitofrontal cortex and parahippocampal gyrus to maintain attentional performance: Activation in these regions weighed more heavily in discriminating between distraction and no-distraction conditions for Ile89Val relative to controls. The present study contributes to a growing body of translational research clarifying the role of cholinergic signaling in human attention and functional neural measures, and begins to outline the risk and resiliency factors associated with potentially suboptimal cholinergic function.

Title: Objective assessment of cognitive workload during varying degrees of task difficulty using a dry EEG system: Relevance for ecological validity

Authors: *K. JAQUESS[1], J. C. RIETSCHEL[2], L.-C. LO[1], M. W. MILLER[3], H. OH[1,4], Y. TAN[1,4], B. D. HATFIELD[1,4], R. J. GENTILI[1,4,5];

Abstracts: The assessment of cognitive workload in individuals can inform the allocation processes of brain resources during demanding tasks which is critical to understand the underpinning principles of cognitive-motor performance in human performance. A possible solution to assess cognitive workload is to combine behavioral performance along with brain signals such as EEG. Although many studies have examined cognitive workload during performance, they employed EEG-gel based (i.e., wet EEG using conductive gel) systems that are well suited for laboratory, but not field, settings. Such wet EEG systems require a high preparation time; can be uncomfortable for participants and the gel can dry-up over time requiring adjusting the quantity of conductive gel during performance. Therefore, the use of wet EEG systems is relatively limited when examining cognitive-motor processes such as cognitive workload during ecologically valid performance. To address this shortcoming, several EEG systems that do not require conductive gel were developed (i.e., dry EEG). The present investigation aims to compare signal quality of between wet and dry EEG systems at four electrode sites (Fz, FCz, Cz, & Pz) and their respective capabilities to provide brain signatures to assess cognitive workload during a previously employed paradigm where participants played a videogame (Tetris®) at three levels of challenge (easy, medium, and hard). Cognitive load was assessed by employing self-report (VAS and NASA TLX) as well as EEG analyses in the spectral and time domain (P3 component). P3 amplitudes were subjected to a series of four 2 x 3 (System [wet vs dry] x Challenge [easy, medium, hard]) repeated-measures ANOVAs which revealed i) no differences between wet and dry EEG signals, ii) no significant interactions, and iii) significant differences between levels of challenge. These results are promising in support of measurement of cognitive load using dry EEG during ecologically valid human cognitive-motor performance. This research was supported by the Lockheed-Martin Corporation (project # 13051318), USA.

Title: Differences in alpha band lateralization between young adults and elderly when performing a lateralized delayed match-to-sample task

Authors: *M. LEENDERS[1,2], D. LOZANO SOLDEVILLA[1], O. JENSEN[1], P. DE WEERD[2,1]; [1]Donders Inst. For Brain, Cognition & Behaviour, Nijmegen, Netherlands; [2]Dept. of Cognitive Neurosci., Fac. of Psychology and Neurosci., Maastricht Univ., Maastricht, Netherlands

Abstracts: Aging has been associated with degraded connectivity in the brain, as well as with declined memory performance and processing speed. Performance in delayed match-to-sample (DMS) tasks relies crucially on these abilities, which makes such tasks a powerful tool to study aging. Here, we compared young adults and elderly by assessing structural connectivity and functional activation of brain regions, using diffusion MRI and MEG, respectively. DMS tasks generally consist of to-be-remembered target stimuli, followed by a retention interval in which the stimuli are absent, and a memory probe which the participant has to compare with the items in memory (cf. Vogel et al., Nature, 2004). We used a lateralized version of this task, which shows target stimuli in a cued (attended) hemifield and similar (ignored) distracters in the other hemifield, while participants fixate centrally. In young adults (n=25, 18-24y), a relative comparison between hemispheres showed a relative increase in alpha band (8-12 Hz) power in the hemisphere ipsilateral to the target stimuli, and a decrease contralateral to the target stimuli. This fits with the proposed inhibitory role for alpha (see Jensen & Mazaheri, Front. Hum. Neurosci., 2010). Importantly, this alpha lateralization pattern was stronger in the stimulus-to-probe retention interval than in the cue-to-stimulus interval. This might reflect the protection of items in memory from distracting signals during retention. Strikingly, older adults (n=35, 60-75y) showed the opposite pattern: they showed weaker alpha lateralization in the retention interval than in the cue interval; a finding paired with declined memory performance compared to the young population. Further analysis will reveal whether the reduced lateralization during retention in elderly reflects an alpha power decrease within the ipsilateral hemisphere (suggesting a declined ability to suppress distracters) or an increase within the contralateral hemisphere (suggesting declined processing of targets). Alternatively, target processing might recruit both hemispheres, reducing alpha power. Bilateral recruitment in elderly where young people show lateralized activity has been a common finding in aging studies. Analysis of diffusion data is currently ongoing. In summary, compared to young adults, elderly have less capacity to maintain lateralized attention and inhibition during maintenance of items in working

memory, as indexed by changes in alpha band lateralization. Hence, deficiencies in alpha lateralization might underlie at least in part working memory problems in the elderly.

Title: The striatum is anatomically linked to large-scale distributed networks

Authors: *E. CHOI[1], Y. TANIMURA[2], S. N. HABER[1];
[1]Dept of Pharmacol. & Physiol., Univ. of Rochester Med. Ctr., Rochester, NY; [2]Kyoto Univ., Kyoto, Japan

Abstracts: Monkey anatomical tract-tracing studies have revealed that frontal cortex projections to the striatum segregate into a broad topography of motor, cognitive, and limbic functional zones in the striatum. Other studies have further identified cortico-striatal projections from nearly the entire cerebral cortex. Consistent with these more global projections, resting-state fMRI of the human striatum shows that striatal regions are functionally coupled to specific large-scale functional networks consisting of regions distributed throughout the cerebral cortex (Choi, Yeo, and Buckner 2012). However, only a few studies have investigated the anatomical organization with conflicting conclusions as to whether connected frontal and non-frontal cortical regions have convergent projections in the striatum (Yeterian and Van Hoesen 1978; Selemon and Goldman-Rakic 1985). A limitation of these studies is their use of anterograde tracer injections in a restricted number of cortical regions. Here, we investigate the potential anatomical network organization of the macaque striatum using retrograde tracer injections in the striatum to comprehensively identify inputs from throughout the cerebral cortex. We found that a retrograde tracer injection in the rostral dorsomedial caudate labels cortical cells in 46, 9, 45, and 7a. These cortical areas are anatomically interconnected and part of a potential cognitive network. Similarly, a retrograde tracer injection in the rostral ventromedial caudate labels cells in 25, OFC areas, and the temporal pole. Likewise, these cortical regions are interconnected and

part of a limbic network. Taken together, our results provide evidence that there are striatal regions receiving convergent projections from frontal and non-frontal members of anatomically and functionally linked cortical networks. This architecture indicates that the striatum may play a key role in integrating large-scale distributed networks.

Title: Frontoparietal cortices show superior to inferior gradients of preferential structural and functional connectivity with visual and auditory regions

Authors: *R. M. BRAGA, P. J. HELLYER, R. J. S. WISE, R. LEECH;
Imperial Col. London, London, United Kingdom

Abstracts: Introduction: Frontoparietal cognitive control networks are thought to control the allocation of attention to auditory and visual sensory inputs. However, it is not clear whether the same frontoparietal regions are active for auditory and visual sensory processing. Moreover, dorsal regions of the superior parietal lobe and frontal eye fields contain retinotopic maps and elicit saccades when microstimulated. We investigated whether frontoparietal cortices show differential structural and functional connectivity with auditory and visual primary cortices. **Methods:** *Structural connectivity*: We used diffusion tensor imaging (DTI) data from the Human Connectome Project and unconstrained probabilistic tractography to assess the structural connectivity of each voxel in the prefrontal and parietal cortices. We compared the number of streamlines projecting to visual and auditory primary cortices to compute a measure of preferential connectivity to each sensory modality. *Functional connectivity*: We used independent component analysis in a resting-state fMRI dataset to decompose the activity of heteromodal cortices into components. This revealed non-dominant signals within a 215 voxel searchlight that was passed across the parietal and frontal cortices. We assessed these subsignals for functional connectivity with primary auditory and visual sensory cortices to compare relative functional connectivity preference of each searchlight with each sensory modality. **Results:** In

both prefrontal and parietal cortices we observed a superior-inferior gradient of preferential connectivity to visual and auditory regions, respectively. Dorsal regions had stronger functional and structural connectivity with visual regions, while ventral regions communicated more strongly with auditory centers. **Discussion:** Our results suggest that audio-visual sensory processing and attentional control may be mediated by different frontoparietal networks, rather than a single cognitive control network. Importantly, our results suggest that sensory modality can also be encoded in the parietal and prefrontal cortices by the relative position of activation along the superior-inferior axis. This has implications for our understanding of how cognitive control of sensory information is organised in the cortex.

Title: Decreased segregation of brain systems across the healthy adult lifespan

Authors: M. Y. CHAN[1], D. C. PARK[1], N. K. SAVALIA[1], S. E. PETERSEN[2], *G. S. WIG[1]; [1]Ctr. for Vital Longevity, Univ. of Texas at Dallas, Dallas, TX; [2]Neurol., Washington Univ. Sch. of Med., St. Louis, MO

Abstracts: Healthy aging has been associated with changing patterns of specialization in brain function. Though much research has focused on descriptions of functional specialization at the level of neurons and areas, less work has explored systems-level descriptions of organization and function. We analyzed patterns of resting-state functional correlations (RSFC) using a graph-theoretic framework to describe systems-level changes in the brain networks of individuals sampled across the adult lifespan. Individuals were a subset of participants from the Dallas Lifespan Brain Study (DLBS) who had completed a resting-state fMRI scan and a neuropsychological battery (N=210; age range: 20-89 years). Brain network nodes were constructed from a recently published area parcellation map (Wig et al. 2014). In this parcellation map, area borders are defined in relation to probabilistic transitions in patterns of RSFC. Each node was labeled according to a RSFC-defined functional system (Power et al.

2011). For each individual in the DLBS sample, brain network edges were defined as the Fisher's z-transformed Pearson correlation of the resting-state time series between each pair of nodes. Young adults' brain systems exhibited a balance of within- and between-system correlations that promoted a modular and segregated organization. Increasing age was accompanied by decreasing segregation of brain systems across a variety of network metrics that focused on patterns of within- and between-system correlations. Interestingly, not all systems exhibited the same pattern of age-related reductions in system segregation. While systems mediating processing operations (e.g., visual, sensory and motor) demonstrated a linear pattern of age-related reduction in system segregation, systems mediating control operations (e.g., frontal-parietal control, cingulo-opercular control, dorsal attention) exhibited a quadratic pattern, with accelerated reductions in segregation following age 50. Of particular importance, a partial correlation revealed that the magnitude of control system segregation was predictive of long-term memory performance, independent of an individual's age. Together, these results provide strong evidence for systems-level changes that accompany healthy aging, and suggest that the organization of brain systems has a direct relationship to cognitive function.

Title: Breaking away from perceptual attention: Electrophysiological signatures of shifts from monitoring to signal-associated response in typically-developing children and those with obsessive-compulsive disorder

Authors: *A. S. BERRY, M. SARTER, G. L. HANNA, W. J. GEHRING, C. LUSTIG; Univ. of Michigan, Ann Arbor, MI

Abstracts: Many situations require monitoring the environment for signals - the stoplight turning green, the beep of the microwave - and activating their associated behaviors - hit the gas, retrieve the popcorn. Distinctions between externally-directed (perceptual) processes involved in

monitoring and internally-directed (reflective) processes involved in activating signal-associated representations are fundamental to the organization of attention. However, only recently has the field engaged with questions of how these attentional modes interact or how processing switches between them (see discussion by Chun & Johnson, 2011). Our previous fMRI research tested adults in a visual signal detection task to investigate the neural activity associated with shifts from perceptual to reflective processing. Specifically, we found increased rostrolateral PFC (RLPFC) activation for hits (signal detections) occurring after extended periods of perceptually-oriented, non-signal processing relative to hits that followed a previous hit and thus did not require as large a shift from perceptual attention (Howe et al., 2013). A complementary event-related potential (ERP) investigation likewise found a right PFC signature for this contrast (larger P3a amplitude). For both studies, shift sequences were associated with increased frontoparietal functional connectivity. Here we investigated this frontoparietal neural activity in typically developing children and those with obsessive-compulsive disorder (OCD) (n = 20 per group; ages 8 - 16). These populations were of particular interest due to known changes in frontoparietal structure and function throughout childhood, and possible dysregulation of rostral PFC activity in OCD. Results suggest that compared to young adults in our previous studies, healthy children show an attenuated right prefrontal response, which is further disrupted in OCD for trials involving shifts from perceptual to reflective attention. Altered RLPFC response in OCD may reflect an impairment in the ability to flexibly shift attention or "break away" from a current task representation.

Title: Visual attention redirection interferes with saccadic performance

Authors: *J. R. TORRES;
ICBM, BNI CENEM Fac. of Med. Univ. De Chile, Santiago, Chile

Abstracts: Based on behavioral evidence, it has been proposed that orientation of visual attention is coupled to oculomotor planning giving that saccade planning leads to a facilitation of the visual processing of targets at the same visual locus. However, there are evidence of a complete mechanistic independence between an oculomotor planning and attentional orientation. We aimed to examine this dependence during a task that requires visual redirection during a saccade execution. Ten subjects (2 male) performed a dual task (adapted from Deubel and Schneider, 1996) in order to track the location of an attentional focus by discriminating the identity of a peripheral target which is indicated with a central cue, while they have to perform a saccade to a target that is in the same location of the primary task, or to a neighboring site. 25% of the trials were “invalid”, because we presented the discrimination target in the opposite side of the one indicated by the central cue. Each trial begins with the gaze on a central fixation while all possible locations for targets presents a premask. The central fixation is replaced by an arrow which direction and color indicate the side of the discrimination target and the position of the saccade, respectively. The saccade has to be withheld during a variable time (900-1400ms) until a new arrow appears indicating the saccade was to be executed (Go signal). The identification target appears 60ms post Go signal and held for 120 milliseconds, and then replaced by a mask. There were significant differences in saccadic performance between valid and invalid trials. In the valid trials subjects obtained a significant higher percentage of hits to the cued location (40.13%, SD 13.31) versus invalid trials (2.6% , SD 1.53), ($p=0.000$; $F=78.4$). Bonferroni test showed a significant difference between congruent valid trials (53.1%, SD 21.0) and invalid congruent trials (21.0%, SD 3.8), $p=0.001$, $F=50.48$. These results suggest that, during invalid trials, the absence of the discrimination target in the cued side triggers an attentional reorienting, interfering the execution of the current saccade. A possible explanation for this phenomenon is the existence of shared resources between attentional orienting and oculomotor planning, causing structural interference between these two processes when attention is reoriented.

Title: Distributed attention is implemented through theta-rhythmic gamma modulation

Authors: ***A. N. LANDAU**[1], S. VAN PELT[2], H. M. SCHREYER[2], P. FRIES[3];
[1]Ernst Strüngmann Inst. (ESI) In Cooperation With Max Planck Society, Frankfurt Am, Germany; [2]Ernst Strüngmann Inst. (ESI) for Neurosci. in Cooperation with Max Planck Society, Frankfurt, Germany, Frankfurt, Germany; [3]Ernst Strüngmann Inst. for Neurosci. (ESI) in Cooperation with Max Planck Society, Frankfurt, Germany, Frankfurt, Germany

Abstracts: When subjects monitor a single spatial location, target detection depends on the pre-target phase of an ~8 Hz brain rhythm. When multiple locations are monitored, performance decrements suggest a division of the 8 Hz rhythm over the number of locations. This suggests that different locations are sequentially sampled. Indeed, when subjects monitor two locations, performance benefits alternate at a 4 Hz rhythm. These performance alternations followed a reset of attention to one location. Although resets are common and important events for attention, it is unknown, whether in the absence of resets, ongoing attention operates rhythmically. Here, we examined whether spatially specific attentional sampling can be revealed by ongoing pre-target brain rhythms. Specifically, visually induced gamma-band activity plays a role in spatial attention and therefore, we hypothesized that performance can be predicted by a theta-rhythmic gamma modulation. Brain rhythms were assessed with MEG, while subjects monitored bilateral grating stimuli for a unilateral target. The corresponding contralateral gamma-band responses were subtracted from each other to isolate spatially-selective, target-related fluctuations. The resulting lateralized-gamma activity (LGA) showed opposite 4 Hz phases prior to detected versus missed targets. The 4 Hz phase of pre-target LGA accounted for a 14% modulation in performance. These findings suggest that spatial attention is an ongoing theta-rhythmic sampling process, with each sampling cycle implemented through gamma-band synchrony. This extends previous findings by demonstrating that in the case of distributed attention, gamma-band synchrony is shaped by the slower sampling rhythm that governs performance benefits.

Abstracts: As a complex system, the cortex has the intriguing ability to shift between states of high and low entropy. In the present work, we examined attention-induced broadband shifts of the slope of the power spectrum of the electroencephalogram (EEG) recorded from human subjects. Our results indicate that the spectral slope becomes significantly more negative over occipital regions contralateral to an attended region of space. This shift is indicative of an increased amount of order (lower entropy) within the visual cortex as a consequence of anticipatory attention. Importanly, this shift occurs in the absence of significant frequency-specific changes in power, indicating a novel computational mechanism by which anticipatory attention prepares sensory regions for impending stimuli.

Title: Cortical and sub-cortical brain regions modulated during spatial attention: A BOLD fMRI study in monkeys

Authors: *A. R. BOGADHI, R. J. KRAUZLIS;
Lab. of Sensorimotor Res., Natl. Eye Inst. - NIH, Bethesda, MD

Abstracts: Studies of spatial attention have focused on neocortical circuits linking sensory cortex with areas in parietal and frontal cortex (e.g., MT/MST, LIP, FEF). However, recent findings demonstrate that subcortical regions (e.g., superior colliculus, SC) play a crucial role in spatial attention (Lovejoy & Krauzlis, 2010) and act down stream of visual cortex (Zenon & Krauzlis, 2012), but the circuit through which the SC acts is not known. Because fMRI data could be useful in identifying potential brain regions that partner with the SC to control spatial attention, we trained a monkey to perform a covert spatial attention task inside a vertical fMRI

scanner. The stimulus sequence on a single imaging run (~550s) consisted of three different blocks: Rest (R), Foveal Attention (FA) and Peripheral Attention (PA) blocks, each lasting 27.5s. R blocks were interleaved between FA and PA blocks. In R block trials, the relevant stimulus was a central fixation point that dimmed at random times. FA block trials were similar to R block trials but added a peripheral motion-change stimulus as an irrelevant distracter. In PA block trials, the fixation point did not dim and the peripheral motion-change was the relevant stimulus. The task of the monkey was to report the relevant stimulus change (fixation dimming in R & FA blocks, peripheral motion change in PA blocks) by releasing a lever to get a juice reward. Eye movements were recorded during each imaging run. Blocks in which eye position fell out of the 20 radius fixation window during any trial were excluded from analysis. A total of 656 R blocks, 296 FA blocks and 141 PA blocks across eight sessions were included. For our preliminary analysis, we defined two anatomical ROIs (MT/MST, SC) on the high-resolution anatomical images of the monkey as the overlap between the stereotaxic atlas coordinates (Saleem & Logothetis, 2007) and the functional contrast between R and FA blocks. A majority (79%) of the voxels in MT/MST (PA: 0.27±0.001%; FA: 0.17±0.001%) and all voxels in SC (PA: 0.24±0.001%; FA: -0.05±0.001%) showed BOLD activation for attention to motion (PA); the activity was significantly modulated when peripheral motion was task-relevant (Wilcoxon rank sum test; $P<0.001$). A minority (21%) of the voxels in MT/MST (PA: -0.58±0.005%; FA: 0.27±0.002%) showed BOLD suppression in blocks with attention to visual motion (PA); this suppression was significantly different from the activation in FA blocks (Wilcoxon rank sum test; $P<0.001$). These results corroborate the findings from physiological studies in monkeys and validate the use of fMRI in monkeys to identify brain regions involved in the control of spatial attention.

Title: Topography and temporal dynamics of resting state network signatures in high-density EEG

Authors: *S. E. SAPERSTEIN[1], R. SEKULER[3], J. W. BOHLAND[2];
[1]Grad. Program for Neurosci., [2]Hlth. Sci., Boston Univ., Boston, MA; [3]Psychology, Brandeis Univ., Waltham, MA

Abstracts: The analysis of resting state functional connectivity using fMRI has gained widespread acceptance and has identified consistent networks engaged at rest, but such approaches remain underdeveloped in EEG. Here we propose methods to identify sensor networks representing resting brain states that can be used to characterize the topography and temporal dynamics of those states. Nine subjects participated in either a sustained attention or working-memory task preceding and following periods of rest with eyes open and fixated while high density (128-channel), high impedance EEG signals were recorded. The resulting sensor time series were manually quality controlled, band-pass filtered, and split into epochs one-second in duration. The maximum values (across a range of lags) of pairwise cross-correlations between electrodes, for each epoch, were compared to an empirical null distribution to generate a percentile rank for each edge, representing functional connectivity between electrodes. A Mann-Whitney U-test identified functional connections that are stronger in either the pre- or post-task resting periods compared to the task period. Comparing the sensor pairs more strongly coupled during each rest period than the task period, a hypergeometric test confirmed that the network overlap, within a session, was highly significant across a range of p-value thresholds from the U-test. The resulting common network can be considered "rest-enhanced," and we compare the topography of these connections across subjects and sessions using a method that combines sensors from nearby locations to account for variability in sensor placement. Using these subject-specific networks as probes, we then calculate an activation time course across the full experiment to determine if this network is transiently activated during the task period, potentially interfering with task performance. In a second analysis, vectors of functional connections and node degrees for each epoch formed the inputs to k-means cluster analyses, for a range of values of k. Patterns of occurrence of the resulting clusters were compared between experimental periods, across k, to find network states that occur preferentially in each experimental period. We found that network clusters tended to recur preferentially during the pre- and post-task resting periods in each subject. Our approach identifies common sensor correlation patterns that occur preferentially during rest, offering the potential to study fast temporal interactions between rest- and task-specific networks during more natural experiments which entail interleaved and unpredictable periods of task and rest.

Title: Strength of task-relevant networks at rest predicts sustained attention performance

Authors: *M. D. ROSENBERG[1], E. S. FINN[2], X. SHEN[4], D. SCHEINOST[4], X. PAPADEMETRIS[4,3], R. T. CONSTABLE[2,4,3,5], M. M. CHUN[1,2,6];

Abstracts: We tested whether the strength of complex brain networks at rest can predict performance on a working memory task requiring sustained attention. Participants performed 3-minute blocks of a go/no-go task (90% go) interleaved with 30-second fixation blocks ("breaks") during high-resolution fMRI (voxel size = 2.5mm^3; TR = 1s). Two 6-min resting state runs were also collected. For functional connectivity analyses, network nodes were defined via a novel functional parcellation scheme (Shen, Tokoglu, Papademetris & Constable, 2013). Connectivity matrices were then calculated, for each participant, from data collected during (1) task performance, (2) resting state runs, and (3) each mid-task break. Using across-subjects rank correlation, we identified connections whose strength during the go/no-go task related to performance (sensitivity, or *d'*). To characterize these task-relevant networks at rest, we summed the z-scores of each component connection in the resting-state matrices. We then correlated summed strength at rest with *d'* to determine whether resting-state connectivity predicted overall task performance. In an attempt to predict performance on individual task blocks, we performed analogous analyses of each mid-task break. Specifically, we summed the strength of task-relevant networks in the break matrices, and correlated these sums with the *d'* of the task block immediately preceding and following the break. We identified networks (consisting of ~3% of 36,000 possible connections) whose strength during task performance correlated with overall *d'*. The summed strength of these networks at rest predicted *d'* across subjects ($|r|$ values > 0.7; p values < 0.01). In addition, we observed a trend such that connectivity during 30-sec task breaks also predicts performance: Network strength during rest breaks correlated with *d'* of the preceding and following (mean $r = 0.46$) task blocks. Thus, resting-state functional connectivity predicts performance on a sustained attention task. In addition, connectivity during brief periods of mid-task fixation can predict proximate attentional performance, suggesting a way to measure the effectiveness of these short breaks. Together, these results highlight the complexity of attention networks, and suggest that task-relevant networks are present to a meaningful degree during both resting state epochs and short task breaks.

Title: Dorsal anterior cingulate cortex mediates decisions about where to attend: Evidence from graph-theoretic analysis of network connectivity

Authors: *Y. LIU[1], X. HONG[1], J. J. BENGSON[1], M. DING[3], G. R. MANGUN[2]; [2]Departments of Neurol. and Psychology, [1]Univ. of California, Davis, Davis, CA; [3]The J Crayton Pruitt Family Dept. of Biomed. Engin., Univ. of Florida, Gainesville, FL

Abstracts: A hallmark of human experience is the sense of volitional control over our actions. Converging evidence from studies of human neuroimaging, electrophysiological recordings, cortical stimulation, and focal brain lesions has pointed to an extensive network consisting of areas in the medial and lateral frontal cortices as well as those in the parietal cortex in the generation of volitional acts. Despite the growing body of evidence, how regions within this network dynamically interact, and how it interacts with other functional networks, in tasks involving internally generated intentions remain unknown. We addressed this issue by recording functional magnetic resonance imaging (fMRI) data from subjects performing a willed attention task where they freely chose which of two spatial locations to selectively attend. Applying graph-theoretic analysis to inter-regional functional connectivity, it was found that the dorsal anterior cingulate cortex (dACC), along with bilateral insula and the right frontopolar cortex, mediated the communication between the dorsal attention network and areas in frontal and parietal cortices involved in volition. Such network community structure was absent during a control condition where the subjects were cued to attend to one of the spatial locations; in this case of instructed attention, the dACC interacted most strongly with the dorsal attention network. Further analyses revealed that in willed attention, dACC served as an "inter-community hub" between the dorsal attention network and the volitional network, exhibiting high values of both betweenness centrality (the fraction of shortest paths traversing a network node) and participation index (connectedness within versus between sub-networks). Moreover, this network configuration is behaviorally relevant, with faster reaction times being associated with higher levels of dACC's participation in mediating inter-community communication under willed

attention. In contrast, during the control condition of instructed attention, faster reaction times were associated with lower dACC participation indices, suggesting stronger dACC connections with the dorsal attention network when subjects performed better. Taken together, our results suggest that dACC dynamically configures its functional interaction with various network constituents to support the generation and execution of instructed and volitional acts.

Title: Detecting the feeling of somatic discomfort using near-infrared spectroscopy on prefrontal cortex

Authors: *K. SAKURAI[1], Y. ONO[1], G. KOBAYASHI[2], R. HAYAMA[3], R. IKUTA[2], H. WAKE[3], K. TAMAKI[2,3];

Abstracts: The numbers of patients that have perceived physical symptoms (discomfort, pain etc.) in orofacial area despite the absence of inflammation or trauma are increasing greatly. A support for quantitatively evaluate the perceived amount of discomfort is required both for patients and doctors for treatment. We aim to develop a machine-learning based classifier that can quantitatively evaluate the severity of occlusal discomfort. Sixteen participants without any perceived symptoms in orofacial area (10 male, average 22.6 years old) participated in this experiment. We used functional near-infrared spectroscopy (ETG-7100; Hitachi Medical Corporation, Tokyo, Japan) to measure the hemodynamic responses from the prefrontal area. Occlusal discomfort was simulated by grinding the first molar with a stacked metal strips (aluminum foil for dental examination, 12mm thickness). The two thickness of metal strips tested were (1) thickness equal to the recognition threshold and (2) Thickness causing maximum

discomfort. Subjects repeated 30s of grinding for 5 times with each thickness of the metal strips with 40s of interval between trials. Total 10 Oxy-Hb data from each participant were used to generate a 2-class classifier that judges the presence of discomfort based on Linear Discriminant Analysis. We extracted 3 features for the classifier; the maximum amplitude, maximum slope, and integral of raw Oxy-Hb response during grinding. We generated classifiers using each of the three features as well as combinations of them to determine an appropriate combination of features. We used cross validation method to evaluate the accuracy of the classifier.Sixteen channels out of total 22 prefrontal channels are significantly higher in discrimination rates than chance level (50%; t-test) in most single or combinations of features. Highest discrimination rate of 80±3.9% was achieved using single feature of integral in dorsolateral prefrontal cortex (DLPFC, BA 9 and 46). Channels corresponding to the bilateral frontal pole (Brodmann area (BA) 10) and the left DLPFC (BA 9 and 46) showed high discrimination rate.Since DLPFC has been known to control the perception of not preferable somatosensory stimuli and play a role in an affective evaluation, the response in the DLPFC might represent the evaluation and regulation of discomfort feeling regarding to the somatic stimuli. Considering the role of the frontal pole in the working memory related to decision making, the responses in the frontal pole with different perceived discomfort might reflect the comparative activity between the currently-perceived, altered somatic stimuli and their original body image.

Title: Cortical representations of absolute and relative sound locations during an auditory spatial attention task

Authors: ***M. J. SEAY**[1], J. R. MOCK[2], E. J. GOLOB[2];
[1]Tulane Univ., Kenner, LA; [2]Psychology, Tulane Univ., New Orleans, LA

Abstracts: Successful human behavior requires allocating attention to the location of goal-related sounds. Yet we must also flexibly attend to unexpected sounds, as they may contain information important for survival. Behavioral studies show that the benefits of attending to a location diminish with distance, indicating an attention gradient. We recently used cortical event-related potentials (ERPs) to measure attention gradients in orienting responses by presenting distractor sounds at varying distances from an attended location. We found a three-phase process in which the slope of the gradient peaked positively over frontal areas, reversed over parietal areas, and again peaked frontally before returning to baseline. The current study sought to better define ERP gradients in terms of their cortical sources and timing. We recorded EEG during a spatial target detection task in which subjects (n=35) heard white noise bursts at five azimuthal locations (from left to right: -90°, -45°, 0°, +45°, +90°) and responded to a target whose location varied between conditions (-90° or +90°). Independent component analysis was used to identify distinct clusters of cortical responses in auditory, frontal, and parietal regions. To quantify the attention gradient we measured the slope of a linear fit across each cluster's constituent response to distractors with increasing distance from the target. Consistent with the first phase, a frontocentral cluster had a positive slope from 200-360 ms ($p<.001$), and two frontal clusters showed a positive slope in the same time range when contralateral to the target (left: $p<.001$, right: $p=.01$). Consistent with the second phase, a midline posterior parietal cluster had a negative slope from 360-500 ms ($p<.001$). Midline and lateralized posterior parietal clusters also showed an event-related decrease in α and β oscillatory power between 250-550 ms that had a negative slope and contralateral pattern. Finally, a cluster originating in left posterior parietal cortex showed an earlier (120-200 ms) ERP response whose amplitude was dependent on the absolute angular location of the distractor ($p<.001$). Our results show that an attention gradient is represented in the brain dynamics that support orienting, predominantly in regions contralateral to the attended location. Distinct frontal and parietal areas function at different times in concert to support our ability to flexibly orient attention among competing environmental sources.

Title: Decoding the locus of attention from the full correlation matrix of the human brain

Authors: *J. HUTCHINSON, Y. WANG, N. B. TURK-BROWNE;
Dept Psychology, Princeton Univ., Princeton, NJ

Abstracts: The ability to selectively process a subset of all available perceptual input is critical for efficient behavior. Such selective attention has been linked to a distributed set of regions in the brain, suggesting that selection arises from dynamic interactions within this network. However, these regions are typically identified because they show univariate activity in attention tasks, not because they have meaningful interactions with other regions in these tasks. Indeed, studies that have linked attention behavior to correlated or synchronous activity between areas have done so based on regions-of-interest defined from activity levels. Here we avoid this bias, applying full correlation matrix analysis (FCMA) to decode where attention is allocated in space from the pairwise correlations of every voxel with every other voxel. In a block design fMRI task, participants were presented with a series of spatial pairs of scene images, with one scene on the left of fixation and the other on the right. Participants were instructed to make a perceptual judgment about the scene on one side for an entire block, while ignoring the other side. We first examined univariate activity for left vs. right attention over the whole brain and then performed a searchlight analysis in which multivariate pattern analysis (MVPA) was applied over small volumes centered around each voxel. For FCMA, we calculated the full pairwise correlation matrix for each block and submitted these massive matrices to MVPA with nested feature selection and across-subject cross-validation. Preliminary results showed that both MVPA and FCMA were able to robustly decode which hemifield was attended. Importantly, the voxels which were most important for classification in these two analyses only partially overlapped with each other and with voxels that showed univariate differences. Taken together, these findings suggest that selective attention may be implemented by regions whose average activity, in both univariate and multivariate analyses, is uninformative. Instead, attentional goals may be represented in these regions in terms of the set of other regions in the brain with which they interact.

Title: Task-related modulations of functional connectivity in primary visual cortex are eccentricity-dependent

Authors: *J. C. GRIFFIS[1], R. H. CHEN[2], A. D. BOWMAN[2], W. K. BURGE[2], J. P. SZAFLARSKI[2], K. M. VISSCHER[2];
[1]Univ. of Alabama At Birmingham, Birmingham, AL; [2]Univ. of Alabama at Birmingham, Birmingham, AL

Abstracts: Primary visual cortex (V1) is organized so that the most posterior regions correspond to central vision, whereas anterior regions correspond to peripheral vision. While there is growing evidence that centrally and peripherally responsive regions of V1 exhibit distinct anatomical and functional characteristics, the effects of eccentricity on the functional connectivity of V1 to other brain regions are not understood. In this study, we investigate the effects of eccentricity on functional connectivity between V1 and a set of brain regions associated with top-down attentional control. We compare functional connectivity at rest and background connectivity during a task requiring sustained visual attention. We used fMRI to collect 10 minutes of resting state data and 28 minutes of task data from 16 healthy young adults. The task data were collected while participants performed either a lateralized peripheral visual discrimination task with auditory and visual distracters or an auditory discrimination task with visual distracters. For each participant, we divided V1 into nine 10mm regions of interest that represented centrally and peripherally responsive parts of cortex. We also defined 41 regions of interest associated with task control networks based on the literature. Resting state and

background functional connectivity measures were calculated from each V1 region of interest to each task control network region of interest. Resting state functional connectivity analyses revealed eccentricity-dependent patterns of connections between V1 and task control network regions. Background functional connectivity analyses revealed strong, dynamic eccentricity and task-dependent patterns of functional connectivity between V1 and various task network regions including frontal, temporal, parietal and higher visual regions. Our results indicate that centrally and peripherally responsive regions of V1 exhibit distinct patterns of functional connectivity to other brain regions previously associated with control of task performance. Importantly, we found that these connections are strongly modulated by a participant's task set, suggesting that functional connections from different regions of V1 to task control areas are dynamic and depend on an individual's cognitive and behavioral state.

Title: Target and oddball detection produce opposing effects on global functional connectivity in human cerebral cortex

Authors: *D. GODWIN[1], R. L. BARRY[2,3], R. MAROIS[1,4,5];
[1]Psychology, [2]Vanderbilt Univ. Inst. of Imaging Sci., [3]Radiology and Radiological Sci., [4]Vanderbilt Vision Res. Ctr., [5]Ctr. for Integrative and Cognitive Neurosci., Vanderbilt Univ., Nashville, TN

Abstracts: Both goal-driven and stimulus-driven factors govern everyday behaviors, controlling how we work to complete current goals while balancing the need to react to novel or salient stimuli. While strong evidence points to the control of goal-driven attention by a dorsal network and control of stimulus-driven attention by a more ventral network, these networks likely do not

operate in isolation to control attention. Further, the impact of target detection and of attentional capture by task-irrelevant 'oddball' stimuli on the brain's functional connectivity has yet to be examined beyond restricted network-level comparisons. Graph theory analysis, combined with fMRI, provides an ideal means for characterizing the large-scale community structure of functional connectivity data for detection of both goal-relevant targets as well as task-irrelevant oddballs. Performed at ultra-high field strength on 14 participants, the present study sought to characterize and contrast the neuro-architecture of functional connections associated with conscious detection of a target in a masking paradigm with the presentation of rare, task-irrelevant oddball images. Functional connectivity between each region of interest (ROI) was assessed via pair-wise psychophysiological interactions (PPI) analysis (Mclaren et al., *NeuroImage*, 2012) in order to examine the interaction of connectivity seed and target/oddball processing. Cortical and subcortical ROIs were defined using a published set of 264 coordinates parsed into 14 distinct networks (Power et al., *Neuron*, 2011). The PPI measures of connectivity for each ROI pair were then submitted to graph theory analyses in order to assess the whole-brain measures of functional integration and segregation. The results suggest that conscious target detection is associated with a decrease in global network modularity (measuring separability of networks), concomitant with an increase in functional participation (measuring the strength of connections between networks). This finding provides evidence in favor of target-induced widespread increases in functional network connectivity brought about by increases in inter-network connectivity. By contrast, detection of an oddball stimulus produced opposing effects on topology: increased modularity, decreased participation, and decreased local efficiency (a measure of functional integration). We conclude that whereas detection of a target produced a more globally connected topology, oddballs shifted graph properties in the opposite direction, favoring a more segregated and less efficient network structure.

Title: Paradoxical increase of the P3 event related potential in oddball tasks requiring motor responses vs. mental counting suggests the need to expand its cognitive domain

Authors: *A. EMERŠIC[1,2], J. DREO[1], B. PIKŠ[1], Z. PIRTOŠEK[1];
[1]Dept. of Neurology, Univ. Med. Ctr. Ljubljana, Lab. For Cognitive Neurosci., Ljubljana, Slovenia; [2]Entrapharm, d.o.o., Ljubljana, Slovenia

Abstracts: One of the best studied physiological windows on attention is the P3 potential (also called P300 or late positive component). The P3 can arguably be named the most intensely studied event related potential. However in spite of more than 40 years of research, fundamental questions regarding its true meaning and the nature of its neural generators still remain unresolved. The 3-stimuli oddball task, most often used to evoke the P3, presents the subject with rare, frequent and distractor stimuli. In active oddball tasks subjects are required to respond to targets while ignoring frequents and distractors. In terms of the required response, most active oddball tasks fall into one of two categories: motor response (button presses, finger raises, vocalizations etc.) and mental counting of targets (with no overt motor responses). We conducted a review of the last 121 published papers on the P3 which revealed that 70% of studies used motor responses, 21% mental counting and 9% were passive oddballs (not response required). Since any kind of motor response generates negative (5-15 μV) motor potentials that superimpose themselves on the positive P3 (5-15 μV), choosing this type of oddball should result in a reduced and more variable P3, compared to mental counting. If the former hypothesis were to be proven accurate, the majority of published studies might be using a sub-optimal variant of the oddball task and future studies might consider using the mental count variant. To test the hypothesis of reduced P3 potentials in motor oddballs we conducted 64-channel EEG recordings on 60 subjects with a visual and auditory oddball in both the motor and mental count variant. The measured maximum P3 amplitudes belonging to each task variant revealed a rather paradoxical result: motor oddballs of both sensory modalities generated statistically significantly ($p<0.001$) larger P3 potentials (5-15% increase in amplitude) even though they were clearly “contaminated” by negative motor potentials. When the superimposed motor potentials were subtracted from the P3 using independently recorded subject-specific motor potentials, the motor response P3 was 10-35% larger in terms of maximum amplitude ($p<0.001$) compared to the mental count P3. These results suggest that the list of cognitive processes the P3 is supposed to signify (categorization, memory, attention) might need to be extended to also include processing, preparation or cognitive control of goal-oriented motor behavior since it seems that oddball tasks requiring overt motor responses produce large increases in P3 amplitude simply due to final task demands and irrespective of stimuli categorization, memory and attention effects.

Title: Leftward prism adaptation modulates PPC-M1 interactions within both hemispheres: A twin-coil paired-pulse TMS approach

Authors: *S. SCHINTU[1,2,3], L. PISELLA[1,2], M. VESIA[4], A. FARNÉ[1,2,3], K. REILLY[1,2];
[1]Impact Team, Lyon Neurosci. Res. Ctr., Lyon, France; [2]Univ. of Lyon 1, Lyon, France; [3]Hospices Civils de Lyon, Neuro-immersion & Mouvement et Handicap, Lyon, France; [4]Div. of Neurol. and Krembil Neurosci. Ctr., Toronto Western Res. Inst., Toronto, ON, Canada

Abstracts: Prism adaptation (PA) to a rightward optical displacement (RPA) is one of the most promising techniques for treating neglect - a complex syndrome that frequently occurs after right parietal damage. While RPA can ameliorate neglect symptoms in patients, leftward PA (LPA) can induce neglect-like behaviour in healthy subjects. The underlying mechanisms of these effects are poorly understood. In patients with neglect, applying inhibitory repetitive transcranial magnetic stimulation (rTMS) to the left (contralesional) posterior parietal cortex (PPC) reduces neglect symptoms. In contrast, applying rTMS to the right PPC in healthy subjects induces neglect-like behaviour. It has been suggested that in neglect patients RPA might decrease the (hyper-) excitability of the left hemisphere and in healthy subjects LPA might decrease the excitability of the right hemisphere. A previous study in neglect patients revealed hyper-excitability within left parietal-motor interactions (PPC-M1) using a twin-coil paired-pulse TMS approach (ppTMS). We used the same technique to examine the effects of LPA in healthy subjects by measuring PPC-M1 interactions in the left (n=13) and right (n=13) hemispheres before and after a single session of LPA. Specifically, we delivered a sub-threshold conditioning pulse (90% resting motor threshold) to either the left or right PPC (P3 or P4 EEG coordinate) at four different inter-stimulus intervals (2 4 6 or 8 ms) followed by a test pulse to the ipsilateral M1 that produced a motor evoked potential of 1mV in the contralateral first dorsal interosseus. Our hypothesis was that LPA would differentially modulate PPC-M1 interactions in the left and right hemispheres. We found that a single session of LPA differentially modulated the PPC-M1 connectivity in the two hemispheres - decreasing the excitability of PPC-M1 interactions in the left hemisphere and increasing them in the right hemisphere. These results suggest that LPA modulates PPC-M1 interactions at rest in opposite directions in each hemisphere. This

modulation could reflect a push-pull pattern induced by LPA, which is consistent with the 'hemispheric rivalry' model that predicts reciprocal interhemispheric competition.

Title: Proactive control and motor urgency: An fMRI study of the stop signal task

Authors: ***S. HU**[1], J. IDE[2,3], S. ZHANG[1], C.-S. LI[1];
[1]Yale Univ., New Haven, CT; [2]SUNY Stony Brook, Stony Brook, NY; [3]Univ. Federal de São Paulo, São José, Brazil

Abstracts: Background: We showed previously the neural processes of proactive control in the stop signal task (Hu et al., 2013 SfN; under review). Specifically, the anterior pre-supplementary motor area (pre-SMA) responds to increased likelihood of the stop signal or p(Stop), as computed by a Bayesian model (Ide et al., 2013 J Neurosci) and posterior pre-SMA and bilateral anterior insulae respond to reaction time (RT) slowing as a result of stop signal anticipation. These findings describe a neural circuit for the sequential effect - a linear correlation between p(Stop) and RT. On the other hand, approximately a quarter of all participants (n=161) did not exhibit a significant sequential effect (pCorr(p(Stop), RT)>0.05). Here, we examined the role of motor urgency - or the fore-period (FP) effect - on the manifestation of sequential effect and its neural correlates. Methods: Participants were studied with 40 minutes of fMRI of the stop signal task. We modeled fMRI signals midway through the FP (1-5 s, random) in a GLM, with individual events parametrically modulated by p(Stop) and fore-period. In a second GLM, fMRI signals are modeled at go signal onsets with go trials parametrically modulated by p(Stop) and RT. Results: Regional activations are identified for longer FP in posterior pre-SMA and SMA,

left M1, bilateral anterior insulae, and the thalamus. These regional activations overlap those in response to RT slowing, while longer FP is associated with faster RT, suggesting that the FP effect counteracts the influence of proactive control of response time. In contrast, the anterior pre-SMA decreases activations to longer FP, consistent with a weakening influence of its role in proactive control during prolonged FP. Additional analyses are to dissect these interacting effects in individuals who show and do not show a sequential effect. Conclusions: The current results highlight interacting influences of proactive control and motor urgency in determining response time in the stop signal task.

Title: Rethinking the bilingual advantage: Evidence from ERP data for a differential impact on control processes

Authors: *K. HEIDLMAYR[1,2], K. DORÉ-MAZARS[1], F. ISEL[1,2];
[1]Inst. of Psychology - Paris Descartes Univ. - Sorbonne Paris Cité, Boulogne-Billancourt, France; [2]Lab. d'Excellence 'Empirical Foundations of Linguistics', Sorbonne Paris Cité, Paris, France

Abstracts: Control of cognitive operations involves executive functions (EF). Due to their lifetime experience in using more than one language, bilinguals usually show better capacity in executive control processes such as conflict monitoring, interference suppression or switching (Diamond & Lee, 2011; Heidlmayr et al., 2013; Kroll & Bialystok, 2013). However, to date the question of whether the different executive control processes are shared by different domains (linguistic, non-linguistic, motor) remains open. Under the hypothesis that domain-general control processes are involved in managing multiple language use, a bilingual advantage should be found in linguistic and in motor control tasks. The goal of the present study was to test this hypothesis by examining whether bilinguals show a benefit for controlling irrelevant distracting information using a linguistic task, i.e. the Stroop task and a motor task, i.e. the saccade task. For this purpose, two EEG experiments were designed: (1) Forty-four French native speakers, amongst which 22 with frequent use of German (bilinguals) and 22 with little foreign language

use (monolinguals), were tested in the Stroop task; (2) 20 new participants in each group were tested in the saccade task. Event-related potential (ERP) analyses on the Stroop task showed that both the Stroop-N400 effect and the late sustained potential were reduced in bilinguals compared to monolinguals, suggesting better interference suppression abilities in bilinguals. In the saccade task, the cue-locked positivity effect reflecting a larger positivity for the pro-saccade than for the anti-saccade and usually peaking around 250 ms was smaller in bilinguals than in monolinguals. We interpreted this finding as the indication of better efficiency for bilinguals in conflict monitoring in the task preparation phase. Moreover, the N2/P3 ERP complex thought to reflect inhibitory processes in the task implementation phase was reduced in bilinguals compared to monolinguals, suggesting a benefit for the former in response inhibition. In contrast, for motor task switching no such bilingual advantage was observed. Therefore, caution is needed before drawing firm conclusions regarding a possible spreading of cognitive advantages on executive control processes observed in bilingualism towards the motor domain. Taken together, the present findings suggest that multiple language use can increase the efficiency of some executive control processes but not of some others. Our data are consistent with the view proposing that in a system of limited resources the strengthening of specific processes and network connections can cause others to weaken.

Title: Neural mechanisms for neurofeedback based on EEG using functional near-infrared spectroscopy (FNIRS)

Authors: *X. ZHANG[1], J. A. NOAH[1], S. YAHIL[1], Y. ONO[3], J. HIRSCH[1,2];
[1]Dept. of Psychiatry, [2]Dept. of Neurobio., Yale Sch. of Med., New Haven, CT; [3]Meiji Univ., Kanagawa, Japan

Abstracts: Control of one's brain state through meditation is thought to enhance mental wellbeing, but learning to meditate effectively is difficult due to the inadequacy of verbal descriptions. A possible tool for learning to regulate brain state is neurofeedback, which visualizes real-time EEG frequency components in the theta (4-9Hz), alpha (10-12Hz), beta (13-

17Hz), and gamma (41-50hz) wave domains. We hypothesize that executive control systems of the frontal lobe are related to volitional changes in brain state. We aim to develop an experimental paradigm as well as recording and analysis tools for investigating the neural mechanisms of brain state control. The neurofeedback device (Jedi Force trainer, Uncle Milton Industries, Inc., CA) consists of a single dry electrode placed at the forehead (prefrontal cortex) and a Neurosky chip that provides frequency bands of EEG and visualizations of low frequency EEG spectrum in the form of a "levitating" ball. Through volitional shifts in their EEG spectra, subjects can move the ball up and down 0-3 levels, with 3 requiring the most effort and concentration. In a pilot experiment, subjects were instructed to maintain a cued level of meditation, which was indicated by the height of the ball at 0, 1, 2 or 3 levels. Each subject received 10 hours of training prior to the experiment, and repeated it twice. The experiment consists of 14 blocks of meditation. The durations of the blocks were random (mean=20 and std=3.5 sec). Neural activity was recorded with either a 10-20 channel EEG cap (G.Tech, Austria) or a 22 channel fNIRS system (Shimadzu OMM-3000) covering right frontal and temporal lobes, in addition to the single dry electrode of the feedback device. ICA analyses were done on EEG time frequency data and fNIRS data. We observed sustained elevations in EEG theta and alpha spectra during meditation states, indicating that subjects were capable of controlling the brain state. In addition, we observed transient spikes of beta and gamma spectra associated with the sustained theta and alpha waves. Functional NIRS data showed activity related to brain state changes that was distributed and anti-correlated between medial and lateral frontal lobe. Both EEG and fNIRS data suggest that major volitional efforts in brain state control are engaged transiently when subjects alter the intensity of their meditation. Functional NIRS yields spatial localization of BOLD signals and is a promising tool for investigating the neural mechanisms of neurofeedback.

Title: The neural cascade of processing underlying response time variability in visual search

Authors: *B. V. BERG[1,2], L. G. APPELBAUM[1], K. CLARK[1], S. R. MITROFF[1], M. G. WOLDORFF[1];
[1]Ctr. for Cognitive Neurosci., Duke Univ., Durham, NC; [2]BCN Neuroimaging Ctr., Univ. of Groningen, Groningen, Netherlands

Abstracts: Visual search, the process of finding target items among distracters, is a critical cognitive function that is at the core of numerous daily and professional activities. While it is important to be able to rapidly detect targets, there is substantial trial-to-trial variability in this ability. Here we explored the neural mechanisms that may underlie this variability by comparing reaction times (RTs) and various electrophysiological markers as 17 participants performed a popout visual search task. In this task, participants were presented (50 ms duration) with search arrays that each contained a lateralized green popout target and, in the opposite hemi field, a red popout nontarget, among a field of 46 blue distracters. The participants' task was to orient their attention to the green target ellipse and indicate whether it was "vertical" or "horizontal" with either a left- or right-hand button response. We subsequently extracted from the electrical recordings the event-related potential (ERP) components that index attentional orienting to a target item (the N2pc) and that index motor response initiation (the lateralized readiness potential [LRP]). In addition, neural oscillatory activity was extracted for time intervals both before and after the stimulus occurrence, which was then related to the stimulus-locked ERP markers and behavioral RTs to describe the neural cascade that precedes faster or slower neural processing and RTs. Results demonstrated that the attentional-orienting-related N2pc was significantly earlier for trials with fast RTs compared to slow ones, and this was followed by earlier response preparation, as indexed by earlier motor-related LRPs. Faster RTs were also associated with post-stimulus decreases in fronto-central oscillatory theta activity (4-7 Hz) and increases in beta oscillations (15-25 Hz), indicating both markers reflect processes that ramify to cognitive task performance. Although bilateral prestimulus alpha levels (8-12 Hz) did not covary with RT, lower alpha contralateral to the target side (which is typically associated with more focused spatial attention) predicted larger N2pc amplitudes to those targets, suggesting that greater prestimulus neural engagement to that side resulted in more robust attentional orienting. Contralateral prestimulus alpha did not, however, manifest in faster RTs, suggesting that such variations do not necessarily ramify into faster RTs, at least for these highly salient popout stimuli. Collectively, the results delineate the cascade of neural processes before and after a stimulus array that do and do not lead to response-time variability in pop-out visual search.

Rosetta Stone

Title: Relationship between performance on mobile brain fitness exercises and cognitive assessment

Authors: *C. H. LIN[1], M. E. BAXTER[2], C. H. RANKIN[1], P. D. NUSSBAUM[3];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Rosetta Stone, Arlington, VA; [3]Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstracts: Mobile cognitive training applications can serve as an effective way to deliver and collect data for cognitive training research. To gather insight into how different mobile cognitive training tasks relate to each other, we are analyzing data from existing mobile training applications by Fit Brains/Rosetta Stone. From over 147 million scores from the Fit Brains Trainer and Cognitive Assessment database, we correlated maximum scores per user from 12 Trainer games and 7 Cognitive Assessments, and studied for performance and relationship between games assigned to 5 different categories (logic, memory, concentration, visual and speed). From analysis of the Trainer data, we found performance in most games within the same category correlated strongly with each other, and performance in some games correlated closely with games in different categories. Memory and visual games had the strongest within category correlation, focus and executive function games had moderately strong within category correlation, and speed games had moderate correlation within category except for “quick blocks”, which correlated more strongly with games in the executive function category. On the other hand, performance in another speed game, “speed sort”, correlated well with performance in the memory, focus and visual category, which might indicate some involvements of similar cognitive processes for these games. The speed game “find it fast” did not correlate easily with any other games, which might suggest a distinct cognitive process might be required in this particular game compared to other games. For the Brain Assessment app, we found performance within the 3 memory assessments correlate strongly with each other. Performance in the speed assessment didn’t correlate with any other domains. Interestingly, this dissociation between performances in the speed category from the rest of the categories was also found in the analysis

in the Trainer app. Overall, our results demonstrated that performance in Trainer games and Cognitive Assessments assigned to the executive function, memory, focus and visual correlated well with each other, while performance in the speed category correlated better with performance in other categories. Subsequent analysis will focus on correlating performances with users between the Trainer and Cognitive Assessment in order to further describe the relationship of user performance between the Trainer and Cognitive Assessment. Further analysis can investigate additional correlations between user training habits, age, gender, medical conditions, geographic region, education, and lifestyle on the performance in Cognitive Assessment.

Title: Inhibitory control over unwanted memories is mediated by hippocampal GABA concentration

Authors: *T. W. SCHMITZ[1], M. CORREIA[1], C. S. FERREIRA[2], A. P. PRESCOT[3], M. C. ANDERSON[1];
[1]Med. Res. Council, Cambridge, United Kingdom; [2]Cimcyc, Univ. of Granada, Granada, Spain; [3]Radiology, Univ. of Utah, Salt Lake City, UT

Abstracts: Sometimes, we are reminded of memories we would prefer not to think about. When this happens, people often seek to suppress retrieval of the unwanted memory, a process shown to impair retention of the excluded trace. A fundamental question concerns how cognitive control is deployed to suppress memories, and the modulatory processes that may underlie memory disruption. In this multimodal Functional Magnetic Resonance Imaging (fMRI) and ^{1}H Magnetic Resonance Spectroscopy (MRS) study, we assessed whether concentrations of GABA in the dorsolateral prefrontal cortex (DPLFC) and the hippocampus, a putative 'top-down' pathway known to be involved in memory suppression, differentially predict inhibitory control over unwanted memories. We investigated this question using a well-established manipulation of

retrieval stopping, the Think/No-Think (TNT) paradigm. In the initial phase of the paradigm, participants learned word pairs. In the TNT phase, participants viewed one of the two words in the pair (cue) and either intentionally retrieved (T) or suppressed (NT) retrieval of the associated target word. FMRI was acquired during the TNT task, and forgetting was measured in a post-task memory probe unanticipated by participants. In a separate session, we obtained ^{1}H MRS from voxels in the right DLPFC, right hippocampus, and visual cortical control site. Our behavioural and fMRI data replicate prior findings obtained from the TNT paradigm. Specifically, we observed that significantly fewer intentionally suppressed (NT) words were recalled compared to both retrieved (T) words, and baseline words presented during the learning phase but not the TNT phase. Moreover, compared to retrieval, suppression evoked higher activation in the right DLPFC, lower activation in the right hippocampus, and increased DLPFC_hippocampal connectivity. We next assessed whether our neural indices of retrieval stopping in the DLPFC_hippocampal pathway related to molecular indices of GABA concentrations in this same pathway, and if so, how these two sources of variation give rise to individual differences in memory suppression capacity. We found that hippocampal GABA concentration predicts both disrupted retention of suppressed memories, and stronger suppression of hippocampal activity during retrieval stopping. These relationships were not observed in the DLPFC. Finally, hippocampal GABA concentration mediated the relationship between hippocampal suppression and forgetting of suppressed items. Our results suggest that the ability to suppress unwanted memories is influenced by GABA concentration in the hippocampal target, rather than the DPFC source, of executive control.

Title: Utilizing functional near-infrared spectroscopy to identify cognitive processes contributing to workload in a dual-task environment

Authors: *D. BELYUSAR[1], B. REIMER[1], B. MEHLER[1], D. AFERGEN[2], J. F. COUGHLIN[1], E. SOLOVEY[3];
[1]AgeLab, MIT, Cambridge, MA; [2]Tufts Univ., Medford, MA; [3]Drexel Univ., Philadelphia, PA

Abstracts: Mental 'workload' is the amount of cognitive effort required to complete a task. However many factors such as expertise, fatigue, distraction and concurrent tasks can affect the workload on any task. Since exceeding one's cognitive capacity can negatively affect performance, the ability to monitor and potentially reduce workload in naturalistic environments, could have significant real-world impact (e.g. for drivers, pilots or other machine operators). Peripheral physiological measures such as galvanic skin response, heart rate and pupil size have previously been used as a proxy for mental workload during naturalistic tasks; however, these measures can be confounded by physical arousal or exertion. Conversely, the measurement of cognitive activity during complex tasks has been thoroughly examined using brain-imaging techniques such as fMRI and EEG. However, electromagnetic interference and space constraints often inhibit naturalistic validity of traditional brain-imaging techniques. Functional near-infrared spectroscopy (fNIRS), like MRI, detects changes in oxygenated hemoglobin in the cortex, but utilizes lightweight, scalp-mounted optical sensors. The combination of fNIRS portability with high spatial and temporal resolution, may thus allow a disentanglement of potentially distinct cognitive activities that contribute to what we call workload such as working memory, task-switching and attention during safety-critical activities such as driving. Here, we recorded levels of oxygenated and deoxygenated hemoglobin using fNIRS along with electrocardiograph (EKG) and electrodermal activity (EDA) from 21 participants while driving in fixed-base driving simulator. In addition to baseline driving, participants also completed a secondary cognitive task (the digit n-back), often used to increase mental workload. Peripheral physiology resembled previous work from our lab revealing an approximately linear increase in both heart rate and skin conductance levels (SCL) as secondary-task difficulty increased. However, fNIRS sensors over the dorsal lateral pre-frontal cortices (DLPFC)(~Fp1-Fp2 in the international 10-20 system) detected first increases, then decreases in oxygen levels as task difficulty increased. Since the n-back task changes from a pure working memory task at the low levels, to include task switching or 'branching' activity as numbers are recalled, replaced and remembered up to 3 places back, we propose the workload captured in peripheral physiology is coupled with the migration of cortical activity from the DLPFC to pre-frontal areas associated with 'branching' activity such as the frontal pole.

Title: Cortical oscillatory networks of synesthetic conflict processing as revealed by MEG source reconstruction

Authors: *J. VAN DRIEL[1], R. ROUW[1], A. HILLEBRAND[2], T. H. DONNER[1], M. X. COHEN[1];
[1]Psychology, Univ. of Amsterdam, Amsterdam, Netherlands; [2]VUMC, Amsterdam, Netherlands

Abstracts: Grapheme-color synesthetes are often confronted with conflicting perceptual information (e.g. a brown "A" might feel 'wrong'). In general, mechanisms of goal-directed action monitoring after conflict have been linked to oscillatory activity in the theta (4-8 Hz) band, within and between medial and lateral frontal brain regions. Moreover, these frontal theta dynamics have been shown to exert top-down control, via phase synchronization, over lower sensory and motor areas to optimize future behavior. Here, we used synesthesia as a novel framework to elucidate these adaptive control processes when triggered by anomalous color sensations. Ten "projector" synesthetes (who report perceiving synesthetic color as appearing in the outside world) performed an adapted Stroop task in which they responded to printed color of letters congruent or incongruent with synesthetic color experience, while we recorded their brain activity with MEG. Behaviorally, we found typical Stroop-effects which were modulated by congruency of the preceding trial (the "Gratton" effect). Sensor-level time-frequency analyses showed, as expected, conflict-related theta power increase over midfrontal sensors. Using minimum-variance beamformer analysis with subject-individual MRI-scans, we furthermore localized the cortical sources underlying these electrophysiological scalp dynamics to anterior cingulate as well as lateral frontal and parietal regions. In addition, we performed connectivity analyses in which we applied source weights of an independent color localizer to the Stroop task data, revealing large-scale fronto-occipital network interactions when synesthetes experienced grapheme-induced conflict. These results thus provide a unique insight into the neurophysiology of frontally mediated top-down control of visual information, even when such visual information is not physically present in the outside world.

Title: Functional parcellation of right inferior frontal cortex and anterior insula: The widely-attended and often-neglected regions in inhibitory control

Authors: *W. CAI[1], S. RYALI[1], T. CHEN[1], C.-S. R. LI[2], V. MENON[1];
[1]Psychiatry and Behavioral Sci., Stanford Univ. Sch. of Med., Palo Alto, CA; [2]Yale Univ. Sch. of Med., New Haven, CT

Abstracts: Inhibitory control, an ability to withhold or override a prepotent response, is crucial in everyday life. A decade of neuroimaging research has repeatedly reported co-activation in the right inferior frontal cortex (rIFC) and its neighboring region, right anterior insula (rAI), in inhibitory control. In contrast to the rIFC whose role has been extensively discussed, the role of the rAI in inhibitory control is underappreciated, and functional dissociation between these regions remains unclear. Here we adopted a data-driven approach to examine whether the rIFC and rAI have different physiological and functional features and to study functional dissociation between the two regions in inhibitory control. We conducted meta-analysis using GinglerALE on 73 inhibitory control studies, including Go/NoGo and Stop-signal tasks (SST), to generate an activation mask in the right frontal operculum. We computed two different features from three different datasets: intrinsic functional connectivity of the voxels within the mask from a resting-state fMRI dataset and task evoked hemodynamic responses in two SST datasets. Using these features, we parcellated voxels within the mask into an optimal number of stable clusters using a novel consensus based clustering algorithm. We then compared the physiological and functional characteristics of the clusters obtained from the two datasets. The parcellation produced two most stable clusters, one at rAI and the other at rIFC, consistently across resting-state and task fMRI datasets. Strikingly, corresponding clusters were highly similar between the two datasets with above 70% of voxels overlapped, despite the vastly different features used in the parcellation algorithm. More importantly, the two clusters (rAI and rIFC) showed distinct physiological and functional characteristics. First, rAI had strong intrinsic connection with anterior cingulate cortex and striatum whereas rIFC had strong intrinsic connection with lateral and dorsomedial prefrontal cortices. Second, although the rAI and rIFC both had stronger activation in successful stop than go trials, the rAI had even greater activation in unsuccessful

stop trials than the IFC. Third, activation in the right IFC had significant correlation with individual's inhibitory control ability while the AI did not. Taken together, our study provides robust and convergent evidence to demonstrate that the rIFC and rAI play different mechanistic roles in inhibitory control.

Title: Neuroanatomical modeling of executive functioning: The algorithmic and reflective minds

Authors: *J. PAN[1,2], A. MIELE[3,2], D. GANSLER[1], S. DEONI[2];
[1]Psychology, Suffolk Univ., Boston, MA; [2]Advanced Baby Imaging Lab., Brown Univ., Providence, RI; [3]Neurodevelopmental Ctr., Providence, RI

Abstracts: Background: In clinical and research practices, performance-based and report-based measures are both used to tap into executive functioning. However, there is growing empirical support that the two types of measures actually tap into distinct constructs that represent different levels of higher cognitive functioning, termed the "algorithmic" and "reflective" minds (Stanovich, 2009). To date, the neural correlates of the algorithmic and reflective minds have not been investigated in a pediatric population. Toward that purpose, we compared the neural correlates of a performance-based and ratings-based measure of inhibition, considered to be a key aspect of executive function, predicting that the ratings-based reflective mind measure would be more strongly associated with default mode network areas. **Methods**: Twenty-four children participated in longitudinal study of brain development (mean age = 8.2, SD = 1.8). Myelin content was estimated throughout the brain using an MRI-based multicomponent relaxometry approach (mcDESPOT). All children completed the Inhibition subtest from the Developmental Neuropsychological Assessment (NEPSY), and parents/guardians also completed one report-based measure, the Behavior Rating Inventory of Executive Functioning- Inhibition Scale (BRIEF). Non-parametric correlations, corrected for multiple comparisons, were examined between myelin content and neurocognitive measures throughout the brain. **Results**: Both performance- and report-based scores yielded significant correlations to the myelin content of the dorsolateral prefrontal cortex (DLPFC) (p values ranged from 0.001 to 0.05), indicating that both

types of measures are related to working memory. While both the BRIEF Inhibition subscores and NEPSY Inhibition subscores were related to the dorsal anterior cingulate cortex (ACC) (*p* values ranged from 0.001 to 0.05), only the former was distinctly related to the ventral ACC (*p* values ranged from 0.001 to 0.05). This is a region theorized to be involved in emotion-based decision making. **Conclusions**: Consistent with a priori hypotheses, only a ratings-based reflective mind measure of inhibition was associated with ventromedial frontal regions associated with the default mode, while both performance and ratings-based measures were related to other frontal regions. These findings give credence to the distinction between the algorithmic and reflective minds, which are present in children as young as 6 years of age.

Title: Parametric Manipulations in Simon and Go/NoGo reveal specificity of neural mechanisms of Response Selection and Inhibition

Authors: *S. WIJEAKUMAR, M. W. VOSS, V. A. MAGNOTTA, A. T. BUSS, R. E. HAZELTINE, J. P. SPENCER;
Univ. of Iowa, Univ. of Iowa, Iowa City, IA

Abstracts: Increased activation in cortical and sub-cortical regions has been reported in response to infrequent inhibition. However, it is unclear whether this increase in activation is due to infrequent inhibition or infrequent trials in general. Further, it is unknown how neural activation changes in response to increased stimulus-response mappings within the context of response selection. We used functional magnetic resonance imaging to investigate the effects on behavior and neural activation for two parametric manipulations in a Simon and a Go/NoGo (GnG): a working memory load manipulation implemented by varying the number of stimulus-response mappings and a proportion manipulation implemented by varying the proportion of excitatory trials. It has also been shown that functional networks involved in task performance have enhanced synchrony during the resting state directly following task engagement. Therefore, we

compared change in resting state networks before to after each task to determine whether the tasks would elicit distinct network interactions. Seed-based analyses were used to extract the default-mode network (DMN), salience network (SALN), executive control network (ECN) and a sensorimotor network (SMN). Behavioral results revealed increased reaction times on infrequent trials and also an increase in reaction times with an increasing number of stimulus-response mappings (load) for both tasks. A broad network of cortical, sub-cortical and cerebellar areas were activated by both tasks. Activation was greater on Go/compatible than Nogo/Incompatible trials at areas involved in motor-planning and control of movement. Bilateral lingual gyrus was selectively activated and de-activated in the Simon and GnG tasks respectively, reflecting a role specific to visuo-spatial attention. Insular-thalamic regions were selectively activated on infrequent events across both tasks. With regard to the load manipulation, there was a decrease in activation in the right inferior parietal lobule at higher loads. Thus, in contrast to the typical increase in neural activation with greater working memory demands, we found a decrease in activation suggesting that an associative memory mechanism underlies the stimulus-response mappings. Reliable resting state networks were identified across all resting-state runs. Both the SALN and ECN showed changes in resting state synchrony following both Response selection tasks. On the other hand, change in synchrony of the posterior cingulate cortex with the DMN was observed following the GnG task. Future work will integrate current theories and models of response selection with changes in neural activation.

Title: Mind-wandering on the good, the bad, and the useful: Distinctive neural correlates of spontaneous thoughts differentiated by emotional valence, utility, and spontaneity

Authors: *K. C. FOX[1], M. L. DIXON[1], M. ELLAMIL[2], M. L. PUERTOLAS[3], A. RAUSCHER[1], K. CHRISTOFF[1];

Abstracts: 'Mind-wandering' (MW) has been most famously tied to activity in brain regions of the default mode network (DMN). However, studies to date have aimed at delineating a general, undifferentiated picture of the neural correlates of MW. We sought to refine this understanding by examining the neural correlates of different kinds of thoughts, specifically investigating the spontaneity, utility, and emotionality of spontaneous thoughts. During an fMRI scan, we allowed subjects to rest and think freely, interrupting their thinking at random intervals with occasional thought probes. Probes asked subjects about (i) whether their thoughts arose spontaneously, or whether they were intentionally directing them; (ii) whether thoughts were related to their current concerns and goals in life, or not; and (iii) whether they were emotionally pleasant, unpleasant or neutral. We used an event-related design to examine neural activity during MW (just prior to the thought probe) according to subjects' responses. We found distinctive neural activity, as well as functional connectivity, underlying spontaneously arising vs. intentionally directed thoughts; thoughts related vs. unrelated to current concerns and goals; and emotionally pleasant vs. unpleasant thoughts. Counter to the prevailing view, thoughts were mostly emotionally positive and related to concerns and goals, suggesting an adaptive function. Our results refine the current understanding of 'the' neural correlates of MW, suggesting that distinctive forms of spontaneous thinking recruit distinctive sets of brain regions. They also speak to clinical disorders involving dysfunctional forms of spontaneous thought, e.g. depressive rumination, by showing that negative, non-useful thoughts are neurally distinct from positive, useful thinking.

Title: Humans and a non-human primate show similar behavior in a novel context-dependent stop signal task

Authors: *K. Z. XU[1], V. STUPHORN[1], S. YANTIS[2], S. COURTNEY[2];
[1]Psychological and Brain Sciences; The Zanvyl Krieger Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD; [2]Psychological and Brain Sci., The Johns Hopkins Univ., Baltimore, MD

Abstracts: Human lesion and imaging (fMRI) studies have demonstrated that the inferior frontal cortex (IFC) is critical for stopping action, but the specific function of IFC activity in stopping is debated. While some argue for a direct role of IFC in response inhibition, others have argued for a role of IFC in either guiding attention to external events, or in encoding which task rules are behaviorally relevant. To test these hypotheses, we previously trained a monkey to perform a novel context-dependent variant of the selective stop signal task. We found that the activity of movement and fixation neurons in frontal eye field was sufficient to control gaze. In contrast, the activity of neurons in ventrolateral prefrontal cortex (VLPFC, which includes IFC) represented context-dependent rules and might be involved in switching between sets of task rules. This supports the hypothesis that VLPFC represents the abstract rules that guide inhibition, but does not instantiate inhibition itself. In order to compare behavior across species to this novel context-dependent stop-signal task, we administered an analogous behavioral task in humans. Each participant received 3 trial types in a pseudo-randomized order: no-stop-signal trials (NSS), stop-signal (SS) trials, and continue-signal (CS) trials, presented in a pseudo-randomized order. All trials started when participants acquired central fixation at a context cue. The shape of the context cue (square or triangle) indicated the rule mapping on that trial, and was visible briefly before it was replaced by a central fixation point. The fixation point was then extinguished and, simultaneously, a peripheral target appeared. On NSS trials, participants were required to generate a speeded saccade to the target. On NS and CS trials, a yellow or blue central point reappeared after a variable delay. In one context, a yellow point cued the participants to cancel the saccade while a blue point cued the participants to ignore it and make a saccade to the peripheral target. In the other context, the rule was reversed. The context alternated every 8,10 or 16 trials, randomly and without prior warning. The first trial following the context alternation was termed a “switch” trial. Humans demonstrated behavior that was similar to the monkey’s: reaction times in CS trials were longer than in the NSS trials, and the non-canceled SS trials yielded the shortest reaction times. On switch trials, reaction times increased and accuracy decreased. Importantly, the behavioral similarity across species will allow us to meaningfully compare primate electrophysiology and future human fMRI experiments.

Title: EEG correlates of individual differences in motor sequence planning and accuracy

Authors: M. A. NIERMEYER[1], *M. J. EULER[2], Y. SUCHY[1], J. MATYI[1], H. SCHRYVER[1], D. CHON[1], V. REDDY[1], P. GIBBS[1], E. VACCARIELLO[1];
[1]Psychology, [2]Univ. of Utah, Salt Lake City, UT

Abstracts: Complex motor sequencing has long been recognized as a sensitive measure of executive dysfunction in neurological disorders. In particular, the Push Turn Taptap (PTT) task from the Behavioral Dyscontrol Scale-Electronic Version has been shown to detect subclinical neurocognitive dysfunction in both mild TBI and older adults (Suchy, Euler, & Eastvold, 2014; Kraybill, Thorgusen, & Suchy, 2012). Prior fMRI research has established a relationship between PTT planning time and accuracy and SMA-basal ganglia connectivity (Marchand et al., 2013). In order to further explore the neural correlates of PTT planning time and accuracy, the current study developed an EEG analogue of the PTT task. It was hypothesized that fronto-central EEG activity would predict both accuracy and intermediate planning times, reflecting performance monitoring processes during complex motor sequencing. *Methods*: Forty-five healthy college students completed the standard PTT task while a subgroup of 27 also completed the EEG analogue. Planning time and accuracy were assessed in both tasks. Each trial of the analogue task involved the presentation of a fixation cross, followed by a slide presenting the correct four-movement sequence. To elicit activity related to response planning as well as performance monitoring, the EEG analogue manipulated response certainty by varying the correct sequence on 10% of trials. *Results:* Planning time and accuracy were correlated across the two tasks (r = .50, p=.009; r = .475, p = .014). Averaging of correct trials time-locked to the onset of participants' first movement revealed a negative potential over fronto-central electrodes beginning at approximately -750 ms and peaking -35 ms prior to the response. When measured at Cz, the amplitude of this negative potential correlated with accuracy in both the EEG analogue (r = .496, p = .01) and the original PTT task (r = .610, p = .001); greater negativity was associated with fewer errors. In addition, the potential showed a curvilinear relationship with analogue planning time such that greater negativity was associated with intermediate planning times (b = .463, β = .520, p = .019). Fewer errors were also associated with intermediate planning times (b = 13.367, β = .398, p = .011). *Conclusions:* These results suggest that medial-frontal performance monitoring processes facilitate accurate responding during complex motor sequencing in the PTT task. The relations between performance and EEG activity in the analogue task suggest that the observed neural correlates support executive functions that balance competing task demands of efficient response planning and accuracy.

Title: Neural correlates of attention in two relaxation techniques

Authors: *S. DEEPESHWAR[1], S. A. VINCHURKAR[2], K. NAVEEN[1], S. TELLES[3]; [1]Yoga and Life Sci., [2]Swami Vivekananda Yoga Res. Fndn., Bangalore, India; [3]Patanajali Res. Fndn., Haridwar, India

Abstracts: Meditation and relaxation have both been known to influence the cognitive abilities of human beings. The aim of the present study was to assess the effect of meditation on stroop task using event related potentials. Fifty healthy right-handed male participants with age ranging between 19-32 years (group age mean, SD; 23.8±6.2 years) recruited from a Yoga University, Bengaluru. Participants had no history of current or past neurological or psychiatric illness. The participants had a minimum of one year experience with 'Cyclic meditation'. Each participant was assessed in two sessions, i.e., Cyclic meditation and supine rest lasted in 23 min and was preceded and followed by an Stroop task. Both sessions were recorded on two consecutive days and consisted of two states i.e., Before and After. EEG was acquired using a 128-channel HydroCel Geodesic Sensor Net (EGI, Eugene, OR). All electrode impedances were kept below 50KΩ. Recordings were referenced to Cz. ERP data was processed using the NetStation software. Scalp potentials sources estimates were modeled using the GeoSource imaging software with the sLORETA constraint to derive source locations based on the MNI coordinates. Activations were seen in the inferior temporal gyrus, middle temporal gyrus for the incongruent and congruent condition whereas middle temporal gyrus for neutral condition. Paired Sample t-test was used to examine scores of the three conditions of Stroop task i.e., neutral, congruent and incongruent before and after meditation and control sessions. Results suggest that there was significant reduction in N1 latency ($p<0.01$) at parietal and temporal regions in Stroop task after meditation, whereas increased latency at left tomporo-occipital and right parietal regions after supine rest indicated that meditation practice facilitated the focusing of attention resources. We also found reduction in amplitude in late negative component N450 at frontal and central regions

following meditation which reflect meditation practice reduced the recruitment of resources during object recognition processes and conflict processing. The mean reaction times were longer in stroop task for neutral ($p<0.05$) and incongruent (0.01) conditions, after supine rest, whereas the mean reaction times were shorter for neutral ($p<0.01$), congruent ($p< 0.05$) and incongruent ($p<0.05$) conditions after meditation. This suggest that meditation improves efficiency, possibly via improved sustained attention with the reduction of interference in Stroop task. To conclude, the results suggest that meditation may alter the efficiency of allocating cognitive resources, leading to improved self-regulation of attention.

Title: The Plaza: Executive function improvement through innovative gameplay

Authors: *T. F. NUGENT III[1], A. KRUSE[1], C. CRAWFORD[2], S. WOLOSIN[2], J. YUILL[2], F. PIERCE[2], J. GARCIA[2], J. WILLIAMS[2], A. MILHOLLUN[2];
[1]Intific, Inc., Alexandria, VA; [2]Intific, Inc., Austin, TX

Abstracts: As the demand for cognitive enhancement tools continues to grow at a rapid pace, it has become apparent that there are definitive and identifiable shortcomings in the standard method and expected impact through their use. This effort looks to improve upon two major facets within this space: tackling the concern of maintaining interest with a sense of replay value and targeting development of an application that has the potential for long standing improvement of cognitive capability. Focusing on cognitive skills tied to executive function, the authors have developed a cognitive enhancement tool entitled The Plaza. With distinct emphasis on creating an engaging narrative, The Plaza leverages the known benefits of established neuropsychological cognitive tests into a story driven single player experience while attempting to address concerns over practice effects and diminishing interest through repeated play. Additionally, The Plaza incorporates cutting edge neuroscience software tools to allow for integration of real-time

biophysiological sensor systems to create an optional, closed-loop experience for the user. Utilization of cognitive state metrics through devices like electroencephalography (EEG) allows for unique, tailored gameplay experiences to each individual, every time they engage the software training tool. Applications of The Plaza could leverage neurofeedback capabilities in addition to the presentation of suggested learning strategies associated with working memory, problem solving, planning, and other executive function based cognitive functions. The tool will measure and train cognitive skills via gameplay in a way that is both motivating and meaningful. This tool is aimed at an older target audience (teen to adult) but the mini games for executive function training could be applied to any age group with the appropriate narrative setting. Effort is funded through the Information Innovation office of the Defense Advanced Research Projects Agency.

Title: No truly domain-general resource in the human cerebral cortex

Authors: *B. J. TAMBER-ROSENAU[1,2], A. T. NEWTON[3,4], R. MAROIS[1,2,5];
[1]Dept. of Psychology, [2]Vanderbilt Vision Res. Ctr., [3]Vanderbilt Univ. Inst. of Imaging Sci., [4]Dept. of Radiology and Radiological Sci., [5]Ctr. for Integrative & Cognitive Neurosci., Vanderbilt Univ., Nashville, TN

Abstracts: Classic psychological theories posit domain-general limited resources whose exhaustion by one task – regardless of demands imposed on any specific sensory or motor modality, cognitive process, or representational format of task-relevant information – interferes with the performance of other tasks. Most primate electrophysiological research instead suggests broadly domain-specific information processing wherein task-relevant variables are coded even in frontal or parietal cortex, generally considered to be home to the most abstract and domain-general representations in the brain. Human functional MRI has addressed these disparate accounts, reporting a frontoparietal multiple-demand (MD) network recruited across a wide variety of tasks that vary on modality, process, and format (e.g., Duncan, Trends Cog Sci 2010). We recently used fMRI and multivariate pattern analysis (MVPA) to show that most MD regions code modality during response selection (RS) tasks (Tamber-Rosenau et al, J Neurosci 2013). Here, we extend these results by examining coding of two other task dimensions, cognitive process and representational format. Sixteen participants were scanned while performing experiments that manipulated either cognitive processes or representational formats in separate 7-Tesla fMRI sessions. We then used MVPA to determine whether information about the specific process or representational format was differentially encoded in the brain. In the Process experiment, we compared a 6-alternative arbitrary stimulus-response mapping task – which loads heavily on RS processes – to No-Go trials of a Go/No-Go task – which load heavily on inhibition processes. In the Representational Format experiment, we compared object identity and object location visual working memory tasks. We defined regions of interest (ROIs) based on overlapping univariate activation for the two tasks in each experiment, respectively. In each ROI, we calculated event-related timecourses of MVPA decoding between tasks within-experiment. We found broad decoding of both process and format: in both sets of ROIs, only subcortical regions and subsets of visual cortex failed to support decoding in each experiment. Furthermore, in additional ROIs drawn from our previous modality-coding work (Tamber-Rosenau et al 2013) and classic MD work (Duncan 2010), we observed similar results. Taking these results together with our previous (2013) work, all tested cortical regions proved to be sensitive to one or more of

modality, process, or format. Thus, we find no evidence for truly domain-general information processing in the human cortex.

Title: The influence of a single session of aerobic exercise on cortical activity during a flanker task

Authors: ***K. B. BEYER**[1], M. D. SAGE[2,3], W. E. MCILROY[1,2,3,4];
[1]Univ. of Waterloo, Waterloo, ON, Canada; [2]Rehabil. Sci., Univ. of Toronto, Toronto, ON, Canada; [3]Mobility Res. Team, Toronto Rehabil. Inst., Toronto, ON, Canada; [4]Canadian Partnership for Stroke Recovery, Sunnybrook Hlth. Sci. Ctr., Toronto, ON, Canada

Abstracts: Aerobic exercise benefits the brain in many ways but appears to influence specific networks differently. Both higher fitness levels and long-term aerobic training are associated with more activity in a network underlying selective attention and less activity in a network underlying action monitoring. Even after a single session of aerobic exercise, the selective attention network is more active but it is not known how the action monitoring network is influenced. We used electroencephalography to probe electrophysiological markers of the activity of these two networks in response to a single session of aerobic exercise. Participants performed a modified flanker task before and after a 40-minute bout of moderate cycle ergometry (i.e., 50-60 % VO_2peak). From continuous EEG, we examined two ERP components: the stimulus-locked P3, which is associated with attention, and the response-locked error-related negativity (ERN), which is associated with action monitoring. Initial results reveal evidence that a single session of aerobic exercise influences electrophysiological markers of attention and action monitoring differently. Following exercise, P3 amplitude was higher indicating more activity in the attention network. Conversely, ERN peak latency was longer signalling a decrease in activity in the action monitoring network. These findings support previous research showing that fitness and long-term aerobic training modulate specific brain networks differently by revealing this phenomenon after just a single session of aerobic exercise. Ongoing analysis will explore event-related activity in the frequency domain and communication between these two

networks to further examine the relationship between aerobic exercise and cortical activity linked to attention and action monitoring.

Title: The relationship between manual dexterity and executive function in healthy older adults

Authors: *O. VASYLENKO, C. RODRIGUEZ-ARANDA;
UiT The Arctic Univ. of Norway, Tromsø, Norway

Abstracts: Aging is associated with cognitive and motor decline. Among the affected cognitive processes is executive function (EF). Manual dexterity also declines with aging. Studies have shown a relationship between decline in dexterity and executive dysfunction in cognitively impaired older adults. In normal aging, however, evidence of this relationship is lacking. A better understanding of the link between manual dexterity and cognitive function can provide information about how and why hand motor control changes with age. Objective: To investigate the relationship between EF and the kinematics of manual dexterity in healthy older adults. Methods: 15 healthy elderly and 15 young adults were tested with two EF tests: the Stroop Color and Word Test and the Trail Making Test. Dexterity of the dominant hand was assessed with two Purdue Pegboard subtests, and recorded with Vicon Motus. Movement times were obtained for each transport (reach to grasp, reach to insert) and manipulation (grasping, inserting) movement. Kinematic variables calculated for each movement were peak and mean angular displacements (PD, MND), peak and mean angular velocities (PV, MNV), times to peak angular displacement and velocity (TPD, TPV), number of changes in angular displacement and velocity (NCD, NCV). To compare EF scores and movement times between groups, we used t-tests. For the movements that showed time differences between groups, kinematics were analyzed by MANOVA. Pearson correlations were used to measure the association between the kinematics and EF scores. Results: Compared to the young group, the elderly group had lower EF scores and longer movement times during grasping and inserting. The elderly group showed lower MNV during grasping on both tasks. On the pins task, the elderly group had lower MND and longer TPD during inserting. On the assembly task the elderly showed larger NCV and NCD during

grasping and larger NCD during inserting. On the pins task, MNV during grasping and MND during inserting were positively related to EF scores. On the assembly task, NCD during grasping and inserting was negatively related to EF scores. Movement variability during grasping and inserting the first 3 parts was inversely related to overall performance. Conclusions: Age differences in manual dexterity were evident during manipulation only. Older adults were slower to manipulate objects on both tasks and showed increased movement variability on the more difficult task. Some of the kinematics were correlated with EF, which suggests that manual dexterity might be dependent on EF in healthy older adults.

Title: Distinct representation of conflict, response, and feedback selectivity by individual neurons in human dorsal anterior cingulate cortex

Authors: *G. HORGA[1], M. K. MIAN[2], S. R. PATEL[2], E. N. ESKANDAR[2], M. M. BOTVINICK[3], S. A. SHETH[4];
[1]Columbia Univ. Med. Ctr. (NYSPI), New York, NY; [2]Neurosurg., Massachusetts Gen. Hosp., Boston, MA; [3]Princeton Univ., Princeton, NJ; [4]Neurosurg., Columbia Univ., New York, NY

Abstracts: The dorsal anterior cingulate cortex (dACC) is a main focus of neuroscience research given its central role in regulating adaptive behavior and its involvement in the pathophysiology of neuropsychiatric illness. Although a unique role for the human dACC remains elusive, current models suggest a complex role with simultaneous contributions to multiple cognitive functions, from computation of effort to reinforcement learning to cognitive control. Research in non-human primates suggests that dACC distinctively encodes multiple decision variables, even at the level of individual neurons, but evidence in this respect is lacking in humans. Here, we

recorded from individual human dACC neurons during a neurosurgical procedure while subjects performed the multi-source interference task (MSIT). On each trial, the cue consisted of a set of three numbers, and subjects were instructed to respond to the identity of the unique number ('target') that differed from the other two numbers ('distractors') via button press. Decision conflict emerged on trials in which the identity of distractor numbers corresponded to possible responses (Eriksen-conflict trials), the position of the target number was incongruent with its identity (Simon-conflict trials), or both. Neutral feedback alternated with non-neutral feedback in a block-wise manner. We used a sliding GLM (ANOVA) to classify individual neurons based on changes in their firing rates as a function of conflict, response selectivity, and feedback sensitivity during three target 500-ms periods: post-cue, choice, and outcome periods. We also evaluated population-level effects using a hierarchical GLM approach. Of the 59 neurons we studied, 27.1% exhibited a significant conflict effect in at least one of the three target periods, 25.4% exhibited response selectivity, and 18.6% exhibited feedback sensitivity; 40.7% showed only one effect and 15.3% showed more than one effect (all $p<0.05$, corrected). None of the neurons exhibited an interaction between conflict and response selectivity or time-on-task effects. Population activity showed a positive bias for conflict, response, and feedback selectivity. Contrary to prior non-human findings, population activity in response neurons did not account for conflict effects. Our findings support the functional heterogeneity of neuronal populations in human dACC, consistent with single-unit recordings in non-human primates. Our data further support the existence of pure conflict signals in individual neurons of human dACC, a finding with relevant implications for integrative models of dACC function and human imaging studies.

Title: Suppressing a motivationally-triggered action tendency reduces future provocation

Authors: *S. FREEMAN, D. ALVERNAZ, A. TONNESEN, D. LINDERMAN, A. R. ARON; UCSD, San Diego, CA

Abstracts: In Freeman, Razhas and Aron (2014), we showed that withholding an instrumental response while provoked by a motivating stimulus recruits top-down response suppression. Here we tested if repeatedly performing such response suppression leads to a change in stimulus-generated motivational provocation. To examine this, we used a hybrid Pavlovian-instrumental transfer and Go-NoGo paradigm in thirsty human subjects. In the first stage, Instrumental, participants continuously pressed a button to obtain juice (Go trials), while, on NoGo trials, they were required to not respond; in the second stage, Pavlovian, participants learned to associate one color with juice (CS+) and the other color with no juice (CS-); the third stage, Transfer, resembled the instrumental phase, with the addition of the CS+ or CS- appearing in the background of the Go/NoGo cue and the CS+ serving as the motivating stimulus. We tested three independent groups of participants who had varying proportions of NoGo CS+ trials in the transfer phase (10%, 25%, and 40%). We examined how provoked subjects were by the CS+ (compared to the CS-) on Go trials, with the dependent measure being RT to press for juice. ANOVA revealed an interaction between Stimulus (CS+/CS-) and Group (10%, 25%, 40%), $p = 0.01$, with reduced CS+ provocation in the groups with a greater proportion of NoGo CS+ trials. The change across groups was highly linear ($r = 0.99$, $p = 0.004$, for the difference between Go RT on CS+ and CS- trials). Subsequent experiments using single-pulse transcranial magnetic stimulation as a probe of corticospinal excitability showed that the group-level changes in CS+ provocation were best explained by the engagement of a response suppression mechanism that selectively monitors for and suppresses motivational provocation on the following trial. These results suggest that when a motivating stimulus is detected in a context where it is inappropriate and response suppression is triggered, the response suppression mechanism stays active for a period of time sufficient, at least, to mitigate motivationally-driven responses on the next trial

Title: Conflict-Specific cognitive control mechanisms for task rules: Switching between task rules and resolving cue incongruence

Authors: *Y.-S. SHEU[1], S. M. COURTNEY[2];
[1]Dept. of Psychological and Brain Sci., [2]Psychological and Brain Sci. Program, Johns Hopkins Univ., Baltimore, MD

Abstracts: To achieve behavioral goals, cognitive control permits flexible use of limited cognitive resources by configuring brain processes according to the currently relevant task rule. This control is critical when the task rules are constantly shifting or when resolution of conflicting task rules is required. The mechanism of cognitive control for task rules has been widely studied using either task-switching paradigms or bivalent/incongruent cue paradigms. In both cases, there is a competition between a relevant and an irrelevant task rule, and participants are required to select the one that is relevant to the current behavioral goal. However, the source of conflict originates differently: in a task-switching paradigm, the conflict arises from the previously activated task rule, whereas in a congruence paradigm, the conflict arises when different dimensions of the cue are simultaneously mapped onto conflicting rule. Hence, an unanswered question is whether different sources of task conflict are associated with dissociable, conflict-specific, cognitive control mechanisms, or whether a single, domain-general, cognitive control mechanism is recruited to resolve all types of task conflict. To test this, we independently manipulated task switching (switch/repeat) and cue congruency (incongruent/congruent) using a single paradigm. This allowed for direct comparison of neural activation patterns associated with these two sources of task conflict. Specifically, participants switched between two different task rules instructed by either the shape or the color dimension of the cues, after extensively learning of cue-rule mappings. Cue congruency was manipulated by having the color and shape dimensions of the cue stimulus associated either with the same task rule (congruent) or different ones (incongruent). Behaviorally, we found a significant main effect for both switching and cue congruency, but no significant interaction between these two. Furthermore, there was no significant correlation between switch cost (switch - repeat) and congruency cost (incongruent - congruent) across participants. The neuroimaging data further revealed distinct neural circuits associated with task switching and cue congruency. A conjunction analysis later confirmed that no common area was shared between these two control processes. Overall, these results indicate that the cognitive control mechanism involved in task switching is different from that involved in resolving cue congruency, supporting the hypothesis that conflict resolution for task rules is achieved via multiple cognitive control mechanisms specific to the source of the conflict.

Title: Single time-point classification of brain activity during emotional feelings using multivariate pattern analysis

Authors: *A. GOTSOPOULOS, H. HEIKKILÄ, I. P. JÄÄSKELÄINEN, M. SAMS, L. NUMMENMAA, J. LAMPINEN;
Deparment of Biomed. Engin. & Computat. Sci., Aalto Univ., Espoo, Finland

Abstracts: Multivariate pattern analysis (MVPA) refers to a set of methods that are able to detect patterns of neural responses. This is an advantage over univariate analysis methods, which measure magnitude of an effect at a single voxel level. All higher-level brain functions, such as emotions, are subserved by connected activity in multiple brain regions. Therefore, MVPA is a promising method for studying their neural basis. Here we introduce a non-linear classification scheme based on artificial neural networks with leave-one-subject-out cross-validation to analyze emotional responses using fMRI data. We exploit the ability of the classifier to classify brain states in single time points, hence unveiling a temporal classification pattern that provides further information about task-related neural signatures. Analysis of the trained neural network's structure provides information on the importance of each voxel in each classification category, as we can recalculate the output of the classifier after removing each voxel separately from the input. This output difference reveals the importance of each voxel for each output class, yielding spatiotemporal brain importance maps for each category and each time point. We applied our method to fMRI data acquired in two experiments involving induction of emotional feelings. In the Movies experiment, 21 subjects were instructed to watch 10-second movie clips that invoked four basic emotions (disgust, fear, happiness, sadness) and a neutral state. In the Words experiment, emotions were induced in 14 subjects by mental imagery of emotional states belonging to six categories after seeing a cue word (anger, fear, disgust, happiness, sadness, surprise). Fixation period and inter-trial interval time points were also included in the analysis to verify our hypothesis of chance-level accuracy during these periods. Our classifier exhibited above-chance accuracy for time points of interest (47.5% against 20% chance level in the Movies experiment and 38.8% against 16.6% chance level in the Words experiment). Classification accuracy over time indicates the duration that a classifier can still detect distinctive activation patterns while the classification importance maps pinpoint the responsible regions for

the classification. The voxels contributing to the classification covered a wide and temporally varying range of brain regions such as frontal pole, posterior cingulate, precuneus, occipital lobe and limbic regions.

Title: Optimizing cognitive task designs to improve learning rates in a large online population

Authors: *N. NG, A. KALUSZKA, J. L. HARDY, M. D. SCANLON;
Lumos Labs, Inc, San Francisco, CA

Abstracts: Though many cognitive training studies have shown improvements in task performance over repetitions, few have sought to optimize these tasks to extend and accelerate learning rates. Recent wide-scale, online studies have shown the feasibility of quickly detecting different learning curves after manipulating multiple psychophysical parameters of specific games in an online cognitive training system (Kaluszka et al 2013). To continue this research, we set out to test the effect of varying other cognitive task parameters (eg up/down rule) on performance on the task over time. We hypothesized that optimizing the level of challenge of cognitive training tasks would lead to accelerated learning of the tasks. Participants were drawn from a pool of millions of users undergoing cognitive training through an online system (Lumosity). These individuals were randomly assigned to different versions of a training task as part of a battery of cognitive tasks that they performed daily. For example, we varied the up/down rule of a visuospatial short-term memory task inspired by the Visual Patterns Test (Della Sala et al 1997). Each session of the task consisted of 15 trials which required subjects to recall the location of a number of highlighted tiles within a grid. The up/down rule is a psychophysical parameter that dictates when the level of task difficulty between trials, as defined by the number of highlighted tiles, moves up or down. This random assignment method was applied to several other cognitive training tasks for which different relevant psychophysical parameters were varied. For all manipulations, participants were blinded to the differences in versions, and performance metrics such as percent correct and maximum span were recorded

across sessions for individuals and compared across groups. This study suggests that optimizing cognitive task difficulty to better match subjects' skill levels leads to faster learning. Additional investigation is needed to determine whether this accelerated learning curve extends to other non-trained cognitive tasks.

Title: Neural correlates of conflict during interpersonal communication observed in dorsal lateral prefrontal cortex using NIRS

Authors: *S. V. YAHIL[1], X. ZHANG[1], A. NOAH[1], P. LAPBORISUTH[1], M. BIRIOTTI[2], J. HIRSCH[1,3];

Abstracts: Although cognitive conflict has long been studied within individual brains, little is known about conflict processing in interpersonal interactions. Prefrontal cortex, known as an executive control center, is targeted as the ROI for this study. We present results of a novel, interpersonal Stroop-like task using natural communicative gestures. Audio or written forms of "yes" and "no" were superimposed on video recordings of actors performing simple

communicative gestures, such as thumbs up/thumbs down and head nodding/head shaking, thereby generating congruent and incongruent stimuli. Subject task was to identify the communicative intent of the gesture as either a “yes” or a “no.” Stimuli were presented for 3s with jittered inter-stimulus intervals of 2.5-3.5s. A single run consisted of 64 trials, for a total run time of 6-7 minutes. Trials were grouped 4 at a time into 8 congruent-dominant or 8 incongruent-dominant blocks, ensuring pseudo-random presentation. Congruent-dominant blocks contained 3 congruent trials and 1 incongruent trial, while incongruent-dominant blocks contained 3 incongruent trials and 1 congruent trial. All trials and blocks were presented continuously. BOLD activation from prefrontal cortex was measured with a portable, Bluetooth-enabled functional near-infrared spectroscopy (fNIRS) system (Astem Hb-13). Standardized Polhemus digitizations were acquired for each subject and used to assure homologous fNIRS optode placement across subjects’ prefrontal cortex. We predicted that our task would elicit the canonical Stroop effect as an increased reaction time for incongruent trials and conflict-related processing in prefrontal cortex. Behavioral results consisted of increased reaction time for incongruent trials over congruent ones, indicating Stroop-like conflict in a multisensory, interpersonal domain. Task-related BOLD activation in prefrontal cortex differed for congruent and incongruent trials, suggesting that frontal structures play a specific role in processing interpersonal conflict. In particular, signal amplitudes were suppressed for conflict-related trials relative to congruent cases. The findings suggest that prefrontal cortical regions are sensitive to types of social information.

Title: Learning from our mistakes: Apoe4 influences misdiagnosis of alzheimer's disease and frontotemporal degeneration

Authors: *J. L. HALEY, M. GROSSMAN, C. MCMILLAN, K. RASCOVSKY, D. IRWIN, D. WOLK, J. TROJANOWSKI, V. VAN DEERLIN, B. MCCARTY WOOD, L. SHAW; Neurol., Univ. of Penn, Philadelphia, PA

Abstracts: FTD and AD are pathologically distinct neurodegenerative diseases but have considerable clinical overlap that make accurate diagnosis challenging. The Ɛ4 allele of the Apolipoprotein E gene (APOE4) is a risk factor associated with late-onset AD that can influence clinical presentation, but has received little attention in FTD. We assessed whether APOE4 status contributes to misdiagnosis of AD and FTD. Furthermore, we utilized neuropsychological test results to determine if there was a difference in cognitive profile related to APOE4 status. Clinically diagnosed AD (n=545) and FTD (n=263) patients were assessed using a detailed neuropathological exam at autopsy or using an autopsy-validated analysis of cerebrospinal fluid (CSF). A previously autopsy-validated CSF total-tau to beta-amyloid ratio was used to classify patients as AD (>0.34) or FTLD (<0.34) pathology. DNA samples were collected via blood draw using standard genotyping methods to determine APOE4 genotype. We categorized patients as carriers of an E4 allele (APOE4+) or non-carriers (APOE4-). We assessed cognition with a standard neuropsychological battery examining the following domains: global (MMSE), working memory (Digit Span Backwards, Logical Memory), executive functioning (Trails B, Digit Symbol), word fluency (Animal and Vegetable Naming) and language (30-item Boston Naming Task). Overall, 84% of clinically-diagnosed AD and FTLD patients revealed consistent pathology with their diagnosis. An assessment of APOE4 status in clinical AD revealed that 66% (n=330/498) of patients consistent with having AD pathology were APOE4+ while only 43% (n=20/47) of inconsistent cases were APOE4+. In contrast, 25% (n=47/184) of clinical FTD patients consistent with having FTLD pathology were APOE4+ while 35% (n=28/79) of inconsistent cases were APOE4+. Together, these findings suggest inconsistent AD cases are more likely to be APOE4- (X^2=13.28; p=.001) while inconsistent FTD cases are more likely to be APOE4+ (X^2=5.66; p=.05). Furthermore, an assessment of Logical Memory revealed significant differences across diagnoses and APOE4+/- status (F=4.36, p<0.001). Our findings suggest that APOE4 status may influence the clinical presentation of AD or FTD and thus may contribute to pathological misdiagnosis. Logical Memory scores may help differentiate between AD and FTD. Future investigations should identify if there are regions of atrophy associated with APOE4 status in AD and FTD that may facilitate differential diagnosis.

Title: Social value orientation and choice type dependent activity in the dorsal prefrontal cortex and amygdala

Authors: ***A. S. R. FERMIN**[1], T. KIYONARI[2], Y. MATSUMOTO[3], Y. LI[1], M. SAKAGAMI[1], T. YAMAGISHI[4];
[1]Brain Sci. Inst., Tamagawa Univ., Machida, Tokyo, Japan; [2]Aoyama Univ., Sagamihara, Japan; [3]Hokkaido Univ., Sapporo, Japan; [4]Tokyo Univ., Tokyo, Japan

Abstracts: Although the neural basis of social cooperative behavior has been recently investigated, little is known whether neuro-anatomical and neuro-functional differences exist in humans with distinct social choice preferences. Here, we investigated these issues in subjects with prosocial or proself value orientations while they played a sequential non-matrix prisoner's dilemma game inside the fMRI scanner, and acquired their anatomical and functional brain data. Subjects played the game, as the first player to make a choice, against trial-by-trial randomly matched anonymous human partners. Subjects received an endowment and had a delay period of 4s-6s to decide to either cooperate or defect. If the subject chose to cooperate the partner received two times the endowment value, but if the subject chose to defect the partner received nothing and the subject received only the actual endowment value. The partner's choices were preprogrammed to cooperate with probability 0.6 if the subject cooperated or with probability 0.1 if the subject defected. Analysis of choice behavior found that subjects with prosocial orientation cooperated significantly more than subjects with proself orientation. The VBM analysis using multiple regression and ROIs revealed that proselves have larger DLPFC GM

volume, whereas prosocials have larger amygdala GM volume. A positive correlation was found between the left amygdala size and cooperation rate. The voxels identified in the VBM analysis were used as mask images to estimate the BOLD signal as subjects made their choices during the delay period. Overall, proselves showed increased BOLD signal in the DLPFC regardless of choice type. Prosocials, on the other hand, had increased BOLD signal in the left DLPFC only when choosing to defect. Amygdala BOLD signal increase was observed only in prosocials regardless of choice type. These results suggest that the DLPFC is required for the implementation of the rational economic decision to defect by both proselves and prosocials, and that prosocials' decisions are guided by an emotional sensitivity of what their choices incur to their partners.

Title: Neural correlates of consciously controlling interpersonal trust

Authors: *M. M. FILKOWSKI, I. W. ANDERSON, B. W. HAAS;
Univ. of Georgia, Athens, GA

Abstracts: Interpersonal trust is an important component of human social interaction. Previous research has investigated the tendency to trust to others. However it is currently unknown how people go about consciously controlling the tendency to either trust or distrust another person. This study was designed to examine how people use conscious control to change how much they trust or distrust another person. We recruited 60 healthy adults to participate in behavioral testing and neuroimaging. Each participant evaluated the trustworthiness of a series of faces presented on a computer screen. On a separate day, each participant underwent fMRI while they were instructed to control how much they either trusted or distrusted each face. The faces within the fMRI experiment were the same as the faces used during the initial trustworthiness behavioral evaluation. Following fMRI, each participant then performed a second trustworthiness evaluation

of each face. Control of distrust of trust was operationalized as the change of trustworthiness evaluation during pre fMRI to post fMRI. Results showed that participants became more distrusting of the faces paired with a distrust instruction, but did not consistently become more trusting of faces paired with a trust instruction. Within the brain, both control of distrust and trust conditions were associated with increased dorsolateral prefrontal cortex (DLPFC) and anterior cingulate cortex (ACC) activity. Lastly, we found that individual differences in the control of trust were associated with precuneus activity. Specifically, greater change of trust scores (pre to post) was associated with greater engagement of the precuneus during the control of trust condition. Together, these findings identify a brain network involved in the top down control of attitudes (DLPFC and ACC) engaged during the conscious control of interpersonal distrust and trust and show that the precunues serves to successfully consolidate the attempt to trust another person.

Title: Neural mechanism of social preferences toward reference persons of the same and different gender

Authors: *K. YAMADA[1], S. C. TANAKA[2], R. KITADA[3], S. K. SUGAWARA[3], H. TAKAHASHI[3], F. OHTAKE[4], N. SADATO[3];
[1]Kindai Univ., Higashi-Osaka, Japan; [2]Advanced Telecommunication Res. Inst. Intl., Kyoto, Japan; [3]Natl. Inst. for Physiological Sci., Okazaki, Japan; [4]Osaka Univ., Ibaraki, Japan

Abstracts: We examined neural mechanism of social preferences by addressing two novel features of the experiment. One is methodological: while much has been uncovered, one shared caveat in previous studies is that neural basis of social preferences was analyzed using self-reported evaluation scores of experimental situations. The reliance on self-reported evaluation

scores would be problematic unless the same numerical sense on the scale was shared across subjects. We employed a new experimental paradigm on social preferences that has been developed in economics and is free from the use of self-evaluation data. The other feature is our focus on the effect of gender of reference persons after a recent finding in economics that the effects of social preferences were asymmetric between genders. We measured brain activity by fMRI at the timing when subjects (N = 26, male 14; female 12) chose, rather than gave scores on, a preferred option out of two, each of which consisted of combination of reward for the subjects and for their fictive male or female rivals (see Figure). Key parameters of the intensities of social preferences toward reference persons of each gender were estimated from choice patterns in the tasks via the Conditional Logit model. By looking at the correlation of estimated parameters of social preferences and the BOLD signal in the DLPFC and the insula, we obtained the following results. Regarding the DLPFC, the correlations of BOLD signal associated with reward information of reference person and estimated parameter of social preference were significant in all combinations of gender of subjects and that of reference persons. For subjects who were estimated to be more jealous via the behavioral data, neural responses representing the information of rivals' reward were stronger in DLPFC. Hence, in terms of gender, DLPFC seems to play an universal role of social preferences. On the other hand, regarding the insula, that correlation was significant only in the case when female subjects compared to male rivals. Hence, the insula plays a very specific role of social preference in term of gender.

Title: The selective involvement of frontal lobes in naming social groups

Authors: *L. PIRETTI[1], A. CARNAGHI[2], F. CAMPANELLA[3], E. AMBRON[1], E. SOMACAL[2], M. SKRAP[3], R. RUMIATI[1];
[1]SISSA, Trieste, Italy; [2]Univ. of Trieste, Trieste, Italy; [3]Azienda Ospedaliero-Universitaria "Santa Maria della Misericordia", Udine, Italy

Abstracts: Introduction: Social groups are defined as categories of individuals that share category-relevant characteristics and/or features (Mason & Macrae, 2004). Preliminary evidence from both neuropsychological and neuroimaging studies indicates that the knowledge about this category may be represented independently of the knowledge about other categories such as animals, plants and tools. Aim: We want to study whether social groups have a representation of their own relative to other categories of knowledge and, if so, where these concepts are stored in the brain. Methods: We tested twenty-nine patients with frontal and temporal brain tumors in the left or right hemisphere and nineteen healthy controls (HC) on three tasks (picture naming, word-to-picture matching and picture sorting) using three categories of stimuli: living things (N=15), non-living things (N=15) and social groups (N=15). The stimuli of the three categories were matched for letter length and word frequency ($p>.05$). Results: Left brain tumor patients (lBTP) performed significantly worse than right brain tumor patients (rBTP) and HC on naming non-living things ($p<.05$) and social groups ($p<.01$). In particular, lBTP named significantly worse non-living things than living things and social groups, while rBTP performed at HC level. Error analysis revealed a higher amount of anomias within the social groups category for lBTP respect to rBTP. All the patients performed at ceiling level on the remaining tasks (word-to-picture matching and picture sorting). Voxel-based lesion-symptom mapping (VLSM) showed that damage to the left inferior frontal gyrus led to the impairment on naming living things, damage to the left inferior temporal cortex led to a deficit in naming non-living things, and damage to left superior and middle frontal gyri gave rise to a deficit in naming social groups. Conclusion: Our results, in particular the lesion analyses, confirmed that the concepts about social groups are represented in specific brain structures, different from those in which other categories of knowledge are represented. Furthermore, the brain areas that when lesioned give rise to naming errors with social groups are similar to those reported in neuroimaging studies concerning social stereotypes.

Title: Mentalizing regions explicitly code quality and source information about other's beliefs

Authors: *J. KOSTER-HALE[1], H. RICHARDSON[1], N. VÉLEZ ALICEA[1], M. ASABA[2], R. SAXE[1];
[1]Brain and Cognitive Sci., MIT, Cambridge, MA; [2]Psychology, Wellesley Col., Wellesley, MA

Abstracts: Predicting and explaining other's behavior depends on understanding mental states: theory of mind (ToM) reasoning. A key open question asks what neural computations underly this ability. ToM reliably recruits specific brain regions, including bilateral temporoparietal junction, precuneus, and medial prefrontal cortex. We used multivoxel pattern analysis in two fMRI experiments to examine how these regions code information about others' beliefs. We probed features that are informative when evaluating someone else's belief: the source and quality of their evidence and the justification of their belief. In Exp. 1, 20 participants listened to 48 stories in which a protagonist is presented with evidence and comes to a conclusion; in each story, we varied the quality (seeing something clearly vs ambiguous evidence) and perceptual source of the evidence (seeing vs hearing). Using a linear support vector machine to identify patterns of neural activity across voxels within independently localized ROIs, we find that bilateral TPJ codes perceptual source of beliefs, and that RTPJ alone distinguishes between good and poor visual evidence. In Exp. 2 we ask whether the discrimination between good and poor visual evidence in the RTPJ generalizes beyond representations about the protagonist's perceptual evidence (how well could they see?) to information about the justification of their belief (how well does their evidence support the inference?). 19 participants read 54 stories in which a protagonist comes to a conclusion (e.g. that their child will wait to get into the swimming pool when asked to do so), that is justified or unjustified given the past experience of the protagonist (e.g., the child always vs never does what they are told). Using the same analysis parameters from Experiment 1, we find that the pattern of response in RTPJ alone distinguishes between justified and unjustified beliefs. Together, the current evidence suggests that the RTPJ

explicitly codes features of beliefs that are crucial in belief evaluation, including the source, quality, and overall justification of the belief.

Title: Empathy impairment in the behavioral variant of frontotemporal dementia: Evidence from resting-state brain activity

Authors: ***N. CANESSA**[1,2], S. CAMINITI[1,2], C. CERAMI[1,2], A. DODICH[1], C. CRESPI[1], A. MARCONE[2], S. IANNACCONE[2], A. FALINI[1,2], S. F. CAPPA[3,2];

[1]Univ. Vita-Salute San Raffaele, Milan, Italy; [2]San Raffaele Scientific Inst., Milan, Italy; [3]Inst. Universitario di Studi Superiori - IUSS, Pavia, Italy

Abstracts: Loss of empathy is a symptom of the behavioral variant of frontotemporal dementia (bvFTD), constituting a clue for early diagnosis. We have previously shown that the affective facets of empathy are more affected than cognitive ones, with this deficit reflecting gray matter atrophy in limbic and frontoinsular regions (Cerami et al., 2014). Here we investigated whether this impairment reflects in anomalous resting-state activity in 12 bvFTD patients compared with 30 healthy controls. We used Independent Components Analysis (ICA) to extract maximally independent and temporally coherent spatial networks from resting-state fMRI scans lasting 8 minutes (Allen et al., 2011). We used different outcome measures to characterize resting-state activity, as well as its relationship with scores related to affective empathy, cognitive empathy and the processing of causal inferences (baseline condition) in a non-verbal cartoon task. Namely, we assessed the power spectra of RSN timecourses (level of coherent activity within a network), the intensities of RSN spatial maps (connectivity and degree of coactivation within a network), as well as functional network connectivity (connectivity between networks). For all these measures, we assessed both group differences and an interaction between group and task performance. Patients displayed a shift from low to middle-high frequencies in spontaneous fluctuations of resting-state activity, as well as reduced inter-network connectivity, in the default-mode, fronto-temporal and attentional networks. They also performed worse than controls in both empathy tasks, and particularly in affective empathy. This pattern reflected in a significant "group by task" interaction, which was specific to the affective empathy condition. Only in the latter, in patients (compared with controls) lower performance was related to a stronger shift towards high-frequency activity in frontal and sensorimotor networks, as well as to reduced connectivity within the default-mode network. No such interaction emerged for cognitive empathy, nor for the processing of causal inferences. We thus confirmed an empathic impairment in bvFTD, involving particularly the ability to infer emotional states. This deficit is related to anomalous patterns of resting-state activity, likely reflecting altered functional connectivity within and between the brain networks supporting the empathic ability. Allen et al. (2011) A baseline for the multivariate comparison of resting-state networks. Front Syst Neurosci 5:2. Cerami et al. Title: The cerebellar contribution to social cognition

Authors: F. HOCHE[1], J. A. HARDING[1], M. VANGEL[2], *J. D. SCHMAHMANN[1];
[1]Dept. of Neurol., Massachusetts Gen. Hosp., Boston, MA; [2]Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hosp., Charlestown, MA

Abstracts: Background: Neuroimaging and brain lesion studies suggest that the cerebellum is incorporated into neural substrates for social cognition, including tests of emotion attribution (EA) and Theory of Mind Reasoning (TOMR) - the ability to interpret the motivations of others. Neuropsychiatric disorders resulting from cerebellar pathology include deficits in social cognition, and small studies in patients with cerebellar disorders have described single domain deficits of social cognition. It remains unclear which domains are affected in patients with cerebellar disease, and how these relate to other neuropsychiatric manifestations of impaired social interaction. Methods: We examined 55 patients with cerebellar pathology (n=25 isolated cerebellar pathology [IC], n= 30 complex cerebrocerebellar pathology [CC]) and 55 healthy controls. We evaluated the overall level of cognitive function as well as mood and behavioural changes. Using a battery of social cognition assessments, we performed tests of emotion attribution (EA) with the Eye Task (Baron-Cohen, 2001); TOM with TOM pictures (Janet C. Sherman, doctoral thesis); and social situation recognition with social situation stories. Results: Impairments were found on EA skills as well as TOM performance. Compared to controls, IC and CC patients committed more errors on the EA task ($p < .0000$; student's t- test) and provided fewer mental answers on TOM tasks ($p < .000$). Social situation recognition was not different between patients and controls. EA skills were similarly affected between IC patients and CC patients ($p = .45$). Higher scores on the eye task were positively correlated with higher numbers of mental interpretations of TOM pictures, whereas Eye Task scores were not correlated with language or visuospatial abilities. Discussion: IC patients were as impaired as CC subjects on tasks of emotion attribution; and EA deficits were positively related with deficits in TOM. These results provide support for the hypothesis that EA is necessary for TOM, and that cerebellum contributes to both emotion attribution and TOM.

Title: Emotional Contagion as an index for positive emotional responses: Mapping the minds-eye with neural substrates in williams syndrome

Authors: *P. FILLET[1], R. NG[4,1], C. O'LOUGHLIN[5,1], M. DEWITT[1], Y. SEARCY[1], P. LAI[6,9,1], M. EARHART[7], T. BROWN[8], A. JÄRVINEN[2], J. KORENBERG[10,1], U. BELLUGI[3]; [2]Lab. for Cognitive Neurosci., [1]Salk Inst., La Jolla, CA; [3]Salk Inst., La Jollac, CA; [4]Developmental Psychopathology, Univ. of Minnesota, Twin Cities, MN; [5]Cognitive Sci., [6]Language and Communication Disorders, [8]Neurosciences, [7]Univ. of California San Diego, San Diego, CA; [9]San Diego State Univ., San Diego, CA; [10]Ctr. for Integrated Neurscience and Human Behavior, Univ. of Utah, Salt Lake City, UT

Abstracts: While empathy can be defined in many ways, there is consensus that at a simple level it refers to an ability to understand and respond to another person's emotional cues. Williams syndrome (WS) is a rare neurogenetic disorder caused by a hemizygous deletion on chromosome 7q11.23 (Korenberg et al., 2009). The unique social phenotype of individuals with WS includes an enigmatic and uneven profile of behaviors (Bellugi et al., 2000; Doyle et al., 2004, Järvinen et al., 2013). Toward this end, we employed the Emotional Contagion Questionnaire (ECQ) and the Salk Institute Sociability Questionnaire (SISQ) as part of a multi-layered ongoing study encompassing neural, behavioral and physiological assessments. The ECQ and SISQ best capture the positive emotional construct that is central to the reported prosocial and empathic sensitivities in WS. The SISQ is designed to tap into social functioning including empathic and approach behaviors while the ECQ is employed to assess the consistency of experiencing the five basic emotions (Doherty, 1997). The combination of behavioral measures with imaging tools, i.e., magnetic resonance imaging (MRI) and diffusion tensor imaging (DTI), allows us to map the neural networks responsible for the positive and emotional biases. Our central aim in analyzing these questionnaires along with imaging methods to explore empathy in WS is to characterize a multifaceted behavioral model that links the underlying neural and genetic mechanisms responsible for some of the intriguing dissociations reported in WS individuals.

Current behavioral findings indicate that those with WS experience positive emotional states in higher intensity/frequency than typically developing individuals. Preliminary imaging results indicated that in WS adults, increased emotional contagion of sadness was associated with reduced cortical surface area of anterior cingulate cortex, whereas experience of love was associated with reduced fractional anisotropy of the cingulum cingulate. Currently, additional exploratory analyses are in progress for other regions of interest (i.e., anterior insular cortex and amygdala) implicated in social-affective functions. Recent studies have implicated the amygdala and insular cortex, and hormonal dysregulation, as specific regions of interest that define uniquely the neurobiological and genetic profile of WS individuals (Brown et al, 2012; Meyer-Lindenberg, et al., 2012; Korenberg et al., 2012). Therefore, our efforts to link these neural substrates to the prosocial tendencies will significantly contribute to the extant literature and further highlights WS are atypically hypervigilant to positive emotions.

Title: NIRS-based hyperscanning reveals sex differences in brain synchronization during cooperation and competition

Authors: ***N. LIU**, J. BAKER, X. CUI, P. VRTICKA, M. SAGGAR, A. REISS; Psychiatry, Stanford Univ., Stanford, CA

Abstracts: Very little is known about how the neural response patterns of multiple brains interact during real-time social interactions. Differences in the social roles played by males and females throughout evolution have led to assumptions that sexual dimorphisms during cooperation and competition are observable today[1]. However, the degree to which men and women differ during real-time neural processing of cooperative and competitive social interactions remains unknown. Here, functional near-infrared spectroscopy (fNIRS)

hyperscanning is used to measure the neural responses of mixed- and same-sex pairs as they engage in cooperative and competitive interactions. Unacquainted participants (n = 118, aged 18-35 y) were randomly assigned into male/male (MM), male/female (MF), or female/female (FF) pairs. Each pair underwent fNIRS hyperscanning while performing a task with their partner. The task[2] was divided into three parts, and required participants to either cooperate, compete, or respond independently, in a counterbalanced order, to earn points. Two primary regions of interest (ROI), the right prefrontal cortex (rPFC) and the right middle temporal cortex (rMTC), were identified based on their roles in social cognition related to cooperation and competition. A single fNIRS recording device, ETG-4000 optical topography system (Hitachi Medical, Japan), was used to measure the hemodynamic response of both participants simultaneously. Wavelet transform coherence (WTC) was used to assess the relationship between the fNIRS signals generated by participant pairs. Coherence increase (*CI*) for each part of the task was calculated by subtracting the average coherence of a rest period from that of two task blocks ($CI = C_{task} - C_{rest}$). The *CI* value for each ROI and pair was then submitted for statistical evaluation. Our results suggest that sex significantly mediates patterns of inter-brain coherence. Inter-brain coherence in the rPFC increased during cooperation for all MM pairs (p = 0.032). Furthermore, MM pairs demonstrated significantly greater inter-brain coherence in the rPFC during cooperation than FF pairs (p = 0.041). Inter-brain coherence in the rMTC was significantly higher for all pairs during competition than during the independent control condition (p = 0.014). Taken together, our results provide the first evidence that cooperative and competitive social interactions elicit different patterns of inter-brain coherence, and that the sex composition of an interacting pair significantly influences inter-brain coherence. Title: Stimulation of the periaqueductal gray alters social perception

Authors: *K. HAROUSH[1], A. SHARMA[2], Z. WILLIAMS[2];
[1]Neurosurg., [2]Harvard Med. Sch., Boston, MA

Abstracts: Perceiving another individual's emotional state is essential for social interaction. However, it remains unknown which brain areas directly mediate such judgment processes. The periaqueductal grey (PAG) is positioned in an intersection between ascending sensory pathways and inputs from higher areas modulating these signals. While functional Magnetic Resonance Imaging studies have suggested that certain brain areas may play a role in social perception, it is unclear which areas causally modulate this cognitive function. Here, pain patients who were implanted with Deep Brain Stimulation (DBS) electrodes in the ventrolateral PAG performed an emotional perception task in front of a computer screen. Morphed images composed of two distinct emotional expressions obtained from a single individual across three emotional axes crossing happy, sad and angry, were displayed at various ambiguity levels while a sub threshold electrical current was delivered via the participants' PAG implant on half of the trials. We find that PAG stimulation lead to a consistent bias in the social perception of another's emotional expression across all axes. Under conditions of maximal ambiguity, the other's expression was perceived as being sad rather than happy or angry and angry rather than happy. Control trials testing for the participants perceived pain levels were obtained every ten trials, ensuring that the participants comfort level was not compromised throughout the experiment and demonstrated no association with stimulation trials. These findings suggest that that the PAG is responsible for modulating sensitivity to certain emotions in another individual, and may thus play a central role in mediating social interchange.

Title: The embedding of social status in person knowledge: An MVPA study

Authors: *J. KOSKI, J. A. COLLINS, I. R. OLSON;
Psychology, Temple Univ., Philadelphia, PA

Abstracts: Both humans and non-human primates rapidly assign status information to others based on a host of variables such as size, lineage, financial status, and reputation. We find the social status of others so salient that it shapes our attention and gaze patterns towards others, as well as our preferences and memories of others. Given the prominence of this variable in person processing, it seems possible that our neural representation of specific individuals contains status information. Here we asked whether the representations of specific individuals in the ventral face circuit (OFA, FFA, vATL, and amydgala) represent status information. Participants were trained to associated names and status information (high versus low ratings) with 8 different objects and 8 different faces over a two-day training regimen. These faces and objects were then presented to the subjects within a block-design fMRI experiment with a target detection task that was orthogonal to the variable of interest. In addition, we functionally localized regions in the extended face circuit, as well as object sensitive regions (LOC) using a localizer task. Data were analyzed using multivoxel searchlight analysis in FSL. The searchlight analysis revealed a network of status-sensitive clusters for faces that was more robustly represented in the right hemisphere than in the left. Regions sensitive to person status included the right vATL, right ventromedial prefrontal cortex, right fusiform gyrus, and bilateral superior temporal sulcus. In contrast, the status of objects was localized to a cluster in the left ventral anterior temporal lobe. Placing this work in the context of the relevant literature, prior work indicates that the anterior temporal lobes play an important role in storing and retrieving semantic information and that a region in the medial aspects of the ventral ATL - perirhinal cortex - contains a patch of neurons particularly sensitive to face identity as well as person-related semantic information such as biographical details. There is a predictable lateralization of this region with the left vATL more sensitive to verbal information such as names, while the right is more sensitive to nonverbal information such as faces. The present findings on the vATL are consistent with this literature. In addition, they suggest that status information becomes embedded into person identity representations stored in this region. We additionally found status-related activations across many regions in the social brain network, possibly because high status objects and people are attentionally salient.

Title: A neuro-computational account of behavioral and neural patterns in altruistic choice

Authors: *C. HUTCHERSON[1], B. BUSHONG[2], A. RANGEL[1];
[1]Humanities and Social Sci., Caltech, PASADENA, CA; [2]United States Dept. of Def., Monterey, CA

Abstracts: An important open question in neuroeconomics and social neuroscience is characterizing the neuro-computational basis of altruistic behavior. We investigated this question in the context of a modified fMRI Dictator Game involving different tradeoffs between the participant's own payoffs and the payoffs of an anonymous partner. We fitted participants' choices to a computational model of social preferences, inspired by drift diffusion models of simple choice, that has five key parameters: the weight given to one's own payoffs, the weight given to the payoffs of others, the height of a choice-determining threshold, the rate at which this threshold decreases over time (to account for time pressure), and a non-decision time. Choices in the model result from the noisy accumulation of a relative value signal derived from the weighted sum of payoffs for self and others, and are made when the accumulated signal becomes strong enough to pass the criterion threshold for making a choice. Behaviorally, we observed a tight correspondence between predictions of the model and observed responses and reaction times: generous choices on average take longer to make, particularly for comparatively selfish individuals. Neurally, we observed that two key model variables (representations of one's own and other's payoffs) correlated with BOLD responses in distinct regions: with one's own payoffs coded in amygdala and ventral striatum, and the other's payoffs coded in TPJ. Rostral anterior cingulate cortex (rACC) was sensitive to both one's own and others' payoffs, and functional connectivity analyses are consistent with the hypothesis that rACC integrates inputs from the amygdala and TPJ to compute a 'net value' for the proposal being evaluated. The model also suggested that dorsal ACC and inferior frontal gyrus (IFG) may be recruited to resolve conflict during generous choices, particularly for less generous individuals. The model suggests a need for caution in interpreting recent work using reaction-time and neural data to support self-control models of generosity, and provides a flexible framework within which to understand not only non-instrumental altruism, but also social decision-making more generally.

Title: Neural systems tracking popularity in real-world social networks

Authors: *N. ZERUBAVEL[1], P. BEARMAN[2], K. OCHSNER[1];
[1]Dept. of Psychology, [2]Columbia Univ., New York, NY

Abstracts: Successfully navigating our complex social world requires understanding the relative status of members of our groups. Sociologists and social psychologists have historically emphasized two kinds of status that have important implications for behavior: power-based status, where individuals vary in their control over resources and outcomes, and affiliation-based status, where individuals vary in the extent to which they are liked by other group members. To date, the majority of neuroscience research has focused on power-based hierarchies rather than affiliation-based popularity. Here we present the first imaging research to examine the neural systems tracking the popularity of members of real-world social networks. To do this we first used social network analysis (SNA) to determine the relative popularity of individuals in in the context of a friendship-based network to which they belonged. We then had members of each network view photographs of other group members and asked, on a trial-by-trial basis, how brain activity parametrically scaled with the popularity the target group member viewed on that trial. We found that activity in two kinds of brain regions tracked target popularity: systems involved in affective valuation (e.g. vmPFC, amygdala, ventral striatum) and social cognition (e.g. dmPFC, TPJ). Importantly, activity in the affective valuation systems mediated the relationship between target popularity and activity in social cognition regions, suggesting that a history of learning about the affective outcomes associated with popular individuals organizes our responses to them. These data have implications for models of affect, person perception and group behavior.

Title: Altered communicative adjustments following ventromedial prefrontal lesions

Authors: *I. TONI[1], G. DI PELLEGRINO[2], D. D'IMPERIO[2], A. STOLK[1];
[1]Radboud Univ. Nijmegen, Donders Inst., Nijmegen, Netherlands; [2]Univ. of Bologna, Bologna, Italy

Abstracts: The ventromedial prefrontal cortex (vmPFC) has been consistently implicated in supporting behaviors guided by a mental model of other agents. For instance, moral judgements made by patients with vmPFC lesions are more strongly influenced by the outcome of a harmful action than by its underlying intention, i.e. whether the harm was attempted or accidental. Yet, during linguistic interactions, patients with vmPFC lesions are able to consider the knowledge of an interlocutor, for instance by using shorter utterances and definite references following repeated verbal exchanges. Here we test whether the inability of vmPFC patients to use a mental model of an interlocutor becomes evident once communicative interactions are not confounded with linguistic phenomena. Communicative abilities of patients with vmPFC lesions (N=8) were quantified in a controlled experimental setting involving the production of referential non-verbal behaviors with a communicative goal. Participants were asked to inform an addressee about the location of a token in a grid (visible only to the communicator) by means of their movements on the grid (visible to both communicator and addressee). Participants spontaneously marked the location of the token in the grid by waiting longer on that location as compared to other locations visited during their movements on the grid (TimeOnTarget effect). Crucially, participants were told this communicative game involved online interactions with a child and with another adult, in alternation. In fact, an adult confederate performed the role of both addressees, while remaining blind to which one of the two roles she was performing in any given trial. These tasks features allowed us to directly tap into patients' ability to spontaneously generate communicative adjustments to their mental model of an addressee, rather than retrieving knowledge from pre-established conventions (e.g. a common language). The specificity of the vmPFC-lesion effects was assessed by comparing communicative behaviors of vmPFC patients with those evoked in patients with brain lesions outside the vmPFC (N=8, lesion-controls) and in age-matched healthy participants (N=15, healthy-controls). Patients with vmPFC lesions communicated as effectively as lesion- and healthy-controls. Crucially, both lesion- and healthy-controls showed a larger TimeOnTarget effect when they thought they were communicating with a child, whereas vmPFC patients did not communicatively differentiate between the two addressees. These findings suggest that vmPFC is necessary for using social knowledge to bias current communicative decisions to the presumed characteristics of an addressee.

Title: Self-other differences in EEG μ-suppression reflect familiarity and perspective-taking.

Authors: *C. C. WOODRUFF, A. GOODMAN, B. VELEZ, A. FORTIN, M. FECHTEL; Psychology, Northern Arizona Univ., Flagstaff, AZ

Abstracts: Previous research demonstrated a relationship between empathy and perspective-taking (PT) and suppression of electroencephalographic μ-rhythms, a putative measure of mirror neuron processing. This research suggested that PT is positively related to the size of the difference between self- and other-induced μ-suppression, but these findings were confounded because the task used involved motion by the participant during the self, but not the other condition. The current study addressed this confound by utilizing a self-condition that did not involve movement by participants. It further tested the size of self-other differences as a function of familiarity of the observed individual. Participants completed an empathic accuracy (EA) paradigm adapted from Zaki et al. (2009). We recorded μ-suppression while participants watched three different videos of facial emotional responses; 1) Self (S) - participant watches video of him/herself, 2) Familiar Other (FO) - watches video of best friend, 3) Stranger Other (SO) - watches video of a stranger. We predicted that self-other differences in μ-suppression would be smaller for S-FO than S-SO and that these differences would be related to EA and to self-report measures of empathy/PT. Results confirmed the prediction that S-FO differences were smaller than S-SO differences, and that the size of difference scores was positively related to PT. We failed however, to find a relationship between empathic accuracy and either simple μ-suppression or S-O μ-suppression differences scores and empathic accuracy. This failure may be due to a ceiling effect resulting from all participants having high accuracy. The results will be discussed in the context of theories of mirror neuron processing and self-other discrimination.

Title: Consistent familial warmth may predict child cortisol levels

Authors: *S. M. DINCES[1], L. N. ROWELL[1], J. F. L. PINNER[1], S. N. HILE[1], M. EMERY THOMPSON[2], A. C. TANG[1,3], R. D. ANNETT[4];
[1]Dept. of Psychology, [2]Anthrop., [3]Neurosciences, Univ. of New Mexico, Albuquerque, NM; [4]Pediatric Neurol., Children's Hosp. of Colorado, Aurora, CO

Abstracts: Research from both animal models and humans has indicated that the quantity of nurturing (maternal care) offspring receive influences their Hypothalamic-Pituitary-Adrenal (HPA) development and function. Using the rodent model, reliability of maternal nurturing has also been shown to be influential in offspring HPA function and behavioral outcomes. Here, we attempt to translate these rodent findings to human children, and examine the relative contributions of both of these components of nurturing to child HPA functioning. The present study included 55 children with mild/moderate asthma and their caregivers from the NHLBI-funded randomized clinical trial (Childhood Asthma Management Program) who provided data for the analyses. Caregivers completed the Family Environment Scale (FES) at enrollment and annually. Familial warmth was calculated from two subscales of the FES ($Cohesion_{score}$ minus $Conflict_{score}$). Children's baseline and evoked cortisol levels were assessed at year three and utilized in the analyses. ANCOVAs revealed that variability in familial warmth across time, but not the amount of warmth across time, predicted child basal cortisol levels at year 3

(F(1,49)=5.758, p=.021; F(1,49)= .733, p=.396 respectively). As familial variability in warmth increases, child baseline cortisol also increases. Over the five years studied, consistency in family warmth, but not the amount of warmth, predicted child baseline cortisol levels, suggesting that predictability in family behaviors influence the development of child HPA function. These findings confirm previous empirical work investigating maternal care reliability in rodents and emphasize the need to look beyond a single time point or single measurement in order to obtain an understanding of contributions of the family environment to child biological regulation.

Title: Evidence of memory generalization in contextual locomotor sensitization induced by amphetamine: A key to addiction?

Authors: ***D. S. ENGELKE**[1], R. FILEV[2], J. G. SANTOS-JUNIOR[3], L. E. A. M. MELLO[2]; [1]NEUROPHYSIOLOGY, [2]UNIFESP, SAO PAULO, Brazil; [3]FCMSCSP, SAO PAULO, Brazil

Abstracts: Animal models of addiction are important to understand its neural basis, which comprises several neuroadaptations. Locomotor sensitization is used to investigate incentive salience and transition from use to abuse. There are studies reporting context influence in locomotor sensitization acquisition and expression. However, is not explored the maintenance and precision of contextual sensitization. Here, we propose a new insight about the transition from use and abuse to addiction. We ask whether contextual memory precision, maintenance and generalization are related with this transition? To test this, male C57bl/6 mice were conducted to contextual locomotor sensitization paradigm. Baseline activity of adult male C57bl/6 mice were accessed in contextual activity box. Animals were treated during five consecutive days: AMPH+CTX (N=40) - animals injected with amphetamine (1mg/kg, i.p) and submitted to

contextual activity box; AMPH+HC (N=40) - animals treated equally, but after acquisition they back to home cage; VEH (N=40) - animals treated daily with saline and submitted to contextual activity box every day. After three (3), Fourteen (14) or twenty eight (28) withdrawal days, all animals were challenged with amphetamine (1mg/Kg) in the same context (context A) or in an alternative context (context B). Locomotor sensitization was evaluated by 40 min. In context A, AMPH+CTX increased locomotion when compared to other experimental groups after 3rd, 14th and 28th days. In context B, after 3 days, all animals traveled the same distance. However, after 14 and 28 days, AMPH+CTX expressed an increased locomotion also in context B. We propose that it might be explained by memory generalization which animals are not able to discriminate between the original and novel contexts and drug effect expressing the locomotor sensitization in all contexts as long as the abstinence time. Thus we suggest that memory generalization could be a key to explain why there is a transition from use and abuse to the development of addiction.

Title: Voluntary wheel running reverses an established cocaine-induced negative affective state in a rodent model

Authors: *J. L. GREEN, L. A. DYKSTRA, R. M. CARELLI;
Psychology, Univ. of North Carolina, Chapel Hill, NC

Abstracts: As reported previously, when a palatable saccharin solution predicts impending, but delayed, cocaine availability the saccharin solution becomes devalued, as evidenced by the emergence of aversive taste reactivity during intraoral tastant infusion. Importantly, this negative affective state predicts the motivation to self-administer cocaine (Wheeler et al., Neuron, 57: 774, 2008). Exercise is a form of environmental enrichment that has been shown to reduce

cocaine-seeking in animal models. Given this well-established protective effect, we hypothesized that exercise may reverse or attenuate the negative affective state that develops following repeated taste-drug pairings. Male, Sprague-Dawley rats (n= 8) were singly housed and received 14 daily taste-drug pairings using this established behavioral design. Briefly, the task was conducted in two phases each day: 1) intra-oral saccharin infusions (0.15%; 0.2ml delivered over 3.5 sec/trial for 45 trials) and 2) cocaine self-administration (0.33 mg/inf; 2 hrs/session). Consistent with prior studies, rats initially showed appetitive taste reactivity and minimal aversive responses during the first phase on day 1 of training. However, following repeated taste-drug pairings (day 14), rats exhibited a decrease in appetitive taste reactivity and an increase in aversive taste reactivity in phase 1, indicative of a shift to a negative affective state. Next, rats were randomly assigned to either the exercise (EX, n=5) or sedentary (SED, n=3) groups. EX rats were given access to a running wheel in their home cages for 24 hrs/d for 7 wks while SED rats were placed in their home cages without wheel access. Preliminary findings show that access to the running wheel had a protective effect on the subsequent expression of negative affect during saccharin intraoral infusion. That is, EX rats exhibited an increase in appetitive taste reactivity and a corresponding decrease in aversive responses following the 7 week abstinence period. In contrast, rats in the SED group continued to show strong aversive taste reactivity during intraoral saccharin infusion, at similar levels to that observed prior to abstinence (day 14). Ongoing studies will increase the numbers of EX and SED rats. These preliminary studies suggest that voluntary wheel running reverses an established cocaine-induced negative affective state observed following repeated taste-drug pairings.

Title: Prolonged abstinence from cocaine self-administration potentiates rapid dopamine signaling in the nucleus accumbens core

Authors: *C. M. CAMERON, R. M. CARELLI;
Univ. North Carolina, Chapel Hill, NC

Abstracts: Drug-seeking behavior progressively increases with longer periods of abstinence from cocaine self-administration, a phenomenon termed 'incubation of craving' (Tran-Nguyen et al., 1998; Grimm et al., 2001). We previously demonstrated a neurophysiological correlate of this incubated state, showing a dramatic (2-fold) increase in nucleus accumbens (NAc) core neural activity that encodes cocaine-associated cues and cocaine-seeking following a month of abstinence (Hollander & Carelli, 2005, 2007). Importantly, the NAc receives a dense dopaminergic input from the ventral tegmental area (VTA); however, less is known about changes in NAc DA release dynamics under cocaine abstinence conditions. Previous work using fast-scan cyclic voltammetry (FSCV) in anaesthetized rats has shown that even a short-term withdrawal paradigm (7 consecutive days of experimenter-delivered cocaine injections followed by 1 day of withdrawal) can cause a potentiation of DA signaling in the NAc in response to a subsequent cocaine challenge (Addy et al., 2010). However, it is possible that larger changes in DA signaling may be observed following a longer period of cocaine abstinence (one month) or as a result of self-administered versus experimenter-administered drug. To address this issue, we examined DA release and uptake dynamics in the NAc core following one month abstinence from cocaine self-administration. Rats underwent 14 days of cocaine self-administration training (0.33 mg/inf; FR1) followed by 1 day (D1; n=7) or 30 days (D30; n=7) of cocaine abstinence (placed in home cage with no drug access). After abstinence, all rats underwent a single extinction session (lever pressing had no programmed consequences). Rats were then deeply anesthetized and FSCV was used to measure DA release and uptake dynamics in the NAc core before and following a single cocaine injection. We found that a month of cocaine abstinence potentiated the peak concentration of electrically-evoked DA in the NAc following an acute injection of cocaine. Examination of release and uptake parameters revealed that the potentiated [DA]max observed in D30 animals was due mainly to a facilitation of release rather than a potentiation of uptake inhibition. Finally, in D30 (but not D1 animals) we observed a correlation between electrically-evoked DA release and behavioral responding during extinction such that a greater potentiation in DA was correlated with less extinction responding. Collectively, these findings reveal dynamic changes in NAc DA signaling following repeated cocaine self-administration and prolonged cocaine abstinence linked to alterations in drug seeking behavior.

Title: Cocaine self-administration experience biases rats towards sign-tracking behavior in a subsequent Pavlovian task

Authors: *M. SADDORIS[1], X. WANG[1], D. R. TERRY[1], J. D. REID[1], R. M. CARELLI[1,2]; [1]Psychology, [2]Neurosci. Ctr., Univ. of North Carolina, Chapel Hill, Chapel Hill, NC

Abstracts: Cues associated with valued outcomes can come to elicit approach behaviors. For example, a Pavlovian cue predictive of a rewarding outcome (e.g., food) may elicit approaches to the location where the food will be delivered (Goal Tracking; GT), or may instead elicit autoshaped approaches to the cue itself (Sign Tracking; ST). Recent discoveries have demonstrated correlations between dopamine (DA) signaling and the form of the conditioned response. Specifically, enhanced DA release in the nucleus accumbens (NAc) appears to relate to greater ST compared to GT (Flagel et al., 2011; Saunders & Robinson, 2012), while drugs of abuse such as cocaine can elicit strong ST for drug-associated stimuli (Uslaner et al., 2006; Saunders & Robinson, 2010). However, it has recently been reported that rapid DA release in the NAc is strongly attenuated following repeated exposure to cocaine, and it is unknown whether this cocaine-induced dampening of the DA signal changes how rats subsequently respond to Pavlovian cues predictive of food reward. Here, thirsty rats self-administered either cocaine i.v. (2 wk, 2h/d, 0.33mg/inf) or water delivered to a foodcup (Controls) following lever presses. Following 30d abstinence, rats were food-restricted, then trained in a distinct context for 10d on a Pavlovian discrimination, where a CS+ cue light (10s) predicted food (3 sucrose pellets) and a CS- cue light (10s) was not reinforced (14 each cue type/d). ST (cue light approaches) and GT (foodcup approaches) for each session were recorded and scored by two experimentally-blind observers during the 10s prior to cue onset (baseline) and the 10s of each cue presentation. When the task was well-learned (day 10), rats in the control group showed a strong bias towards GT during cue presentations, while in contrast, cocaine rats showed the opposite bias towards ST during the cue ($\chi 2$: $p<0.05$). However, total associative behavior during the cue did not differ between groups. Further, the same cocaine-experienced rats displaying ST behavior during Pavlovian conditioning later displayed enhanced reinstated lever pressing (under extinction) compared to GT rats when returned to the original self-administration context. Voltammetric recordings of DA release in the NAc of cocaine-treated subjects taken during the task showed attenuated signaling during the cue compared to controls. However, within the control population, ST rats showed greater DA release than GT, consistent with previous results. These

findings demonstrate that shifts to ST can occur in the absence of enhanced DA release, and may be potentiated by chronic exposure to drugs of abuse like cocaine.

Title: Neural encoding in the nucleus accumbens core during learning predicts subsequent test accuracy in a sensory preconditioning task

Authors: *D. H. CERRI[1], M. P. SADDORIS[1], R. M. CARELLI[1,2];
[1]Psychology, Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; [2]Neurosci. Ctr., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstracts: Environmental stimuli that predict natural reinforcers, such as food, can acquire salience through learned associations. Studies have shown that the nucleus accumbens (NAc) encodes important features of these associations, as evidenced by phasic changes in cell firing to the presentation of reinforcers and associated stimuli. However, it is not currently known whether this encoding is important for all associations, such as predictive relationships between neutral stimuli, or if instead the NAc only encodes motivationally salient associations between cues and valued outcomes. Here, electrophysiological recordings were taken from neurons in the NAc core during a sensory preconditioning task where rats were pre-exposed to neutral stimuli such as lights and tones. For rats in the Paired group (n=21), one of four stimuli (*A*; either tone, white-noise, flashing light, or solid light) was repeatedly followed by one of the other stimuli (*X*), while the remaining two stimuli (*B*; *Y*) were paired in the same manner. Alternatively, rats in the Unpaired control group (n=8) experienced random presentations of the same stimuli. Subsequently, in a first-order conditioning phase, all rats were trained that *X* predicted food, and

Y did not. Finally, during a test session, *A* and *B* were presented alone, and food-cup entries during stimulus presentation were recorded. Intriguingly, at test only a subset of Paired rats (n=9) showed evidence of successful preconditioning, as indicated by a selective increase in food-cup entry behavior to *A,* but not *B*. The remaining Paired rats (n=12) failed to behaviorally discriminate between *A* and *B* and did not differ in performance from Unpaired rats. Neural data from the NAc core was in accordance with these findings. “Good Learners” showed enhanced excitatory cell firing to each of the four stimuli presented during preconditioning relative to "Poor Learners" and Unpaired rats. Further, Good Learners, but not Poor Learners or Unpaired rats, exhibited increased excitatory cell firing to *A* relative to *B* during the test session. Unlike excitatory activity, differential inhibitory firing to stimuli was not observed at preconditioning or test. These data suggest that neural encoding in the NAc core may be important for the initial acquisition of associative relationships, even in the absence of explicit reward, and that these associative relationships can provide a critical foundation for the expression of later higher-order learning and behavior.

Title: Dynamic shifts in nucleus accumbens neural encoding of reward-associated cues following reinforcer devaluation

Authors: *E. A. WEST[1], E. L. THOMAS[1], R. M. CARELLI[1,2];
[1]Psychology, [2]Neurosci. Ctr., Univ. of North Carolina, Chapel Hill, NC

Abstracts: Nucleus accumbens (NAc) neurons encode important features of stimulus learning and action selection associated with rewards. Additionally, the NAc is necessary for using information about expected outcome values to guide behavior as measured by reinforcer devaluation tasks (Singh et al., 2010). Based on its anatomical connections and role as a “limbic-motor” interface, it is likely that the NAc acts as a point of convergence between value encoding in limbic and prefrontal brain regions to modify behavior following changes in reward value.

Here, we investigated how NAc neurons encode reward-associated cues when the outcome value of the reward has been devalued. Male Long-Evans rats (n=11) were trained to press a lever following an illuminated cue light that predicted a specific reinforcer (e.g., raspberry flavored pellet). Rats received an alternative reinforcer in their home cages following training (e.g., peanut butter food pellets). Once rats achieved 90% accuracy during training (receiving a reward on 45 out of 50 trials), they were probed in a devaluation test under extinction conditions. Specifically, each rat was allowed ad libitum access to one of the two foods (selective satiation). Subsequently, we assessed NAc neural activity to the reward-associated cue (prior to lever extension) following either the devaluation of the same reinforcer received during training (devalued) or the different alternative reinforcer (nondevalued). On a separate day, the other food was devalued (counterbalanced). Behaviorally, rats responded significantly less when the same reinforcer received during training was devalued (52.5 +/- 11.5) compared to devaluation of the alternative reinforcer (nondevalued, 79.5 +/- 13.2; $p<.05$) showing successful outcome specific devaluation. Previous findings in other value based tasks suggest that NAc neurons encode the expected value of future rewards and promote action selection. Preliminary electrophysiological evidence from this study expands on these findings. Specifically, we observed a significant decrease in the percentage of NAc neurons that showed phasic responsiveness (i.e., cells that either increased or decreased firing) to the reward-associated cue when the same reinforcer received during training was devalued (7 out of 68, 10%) compared to the devaluation of the alternative different reinforcer (nondevalued, 21 out of 81, 26%). These data suggest that NAc neurons dynamically encode information regarding the value of the specific reward, and apply that new value to the reward-associated cue to guide behavior.

Title: Effects of prolonged abstinence on cocaine-induced negative affect and the encoding of this information by nucleus accumbens neurons

Authors: *M. A. PRESKER, JR, E. A. WEST, R. M. CARELLI;
Psychology, Univ. of North Carolina, Chapel Hill, NC

Abstracts: We previously reported that when a palatable saccharin solution predicts impending, but delayed, cocaine availability the saccharin solution becomes devalued as evidenced by the emergence of aversive taste reactivity and increased motivation to self-administer cocaine (Wheeler et al., Neuron, 57: 774, 2008). This shift in the affective state of the rat is dynamically encoded by a subset of nucleus accumbens (NAc) neurons: cells shift from exhibiting primarily inhibitory cell firing to mostly excitatory activity during infusion of the devalued tastant. It is not known, however, if the neural encoding of this negative affective state is altered by prolonged cocaine abstinence. Notably, 30 days of abstinence from cocaine leads to increased effort to obtain the drug, as well as increases in the percentage of NAc cells that encode cocaine-predictive cues and cocaine-seeking behavior (Hollander and Carelli 2007). Here, we extend previous findings to determine the effects of 30 days of cocaine abstinence on NAc cell firing and taste reactivity measures following 14 days of saccharin-cocaine pairings. Before abstinence, daily sessions were completed in two phases. In phase 1, saccharin (0.15%; 0.2 ml delivered over 3.5 sec/trial for 45 trials) was intra-orally infused. This was immediately followed by cocaine self-administration (0.33mg/kg/inf) for 2 hours (phase 2). Orofacial movements were measured in phase 1 while electrophysiological recordings were conducted in both phases. Behavioral data (n=5) indicate that aversive taste reactivity to the devalued saccharin tastant increased following 14 sessions prior to abstinence, as previously reported. Next, animals were placed in abstinence (homecage, no access to drug) for 30 days. Following abstinence, rats were tested in a single test session conduced in three phases, 1) intraoral saccharin delivery 2) extinction and 3) cocaine self-administration, and NAc cell firing and behavioral responses were measured. Preliminary findings indicate an increase in the number of aversive taste reactivity responses (gapes) to saccharin following abstinence, compared to that observed on day 14. Importantly, this was accompanied by an increase in NAc excitatory firing during saccharin delivery (n= 7/7 phasic cells, 100%) compared to immediately prior to abstinence (day 14; n=9/13 phasic cells, 66%). Although preliminary, these data suggest that cocaine abstinence has a profound ‘incubating’ effect on the negative affective state that develops following repeated taste-drug pairings and the encoding of this information by NAc neurons.

Title: Rapid dopamine signaling in the nucleus accumbens during a magnitude-based decision making task

Authors: *D. SACKETT, M. P. SADDORIS, X. WANG, R. M. CARELLI;
Psychology Dept., UNC Chapel Hill, Chapel Hill, NC

Abstracts: To maximize resources, organisms must choose actions that result in the most valuable outcome available and maintain that information to guide future behaviors. Integral to this decision making process is a neural circuit that includes the nucleus accumbens (NAc) and its dopaminergic input. In the rat, the NAc is divided into two discrete subregions, the core and the shell, believed to process information about reward learning, reward value, and decision making related to goal-directed actions. However, the precise role of those subregions in processing information about magnitude-based decisions remains unclear. Here, dopamine (DA) release in the NAc was monitored using fast-scan cyclic voltammetry during a magnitude-based decision making task. Male Sprague-Dawley rats (n=4) were trained to lever press following distinct visual cues that predicted the magnitude of future rewards. On Forced Choice Low Magnitude trials, a cue light predicted the opportunity to press a lever for a small reward (one 45mg sucrose pellet). On Forced Choice High Magnitude trials, another distinct cue light predicted the opportunity to press a different lever for a large reward (two 45 mg sucrose pellets). Finally, on Free Choice trials, both cue lights and levers were presented and rats were able to choose between both magnitude options. All rats accurately discriminated between cue types on Forced Choice trials and developed preferences for the high magnitude option on Free Choice trials. Preliminary electrochemical recordings from electrodes aimed at the NAc shell show increases in rapid DA release following presentation of Forced Choice cues, though peak DA concentrations did not differ for cues predictive of different magnitude rewards. However, preliminary results on the Free Choice trials indicate that peak DA during the choice cue was significantly greater when the animal subsequently chose the large magnitude option versus when it chose the small magnitude option. Despite this, there was no difference in peak DA during reward consumption of either magnitude. The current findings support previous reports that implicate the NAc shell in encoding comparative reward value during reward magnitude-based decision making. Ongoing studies are being completed to replicate these findings, and to examine DA release dynamics in the NAc core during the same task.

Title: Selective enhancement of performance in contingent reward assays, but not non-contingent assays, by DREADD activation of mPFC pyramidal neurons

Authors: *D. M. WARTHEN, P. S. LAMBETH, B. A. NEWMYER, R. P. GAYKEMA, M. M. SCOTT;
Pharmacol., Univ. of Virginia, Charlottesville, VA

Abstracts: The medial prefrontal cortex (mPFC) is implicated in a wide range of cognitive functions, including reward evaluation, decision making, memory extinction, mood, and task switching. The mPFC exerts its executive control function via projections composed exclusively of excitatory pyramidal neurons that innervate targets throughout the brain. We sought to determine the behavioral effects of varying excitatory outflow from the mPFC of mice using Designer Receptors Exclusively Activated by Designer Drugs (DREADD) and a panel of behavioral assays. To drive mPFC excitatory output, we expressed Gq-coupled DREADD receptors in mPFC pyramidal neurons. We found that increasing excitatory output from the mPFC via DREADD enhances performance in high cognitive demand, instrumental food reward assays, while having no impact on performance in non-contingent, low cognitive demand assays. Specifically, activation of mPFC pyramidal neurons enhances operant responding for food reward, reinstatement of palatable food seeking, and suppression of impulsive responding for food reward. Activation of mPFC pyramidal neurons has no effect on non-contingent food intake, either when sated or when fasted, or when given a choice between two highly palatable diets (one high carb, one high fat). Activation of mPFC pyramidal neurons also has no effect on social interaction, behavior in an open field or elevated plus maze, or exploration of a novel environment. Furthermore, by testing our mice at varying concentrations of the DREADD receptor ligand clozapine-N-oxide (CNO), we found that the behavioral outcome is influenced by the degree of mPFC activation. Low CNO doses enhance operant responding, while higher doses are required to observe an effect on reinstatement and impulsivity. We hypothesize that this difference is due in part to alterations in neuronal activity in the mPFC, a hypothesis we are

testing by recording local field potentials in the mPFC before and during CNO challenge. Our data indicate that modestly increasing excitatory drive from the mPFC is sufficient to enhance performance of high cognitive demand, instrumental behaviors, while avoiding additional effects on low cognitive demand, non-contingent behaviors, such as have been reported by other groups using alternate stimulation methods.

Title: Patterns of activation of excitatory and inhibitory neurons in the mouse medial prefrontal cortex associated with palatable food ingestion and food driven exploratory behavior

Authors: *R. P. GAYKEMA, X.-M. NGUYEN, J. M. BOEHRET, P. S. LAMBETH, J. JOY-GABA, D. M. WARTHEN, M. M. SCOTT;
Pharmacol., Univ. of Virginia Sch. of Med., Charlottesville, VA

Abstracts: The medial prefrontal cortex (mPFC) controls many aspects of executive function, which include attentional control and goal selection. Food-seeking behavior has been shown to involve activation of the mPFC, both during the execution of strategies designed to obtain food and during the consumption of food itself. As these behaviors likely require differential engagement of the prefrontal cortex, we hypothesized that the pattern of neuronal activation would also be behavior-dependent. In this study we describe patterns of Fos expression in different layers and cell types of the dorsal (prelimbic/anterior cingulate) and ventral (infralimbic/dorsal peduncular) subdivisions of the mouse mPFC following both the consumption of palatable food and exploratory activity directed at obtaining food reward. While both manipulations led to increases of Fos expression in principal excitatory neurons relative to the control group, food-directed exploratory activity produced a significantly greater increase in Fos expression than observed in the food-consuming condition. Consequently, we hypothesized that interneuron activation would be differentially engaged in a similar fashion. However, Fos

induction in interneurons depended heavily on interneuron subtype and did not exhibit the same differences in intensity between experimental groups as seen in the excitatory neuronal populations, illustrating how the differential engagement of subsets of mPFC interneurons depends on the behavioral state. In our experiments, both vasoactive intestinal peptide- and parvalbumin-expressing interneurons showed enhanced Fos expression only during the food-dependent exploratory task and not during food intake. Our data suggest that select activation of these cell types may be required to support high cognitive demand states such as observed during exploration while not being similarly engaged during the ingestion of freely available food.

Title: Plasticity within the basolateral amygdala pathways to the prelimbic cortex during Pavlovian appetitive conditioning

Authors: *S. E. KEEFER, C. J. REPPUCCI, H. S. MAYER, G. D. PETROVICH; Psychology, Boston Col., Chestnut Hill, MA

Abstracts: The amygdala and medial prefrontal cortex (mPFC) are important for associative learning and memory, and these structures are heavily interconnected via topographically organized pathways. How these two areas communicate throughout different stages of learning is not well understood. Our laboratory recently found that the anterior and posterior basolateral nuclei of the amygdala (BLAa, BLAp) are differentially recruited during early and late stages of cue-food associative learning using a Pavlovian appetitive conditioning paradigm. Projections from the BLAa and BLAp to the mPFC are distinct, suggesting activation in these nuclei could differentially influence the mPFC throughout learning. Thus, we examined whether BLA neurons that send direct projections to the mPFC are selectively recruited during cue-food associative learning, and whether specific pathways from the BLAa and BLAp to the mPFC are differentially recruited across learning. To accomplish this, we used neuroanatomical tract

tracing combined with Fos induction analysis. Male Long-Evans rats received an injection of the retrograde tracer Fluoro-Gold (FG) into the prelimbic area (PL) of the mPFC via iontophoresis. Rats in the conditioned group (Paired) were given presentations of a tone (conditioned stimulus, CS) followed by immediate delivery of food pellets (unconditioned stimulus, US) in the conditioning chamber. Rats in the Control group received tones (CS) in the conditioning chamber and food pellets (US) in their home cage. Each training group received either one or ten days of training (one session per day) to examine early and late learning, respectively. Learning was measured as an increase in the percent of time rats spent at the food receptacle ('food cup behavior') during the tone presentations. The Paired group learned the tone-food association quickly and robustly, evident by a tone-specific increase in food cup behavior during training. Rats were sacrificed 90 minutes after either one or ten days of training, and brain tissue was processed with double-label fluorescent immunohistochemistry for FG and Fos detection. Neurons within the BLAa and BLAp were analyzed, and the number of double-labeled (FG + Fos) neurons was quantified for each nucleus. We found more FG + Fos neurons in the Paired compared to the Control group in the BLAa during late, but not during early training. Conversely, we found no differences between groups in the BLAp at either time point. Our findings indicate selective recruitment of the BLAa-PL pathway emerges by late training of the tone-food association, which suggests plasticity of this pathway across appetitive associative learning.

Title: Male and female rats show differential Fos induction within distinct medial prefrontal areas during renewal of Pavlovian appetitive conditioned responses

Authors: *L. C. ANDERSON, G. D. PETROVICH;
Psychology, Boston Col., Chestnut Hill, MA

Abstracts: Recently, we began investigating contextual processing in associative learning and memory and found sex differences. In context-dependent renewal of extinguished appetitive Pavlovian conditioned responses we found that males showed renewal of responding while females did not. In that protocol, conditioning and extinction are conducted in different contexts and the renewal of responding is induced by return to the conditioning context ("ABA renewal"). In the current study, we examined recruitment of the medial prefrontal cortex (mPFC) during the test for renewal in male and female rats. We used Fos induction to evaluate distinct mPFC areas, the infralimbic (ILA), prelimbic (PL), and anterior cingulate (ACAd). First, male and female rats were conditioned to associate a tone (conditioned stimulus, CS) with food (unconditioned stimulus, US) in 5 acquisition sessions. Acquisition was followed by 2 extinction sessions with CS-only presentations. Rats were then tested for renewal with CS-only presentations in a single test session. Experimental groups experienced extinction in a context different than the acquisition context and then were tested for renewal in the original acquisition context (ABA, BAB). Control groups remained in the same context during acquisition, extinction, and test (AAA, BBB). A CS-specific increase in the expression of food cup behavior (conditioned response, CR) was the measure of learning. We found no sex differences in acquisition and similar responding in extinction. During the test males showed renewal of CRs, while females did not. There was a main effect of sex and group interaction for food cup responding ($F(1,28)=5.522$, $p < 0.05$), and a significant difference between male groups (Experimental Males: 40.12 +/- 6, Control Males: 17.9 +/- 7; $t(1,12)=1.045$, $p < 0.05$), but no differences between female groups (Experimental Females: 15.2 +/- 5, Control Females: 19.73 +/- 5; $p > 0.05$). Brains from these animals were processed with immunohistochemistry for detection of Fos and then total number of neurons with Fos analyzed. There was a significant sex by group interaction in the ILA and the PL (ILA: $F(23,1)=12.439$, $p < 0.01$; PL: $F(23,1)=12.439$, $p < 0.01$). In both the ILA and PL, Fos induction in males was significantly higher in experimental compared to control groups ($p < 0.05$). The pattern of Fos induction was the opposite in females: Fos induction was significantly lower in the experimental compared to control groups ($p < 0.05$). In contrast, within the ACAd there were no sex or group differences in Fos induction. Our results suggest distinct mPFC areas, specifically the ILA and the PL, are recruited during appetitive renewal in a sex-specific way.

Title: A parametric study of appetitive Pavlovian conditioning and conditioned reinforcement in rats

Authors: R. I. TABBARA, P. BEHARRY, *N. CHAUDHRI;
Concordia University, Psychology, CSBN/GRNC, Montreal, QC, Canada

Abstracts: Objective: An appetitive Pavlovian conditioned stimulus (CS) can predict the delivery of an unconditioned stimulus (US), acquire incentive value, and reinforce new behavior. We examined the impact of water-deprivation and sucrose concentration on the acquisition of Pavlovian conditioning and expression of conditioned reinforcement (CR). We also tested the effect of nicotine (NIC) on CR. Methods: Male, Long-Evans rats (Harlan, 220-240 g on arrival, *n* = 96) were acclimated to 3% (3S) or 20% (20S) sucrose in the home-cage. Within each concentration, rats were then divided into two equal groups that received either unrestricted water (NWD: non water-deprived) or water for 1-hr per day (WD: water-deprived). All rats then underwent 7 Pavlovian conditioning sessions. For half of the rats in each deprivation and concentration condition (PAIRED), a 10-sec tone-light CS was paired with 0.2 ml of sucrose (16 trials/session; 3.2 ml/session). The remainder (UNPAIRED) received explicitly unpaired CS and US trials. Entries into the fluid port where sucrose was delivered were recorded. Next, tests for CR were conducted. Two novel levers were introduced. Presses on the 'active' lever produced the CS without the US, whereas presses on the 'inactive' lever had no consequences. Before one of these tests, rats received an injection of saline or nicotine (0.4 mg/kg, free base, s.c.). Results: For rats in the PAIRED but not UNPAIRED condition, the proportion of total port-entries that occurred during the CS (Percent CS) increased across session. NWD rats that received paired CS-US trials achieved higher Percent CS port-entries compared to WD rats. There was no impact of sucrose concentration on acquisition. During the test for CR, PAIRED rats in the WD, 20S condition responded more on the active lever than the inactive lever, and made more active lever responses than UNPAIRED rats. NIC selectively enhanced responding for CR in rats in all PAIRED conditions. Conclusions: A CS that is repeatedly paired with sucrose can come to predict the delivery of sucrose, and the acquisition of this association is influenced by water-deprivation. A CS can acquire predictive properties but not incentive value, as indicated by the finding that only a CS associated with 20S in WD rats served as a CR. NIC can non-associatively enhance the conditioned reinforcing properties of appetitive Pavlovian cues.

Title: The effects of a ghrelin agonist without increased energy intake on age-related cognitive, metabolic and circadian changes in SAMR1/SAMP8 mice

Authors: *I. KADISH[1], M. SHARPE[1], T. VAN GROEN[1], J. PAUL[2], K. L. GAMBLE[2], M. E. YOUNG[3], D. B. ALLISON[4];
[1]Dept Cell, Developmental and Integrative Bio, [2]Dept Psychiatry, [3]Dept Med., [4]4School of Publ. Health, Office of Energetics, Nutr. Obesity Res. Ctr., Univ. Alabama Birmingham, BIRMINGHAM, AL

Abstracts: Caloric restriction (CR) is a long established paradigm which extends longevity and slows symptoms of aging through mechanisms which have yet to be clearly elucidated. Ghrelin is a hunger-inducing gut peptide, and the interoceptive cues caused by ghrelin are likely similar to those produced by CR. In this study we tested the novel hypothesis that a ghrelin agonist, when animals are not permitted to increase their energy intake, induces neuroendocrine effects consistent with hunger and thereby attenuates behavioral and cognitive decline, and also changes energy metabolism and circadian rhythm in aged SAMR1/SAMP8 mice, and that these changes involve interoceptive cues, rather than reduced energy intake per se. Two groups of 2 month old male SAMR1 and SAMP8 mice were used in this study. One group (control) from each strain had ad libitum access to food, while the second group (ghrelin) received the mean amount of diet consumed by the control group and a ghrelin agonist (LY444711; 30 mg/kg of LY in a 45 mg sucrose pellet) daily for 6 months. At the end of the experimental feeding protocol all mice were analyzed for body composition using quantitative magnetic resonance (QMR). A battery of behavioral and cognitive tests was carried out to analyze behavioral/cognitive differences. All animals were also assessed in CLAMS cages for energy expenditure and circadian rhythms. Biochemistry and immunohistochemistry analysis were carried out to assess the changes in brain tissue and plasma. NIH Image J was used to analyze protein expression changes, between-group ANOVA and Bonferroni post tests were used to determine the statistical significance. Six months of ghrelin agonist treatment did not alter the body composition of either group. Cognition

was significantly (p=0.03) improved in ghrelin group of SAMR1 mice compared to control group, but did not influence the cognitive outcome of SAMP8 mice. In a 12:12 light-dark cycle, both SAMR1 and SAMP8 mice exhibited typical 24-hour rhythmicity in general cage activity, respiratory exchange ratio (RER), and energy expenditure; however, SAMP8 mice exhibited pronounced ultradian (12-hour) rhythms in all measurements as well. Daily ghrelin administration to SAMP8 mice eliminated the ultradian phenotype and restored the amplitude of 24-hour rhythms in behavior and metabolism up to the level seen in SAMR1 controls. In conclusion, "hunger" without CR has similar cognitive and metabolic benefits compared to CR without the potential problem of weight loss in aging organisms.

Abstracts: Learning is thought to occur through selective alterations in neuronal excitability that contribute to adaptive responses to environmental stimuli. In the nucleus accumbens (Acb), the differential modulation of D1- and D2-dopamine receptor expressing medium spiny neurons (MSNs) by stimulus-elicited dopamine release is hypothesized to be critical for associative learning and goal-directed behavior. To date, efforts to validate this hypothesis have been limited by the inability to differentiate the two cell types using traditional recording techniques. To overcome this limitation, we conditionally expressed GCaMP6 in Acb D1- and D2-MSNs and then used a miniature fluorescence microscope to image the simultaneous Ca^{2+} dynamics of hundreds of individual neurons during acquisition, extinction, and reinstatement of an appetitive

Pavlovian association in freely-moving mice. Activity in both D1- and D2-MSNs was organized into spatiotemporally coordinated ensembles, which exhibited similar dynamics of activation in response to conditioned stimulus presentation. Although reward consumption was correlated with a dramatic decrease in neural activity, we observed transient and pathway-specific reactivation of neuronal ensembles in response to rewarded licking. During extinction or systemic D1R antagonism, conditioned responding diminished and task-related Acb network activity closely resembled the unlearned state. Taken together, our results reveal novel ensemble features of Acb D1- and D2-MSNs during dopamine-dependent learning.

Title: A model of negative automaintenance in pigeons: Dual learning and factored representations

Authors: F. LESAINT[1], O. SIGAUD[1], *M. KHAMASSI[2];
[1]Inst. des Systèmes Intelligents et de Robotique, CNRS - Univ. Pierre Et Marie Curie, Paris, France; [2]Inst. des Systèmes Intelligents et de Robotique (UMR 7222), CNRS - Univ. Pierre Et Marie Curie (ISIR UMR 7222), Paris, France

Abstracts: In this work, we apply a model that combines dual-learning systems and factored representations to experimental data about negative automaintenance in pigeons. In such a procedure, a key light is paired with the subsequent delivery of food where any peck at it results in the omission of reward. Various studies reported very distinct behaviours between pigeons. Some observed that pigeons persisted in pecking despite its negative consequence, while others

observed that pigeons quickly learned to refrain from it and maximized their cumulative rewards. Interestingly, in a previous work, we showed that the model already accounts for the variability of behaviours observed in a population of rats undergoing an autoshaping experiment, a similar procedure where the conditioned stimulus has no negative impact (Lesaint et al., 2014). More precisely, it accounts for the presence of goal-trackers and sign-trackers amongst rats (Flagel et al., 2011). We show that the model can similarity account for the variability of behaviours observed in pigeons, suggesting that the dichotomy between sign-tracking and goal-tracking might apply in pigeons. It also explains why the introduction of an irrelevant key light, on which pecking has no effect, allows pigeons that are unable to refrain from pecking to shifts their pecks towards it. Finally, it also reproduces the incapacity of a continuous irrelevant key light, which is never turned off, to attract such detrimental pecks when combined with the negative key light. We discuss the interest of the main mechanisms combined in the model (factored representations and dual-learning) in reproducing experiments about Pavlovian and instrumental conditioning, especially during their interaction. The model provides a tool to further investigate the neural mechanisms that lead to such observations and allows us to draw predictions that may be experimentally verified, for example about the dopaminergic patterns that should be expected to be recorded.

Title: Value learning mechanisms for novel stimuli in orbitofrontal and anterior cingulate cortex

Authors: *S. KENNERLEY, L. T. HUNT, N. MALALASEKERA;
Sobell Dept of Motor Neurosci., Univ. Col. London, London, United Kingdom

Abstracts: Neurons whose activity reflects the value of choice alternatives are reliably isolated in studies of orbitofrontal cortex (OFC) and anterior cingulate cortex (ACC). Such studies frequently use ‘overlearnt’ stimuli to indicate decision values to the subject, which have been seen by the subject in a large number of previous sessions. In the present study, we: (i)

investigated how neuronal activity in OFC and ACC varied as subjects learnt the value of, and made choices between, entirely novel stimuli, and (ii) compared value coding selectivity of the same neurons during choices of overlearnt stimuli. Each experimental session consisted of two phases. In the first phase ('learning' trials), subjects were presented with one of 10 novel cues. Each cue was followed by a secondary reinforcer that predicted either the probability or magnitude of reward, and then juice reward was delivered after a delay. During this phase, subjects' learning was probed using 'catch' trials in which they chose between two of the novel stimuli. In the second experimental phase ('choice' trials), subjects either chose between two novel stimuli, two overlearnt stimuli, or one novel and one overlearnt stimulus. Activity from 112 single neurons (57 ACC, 55 OFC) was investigated. Subjects learnt the value of the novel stimuli with remarkable speed and accuracy, such that their performance in catch trials at the end of the learning phase (10 exposures per cue, 100 trials total) often exceeded 90% accuracy. Moreover, subjects reliably used this information to choose reliably between novel and overlearnt stimuli in the choice phase. In spite of this, there was a clear distinction in neuronal responses of OFC (but not ACC) to novel vs. overlearnt stimuli in the choice phase. A similar proportion of ACC and OFC neurons reflected the value of the chosen option. However, whereas ACC chosen value neurons responded similarly irrespective of cue novelty, OFC chosen value neurons again differentiated between novel and overlearnt cues. This suggests that whereas ACC carries an abstract value code irrespective of cue identity, OFC carries a specific code that discriminates novel from familiar stimuli. The same "stimulus code" profile of OFC (but not ACC) activity also occurred during the learning phase of the experiment as during the choice phase. Intriguingly, this stimulus code persisted until the end of the secondary reinforcer epoch in early learning trials, but attenuated shortly after stimulus onset as learning progressed. This suggests a mechanism by which value might be ascribed to novel stimuli in orbitofrontal cortex during learning.

Title: Induction of associative olfactory memory by targeted activation of single olfactory neurons in *Drosophila* larvae

Authors: *T. HONDA[1,2], C.-Y. LEE[2], M. YOSHIDA-KASHIKAWA[2], K. HONJO[2], K. FURUKUBO-TOKUNAGA[2];
[1]Ph.D. Program in Human Biology, Sch. of Integrative and Global Majors, Univ. of Tsukuba, 1-1-1, Tennodai, Tsukuba, Ibaraki, Japan; [2]Inst. of Biol. Sci., Tsukuba, Japan

Abstracts: Appetitive olfactory memory is formed in *Drosophila* by at least two sets of external stimuli, conditioned odor stimuli (CS) mediated by the olfactory receptor neurons (ORNs) and unconditioned reward stimuli (US) mediated by the octopaminergic (OA) neurons. Previous studies demonstrated that neural signaling of OA neurons is required for the acquisition of appetitive memory in both adult flies and larvae. It has also been shown that induced activation of OA neurons substitutes appetitive US. While these studies have uncovered the functional neural circuitries that mediate US information during the course of associative memory induction, the contribution of CS pathway in memory acquisition is yet to be addressed by targeted activation approaches. In particular, whether associative memory can be induced by targeted activation of only the olfactory CS and the OA-mediated US pathways remains to be elucidated. Moreover, whether the complex combinatorial signals mediated by the activation of multiple ORNs are necessary to induce distinctive associative memory has not been addressed so far. With its simple neuroanatomical design, the larval brain of *Drosophila melanogaster* can be utilized as an excellent model system for the elucidation of the neurocircuitry mechanism of memory. The architecture of the larval brain is a simple extension of the embryonic axonal plan, and the neuronal pathway of olfactory information is straightforward without redundancy. Using a single-odor paradigm, we described previously that sugar-reward training produces appetitive olfactory memory that persists medium term in the third instar larvae. In this study, we applied optogenetic and thermogenetic techniques to the analysis of the neurocircuitry mechanism of memory induction in the larval brain. We substituted sugar reward stimuli by thermogenetic activation of OA neurons with the dTrpA1 channel, and odor stimuli by optical activation of a specific class of ORNs with Channelrhodopsin-2 (ChR2). We showed that targeted activation of the converging memory circuitry with blue light and heat produces associative memory in the transgenic larvae. We also showed that memory thus produced is specific to the odorant determined by the type of the activated ORNs. Furthermore, we successfully demonstrated that this artificial olfactory memory persists for medium term, and as stable as natural memory produced by the activation of multiple ORNs using a real odorant.

Title: Autoshaping the lever-press response and its subsequent continuous reinforcement in spontaneously hypertensive rats: Effects of distant placement of the lever

Authors: *T. SATO[1], J. GYOBA[2];
[1]Hlth. and Social Services, Tohoku Bunka Gakuen Univ., sendai, Japan; [2]Psychology, Tohoku Univ., Sendai, Japan

Abstracts: In the autoshaping paradigm, animals engage in goal tracking first, followed by sign tracking. The progress to sign tracking could be strongly affected by the spatial location of the lever (i.e., "sign" for food delivery) and food cup (i.e., "goal" of the food reinforcement). It becomes more difficult for rats to find the sign if it is located away from the goal or out of their spatial attention span. Further, rats with shorter attention spans might show lower performance in the autoshaping paradigm when the sign is located away from the goal. The present study examined the acquisition of a lever-pressing response in a spontaneously hypertensive rat (SHR), a rodent model of human ADHD. Eight male SHRs and Wistar Kyoto (WKY) rats were used. Half were allocated to an autoshaping test in which a retractable lever was placed on the same wall as the food cup and the distance between them was short (adjacent placement). The others were allocated to a test in which the lever was placed on the wall opposite to the food cup (distant placement). After food cup training, four test sessions were conducted, each with 50 trials. At the beginning of each trial, one lever was introduced in the chamber and a cue light was simultaneously turned on. If a lever-pressing response appeared within 15 s since lever presentation, a 45-mg food pellet was presented in the food cup, the lever was retracted, and the cue light was turned off immediately after the criterion response. If the criterion response did not appear, the food pellet was presented, lever was retracted, and cue light was turned off 15 s after the lever presentation. Subsequently, using the rats in the distant placement condition, one or more sessions of continuous reinforcement, or an FR1 schedule, were performed. In this, three retractable levers were introduced on the wall opposite to the food cup. The test was considered complete when 30 food pellets were acquired by pressing these levers within 400 s. In the adjacent placement, both strains rapidly acquired the lever-press response in the first session; the SHRs showed a similar increase in the frequency of the lever-press as did the WKY rats. However, in the distant lever placement, the SHRs could not acquire the lever-press response through all four autoshaping sessions, while three out of the four WKY rats acquired it at least by the third session. Their performance in subsequent reinforcement sessions also indicated that acquisition of the lever-pressing response further deteriorated in the SHRs in this placement. In

the continuous reinforcement task, the SHRs required two or more sessions to achieve the criterion to complete it, while all WKY rats successfully completed it in the first session.

Title: Differential role of VTA cholinergic and glutamatergic receptors in conditioned reinforcement

Authors: ***R. WICKHAM**, W. SOLECKI, E. NUNES, N. ADDY;
Yale Univ., New Haven, CT

Abstracts: **Abstract** Stimuli which have been associated with rewards (cues) can become strong motivators and drivers of food-seeking and drug-seeking behavior. Dopamine (DA) cells in the ventral tegmental area (VTA) encode rewards and cues by switching from a tonic to burst-like firing pattern - leading to elevated nucleus accumbens (NAc) DA release. VTA nicotinic acetylcholine receptors (nAChRs), muscarinic acetylcholine receptors (mAChRs), and N-methyl-D-aspartate receptors (NMDARs) are critical for NAc phasic DA release. This increase in DA release has been shown to be important for the reinforcing properties of cues. Thus, we tested the role of nAChRs, mAChRs, and NMDARs in permitting a cue to act as a reinforcer. Rats received 10 days (25 pairings per day) of an 8-second lever cue presentation followed by delivery of a banana-flavored sucrose pellet. Rats either developed sign-tracking (approach to the cue), goal-tracking (approach to the food receptacle), or intermediate approach strategies during Pavlovian conditioning. The day after training, rats were tested on the acquisition of a novel response with conditioned reinforcement. We infused either saline, the NMDAR antagonist AP-5 (0.1 or 1μg),

the nAChR antagonist mecamylamine (MEC: 3 or 30µg), or the mAChR antagonist scopolamine (SCOP: 3 or 66.7µg) bilaterally into the VTA immediately before conditioned reinforcement testing. During the test, nosepoking in the port assigned as active (CR) produced the lever cue while nosepoking on the port assigned inactive (NCR) had no consequence. AP-5 robustly decreased CR, and not NCR responding, but did not block the subjects' ability to discriminate between CR and NCR. The 3µg MEC dose had no effect on either CR nor NCR, while the 30µg MEC dose nonspecifically decreased both CR and NCR responding. The 3µg SCOP dose had no effect on either CR nor NCR while the 66.7µg SCOP dose increased NCR and disrupted the subject's ability to discriminate between CR and NCR. These results provide new insight of the role of VTA NMDARs and AChRs in mediating the ability of natural reward associated cues to act as a conditioned reinforcer.

Title: Ventral hippocampal lesions attenuate the acquisition of sign-tracking behavior in rats

Authors: *C. J. FITZPATRICK, J. D. MORROW;
Dept. of Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstracts: It is important to understand why some individuals can try potentially addictive drugs without developing addiction, while others try the same drug and are quickly rendered incapable of controlling their urges to repeat the experience. In order to model addiction vulnerability in animals, we use a Pavlovian conditioned approach procedure to identify individual rats, called "sign-trackers," that become attracted to and motivated by a cue that predicts reward. Other rats, called "goal-trackers," remain motivationally fixated on the reward itself. Sign-trackers are more susceptible to cue-induced reinstatement of cocaine self-administration and seek drug even in the face of adverse consequences, two hallmarks of addiction in humans. Thus, sign-tracking for

food reward predicts addiction-like behaviors and can be used as a proxy for addiction vulnerability. Sign-trackers release more dopamine in the nucleus accumbens than goal-trackers in response to reward cues. Sign-tracking has also been shown to be dopamine-dependent, while goal-tracking is not. Afferents from the ventral hippocampus are the most potent drivers of dopaminergic activity and thought to thereby enhance the motivational salience of relevant cues. A reduction of activity in the ventral hippocampus would therefore be expected to decrease dopaminergic activity in response to reward cues and consequently reduce sign-tracking behavior. In agreement with this hypothesis, we found that rats with excitotoxic lesions of the ventral hippocampus exhibited less sign-tracking and more goal-tracking behavior than sham-operated rats. This suggests that activity within the ventral hippocampus may promote sign-tracking behavior to the exclusion of goal-tracking behavior. Individual variation in the strength of ventral hippocampal influence over dopaminergic activity may therefore be one source of individual variation in susceptibility to addiction.

Title: Neuronal correlates of choosing and stopping in macaque frontal eye field

Authors: *P. MIDDLEBROOKS, J. D. SCHALL;
Psychology, Vanderbilt Univ., Nashville, TN

Abstracts: Perceptual choice and response inhibition have each been a major focus of decision-making research for decades. To date no studies examined the relationship between them at the single neuron level. Neuronal correlates of response inhibition have been described in saccadic

stop or step tasks. Whereas visual neurons simply register current location of target, pre-saccadic movement neurons in the frontal eye field (FEF) and superior colliculus have different firing rate dynamics for no-stop, noncanceled stop, and canceled stop trials. During no-stop and noncanceled stop trials, firing rate increases to a constant threshold and a saccade is triggered. During canceled stop trials, firing rates increase but are modulated before reaching threshold. Critically, the modulation occurs before a point of no return, the stop signal reaction time (SSRT), indicating the neurons control whether a saccade is withheld. Neuronal correlates of perceptual choice have been described in saccadic choice response time (RT) tasks. Neuron activity in multiple brain areas such as LIP and FEF increase quickly (slowly) during easy (difficult) trials, followed by short (long) reaction times (RTs) We explored FEF neuron activity of monkeys performing a saccadic choice RT stop-signal task (Middlebrooks & Schall 2014 Atten, Percept & Psychophys). The choice stimulus was a cyan-magenta checkerboard. Saccade choice was specified by the fraction of cyan or magenta in the checkerboard, varied around discrimination threshold. On 25-40% of trials a visual stop signal replaced the central fixation spot after a variable stop-signal delay. On no-stop signal trials reinforcement was earned for a correct choice. On stop signal trials reinforcement was earned for inhibiting the saccade. We recorded FEF visual, visual-movement, and movement neurons. We observed a variety of task-related modulations, including the following. Visual neuron activity selected the eventual target but did not rise to a threshold immediately before a saccade during no-stop and noncanceled stop trials. During canceled stop trials visual neuron activity did not modulate before SSRT and thus could not play a role in withholding a response. Movement neuron activity rose to a threshold before a saccade during no-stop and noncaneled stop trials. The rate of rise varied with choice difficulty. During canceled stop trials movement neurons modulated before SSRT and thus could contribute to withholding a response. These behavioral and neural results, in conjunction with ongoing stochastic accumulator modeling, provide the opportunity to unify two major frameworks of decision-making, perceptual choice and response inhibition.

Title: The effect of stop signal perceptual manipulations on upper limb suppression process

Authors: *P. PANI, R. MONTANARI, F. FABBRINI, F. GIARROCCO, V. MIONE, E. BRUNAMONTI, S. FERRAINA;
Dept. Physiol. Pharmacol., Sapienza Rome Univ., Rome, Italy

Abstracts: Primates may have occasionally to inhibit an impending action because of sudden changes in the environment. This ability has been studied by using the countermanding task, that permits to evaluate how long it takes to stop an impending movement in response to a stop signal(Stop signal reaction time, SSRT). To a first approximation SSRT can be considered composed by two different processing stages: a perceptual stage, in which the stop signal is perceived and a late inhibitory stage. An open question is how the information between these stages is transmitted: discretely, thus requiring that the previous stage is completed before the late stage starts; or continuously, so that some information can be transmitted to the late stage before the completion of the perceptual one.. To gain insight on this topic we first analyzed the behavior of a rhesus monkey that performed a delayed reach version of the countermanding task. Each trial started with the presentation of a central circular target (CT)and two small dots above it. The monkey had to hold the CT and after 0.4-0.8s a peripheral target (PT) appeared either to the left or to the right. Then, after a delay(0.8-1.2 s) the right small dot (RSD) above the CT changed color (from red to green, Go signal) and the monkey had to reach and touch the PT (no-stop trials). Unpredictably, in 34% of the trials (stop trials), after a variable time from the Go signal RSD changed color again thus instructing the monkey to refrain (stop signal). The stop signal color was selected from a sample of 5 different colors between blue and green, making the stop signal progressively similar to the go signal and more difficult to be perceived. In fact at the behavioral level the color of the stop signals strongly affected the ability to inhibit the response. The closer color of the stop signal to the green, the longer the SSRT and the more disrupted the ability to stop (SSRT:196, 284 ,301, and disrupted performance for the last two). While the monkey performed the task we recorded the neural activity from a 96 electrodes chronic array. A preliminary investigation shows that the lengthening of the SSRT is associated with different changes in activity: while some neurons show a change in the onset of the activity after different stop signals, others show a change in the rate of rise or decrease of activity. These data suggests that in the premotor area, probably both continuous and discrete mechanism of information transmission are at play during motor control.

Title: A model of perceptual discrimination under sequential sensory evidence

Authors: *E. HUGUES[1], C. STEIN NAVES DE BRITO[2], W. GERSTNER[2], R. ROMO[3], G. DECO[1,4];
[1]Univ. Pompeu Fabra, Barcelona, Spain; [2]Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland; [3]Univ. Nacional Autónoma de México, Mexico, Mexico; [4]Institució Catalana de Recerca i Estudis Avançats, Barcelona, Spain

Abstracts: Perceptual discrimination may be interpreted as a decision between alternatives based on available sensory evidence. In many experiments, the different alternatives are presented simultaneously and encoded by quite distinct neuronal groups. In this case, proposed biophysical neural models consider that the decision results from the competition between decision-specific neuronal groups, each of these integrating distinct sensory evidence. Alternatively, evidence may be presented in a sequential manner, and the different stimuli may be encoded by the same neuronal group, as exemplified by experiments where monkeys are engaged in a vibrotactile discrimination task [1]. To achieve discrimination in this case, the nervous system needs to keep a trace of the previously presented stimuli. How the nervous system manages to achieve a good performance in such perceptual discrimination tasks is not understood. To address these questions, we propose a biophysical model inspired from electrophysiological data obtained in a vibrotactile discrimination task [1]. In this task, a monkey is presented two vibrotactile stimuli (with frequencies f1 and f2), separated by a delay period: the animal is instructed to decide whether f1 > f2 or f1 < f2. The diversity of partial differential (PD) neurons which encode both stimuli by keeping the memory of the first one during the delay period is shown to be reproduced by a spiking neuron network model with short-term facilitating synapses. To achieve the decision, we consider a decision making (DM) spiking neuron network, whose input is given by the heterogeneous population of PD neurons. To learn how to decide from this input, the strengths of the projecting synapses are learned using a reinforcement learning based rule applied after the decision. The task is found to be efficiently learned across trials, reproducing the experimental results. In this respect, the PD neurons heterogeneity is crucial to provide the necessary information to the DM network. More generally, we have shown that our proposed biophysical two-networks model, including both working memory and decision-making capabilities, provides a way by which a perceptual discrimination task under

sequential sensory evidence could be achieved by the nervous system. 1. Hernández et al. 2010, Neuron 66:300-314.

Title: Micro-stimulation of premotor and motor cortex delays the commitment to an action choice

Authors: ***D. THURA**, P. CISEK;
Dept Neurosci., Univ. Montreal, Montreal, QC, Canada

Abstracts: Are decisions about actions determined in cognitive or motor regions? We have recently shown that when monkeys perform a task in which relevant sensory information for action selection varies over time and they are free to respond at any moment, neurons in dorsal premotor (PMd) and primary motor cortex (M1) appear to be involved in the processes of deliberation and commitment (Thura and Cisek, 2014). In particular, during deliberation many PMd and M1 neurons reflect the evolution of the sensory information along with a signal related to the growing urgency to respond. Furthermore, approximately 280ms prior to movement onset, the activity of these cells reveals the resolution of a competition between the choices, implicating them in the process of volitional commitment. Here, to test whether these cells are causally

involved in commitment, we perturb their activity using brief pulses of subthreshold micro-stimulation. One monkey performed a reaching decision task in which sensory evidence continuously evolves during the time course of a trial. In different blocks, the temporal properties of the task were varied to induce adjustments of monkey's speed-accuracy trade-off. On about 2/3 of trials, we stimulated sites in either PMd or M1 where we had recorded task-related neurons. Stimulation (57ms train of 0.2ms pulses at 330Hz with amplitude ranging from 20-70μA) was applied at different times during the deliberation process: either at trial onset, 800ms or 1400ms later. We found a time-dependant effect of stimulation in both PMd and M1 on the monkey's reactions times (RTs). When applied at trial onset, stimulation had almost no effect. However, when applied later, stimulation caused a significant increase of RTs depending on trial difficulty. A comparison between conditions where the monkey either favored decision speed or accuracy suggests that stimulation was more effective when the monkey was close to commitment. This effect was also most pronounced when stimulation preceded movement onset by about 300ms, suggesting that stimulation interfered with the normal process of volitional commitment, and not the process of movement initiation. In contrast, during a task in which movement initiation was externally instructed, we found that stimulation of PMd, but not M1, significantly shortened RTs. Together, our results suggest that PMd and M1 neurons are causally involved in the volitional commitment to an action choice. Thura D, Cisek P. Title: Supplementary eye field activity during and after self-selection of abstract rules

Authors: *Z. M. ABZUG, M. A. SOMMER;
Duke Univ., Durham, NC

Abstracts: Selection and implementation of abstract rules is a crucial part of human cognition. Previous work has shown that neurons in the frontal cortex of monkeys (Macaca mulatta), including Supplementary Eye Field (SEF), encode instructed rules through firing rate modulations (White & Wise, 1999). However, there is a dearth of work addressing whether or not neurons in frontal cortex encode self-selected rules, or if they differentiate between self-selected and instructed rules (i.e. agency selectivity). We previously designed and validated an oculomotor task, compatible with neurophysiological recordings in monkeys, constructed to answer this question and showed that one monkey was able to perform the task appropriately (Abzug & Sommer, SfN 2013). In the first stage of this two-stage task, the monkey was required to saccade to one of two colored peripheral targets. The color of each target was associated with a particular rule, and the targets could be either different colors (allowing the monkey to select between different rules) or the same color (forcing the monkey to select an instructed rule). After refixating a central location, the monkey then had to correctly apply the selected or instructed rule in a perceptual discrimination between two visual targets in order to receive liquid reward. Many neurons in SEF show complex and variable activity throughout the duration of this task. Consistent with previous reports, a subset of neurons distinguish between the two rules in various time epochs during the task. We have also found a sub-population of agency-selective cells that distinguish between self-selected and instructed trials. These cells may help fill an important metacognitive role by distinguishing between rules inherited through cognitive decision-making and rules inherited through simple sensory cueing.

Title: Dopaminergic and opioidergic neuronal mechanisms in decision making under risk in rats: Studies using a novel operant task

Authors: V. OINIO[1,2], P. BÄCKSTRÖM[1], J. UHARI-VÄÄNÄNEN[1,2], A. RAASMAJA[2], *T. PIEPPONEN[2], K. KIIANMAA[1];

Abstracts: We present a novel method for studies on the role of different central neuronal processes of decision making in a gambling situation in rats. Based on existing decision making models, our model employs probabilistic discounting in a long run protocol, i.e. devaluing a reinforcer by decreasing the probability of obtaining it in a between-sessions manner. The model can be used to investigate how decision making under risk can be modulated with different pharmacological treatments. The aim of the present study was to investigate the role of dopaminergic and opioidergic neuronal mechanisms in decision making in rats. Male alcohol preferring AA (Alko Alcohol) rats where trained to self-administer sucrose pellets (45 mg) in an operant chamber. Depending on the lever they chose, the rats could obtain one or three sucrose pellets in a 15-minute two-lever choice task. The probability for obtaining three pellets was decreased over time (100%, 50%, 33%, 25%, and 20%, "large, risky reward"), whereas the probability for obtaining one pellet was kept constant at 100% ("small, certain reward"). Thus, in this model the probability at which the levers were equally advantageous was 33%. At higher probabilities the rational choice to obtain a maximum amount of pellets would have been the 3-pellet lever and at lower probabilities the one-pellet lever. Once the choice of lever at a designated probability level had stabilized, rats were administered d-amphetamine (0.1, 0.3, 1.0 mg/kg s.c.), morphine (0.3, 1.0, 3.0 mg/kg s.c.) or their vehicle. D-amphetamine induced some irrationality in lever choice when the probability was set at the level of 100% and 50%, but it had no effect at the level of 33%. When the probability was set at 25% and 20%, d-amphetamine significantly increased risky and irrational choice in a dose-dependent manner. Morphine had, however, no effect on choice of lever. The results suggest that increased dopaminergic activity impairs rats ability to make rational choices especially under risk, and that reward-related opioidergic processes are not involved in this process. They also support a role for dopaminergic mechanisms in decision making under risk, and show the feasibility of our model in studies on decision making under risk.

Title: The impact of prior expectations in an auditory discrimination task

Authors: A. HERMOSO-MENDIZABAL[1], P. E. RUEDA-OROZCO[2], S. JARAMILLO[3], D. ROBBE[2], *J. DE LA ROCHA[1];

Abstracts: Previous experience plays a critical role in how subjects acquire and interpret sensory information. Expected stimuli for instance produce faster responses and can be discriminated with greater accuracy. Little is known however about how the brain circuitry accumulates experience over different time scales to build expectations that combined with sensory information give rise to perception. In order to identify the neural basis of expectation and its impact on perceptual decisions we designed a variant of a standard two alternative forced-choice (2AFC) task that required the generation of an unbalanced prior that had to be updated trial-by-trial in order to maximize performance. Acoustic stimuli consisting in the superposition of two amplitude modulated tones of high and low frequency (31 kHz and 6.5 kHz) were presented to rats that were trained to associate each frequency to the delivery of water in the Right and Left ports. Stimuli were parameterized by the coherence c that set the relative weight of each tone: c = +1 or -1 represented the high and low tones in isolation, respectively, and c =0 a balanced superposition of the two. The two stimulus categories, i.e. sign(c) = ±1, were presented randomly using a two-state Markov chain. Transitions were parameterized such that the probability of repeating the previous stimulus category was 0.5+λ and the probability to switch was 0.5-λ. The absolute value of the coherence was picked among the values 0, 0.1, 0.4 and 1, randomly and independently of previous history. We presented blocks of ~100 trials with fixed λ=0.2 and -0.2. We termed these blocks the repetitive and switching environments, respectively, and cued them to the animals using different lighting. We found that animals learned the statistics of each environment and made use of them to increase reward rate. Specifically, after error trials animals did not show a choice bias that depended on recent trial history. After a correct trial however, the

behavior showed a bias towards the same or the opposite choice depending on whether they were in the repetitive or in the switching environments. Moreover, the magnitude of this bias increased with the number of correct past responses following the environment's sequence pattern (e.g. in the switching environment, the probability of choosing Right conditioned of trial history grew as P(R|Error) < P(R|L, Error)< P(R|L,R, Error) < P(R|L,R,L,Error) <⋯). The magnitude of the biases were greater in the repeating than in the switching environment. These results demonstrate that perceptual decisions are influenced by the statistics of the sensory environment.

Title: A computational model of cognitive control for context effects on multi-attribute decisions

Authors: ***K. JUNG**[1], J. JEONG[2], J. D. KRALIK[1];
[1]Psychological and Brain Sci., Dartmouth Col., Hanover, NH; [2]Bio and Brain Engin., KAIST, Daejeon, Korea, Republic of

Abstracts: Real-life decisions are often made among multiple alternatives with multiple attributes such as reward value, effort, and visual saliency. Daily life also entails multiple sequential decisions, leading to choice burstiness: i.e., bursts of long consecutive series of identical choices interspersed with multiple switches among choice options. This burstiness can be characterized by two key features of sequential choices: preference bias, defined as the skew of the distribution of choices among alternatives; and choice persistence, defined as the tendency to repeat a choice previously made. Although context effects in decision-making have been extensively studied, the underlying computational process of how cognitive control for context effects dynamically modulates preference bias and choice persistence in multi-attribute decisions is not fully understood. Here we propose a computational model of this cognitive control. Taking into account selective attention and motivation for preference bias and choice persistence, respectively, our model can capture the dynamic choice patterns of rhesus monkeys under different choice contexts. Our modeling results suggest that context effects based on attention and motivation distinctly influence preference bias and persistence, respectively, and provide

insight into the computational and neural mechanisms of context effects on sequential choice dynamics of long-term multi-attribute decisions.

Mannheim, Heidelberg Univ., Mannheim, Germany; [3]Dept. of Psychology, Goethe Univ., Frankfurt am Main, Germany; [4]Dept. of Pharmacol. and Biomolecular Sciences, Univ. of Milan, Milan, Italy

Abstracts: The abilities to either flexibly adjust behavior according to changing demands (cognitive flexibility) or to maintain it in the face of potential distractors (cognitive stability) are critical for adaptive behavior in many situations. Recently, a novel human paradigm has found individual differences of cognitive flexibility and stability to be related to common prefrontal networks. The aims of the present study were, first, to translate this paradigm from humans to mice and, second, to test conceptual predictions of a computational model of prefrontal working memory mechanisms, the *Dual State Theory*, which assumes an antagonistic relation between cognitive flexibility and stability. Mice were trained in a touchscreen-paradigm to discriminate visual cues. The task involved “ongoing” and cued “switch” trials. In addition distractor cues were interspersed to test the ability to resist distraction, and an ambiguous condition assessed the

spontaneous switching between two possible responses without explicit cues. While response times did not differ substantially between conditions, error rates (ER) increased from the "ongoing" baseline condition to the most complex condition, where subjects were required to switch between two responses in the presence of a distracting cue. Importantly, subjects switching more often spontaneously were found to be more distractible by task irrelevant cues, but also more flexible *in situ*ations, where switching was required. These results support a dichotomy of cognitive flexibility and stability as predicted by the *Dual State Theory*. Furthermore, they replicate critical aspects of the human paradigm, which indicates the translational potential of the testing procedure and supports the use of touchscreen procedures in preclinical animal research.

Title: Rats' preferences for differently priced liquid reinforcers are modulated by budget constraints in a two alternative forced choice decision making task

Authors: *M. VAN WINGERDEN, C. MARX, T. KALENSCHER;
Inst. for Exptl. Psychology, Heinrich-Heine Univ. Düsseldorf, Düsseldorf, Germany

Abstracts: Classic analysis of consumer demand investigates the changes in purchases of a commodity as a function of its price. When using animal consumers, price is typically operationalized as a work required, such as a fixed-ratio (FR) schedule to obtain a reinforcer. If two alternative commodities are concurrently available, the elasticity and cross-elasticity of demand for both choice options can be calculated, using a set of different price ratio regimes. Changing prices affects the animals' choice distribution between the alternatives even when budgets are adjusted to allow reselection of the previously chosen bundle. Animals have been shown to exhibit budget sensitivity in their demand elasticity, however it remains unclear if the changes in budgets are reflected in the animals' dynamic preferences for both commodities, or whether the number of choices available under normal versus compensated budgets can account

for the differences in demand elasticity. If the latter is true, then an analysis of choice frequency using the Matching Law framework should not differentiate between normal and compensated budget conditions, as work requirements and reinforcer quantity remain stable between these conditions. We trained 8 male Long-Evans rats to make choices between chocolate and vanilla flavored soymilk by making nosepokes to spend their daily budget. The concurrent FR-schedules were set at 4:4 during baseline, and each rat went through four additional conditions: uncompensated price shifts to 5:3 and 3:5, and similar price shifts with budget compensation (5:3C and 3:5C). We found relatively inelastic demand ($0 > e > -1$) for the preferred commodity (chocolate soymilk) that was significantly less elastic than demand for vanilla. Demand for chocolate was less elastic under compensated the under uncompensated budgets. When we compared time-resolved preference estimates between compensated and uncompensated conditions, using equal-length sets of trials, we found significantly higher preferences for chocolate in the 5:3C condition. Importantly, this difference emerged before the budget would have run out, confirming that rats' preferences are dynamically sensitive to budget conditions. Accordingly, the behavioral data could only be fit in an extended Matching Law framework when allowing for an effect of budget condition on the sensitivity parameter. This parameter, which indexes under- or overmatching to non-unitary FR ratios was found to be significantly lower under compensated versus uncompensated budget conditions, confirming that compensating budgets reduces sensitivity to price changes in line with the observed reduced elasticity of demand.

Title: Exploration and uncertainty in the frontal eye field during value-guided choice

Authors: *B. A. EBITZ[1], E. ALBARRAN[2], A. SOLTANI[3], T. MOORE[2];
[1]Stanford Univ., San Mateo, CA; [2]Stanford Univ., Stanford, CA; [3]Dartmouth Col., Hanover, NH

Abstracts: Reward value can have profound effects on gaze, perhaps via its well-established modulation of neural activity throughout the oculomotor system. However, it remains unclear whether other factors critical for decision-making also affect gaze-related signals in the brain. In particular, the effects of exploratory states on saccadic target selection have yet to be elucidated. Moreover, although exploration is thought to increase information seeking via modulating attention, it is unclear if this state affects activity in neural structures that regulate attentional selection. In order to address this question, we recorded from neurons in the frontal eye field (FEF) of rhesus macaques while they performed a saccadic two-armed bandit task. The FEF is involved in both target selection and visual attention, and contain well-characterized classes of neurons differentially implicated in these two processes. The FEF is therefore an ideal structure in which to study the effects of exploratory states on visual selection. In the bandit task, the monkeys made decisions between saccades towards probabilistically rewarded targets. On each trial, the monkeys were presented with two targets. The monkeys made a saccade to one of the targets, at which point they were either rewarded or not, depending on the reward probability parameter of the selected target. The reward probabilities of the targets walked randomly and independently over time. In order to maximize reward intake, the monkey had to infer the current reward values via integrating reward information over past outcomes. The monkeys tracked reward history over multiple trials, outperforming simulated operators that used various alternative heuristic strategies. Therefore, we fit a model to the monkeys' choice behavior to infer the monkeys' subjective trial-by-trial estimate of the targets' underlying reward values. This model allowed us to quantify both the subjective reward value and the subjective uncertainty of each target while the monkeys made saccades. The monkeys' decisions were informed by the difference in subjective reward probability between the targets, but also by other factors not directly related to the probability of reward on the current trial, including value uncertainty. In addition, FEF responses were also dependent on value information beyond the immediate likelihood of receiving a reward for a given choice. In particular, FEF activity differentiated between exploitative or exploratory saccades to the same target. These preliminary results suggest that information-seeking saccades are represented uniquely in at least one structure implicated in attention and gaze control.

Title: Reciprocal cooperation in rats playing iterated Prisoner's Dilemma

Authors: *R. I. WOOD[1], J. Y. KIM[2], G. R. LI[2];
[2]Cell & Neurobio., [1]Keck Sch. Med. USC, Los Angeles, CA

Abstracts: Humans and animals show cooperative behavior, but our understanding of the neurobiology of cooperation among unrelated individuals is limited. The classic laboratory model to test cooperation in humans is the Prisoner's Dilemma game, where two players receive varying payoffs for cooperation or defection. We tested rats with Prisoner's Dilemma using operant responses for food reward. An operant chamber was bisected by a metal screen, with a retractable lever and pellet dispenser on each side. Cage-mates were tested as pairs in 25 trials/day over 4 days. When the levers extended, each rat had 2 seconds to respond. Mutual cooperation (Reward) delivered 3 pellets to each rat, mutual defection (Punishment) provided no pellets, and unilateral defection (Temptation) gave 5 pellets while the cooperative partner (Sucker) received none. In 8 pairs of rats, cooperation was defined by withholding a response (Reward-). In 7 pairs, cooperation was defined by responding on the lever (Reward+). Rats in the Reward- and Reward+ groups received an average of 57.3±3.4 pellets/day, 54.0±3.8% from Reward trials and 46.0±3.8% from Temptation. Individual rats cooperated on 62.0±3.6% of all trials, resulting in 40.4±3.3% Reward trials, 43.1±1.6% Temptation/Sucker, and 16.5±3.0% Punishment. However, rats did not use either tit-for-tat or Pavlov response strategies. In each pair, the dominant rat made more responses (15.5±1.5 per day) than the subordinate (12.2±1.4 responses, $p<0.05$). Dominant rats earned more pellets than subordinates in Reward- pairs (62.7±5.3 vs 43.2±7.0), but received fewer pellets in Reward+ pairs (55.8±5.1 vs 68.6±6.8). In the same bisected chamber, we subsequently tested pairs of rats for reciprocity in 24 alternating trials/day. A response on the lever within 10 seconds delivered 3 pellets to the partner. Reciprocity was correlated in pairs of rats when tested either with cage-mates ($R2=0.67$) or in unfamiliar pairs ($R2=0.73$). However, rats made more responses for their cage-mate (6.3±0.4 responses/12 trials) than for an unfamiliar partner (5.3±0.4). When no partner was present, responses declined significantly to 3.8±0.4 per 12 trials after 5 days, but increased to 6.2±0.7 responses/12 trials on the first day when paired with an unfamiliar partner who never reciprocated (bad stooge). These results demonstrate that rats working for food reward show both reciprocity and reciprocal cooperation in an iterative Prisoner's Dilemma game. Their responses

depend on familiarity with their partner and dominance status. This can be a useful model to explore the neurobiology of cooperative behavior.

Title: Environmental rearing effects on impulsivity, reward sensitivity, and behavioral flexibility

Authors: ***Z. WANG**[1], A. T. MARSHALL[2], K. KIRKPATRICK[2];
[2]Psychological Sci., [1]Kansas State Univ., Manhattan, KS

Abstracts: The goal of the current study was to test the effect of the early-life rearing environment, especially novel object and/or social enrichment, on impulsive choice behavior, behavioral flexibility, action inhibition, and reward sensitivity in rats. Four rearing conditions were implemented (n = 6): isolated, isolated with novel objects, socially paired, and socially paired with novel objects. Subsequently, an impulsive choice task was delivered, in which the rats were given a choice between a 10-s smaller-sooner (SS) versus a 30-s larger-later (LL) reward. The SS reward was one pellet throughout the task, whereas the LL reward was one, two or three pellet(s) manipulated across three phases. All rats were then tested on a set-switching task to assess behavioral flexibility. Afterwards, a differential reinforcement of low rate (DRL) 30-s procedure was delivered to measure the rats' ability to inhibit action. Finally, the rats experienced a reward sensitivity task in which they were given a choice between a smaller lever with one pellet reward on a VI-30 schedule and a simultaneously presented larger lever with one, two, or three pellet(s) changing across three phases on a concurrent VI-30 schedule. A buffer task was implemented between the tasks mentioned to minimize carry-over effects. The rats were sensitive to changes in the LL magnitude of reward, and rats from different rearing conditions showed differential acquisition efficiency in the behavioral flexibility task. These results suggest that novelty and social enrichment may affect impulsivity, reward sensitivity, and the flexibility in rule-governed learning.

Title: The role of timing processes in three different impulsive choice procedures

Authors: ***J. R. PETERSON**, C. HILL, K. KIRKPATRICK;
Dept. of Psychological Sci., Kansas State Univ., Manhattan, KS

Abstracts: Measures of impulsive behavior are often used interchangeably in studies examining choice behavior. Moreover, individual differences are generally overlooked or eliminated by considering only group means and effects. This study compared three paradigms commonly used to assess the effect of delay manipulations in impulsive choice behavior and to determine the validity and reliability of each measure. Measures of both timing and choice behavior were collected for each procedure. Delay tolerance, or the ability to wait longer for a larger reward, is indicative of self control and lower impulsivity. Individual differences in timing measures within the choice paradigms and a progressive interval task were examined. Forty-eight male Sprague-Dawley rats were randomly assigned to one of three groups (n =16). The SS outcome was always a 5-s delay for 1 pellet and the LL was always 2 pellets but the delay was altered. In the first systematic procedure (Green & Estle, 2003) the LL delay incremented across phases, whereas in the second systematic procedure (Evenden & Ryan, 1996) the LL delays incremented within each session: 5, 15, 30, 60 s. In the adjusting procedure (Mazur, 1987), the LL delay increased or decreased by 1 s as a function of the rats' most recent choice. After 20 sessions, the rats were tested on one of the other two choice procedures and then were re-tested on the second procedure and finally retested on the original procedure for complete counter balancing. Next, a progressive interval schedule was used for all rats to assess delay tolerance and its potential relationship with timing and choice behavior. These data suggest that, while different procedures may yield somewhat different measures of impulsive choice and timing, individual differences are relatively stable across procedures.

Title: A computational analysis of the influence of elapsed time on reward-modulated perceptual decisions

Authors: *Y. FAN[1], J. I. GOLD[2], L. DING[2];
[1]Neurosci. Grad. Group, Univ. of Pennsylvania, [2]Dept. of Neuroscience, Univ. of Pennsylvania, Univ. of Pennsylvania, Philadelphia, PA

Abstracts: Perceptual decisions can be influenced by many non-sensory factors, including stimulus prior probabilities and expected reward outcomes. In a drift-diffusion model (DDM) of perceptual decision making, sensory evidence is accumulated over time into a decision variable (DV). When the DV reaches a threshold, a decision corresponding to that threshold is made. Under certain conditions, decisions biased by unequal prior probabilities or reward expectations can be well accounted for by adding a static bias term to the DV. Recently, however, Hanks and colleagues (2011) found that decision biases that result from unequal prior probabilities may be better accounted for using a dynamic bias that increases over time. According to this idea, elapsed time helps to calibrate the relative influence of sensory and non-sensory factors: the more time that has elapsed before reaching a decision threshold implies weaker sensory evidence and thus an increasing reliance on the priors. In this study, we tested whether a dynamic-bias DDM also performs better than a static-bias DDM for unequal reward-biased decisions. We trained a monkey to discriminate the net motion direction of a field of randomly moving dots. Motion strength was determined by the percentage of the dots moving in the same direction. The monkey indicated its choice by making a saccade to the corresponding choice target at a self-controlled time. Correct choices were rewarded with juice. In some blocks of trials, leftward correct choices were rewarded with more juice than rightward correct choices. In alternate blocks, the reward contingency was reversed. The monkey's performance was influenced by both motion strength and reward magnitude. We constructed two DDM-based bias models, with static and dynamic reward biases, respectively, and fitted them to choice and reaction-time data using maximum likelihood methods. As a control, we also constructed a DDM-based momentary-evidence model, in which reward asymmetry modulates moment-to-moment evidence. Our preliminary fitting results (n=50 sessions of data from one monkey) show that

both bias models are superior to the momentary-evidence model, but do not reveal consistent differences in the goodness of fits between the two bias models. We thus did not find evidence of a dynamic bias that increases with elapsed time in this unequal reward-biased perceptual decision. It remains to be tested whether this negative finding extends to other individual subjects and whether the discrepancy reflects differences in neural implementation of prior probability and reward expectation information. Title: The role of different dopaminergic populations in *Drosophila* choice behavior

Authors: C. ROHRSEN, *B. BREMBS;
Inst. of Zoology - Neurogenetics, Univ. Regensburg, Regensburg, Germany

Abstracts: Dopamine (DA) appears to be an important neurotransmitter involved in assigning value in vertebrates and invertebrates. In *Drosophila*, DA neurons are known to play an essential role in associative learning. The valence of learning depends on the DA cluster involved: whereas the protocerebral anterior medial cluster (PAM) mediates appetitive learning, the protocerebral posterior lateral cluster 1 (PPL1) mediates aversive learning. Studies in the fruit fly have focused in these two clusters because they are the DA clusters projecting to the mushroom body, an essential brain structure for olfactory classical conditioning. Assuming that neurons mediating appetitive and aversive valence in conditioning experiments ought to influence choice behavior also directly, we decided to identify DA neurons, projecting and non-projecting to the mushroom bodies, which are directly involved in choice behavior. For assessing the role of different DA clusters in mediating valence we took advantage of flies expressing Channelrhodopsin (ChR) under different DA promoters. These flies were tested in a T-maze so that if an individual fly approached one arm illuminated by the ChR excitable-wavelength, a given cluster is activated whereas when approaching the other arm with non-excitable light, no neurons are activated. In contrast to our expectations, we found that the flies preferred activity in most, but not all of the different DAergic subpopulations we were able to test. Interestingly, the

pattern of preference we obtained did not correlate very well with the pattern of preference obtained using classical conditioning protocols. We hypothesize that the DA neurons function rather differently when modulating actively ongoing behavior as opposed to when the animals are passively perceiving stimuli in a classical conditioning experiment.

Title: Behavioral flexibility in *Drosophila* phototaxis

Authors: *E. A. GOROSTIZA, B. BREMBS;
Inst. of Zoology, Univ. Regensburg, Regensburg, Germany

Abstracts: Animals exhibit innate preferences for different stimulus modalities and intensities, which likely reflect evolutionary responses to specific ecological needs. Insects such as *Drosophila* move towards a light source when startled. Given the robustness of this response, positive phototaxis has been categorized as an example of hard-wired input-output behaviors. However, classic experiments performed by McEwen in 1918 and Benzer in 1967 demonstrated that wing defects, caused by mutation or damage, profoundly affect phototaxis preferences in walking *Drosophila* [1,2]. The fact that manipulating an unrelated organ (wings), affects positive phototaxis stands against the hard-wired conception of this behavior, showing that it contains a certain element of flexibility. We hypothesize that phototaxis is not just an automated response, but that there may be a central decision-making stage influenced by a number of environmental and physiological variables, such as flying ability, that are continually monitored. To test our hypothesis we evaluated flies in two different phototactic paradigms (Benzer Countercurrent Apparatus and T-Maze) after altering their flying ability using a range of mechanical and genetic manipulations. Here we show that flies unable to fly exhibit a negative phototactic behavior. This reversal is not learned, as neither learning mutants nor transgenic flies deficient in various learning paradigms show any deficit, and the effect is immediate. The effect is neither due to injury, as injuries not affecting flight ability do not affect phototaxis. Genetic manipulations

preventing the flies from flying but leaving wing-morphology intact also affect phototaxis. Finally, if flying ability is temporarily compromised and then restored, the phototactic behavior changes concomitantly, demonstrating the reversibility of the phototactic effect. These results reveal the flexibility of this taxis, and the existence of an evaluation step prior to behavioral performance. 1. McEwen, R. S. Title: Dopaminergic and serotonergic modulation of anterior insular and orbitofrontal cortex in risky decision making

Authors: *H. ISHII[1], S. OHARA[1], Y. KAIZU[1], P. N. TOBLER[2], K.-I. TSUTSUI[1], T. IIJIMA[1]; [1]Div. of Sys. Neurosci., Tohoku Univ., Miyagi-Ken Sendai-Si, Japan; [2]Dept. of Econ., Univ. of Zurich, Zurich, Switzerland

Abstracts: To obtain desired outcomes we sometimes need to take risks although excessive risk taking also can lead to ruin. However, dysfunction of two neuromodulators, dopamine and serotonin can cause abnormal risky decision making (Cools et al, 2011; Takahashi, 2012; Rogers, 2011). Previous animal model studies using systemic manipulations of dopamine and serotonin have shown that these neuromodulators are involved in risky decision making. Amphetamine increases risk preference of rats, an effect that is blocked by co-administration of either D1 or D2 receptor antagonists (St Onge and Floresco, 2009). Transgenic mice lacking GABAA receptors in dopamine neurons show higher risk preference than controls (Parker et al, 2011). Moreover, serotonin-depleted monkeys and rats show higher risk preference (Long et al,

2009; Koot et al, 2012). However, how dopamine and serotonin work in their target regions remains unclear. The present study investigated the role of dopamine and serotonin in the rat anterior insular cortex (AIC) and orbitofrontal cortex (OFC), which make different contributions to risky decision making (Ishii et al, 2012). We examined the effects of local injection of either the D1 (SCH23390), D2 (eticlopride), 5-HT1A (WAY100635) or 5-HT2A (M100907) receptor antagonists into the AIC or OFC on risk preference in a gambling task. The gambling task required the rats to choose between a risky option (4 drops or no water, 50-50 chance, random order) and a sure option (2 drops). Intra-AIC injection of the D2R and 5-HT1AR blockers increased risk preference, whereas intra-OFC injection of the 5-HT1AR blocker decreased risk preference. Risk preference was not altered by intra-AIC injection of D1R and 5-HT2AR blockers or by intra-OFC injection of D1R, D2R, and 5-HT2AR blockers. Furthermore, intra-AIC injection of the D2R blocker increased risk preference particularly after winning in a previous risky choice, whereas intra-AIC injection of the 5-HT1AR blocker increased risk preference after losing. These results suggest that different dopamine and serotonin receptor subtypes in the AIC and OFC play different and experience-dependent roles in risky decision making.

Title: Reduced temporal discounting by methylphenidate in non-human primates

Authors: A. Z. RAJALA[1], R. L. JENISON[2], *L. C. POPULIN[3];
[1]Neurosci. Training Program, [2]Dept. of Psychology, [3]Dept of Neurosci., Univ. Wisconsin, MADISON, WI

Abstracts: When given a choice, humans and animals prefer a smaller reward immediately over a larger reward that is delayed in time, a phenomenon known as temporal discounting. Impulsivity, the tendency to act without forethought, is associated with impaired dopamine (DA) transmission and excessive discounting of larger delayed rewards, which has been documented in patients with attention deficit hyperactivity disorder combined type (ADHD-C). Delayed reward value is encoded in the discharges of DA neurons and DA neurotransmission is crucial for reward processing. Methylphenidate (MPH), which blocks the DA transporter and increases extracellular DA in the basal ganglia and prefrontal cortex, is a primary treatment for ADHD and, at low doses, ameliorates impulsivity in both humans and animals. We tested the hypothesis that low doses of MPH will reduce temporal discounting in both impulsive and calm subjects, shifting preference towards larger delayed rewards. Two male rhesus monkeys, one impulsive and one calm, were tested in a reward preference task that required them to choose between a smaller reward right away (SS) or a larger reward after a delay (LL). The task required fixating a red dot straight ahead, after which two images appear to the right and left of the fixation representing the SS and LL. When the fixation dot was turned off, the subject made an eye movement towards one of the images indicating his choice. Eight fractal images represented each of the 4 SS and LL conditions. The SS delay was constant at 0 sec with 4 reward magnitudes (0.2, 0.3, 0.4, and 0.5 mL) while the LL reward magnitude was constant at 0.59 mL with 4 delay times (2, 4, 8, and 16 sec). A set of 16 blocks of 14 trials each contained all possible combinations of SS and LL and were presented in either ascending or descending order. The inter-trial time was adjusted to have constant trial length within each block. Methylphenidate was administered orally, dissolved in 0.5 mL juice 45 min prior to testing; juice alone was delivered on control days. Both monkeys exhibited hyperbolic temporal discounting estimated from a single logit probability choice model. The impulsive subject had steeper discounting and chose the SS significantly more often compared to the calm. Low doses of MPH shifted the choices of both subjects toward the LL and reduced discounting of LL reward value. Furthermore, MPH increased the randomness of choice significantly in a dose dependent manner, and decreased overall reaction time (RT) for both monkeys. The RT function has an inverted U-shape, which differentially shifts under MPH. These results suggest that MPH could improve impulsive behavior by altering the computation of reward value.

Title: Genetic influences on delay discounting

Authors: *L. MILITELLO[1], J. B. RICHARDS[1], A. A. PALMER[2];
[1]Res. Inst. On Addictions, State Univ., Buffalo, NY; [2]Dept. of Human Genet., Univ. of Chicago, Chicago, IL

Abstracts: Delay discounting (DD) was tested using a sequential choice procedure that simulates contingencies of reinforcement similar to those that animals encounter while foraging for important resources in patchy environments. Rats chose between an immediate but small amount of water by staying in a rapidly depleting patch and a larger amount of water that required the animal to invest the time needed to change to a new full patch. Longer delays to a new patch make staying in the old depleting patch a better choice, while shorter delays to new patches make staying in the old depleting patch longer a worse choice. Greater DD is indicated by longer stays in the depleting patch while consuming smaller amounts of water. Optimal foraging theory predicts that evolutionary processes will select genes which enable the animal to maximize the long term intake amount. Performance on DD tasks has been used as a measure of impulsivity and there is evidence that more rapid discounting is associated with drug abuse in humans and drug self-administration in animals. In a previous paper (Richards et al, 2013), we reported strong heritability for this behavior as measured by strong between-strain differences in DD using this procedure. Here we extend those results with comprehensive testing over a 6 month time period of two of the previously studied rat strains: August Copenhagen Irish (ACI/SegHsd) and Dahl Salt Sensitive (SS/JrHsd). The rats were tested on a variety of discounting procedures in which changing patches involves either long delays to the new patch, low probabilities of finding a new patch or both. In all cases the SS rats discounted less than the ACI rats. In relatively rich testing contexts (shorter delays and higher probabilities), the decision strategy of the SS rats produced larger overall rates of water consumption. In poor testing contexts (longer delays and lower probabilities), however, the decision strategy of the ACI rats produced larger overall rates of water consumption. Strain differences in domestic rats produced consistent biases in decision-making which may direct individual animals away from (or toward) optimality. Domestic rats, however, may have alleles that are quite different from those that would be found in a natural population and it is unclear if similar genetic effects would be observed in wild rats that are exposed to selective pressure. These results suggest that genetically

determined biases in decision-making may underlie personality differences described as 'impulsivity' in humans.

Title: Expected information signals in the posterior cingulate cortex

Authors: *D. L. BARACK[1], J.-F. GARIEPY[2], M. L. PLATT[2];
[1]Ctr. for Cog Neurosci, Duke Univ., DURHAM, NC; [2]Duke Univ., Durham, NC

Abstracts: Animals must balance learning about the environment with collecting rewards. The neural mechanisms that encode rewards and their predictive cues are well-understood. The neural mechanisms that encode information about the environment independently of reward value, by contrast, remain unexplored. Rewards collected while foraging carry information about the state of the environment, useful for guiding future decisions, and animals may anticipate the information learned from these decisions. We hypothesize that foraging animals maximize this expected information, defined as the amount of information learned from an outcome multiplied by the probability of that outcome, with independent neuronal encoding of expected information and expected value. We test these ideas with a novel behavioral paradigm that decorrelates expected value and expected information in a single task. In our experiment, two different fixed rewards randomly assigned to two of six locations in the environment. The rewarded targets' locations vary from trial to trial and are uncorrelated, though every target had to be selected on each trial in order to continue to the next trial. The amount of information about the reward sequence on every trial decreased over the course of the trial, while the expected value of upcoming actions could decrease or increase, depending on that trial's history of received rewards. Response times correlated with expected value and expected information over the course of the trial, with faster responses for higher value or greater information, as well as slower response for later choices in the trial (multilinear regression, $p < 0.05$). Cells in the posterior cingulate cortex (CGp), an area known to be involved in strategic choice, policy selection and adaptive behavior, preferentially encode expected information over expected value. We collected 33 cells from CGp from one animal running our task. During a whole choice epoch, from 500 ms

before feedback to 250 ms after, CGp cells encode the choice number in a trial (GLM, $p < 0.05$, 13/33 cells) and expected information (16/33), but not the expected value (0/33) of a choice. Our data suggest that an animal's choices are influenced by both expected value and expected information when exploring an environment with an unknown spatial distribution of rewards, and that expected information dominates CGp cell encoding, possibly serving as a substrate for the influence of expected information on decision behavior.

Title: How indirect pathway works - Stable object value coding by pallidal neurons

Authors: *H. F. KIM, O. HIKOSAKA;
NIH, NEI, LSR, Bethesda, MD

Abstracts: The output of the striatum is mediated by direct and indirect pathways which are thought to control behavior in opposite manners: direct pathway for GO and indirect pathway for NOGO. However, an important question remains unsolved, especially for the indirect pathway: What information is used for NOGO? A key structure of the indirect pathway is globus pallidus external segment (GPe), but little is known about its information processing. GO-NOGO mechanism would be critical when animals choose high-valued objects (GO) among low-valued objects (NOGO). Our studies have shown that tail of caudate nucleus (CDt) is necessary for choosing high-valued objects based on long-term experience (Kim & Hikosaka, 2013). Here we examined how GPe neurons process such stable value information. After injecting CTB in the CDt, we found that anterogradly labeled axon terminals were localized in the caudal-ventral region of the GPe (GPe(cv)) (indirect pathway) in addition to the caudal-dorsal-lateral region of the substantia nigra pars reticulata (SNr(cdl)) (direct pathway). We then recorded activity of single GPe(cv) neurons while high-valued and low-valued fractal objects were presented to monkey. The monkey had experienced each of these objects in association with a water reward or no reward consistently for many days, and thus had developed a strong preference of looking at reward-associated (high-valued) objects (GO) and avoiding non-reward-associated (low-valued) objects (NOGO), even when no reward outcome was presented. In GPe(cv) we found

many neurons that responded to these fractal objects. Among 31 visually responsive GPe(cv) neurons, 18 neurons (58.1%) responded to the objects differentially by their stable values. Importantly, a majority of them (n=13) were inhibited more strongly by low-valued objects than high-valued objects. Since GPe has inhibitory connections to the basal ganglia output regions, an inhibitory response of GPe(cv) neurons would be converted to a disinhibition of SNr(cdl) neurons. Indeed, SNr(cdl) neurons are excited by low-valued objects (Yasuda et al., 2012). These results suggest that the object-sensitive indirect pathway, CDt-GPe(cv)-SNr(cdl) circuit, transmits stable value information which would be used to suppress saccades to low-valued objects.

Title: A 3-choice visual discrimination learning and reversal task for mice

Authors: *K. KAUGARS, H. BERGSTROM, M. REGER, L. HALLADAY, E. BUSCH, C. PICKENS, M. BACHU, A. HOLMES;
Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD

Abstracts: Alcohol use disorders and other addictions are characterized by cognitive abnormalities. Pairwise discrimination and reversal paradigms have proven valuable to studies of the neural mechanisms underlying rewarded learning and cognitive flexibility. One limitation of procedures that use 2 stimuli is that, following reversal of learned stimulus-reward contingencies, it is unclear whether errors committed are due to a failure to inhibit responding to the previously rewarded stimulus, or an inability to form the new stimulus-reward association. To better disambiguate perseveration and learning during reversal, we tested the performance of mice in a 3-stimulus task. In this task, the mouse is presented with 3 stimuli during discrimination, one of which is rewarded, and trained to criterion (75%) levels of accuracy. On reversal, the same 3 stimuli are presented: the previously rewarded stimulus is now unrewarded (‘previous’), one of the previously non-rewarded stimuli is now rewarded (‘new’) and the other non-rewarded

stimulus remains unrewarded ('never'). Responses to the 'never' stimulus represent learning errors, while responses to 'previous' will primarily (though not exclusively) reflect perseverative errors. To investigate the neural circuits mediating performance in the task, C57BL/6J mice received bilateral excitotoxic lesions of the PL prior to reversal testing and were compared to sham controls for learning and perseverative errors. Additionally, mice with deletions of the GluN2A (brain-wide) or GluN2B (in cortical pyramidal neurons) NMDA receptor subunits were phenotyped for discrimination and reversal. These experiments could provide new insight into the role of the prelimbic cortex and NMDA receptors in rewarded learning and cognitive flexibility, with potential implications for understanding the neurobiology of cognitive abnormalities in psychiatric disorders and addictions. Research funded by the NIAAA Intramural Research Program.

Title: Short- and long-term effects of adolescent methylphenidate exposure on decision-making in rats

Authors: *L. R. AMODEO, M. S. MCMURRAY, C. R. SHORT, J. D. ROITMAN; Psychology, Univ. of Illinois, Chicago, Chicago, IL

Abstracts: Adolescence is transitional stages hallmarked by decisions that disproportionately favor immediate rewarding outcomes. This lack of forethought can be consequently dangerous. While an increase in behaviors that are impulsive and risky are normal in this stage of development, failure to inhibit inappropriate behaviors, such as experimentation with alcohol or illicit drugs, can lead to detrimental consequences. Differences in the developmental stage of prefrontal cortical and subcortical systems in adolescents might explain the relative increase in maladaptive decisions during this period. Specifically, the orbitofrontal region of prefrontal cortex (OFC) has been shown to play a central role in processing value expectation in a Delay

Discounting task. Recent evidence suggests that dopaminergic innervation of the OFC plays an important role in mediating delay discounting choices and pharmacological treatment with methylphenidate (MPH; an ADHD medication) decreases impulsive behavior in adolescents. For this study, adolescent rats were injected with MPH (2, 5, 10 mg/kg/day) twice daily from PD35 to PD52. During this period, rats performed a progressive delay discounting task, in which rats were given the choice between two levers: one leading to a smaller sooner (SS) reward and the other to a larger later (LL) reward. On each day the delay to the LL reward increased (5, 10, 15, 20, 30, 50s). In contrast to prior studies in hyperactive rats, we found that treatment with MPH did not decrease naturally impulsive behavior in normal (non-hyperactive) adolescent rats. However, continual administration of MPH during this crucial stage in development caused deficiencies in behavioral flexibility in normal rats. After discontinuation of MPH, risk-preference was subsequently assessed in adulthood. Rats performed a risk task in which they chose between small-certain and large-risky options. Probability payoff for the large-risky option (16%, 33%, 67%) varied every second day. Preliminary data indicated that the high dose of MPH (10 mg/kg) during adolescence increased risk preference in adulthood. These results provide an interesting platform for future research studying the involvement of OFC in impulsivity and risky decision-making.

Title: Frontal beta oscillations are differentially modulated by time-on-task, cognitive control, and pauses in work

Authors: *C. R. WILSON[1,2], F. M. STOLL[1,2], M. C. M. FARAUT[1,2], K. KNOBLAUCH[1,2], J. VEZOLI[3], E. PROCYK[1,2];
[1]Stem Cell and Brain Res. Inst., Inserm U846, Stem Cell & Brain Res. Inst., Bron, France; [2]Univ. de Lyon, UCBL, Lyon, France; [3]Ernst Strüngmann Inst. (ESI) for Neurosci. in Cooperation with Max Planck Society, Frankfurt, Germany

Abstracts: Beta oscillations are associated with top-down control mechanisms, but little is known about their contribution to cognitive functions. 15-30Hz oscillations are widespread in the brain, with a variety of characteristics, but it remains unclear whether they reflect a unitary or multiple mechanisms. We investigated whether frontal beta oscillations are differentially modulated by cognitive control and time-on-task. Vigilance and attention decrements over time, referred to as the time-on-task effect, have been shown to alter cognitive performance and some EEG patterns in humans. Two macaque monkeys learned the Problem Solving Task (PST), using visual feedback to search by trial and error amongst several targets for one that was associated with juice reward (the search phase, SEA), and then repeating this correct response a number of times (the repetition phase, REP). A change signal then instructed them to begin a new problem by searching again. The contrast between SEA and REP phases provides an index of cognitive control (Procyk & Goldman-Rakic 2006). Cognitive and execution performance were studied continuously through the session, during which the monkeys worked for a fixed number of problems, thus permitting time-on-task measures. Monkeys were chronically implanted with at least 22 electrodes resting on the dura mater to provide electroencephalographic (ECoG) recordings. We characterized 15-30Hz beta oscillations in the delay period of each trial prior to stimulus onset. To test for multiple modulating influences on the beta power, we used mixed effects modelling. We showed that beta power is modulated by the cognitive control demands of the task. Critically, beta oscillations in this same period showed a significant within-session change, seemingly tracking time-on-task. The separate modulations of beta oscillations by cognitive control and time-on-task did not interact. Importantly, when the monkey spontaneously paused for several minutes during the session, these beta power modulations were reset, and the time-on-task effect was re-initialised. The magnitude of this reset depended on multiple behavioural factors. This striking effect of spontaneous pauses in work strongly suggests that such pauses should be systematically taken into account in neural measures of time-on-task and fatigue. Comparisons of time-on-task changes in beta with behavioural performance suggest that modulation in beta oscillations within the session reflect a stabilization of cognitive but not execution performance throughout the session. Hence, frontal beta oscillations associated with cognitive performance are modulated by multiple separate mechanisms.

Title: From learning-set to task-set in macaque monkeys: Behaviour and neural correlates

Authors: *M. C. FARAUT, C. R. E. WILSON, E. PROCYK;
INSERM U846, Stem Cell and Brain Res. Inst., Bron, France

Abstracts: Learning from the environment in order to reach our goals efficiently, and reacting flexibly when the environment changes, are important capacities of primate behaviour that enable efficient decision making. An important process is task-set, referring to the ability to link together information that is relevant for doing a task and to modify it in a flexible manner when it ceases to be optimal. However, questions remain about how we acquire these abilities, how this flexibility is implemented, and what the neural correlates of such processes are. We tested cognitive flexibility in macaque monkeys with chronic electrophysiological recordings, using a test of their ability to adapt to changing task information in an environment that doesn't always give the right answer. 3 monkeys learned a test of Task-Set Manipulation, a monkey equivalent of the task of Collins & Koechlin (2012).The task consisted of 2 concurrent stimulus-target associations in a noisy feedback environment (10% trap feedback: an incorrect feedback was given after a correct response and a correct feedback after an incorrect response). Once the monkey reached a performance criterion, the associations were changed in an unpredictable manner. This task enables us to contrast phases of exploration and exploitation of the environment by the monkey, which require different levels of cognitive control. In order to understand the basic processes of this complex behaviour, we trained the monkeys in 2 steps. First monkeys acquired a learning set for a version of the task in which shifts between problems were signaled by changes of stimuli. A learning set is the ability to learn to learn. Learning becomes more and more efficient as more problems are solved in a task. We show that monkeys formed a stable learning set and adapted their responses to the stochastic environment. Second monkeys learned the Task-Set version of the task, in which shifts between problems were not cued any more, and the 2 stimuli always remained the same. Thus, an efficient way to perform

this task is to link the 2 stimulus-target associations into a task-set and modify this task-set when it is changed. Monkeys were able to transfer their learning set to this task, showing striking performance from the start. We show some evidence that monkeys created task-sets and modified them when contingencies changed. Finally, monkeys were implanted with chronic electrocorticography electrodes covering prefrontal and parietal cortex. We investigated task-related changes in cortical oscillatory dynamics and event-related signals.

Title: Demonstrating a stress-free way to administer drugs during behavioural testing: Modafinil restores attentional deficits in rats with lesions of the subthalamic nucleus

Authors: E. E. BOWMAN, S. XIA, D. S. TAIT, *V. J. BROWN;
Sch. of Psychology & Neurosci., Univ. St Andrews, St Andrews, United Kingdom

Abstracts: Choice of route of drug administration is influenced by the chemical and pharmacokinetic/pharmacodynamics properties of the compound. Modafinil - a putative cognitive enhancer - is a large molecule which does not easily dissolve in water and therefore solvents or detergents are required: modafinil can be administered to rats by i.p. injection in a vehicle of DMSO (soluble to 75 mM). However, when testing for behavioral effects of cognitive enhancers, the additional factors of timing of drug administration as well as the impact of the stress of handling during administration become important considerations. In our experience using the attentional set-shifting task, interrupting testing to administer compounds by gavage or injection can be so disruptive to performance that collection of useful behavioral data is often compromised. Furthermore, the solvents in the vehicles may also be neuroactive. In this study, we sought to test the effects of modafinil on performance in an attentional set-shifting task. We tested 14 rats, 6 controls and 8 of which had lesions of the subthalamic nucleus (STN) and a stable impairment, established over 5 testing sessions, in forming an attentional set. A modified version of the set-shifting task was used, with 9 stages, to maximise the opportunity to form an attentional set, including a series of novel acquisitions, reversal and probe stages. To minimize stress of administration during testing, the drug was given to the rats in flavored sugar-free jellies

which they ate. Individual modafinil jellies were made for each rat, with drug concentration of 30mg/kg. The rats were given jellies without modafinil several times in their home-cage in the days preceding testing to overcome neophobia. On the day of the test, a modafinil (or non-drug) jelly was given 30mins before the start of testing and a second jelly was given 60mins later. The interval between two jellies was chosen based on the established half-life of modafinil. All rats were tested once with and once without modafinil, with order of testing counterbalanced. Non-drug jellies were without behavioral effects, but jellies with modafinil significantly improved performance of the STN lesioned rats on the final ID stage, restoring the ID/ED difference to the same level as controls, from which they no longer differed. While modafinil had a significant cognitive benefit in STN lesioned rats, it was without effect in the control group. Using jellies had several advantages, including: that it overcame the difficulties of getting the drug into solution; stressful handling and injections were avoided; testing was not disrupted; and the tester was blind to drug condition.

Title: Implication of motor effort and reward size encoding in the monkey basal ganglia for decision making

Authors: S. NOUGARET[1], R. ABITBOL[2], C. BAUNEZ[1], M. PESSIGLIONE[2], *S. RAVEL[1]; [1]CNRS-AMU, Inst. De Neurosciences De La Timone, Marseille, France; [2]Inserm U1125, Univ. Pierre et Marie Curie (UPMC - Paris 6), Motivation, Brain & Behavior lab, Brain & Spine Institute, Pitié-Salpêtrière Hosp., Paris, France

Abstracts: Motivation to perform an action can be defined by the subjective value of this action, and quantified by the ratio between its cost and its benefit. It requires convergence and integration of limbic, motor and associative information to adapt behaviors accordingly. The

basal ganglia (BG) are known for their implication in processes involving these different types of information. The striatum and the subthalamic nucleus (STN), considered as the two input structures of this subcortical system, are functionally divided into 3 different areas, sensorimotor, associative and limbic, based on the distribution of the cortical inputs. The external segment of the globus pallidus (GPe) is well positioned to play a key role in the integration of information from the different striatal and subthalamic territories before their transmission to the BG output structures and, consequently to encode information about motivation to perform an action. We recorded 532 neurons in the striatum, STN and GPe of two monkeys (N=307, 93, 132, respectively), in a visuomotor task requiring a motor effort to get a reward. Four distinct associations of visual stimuli determine four cost (force to develop on a lever: small or high)/benefit (reward size: small or large) ratios for the animal. Behavioral data showed that animals discriminate the different conditions of the task and modulate their behavior accordingly, making more errors in conditions in which a high pressing force is required and less errors when the upcoming reward is large. Single-unit activities were analyzed using iterative multiple linear regressions. We first examined the influence of the internal motivational state of the animals (cumulative reward received, cumulative effort developed and number of trials performed in the session) on the baseline neuronal activity. Secondly, we investigated how the baseline activity and the effort and reward information were combined to explain the response evoked by visual stimuli. Finally, we studied the influence of the evoked response on the decision of the animals to perform or not the action. A striking result across structures was the strong impact of baseline activity, which mediated the effects of internal motivational state on behavioral outputs. Our preliminary analyses also revealed dissociations between structures, with a particular influence of the evoked response in the STN and in the limbic part of the GPe on the propensity to perform the task.

Title: Self-control signals in the supplementary eye field of monkeys during a temptation task

Authors: *J. HWANG[1], E. E. EMERIC[1], V. STUPHORN[1,2];
[1]Zanvyl Krieger Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD; [2]Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstracts: Self-control is the ability to resist rewards that are tempting, but lead to suboptimal long-term outcomes. It has been suggested that the intertemporal choice task can be used as a measure of self-control, because the task requires subjects to choose between a smaller, sooner reward (S) and a larger, later reward (L). However, it has been difficult to behaviorally estimate self-control in this task, because self-control is required only for a short period just before a choice is made and there are too many other factors that affect the choices of the subjects. Therefore, we developed a new temptation task that provides a measure of resistance to persistent temptation and trained monkey subjects with it. In every trial, two annulus-shaped targets (S and L) were presented after a fixation period. Each annulus had a colored section, whose length and color indicated the delay and amount of rewards, respectively. The subjects had to make a saccade to one of the targets and fixate it, until they received the indicated reward amount. In no-temptation trials, the unchosen target disappeared upon the choice of either target. However, in temptation trials, the unchosen target did not disappear and the subjects were allowed to change their initial choice as long as the time of the chosen target did not run out. Since temptation and no-temptation trials were randomly interleaved with no cue, the subjects' initial choice functions were identical in both conditions and therefore indicated their true preferences regardless of the conditions. Nevertheless, the subjects sometimes switched targets in temptation trials. This typically involved a switch from an initial delayed L target to an immediate S target (L-S switch). The opposite switch (S-L switch) almost never occurred. These results indicate that an L-S switch is the result of a failure in resisting temptation of the immediate reward and not the correction of a mistake in the initial choice. To investigate the neural correlates of self-control, we recorded single-unit activity from the supplementary eye field (SEF) while the subjects performed the temptation task. We found that some SEF neurons were more active when the subjects succeeded in exerting self-control and stayed with the initial delayed large reward target (L-L stay) than when they failed in exerting self-control and switched to the immediate small reward target (L-S switch). Next, we inactivated SEF by cooling it down. This caused a significant shift in the choice functions so that the subjects chose S more often at the initial choice and also switched from L to S at a shorter L delay. These results suggest that SEF has a causal role in exerting self-control.

Title: Comparing monkey and human multi-item memory

Authors: *S. HOCHSTEIN[1], V. YAKOVLEV[2];
[1]Hebrew Univ. Jerusalem, Jerusalem, Israel; [2]Hebrew Univ., Jerusalem, Israel

Abstracts: Are the memory capabilities of humans and monkeys similar or does one species have superior abilities? In particular, does language afford better memory facilities? To answer these questions, we compared memory capabilities of human and monkey participants in a delay-match-to-multiple-item memory task. In each trial, a series of samples was presented and the task was to detect and respond to a repetition of any previous item seen in the same trial. Two difficulties are included that are not present in standard delay-match-to-sample tasks: First, the repetition can be for any image in the trial, not only for the first image, so that participants must remember all the images seen. Secondly, repetition of an image that appeared in a previous trial is not considered a valid repetition, and should be ignored. Thus, participants need not only remember all the images of the trial, they must also remember if the image was seen in the current trial. In general, we used novel images that had not been seen before, introducing a small number of catch images that had appeared in previous trials, which should be ignored. Performance Hit rate is similar for monkeys and humans, about 90% except for the longest trials. The False Positive (FP) rate is very different, however, about 80% for monkeys and 30% for humans, for images from the preceding trial. When monkeys are intensively trained with a limited set of images, they necessarily develop a reset mechanism that allows them to reject the frequent presentation of images seen in earlier trials. Interestingly, they are able to transfer this reset capability to task performance with novel (and catch) images, reducing the FP rate to below 20%. Thus, there is a surprising similarity between human performance and monkey performance following intensive training with a limited set of images, forcing acquisition of a reset mechanism. This similarity is found even for human performance without such prior training. We conclude that human participants have an inherent reset mechanism before visiting our laboratory.

Title: Cav2.1 P/Q type calcium channel in CA1 region contributes to properties of the place field as well as neuronal firing pattern of the pyramidal cells

Authors: *D. JUNG[1,2], H. SHIN[3], J. CHO[1,4];
[1]Seongbok-Gu, Korea Institude of Sci. and Technology(Kist), Seoul, Korea, Republic of; [2]Univ. of Sci. and technology, Daejeon, Korea, Republic of; [3]Inst. for Basic Sci., Daejeon, Korea, Republic of; [4]Univ. of Sci. and Technol. (UST), Daejeon, Korea, Republic of

Abstracts: The hippocampus has a critical role in learning and memory and has been especially known to process the spatial information in respect to place-dependent firing of the pyramidal neurons. The hippocampus has distinct firing modes (tonic and burst firing) and burst firing is thought to transmit signals and participates more efficiently in formation of hippocampal-dependent memories. It is evidenced that Voltage gated calcium channels (VGCCs) in the hippocampus modulate the action potentials and the distinct properties of different types of VGCCs result in different structures of firing pattern. However, electrophysiological and behavioral effects of Cav2.1 P/Q type calcium channel in the hippocampus have not been well studied in spite of its abundant expression. Therefore, we examined the role of Cav2.1 P/Q type calcium channel by measuring unit signals of behaving mice with CA1 specific deletion of Cav2.1 P/Q type calcium channel (CA1-Cav2.1 KO). The mice were introduced to an open-field arena with a local cue attached for 2 consecutive sessions with a 30 min interval in order to investigate firing pattern and spatial representation of place cell during exploring the same environment. In the firing pattern between the groups in each session showed the same tendency in terms of burst firing: The ratio of burst and burst length were modulated in the CA1-Cav2.1 KO mice compared to the control. In addition, the spatial information in the CA1-cav2.1 KO

group was decreased in both sessions, suggesting that deletion of Cav2.1 calcium channel reduced the ability to encode the location information using a local cue. Moreover, the CA1-Cav2.1 KO mice showed reduction in the similarity index of the place field between the two sessions, indicating retention of memory about the same environment was impaired in the KO mice. Together, this study suggests that the Cav2.1 P/Q type calcium channel in CA1 region modulates not only the intrinsic neuronal discharging but also spatial representation of place cells.

Title: Diet-induced obesity induces insulin resistance and hyperactivity

Authors: *S. BLYTHE, S. MARWITZ, L. WOODIE;
Biol., Washington & Lee Univ., Lexington, VA

Abstracts: The prevalence of obesity in children and adolescents has increased rapidly over the past 30 years, as has the incidence of attention deficit hyperactivity disorder (ADHD). In 2012, it was found that overweight children have a twofold higher chance of developing ADHD than their normal weight counterparts. Previous work from our lab and others has documented learning and memory impairments linked to consumption of a Western-style diet in rats, but the relationship between diet and ADHD-like behaviors has yet to be explored using animal models. Therefore, the purpose of this study was to explore the role of diet in the etiology of attention and hyperactivity disorders using a rat model of diet-induced obesity. Male, Sprague Dawley rats (p40) were fed either a control diet (n=8) or a Western-style diet (n=9) for ten weeks, and the physiological and behavioral effects were examined. Tail blood samples were collected to measure fasting blood glucose and insulin levels in order to assess insulin insensitivity. Rats also performed several behavioral tasks, including the novel object task, attentional set-shifting task, and open field test. Rats exposed to a Western-style diet (67.4 ± 5.03 pmol/L) had significantly higher fasting insulin levels than controls (28.8 ± 3.64 pmol/L), but both groups had similar glucose levels. The quantitative insulin sensitivity check index (QUICKI) indicated the development of insulin resistance in Western-style diet rats. Furthermore, control diet animals

were able to discriminate between old and novel objects (exploration ratio: 0.72 ± 0.11), whereas the Western-style diet animals were significantly impaired in object recognition (0.56 ± 0.08). However, regardless of dietary condition, rats were able to perform the attentional set-shifting paradigm. Finally, performance on the open field test indicated that Western-style diet induced pronounced hyperactivity. Western-style animals spent considerably more time moving (280 ± 12 seconds) compared with control animals (200 ± 12 seconds). While Western-style diet impairs episodic memory and induces hyperactivity, attentional set-shifting capabilities are unaffected. With the increasing prevalence of both obesity and ADHD, understanding the potential links between the two conditions is clinically important.

Title: Effects of ginkgo biloba supplementation on locomotor activity and anxiety levels in aged female rats

Authors: *N. OKUDAN[1], M. BELVIRANLI[2];
[1]Dept. of Physiol. Fac. of Med. Selcu, Konya, Turkey; [2]Dept. of Physiol., Fac. of Med. Selcuk Univ., Konya, Turkey

Abstracts: The aim of study was to investigate the effects of ginkgo biloba supplementation on locomotor activity and anxiety levels in aged female rats. The study protocol was approved by the Local Ethics Committee. The principle of laboratory animal care of the National Institute of Health guideline was followed in all these experiments. Twenty-eight female Wistar rats were divided into the four groups according to their age (young vs. aged) and treatment (ginkgo biloba vs. vehicle) status. Supplements were given once daily for a period of 30 days, beginning 28 days prior to and 2 days during the behavioral tests. Locomotor activity was assessed in open field (OF) and anxiety levels were measured in elevated plus maze (EPM). All behavioral tests were recorded online and analyzed offline with analytical software. Both locomotor activity and exploratory behavior were lower and anxiety levels were higher in the aged rats compared to the young rats ($P<0.05$). In conclusion, aging affects spatial and emotional memory in different aspects and ginkgo biloba supplementation has limited protective effects in aged female rats.

Title: The role of the supramammillary area in spatial learning and memory

Authors: *H. SHIM[1], H.-J. PARK[2], H. LEE[2], I. SHIM[2];
[1]Dept. of Sci. in Korean Med., Grad. School, Col. of Korean Medicine, Kyung Hee Univ., Seoul 137-701, Korea, Republic of; [2]Acupuncture and Meridian Sci. Res. Center, Kyung Hee Univ., Seoul, Korea, Republic of

Abstracts: The supramammillary area (SuM) of the hypothalamus, although small in size, has wide spread connection with numerous brain structures. It is known that the SuM can control the frequency of the hippocampal theta rhythm, which plays a role in the cognitive functions of the hippocampal formation. In order to examine the role of the specific cells of the SuM in learning and memory, selective cholinergic neurotoxic or excitotoxic lesioned rats of the SuM were tested for spatial memory on the Morris water maze (MWM) test. After the behavior tests, the expression of acetylcholine esterase (AChE) in the hippocampus was studied using the immunohistochemistry. In the MWM test, both lesion of the SuM with 192 IgG-saporin and ibotenic acid produced the impairment of spatial learning and memory. In the immunohistochemistry, the SuM-lesioned rat model by selective cholinergic neurotoxin showed decrease in the AChE expression in the hippocampal CA3. These findings suggest that cholinergic cells of the SuM area play a critical role in the process of consolidation of memory.

Title: Behavioral and neurobiochemical comparative study between males and females that have been separated from their mother during nursing

Authors: L. CORREDOR-VELANDIA, *Z. DUENAS;
Ciencias Fisiológicas, Univ. Nacional De Colombia, Bogota DC, Colombia

Abstracts: Early experiences affect brain development and the behavior of individuals. Clinical studies assessing the consequences of adverse early experiences such as child abuse, maternal neglect and psychosocial stress, suggest that these factors may increase susceptibility to developing several psychopathologies, particularly during adolescence and adult ages. A study was made searching for possible differences in the expression of GFAP and BDNF proteins in adult Wistar rats that were submitted to maternal separation during nursing, as well as the relationship of this with the assessment of spatial learning made with Barnes maze, on the prelimbic cortex, cingulate cortex, hippocampus and amygdala, areas well known for their role in memory processes. Wistar rats with reversed light-dark cycle with water and food ad libitum were separated from their mother from postnatal day 1 and until day 21, in two periods of 180 minutes. During the period of 60 to 65 days, the performance of rats on the Barnes maze was assessed and immunohistochemistry for GFAP and BDNF was made. Spatial learning measured with latency, errors, path length and exploration of the escape hole were significantly different in the groups studied. Positive cells were counted in the mentioned areas finding that maternal separation during nursing leads to a reduction of the amount of positive cells for both proteins as well as a differential significant effect between separated males and females.

Title: High fat diet-induced obesity promotes anxiety-like behavior in Wistar rats

Authors: *S. I. NORONHA, A. R. R. ABREU, G. S. V. CAMPOS, A. M. A. DE SOUZA, D. A. CHIANCA JR, R. C. A. MENEZES;
Dept. of Biol. Sci., Federal Univ. Of Ouro Preto, Ouro Preto, Brazil

Abstracts: It has been shown that obesity potentiates the cardiovascular response to stress in rats due to an inefficient GABAA-mediated inhibition within the dorsomedial hypothalamus. Changes in GABAergic inhibition within the hypothalamus have been linked to generalized anxiety disorder and panic disorder. Thus, the aim of our study was to evaluate the effect produced by a high fat diet 45% w/w fat (HFD) on the behavior of rats. We investigated the anxiety-like and panic-like behaviors in these animals by using the Elevated-T-Maze (ETM), an apparatus that permits determining behavioral changes related to escape, inhibitory avoidance and memory. Male Wistar rats (100 ± 10g) were fed with CD (n=16) and HFD (n=17) for 9 weeks. These groups were submitted to an ETM during 3 subsequently days. On the first day animals were exposed to an open arm of the ETM for 30 min. On the second day, the animals were placed, initially, at the distal end of the enclosed arm of the ETM, facing the intersection of the arms. The time taken by the rat to leave this arm with four paws was recorded (avoidance 1). This measurement was repeated in two subsequent trials (avoidance 2 and 3) at 30s intervals. After 30s from avoidance training, rats were placed at the end of the open arm, and the time taken to leave this arm with four paws was recorded 3 times, (escape 1, 2 and 3), with 30s intervals between it. On the third day animals were replaced once on the enclosed arms and after 30s on the open arm. A cutoff time of 300s was established for the avoidance and escape latencies. Our results showed that obesity facilitate ETM avoidance, an anxiogenic response (diet effect [$F(1,124=16,57, p<0,05$]). When compared to control (125 ± 34 s) the obese (231±22 s, Bonferroni post hoc test; $p<0.05$) animals spent more time in the enclosed arm during the avoidance 3. The third day of experiment confirm this results, showing that the control rats (135±33 s) spent less time in the enclosed arms than the obese rats (248±24 s, Bonferroni post hoc test; $p<0.01$). No differences were observed on escape tests. These results indicate that obese animals fed with a high-fat-diet exhibit anxiety-like behavior but not panic-like behavior.

Title: Over-expression of the L-type voltage-gated calcium channel CaV1.3 leads to alterations in neuronal function associated with aging

Authors: *S. J. MOORE[1], J. N. SLATER[1], G. G. MURPHY[1,2];
[1]Mol. & Behavioral Neurosci Inst., [2]Mol. and Integrative Physiol., Univ. of Michigan, Ann Arbor, MI

Abstracts: Cognitive impairments in the aged population are usually associated with neurodegenerative disorders like Alzheimer's disease, but in fact they often occur in the absence of any overt pathology. However, the neurobiological mechanisms that mediate this "normal" age-related cognitive decline are not fully understood. Previous work in rodent models has shown that aging is associated with an up-regulation of L-type voltage-gated calcium channels (LVGCCs) and that this increase is correlated with age-related memory impairments in a hippocampus-dependent learning and memory task. We have generated a novel transgenic mouse line in which the αCamKII promotor drives exogenous expression of an HA-tagged subtype of LVGCCs (CaV1.3) to directly examine the relative contribution of increased LVGCCs to cognitive function. We have shown that young CaV1.3 HA+ mice exhibit impairments in hippocampus-dependent learning and memory tasks, such as the Morris water maze and contextual fear conditioning. We now investigate molecular mechanisms that may contribute to these cognitive deficits by examining electrophysiological measures of neuronal function, including alterations in intrinsic excitability and synaptic plasticity. Taken together, our results suggest that an age-dependent up-regulation of the LVGCC CaV1.3 contributes to cognitive deficits in learning and memory and thus may represent a novel therapeutic target for the amelioration of age-related cognitive decline.

Title: Sustained firing patterns in rat perirhinal cortex chunk large segments of spatial trajectories in a visual discrimination task

Authors: *J. J. BOS[1], M. VINCK[2], A. B. MOURIK-DONGA[1], J. C. JACKSON[3], M. P. WITTER[4], C. M. A. PENNARTZ[1];
[1]Swammerdam Inst. for Life Sciences, Cogn NeuroSci, Cognition Systems Neurosci., Univ. of Amsterdam, Amsterdam, Netherlands; [2]Dept. of Neurobio., Yale Univ., New Haven, CT; [3]Biol., Univ. of St. Thomas, St. Paul, MN; [4]Ctr. for Neural Computation, Kavli Inst. for Systems Neurosci., Trondheim, Norway

Abstracts: The perirhinal cortex (PRh) is widely associated with higher-order sensory processing and object recognition. It is generally classified as part of the “what” pathway of the medial temporal lobe memory system. However, the role of this structure in spatial coding remains unclear. In the present study, in addition to units tuned to sensory events, we found units showing sustained activations and deactivations for large segments of a figure-8 maze. These units showed differential responses for leftward vs. rightward trials. Three rats were trained on a spatial, visual discrimination task. A target and a distracter stimulus were presented simultaneously on two screens flanking the two arms of the figure-8 maze. Rewards could be obtained at the end of the arm corresponding to the target image. Tactile cues at the beginning of the arms indicated reward amount. The rats performed ~80 trials with an average performance of 75% correct per session. Using 36 tetrode drives we recorded spikes and local field potentials from four brain areas simultaneously: PRh, dorsal CA1, barrel cortex and visual cortex. In total we recorded >1500 well-isolated single units. The sustained, left-right discriminating responses found in PRh were dissimilar from responses found in the other areas. For instance, place fields found in area CA1 were much more focal than PRh patterns. In contrast, PRh units showed consistent, sustained differential firing throughout the side arms. Examples were found of both in- and decreases in firing rate on a given arm, compared to baseline or the other arm. The units appear to chunk the environment and/or the corresponding segment of the behavioral task. The left-right discriminating responses as found in PRh could not be explained by differences in task variables such as presented images, textures, correct/incorrect trials or running speed. These

results show an involvement of PRh in chunking the environment and the task segments associated with the animal's trajectory. As such, these results argue in favor of a less narrow definition of PRh as being restricted to the "what" pathway, emphasizing a unitizing or "chunking" function in spatial behaviors.

Title: Corticosterone impairs adaptation in an associative place-reward learning task

Authors: ***S. I. RUSU**[1], M. JOËLS[2], C. M. PENNARTZ[1];
[1]Neurosciences, Swammerdam Inst. For Life Sci., Amsterdam, Netherlands; [2]Dept. of Neurosci. and Pharmacol., Brain Ctr. Rudolf Magnus, Utrecht, Netherlands

Abstracts: Within a normal physiological range, acute stress-induced responses may be beneficial in coping with challenging situations. However, they can become maladaptive in extreme circumstances or following prolonged stress exposure, impairing both memory and behavioral flexibility. Stress is a major risk factor in a multitude of psycho-pathological conditions such as PTSD, depression and anxiety, with effects ranging from over-consolidation of emotional memories to debilitating memory loss and impaired executive function. A key player in the brain's response to stressors in rodents is the hormone corticosterone (CORT), which binds, amongst others, to receptors in the hippocampus (HPC) and prefrontal cortex (PFC). Navigational strategies employed by rodents are often driven by associations made between spatial information and specific reward contingencies, recruiting therefore both HPC and associated areas. The HPC, ventral striatum, amygdala (AMY) and PFC are core structures involved in encoding and updating spatial information, emotional management and the control of cognitive processes such as flexible decision-making and behavioural inhibition. Recent electrophysiological data support a robust interaction between HPC, PFC and AMY during anxiety-related behaviors, as suggested by both an increased local field potential synchrony and

the synaptic modulation of perceived anxiety. However, it remains unclear how motivational and spatial memory systems are altered by stress hormones during complex behavior. In this study we trained a total of 22 male rats on an hexagonal track fitted with six spatially symmetric reward ports. Of these, 21 were subjected to a partial extinction procedure across 5 sessions, with each daily session immediately followed by systemic administration of either CORT or saline. We showed that, during the first three sessions, performance is significantly impaired by CORT ($p = 0.042$), suggesting that post-task hormone treatment retards adaptation. Furthermore, 4 rats were implanted with a hyperdrive containing 14 independently moveable tetrodes directed at the HPC and the orbitofrontal cortex. By repeatedly changing contingencies every 3rd session on at least 4 reward sites, we estimated how associative place-reward information is updated following post-task CORT administration. Preliminary analysis of local field potential data recorded from the CA1 subfield shows a decrease in hippocampal ripple activity during post-task slow wave sleep epochs, consistent with an adverse effect of CORT on mnemonic function.

Title: Impact of L-type voltage gated calcium channels on neurogenesis and cognition in adult and aged mice

Authors: J. MARSCHALLINGER[1], P. ROTHENEICHNER[2], C. SCHMUCKERMAIR[3], A. SAH[3], N. SINGEWALD[3], S. COUILLARD-DESPRES[2], *L. J. AIGNER[1];
[1]Paracelsus Med. Univ., Salzburg, Austria; [2]Exptl. Neuroregeneration, PMU Salzburg, Salzburg, Austria; [3]Pharm. and CMBI, Leopold-Franzens-University of Innsbruck, Innsbruck, Austria

Abstracts: L-type voltage gated Calcium channels (LTCCs) are widely expressed within the CNS and play an important modulatory role in brain function. Aberrant activity of brain LTCCs is involved in various CNS pathologies (e.g. PD, AD), and modulation of LTCCs may demonstrate a therapeutic approach to treat these disorders. However, the LTCC channel subtypes Cav1.2 and Cav1.3 are also expressed within the adult neurogenic brain regions

(dentate gyrus, subventricular zone), and modification of these channels may have profound impact on neurogenesis. Hence, this study examined the involvement of LTCCs in adult neurogenesis. Expression patterns of Cav1.2 and Cav1.3 within the neurogenic regions of adult mice were examined immunohistologically, and the impact of Cav1.3 inhibition on neurogenesis and a possible relevance for cognitive performance was analysed in adult and aged Cav1.3-/- mice. Cav1.2 and Cav1.3 expression was predominately found in mature granular neurons in the dentate gyrus. Cav1.3 was further observed in neural stem cells and astrocytes, but was nearly absent in neuronal progenitors. Cav1.3-/- mice showed increased cell proliferation, reduced cell survival, and a reduced number of neural stem cells in the dentate gyrus. In addition, Cav1.3-/- mice exhibited a reduced surface area of GFAP+ astrocytes in the hippocampus compared to wildtype controls. Addressing possible effects of Cav1.3 knockout on cognition, the Object Location Memory Test revealed a significant impairment in Memory performance of young adult (3 months) Cav1.3 -/- mice compared to age-matched wildtype mice. The expression of Cav1.2 and Cav1.3 within the neurogenic niches, together with the observed alterations of adult neurogenesis and of memory skills in Cav1.3-/- mice, let strongly suggest an involvement of LTCCs in adult neurogenic processes. Thus, modulation of LTCC activities may have a crucial impact on neurogenic responses, which should be considered for future therapeutic administration of LTCCs.

Title: Ginkgo biloba improves spatial memory and decreases oxidative damage in aged female rats

Authors: *M. BELVIRANLI[1], N. OKUDAN[2];
[1]Dept. of Physiol. Fac. of Med. Selcu, Konya, Turkey; [2]Dept. of Physiol., Fac. of Med. Selcuk Univ., Konya, Turkey

Abstracts: The purpose of the present study was to investigate the effects of ginkgo biloba supplementation on cognitive impairment evaluated by Morris Water Maze (MWM) as well as

the oxidative stress in brain tissue induced by aging in female rats. The study protocol was approved by the Ethics Committee of the Experimental Medicine Research and Application Center. Twenty-eight Wistar rats were divided into the four groups according to their age (young vs. aged) and treatment (ginkgo biloba vs. vehicle) status. Ginkgo biloba or vehicle (corn oil) were given once daily for a period of 30 days, beginning 25 days prior to and 5 days during the behavioral tests at a dose of 100 mg.kg-1.day-1. Behavioral assessment was performed in MWM. All behavioral tests were recorded online and analyzed offline with analytical software. At the end of the behavioral test, brain tissues were taken for the analysis of malondialdeyde (MDA), glutathione (GSH) and 8-hydroxydeoxyguanosine (8-OHdG) levels and superoxide dismutase (SOD) activities. During the training session, ginkgo biloba supplementation decreased latency to reach to the platform and the total distance traveled ($P<0.05$). During the probe trial, ginkgo biloba supplementation increased the number of platform crossings ($P<0.05$). In addition to the behavioral testing, biochemical results showed that GSH levels decreased and 8-OHdG levels increased in brain tissue of aged rats ($P<0.05$). It may be concluded that, ginkgo biloba supplementation improves cognitive functions by decreasing the oxidative stress in brain tissue of aged female rats.

Title: Evaluating neurophysiological representations of hippocampal-dependent reversal learning with multifractal analysis

Authors: ***D. FETTERHOFF**[1], R. A. KRAFT[2], I. OPRIS[3], A. J. SWEATT[3], C. A. SEXTON[3], S. A. DEADWYLER[3], R. E. HAMPSON[3];

Abstracts: Successful performance on the delayed nonmatch-to-sample (DNMS) working memory task requires rats to combine spatial and nonspatial information. However, the DNMS paradigm is limited by a two-choice decision. Therefore, to further examine cognitive and behavioral flexibility as well as neural encoding of additional behavioral events by the same neurons, a reversal learning paradigm was implemented. Rats initially learned to perform a delayed match-to-sample (DMS) task before the operant rule was "reversed" to nonmatch. Hippocampal neuronal spike trains were recorded using chronic bilateral microelectrode arrays implanted in CA3 and CA1 sub-regions and neuronal discharge patterns were investigated with peri-event histogram analysis and Wavelet Leaders-based Multifractal Analysis. Behaviorally, all rats tested successfully learned the reversal over a variable period of 3 to 12 days. Distinct changes in the neuronal representation of the task occurred during the operant rule change which depended on each individual neuron's firing correlates of the pre-reversal phase. Neurons with stronger involvement in reversal learning also exhibited larger multifractal complexity compared to neurons without task correlates. On average, multifractal complexity decreased immediately after the rule change, but returned to pre-reversal levels when animals acquired the newly informed behavior, with a few neurons exhibiting opposite polarity trends. In this test of behavioral flexibility and re-learning, single neuron alterations in multifractal complexity correlated with the neuronal firing rate relationship to behavioral performance. This presentation will discuss implications of multifractal analysis for cognitive neuroscience and neural encoding and compare with other measures of interspike-interval variability.

Title: Food restriction induces anxiety-like behaviour in female Fischer rats

Authors: *G. S. CAMPOS[1], A. M. A. DE SOUZA[2], S. I. S. R. NORONHA[2], A. R. R. ABREU[2], D. A. CHIANCA JR[2], R. A. C. MENEZES[2];
[1]Dept. of Biol. Sci., [2]Dept. of Sci. Biol., Federal Univ. of Ouro Preto, Ouro Preto, Brazil

Abstracts: Studies have indicate a strong association between food restriction (FR) and the development of anxiety disorders (generalized anxiety and panic), relating these behavioral alterations to malnutrition caused by FR. Many hypotheses are being studied to explain this mechanism, however, still unclear whether anxiety disorders could be complete or partial consequence of malnutrition caused by reducing caloric and nutrient intake. Thereby, the aim of this study is evaluate whether food restriction can alter behavioral responses (anxiety and panic) compared to control animals. For this, female Fischer rats (210 ± 10g) were divided into control and food restriction (FR) and housed individually. For 15 days the control animals received ad libitum and FR animals received 40% of the average intake of the control group. On the 14th day, the animals were exposed to the Elevated T-Maze (ETM), an apparatus that permits determining behavioral changes related to escape, inhibitory avoidance and memory, to perform behavioral tests of anxiety (3 trials: avoidance 1, 2 and 3), the time taken by the rat to leave the enclosed arm with four paws and panic (3 trials: escape 1, 2 and 3), the time taken by the rat to leave the open arm with four paws. The test was repeated the next day (ND) (anxiety: 1 trial; panic: 1 trial) to confirm the results of the previous day. A cutoff time of 300s was established for the avoidance and escape latencies Our result demonstrates that when comparing the trials of control animals in the avoidance test, we found differences between all trials (9.9 ± 2.8 s, 126.0 ± 43.9 s, 254.9 ± 24.66 s, $n = 10$, $p < 0.005$) and also between avoidance 1 and ND (213.5 ± 44.08 s, $n = 10$, $p < 0.05$). Among the FR, we found a significant increase avoidance between 1 and 3 (109.2 ± 60.4 s, 300.0 ± 0.0 s, $n = 6$, $p < 0.05$) and avoidance 1 and ND (109.2 ± 60.4 s, 300.0 ± 0.0 s, $n = 6$, $p < 0.05$) by one-way ANOVA followed by the Tukey's post hoc test. When comparing the intergroup trial, we observed that the control animals spent less time in the first trial shorter that submited to FR (C: 9.9 ± 2.8 s, $n = 10$ vs FR: 109.2 ± 60.4 s, $n = 6$, $p = 0.0480$) while trials 2, 3 and ND are similar between groups. No differences were found in the panic test. These results suggest that food restriction promotes anxiety -like behavior, but not observed panic-like responses.

Title: Hippocampal encoding of unfamiliar events

Authors: *S. A. DEADWYLER, A. J. SWEATT, I. OPRIS, F. M. MILLER, D. FETTERHOFF, C. A. SEXTON, R. E. HAMPSON;
Wake Forest Sch. of Med., Winston-Salem, NC

Abstracts: Recordings from well trained rodents performing a touchscreen image delayed match to sample discrimination task show a unique type of encoding related to visual features of the image sets that were changed on a weekly (5 day) basis. Performance was shown to improve as a function of the number of random exposures to each combination of Sample (n=5) and Distracter (n=5) images (total of 25 different Sample-Distracter combinations). Hippocampal neural activity was recorded with microwire multielectrode arrays bilaterally implanted in CA3 and CA1, and recorded with respect to firing in sample and match phases of the task. Cell responses were varied according to specific combinations of Sample and Distracter as well as a function of correct or incorrect performance. However, much of the variance with respect to performance was related to two major factors: 1) asynchronous discharge related to match screen onset in which the distracter and sample image were both presented in different spatial positions or 2) eliciting a firing pattern appropriate for a different image combination: i.e. same Sample but and a different Distracter, or same Distracter and different Sample image. The major differentiation in firing on correct vs. incorrect trials was the synchrony of oscillations after image presentation but prior to the occurrence of the match response. These firing tendencies reflect inherent hippocampal encoding patterns for different images and may well reflect categorical processing to facilitate improvement in performance related to occurrences of unfamiliar events.

Title: Locus coeruleus activity time-locked to hippocampal rythmns during sleep

Authors: G. POE[1], *S. J. SARA[2];
[1]Anesthesiol., Univ. of Michigan, Ann Arbor, MI; [2]Collège de France, Paris, France

Abstracts: Locus coeruleus (LC) involvement in memory formation, retrieval and other cognitive processes is well established. Noradrenaline (NA) provided to the forebrain by the LC facilitates LTP and prevents depotentiation. There is an increase in LC activity during nonREM sleep specifically following learning, when replay is thought to reinforce memory. The LC is silent during REM sleep and this silence is hypothesized to allow depotentiation within neural networks consolidating memories. During nonREM sleep, LC activity is phase locked to cortical slow oscillations(1). The LC also falls silent just prior to the onset of cortical sleep spindles (10-15 Hz activity) that, in themselves, have been well correlated with sleep dependent memory consolidation. In order to further understand the action of NA in off-line memory consolidation during sleep, we investigated the precise temporal relationship between LC unit activity and the predominant hippocampal and prefrontal cortical EEG frequencies during REM and nonREM sleep in the freely behaving, learning, sleeping rat. Rats were implanted under electrophysiological control with movable micro electrodes in the LC for unit recording, and with fixed tungsten wire electrodes to record, simultaneously, LFPs in dorsal CA1 and medial prefrontal cortex. They were submitted to various appetitive, nonstressful learning situations, followed by a 2-3 hour recording session, during which the rat slept most of the time. Firing of LC neurons significantly reduced spindles, beginning immediately for hippocampal spindles and with a 120ms delay for cortical spindles. The spindle power nadir, revealed by root mean square (RMS), occurred at 1 sec post LC spiking for hippocampus and slightly later in cortex. LC activity was time locked to hippocampal delta (0-4 Hz) oscillations and reset theta and gamma waves. RMS analysis showed that LC neurons spiked 0.5 to 1 seconds before the nadir and onset of rebound in power for gamma, theta and slow wave oscillations, and at the nadir/inflection

point for delta power. These results lend strong support to the notion, derived mainly from *in vitro* or anesthetized preparations, that LC activity plays an intimate role in shaping cortical and hippocampal oscillatory activity that promotes off-line memory consolidation during sleep. We are currently investigating the effect of manipulation of LC activity on sleep-related hippocampal rythmns and consequences for memory consolidation. (1) Eschenko et al Cerebral Cortex, 2012

Title: Peripheral injection of macrophages ameliorates learning deficits in aged mice by a phagocytosis-dependent mechanism

Authors: *N. C. DERECKI, I. SMIRNOV, J. KIPNIS;
Neurosci., Univ. of Virginia, Charlottesville, VA

Abstracts: Age-associated cognitive decline is paralleled by immune system decline. Along these lines, past work from our lab has shown that normal learning and memory is associated with a robustly functioning immune system. We showed that an influx of CNS-directed T cells, acting in the meningeal spaces surrounding the brain, were critical to performance in the Morris water maze (MWM) via production of interleukin (IL)-4, an anti-inflammatory cytokine. Influx of anti-inflammatory T cells was associated with a subsequent anti-inflammatory skew of meningeal myeloid cells, suggesting a possible connection between meningeal myeloid cell skew and learning and memory. Intriguingly, when we examined aged mice, isolated meningeal cells expressed high levels of pro-inflammatory cytokines. Furthermore, meninges of aged mice showed substantial reduction in IL-4 producing T cells. These findings suggested a mechanistic connection between immune decline and cognitive impairment in aged mice. Here, we show that aged (18-22 mo) mice, normally impaired in MWM as compared to young counterparts, display significantly improved performance (compared to PBS-injected controls) following a single i.v. injection of anti-inflammatory skewed macrophages. Interestingly, injected macrophages were completely cleared from mice by the end of the MWM task; yet, meningeal macrophages

isolated from cell injected mice displayed a marked anti-inflammatory phenotype as compared to controls. Along these lines, it is known that phagocytosis of apoptotic cells is sufficient to guide resident macrophages to anti-inflammatory phenotype. Thus, we reasoned that phagocytosis of injected cells might underlie the observed anti-inflammatory skew by resident cells. Indeed, our studies indicate that apoptotic macrophages promote anti-inflammatory skew in phagocytosing macrophages. When phagocytosis is blocked using Annexin V, which masks phosphatidyserine residues on apoptotic cells, anti-inflammatory skew of phagocytosing macrophages is abolished. These results suggest that age-associated immune system decline may indeed contribute to cognitive decline, and that boost of phagocytic activity might represent a possible method of ameliorating cognitive decline by immune manipulation.

Title: Spatial memory deficits in old homing pigeons (Columba livia): A novel experimental model for age-related cognitive decline

Authors: *V. J. COPPOLA[1,2], V. P. BINGMAN[1,2];
[1]Psychology, Bowling Green State Univ., Bowling Green, OH; [2]J.P. Scott Ctr. for Neuroscience, Mind, and Behavior, Bowling Green, OH

Abstracts: The mammalian hippocampus is particularly susceptible to age-related degeneration that, like hippocampal lesions, results in spatial-cognitive deficits. Lesions to the avian hippocampal formation (HF) also result in spatial-cognitive deficits, but it is currently unknown what, if any, affect aging has on HF-dependent spatial cognition. Therefore, this study investigated the possibility of an age-related spatial working memory deficit in old homing pigeons. Young adult (1 - 2 years) and old (10 - 13 years) pigeons were tested on a spatial, delayed non-match-to-sample task in a modified radial arm maze. Compared to young adults, old pigeons required more choices to task completion (i.e., they committed more errors) and were less accurate with their first four choices. Additionally, old pigeons were much more likely to adopt a stereotyped sampling strategy, a behavior typical of hippocampal-lesioned animals. These results suggest that birds, like mammals, experience age-related memory impairment, and

are a critical first step in promoting the homing pigeon as an additional model species for cognitive aging research. Future directions include a broader behavioral assay, as well as investigations of potential neural correlates of age-related cognitive decline in birds.

Title: Environmental enrichment induces hippocampal plasticity in the aged brain through a reduction in ccl11/eotaxin

Authors: *M. MAINARDI[1,2], M. SCALI[2], G. SCABIA[4], M. MAFFEI[4,3], L. MAFFEI[2,5]; [1]Inst. of Physiol., Sacred Heart Catholic Univ., Rome, Italy; [2]Neurosci. Inst., [3]Inst. of Clin. Physiol., CNR - Natl. Res. Council, Pisa, Italy; [4]Dept. of Clin. and Exptl. Med. - Obesity Ctr., Univ. Hosp., Pisa, Italy; [5]Accademia Nazionale dei Lincei, Rome, Italy

Abstracts: Increasing physical and mental exercise can represent an effective strategy to improve brain health during aging. However, the precise details explaining this beneficial action are still poorly understood. To explore this problem, we exploited environmental enrichment (EE) on aged mice. EE is based on rearing mice in large social groups, with free access to voluntary physical exercise and cognitive stimulation, provided by novel objects to be explored. It therefore represents an accurate way to model an active life style. Moreover, EE has been shown to be highly effective in inducing neural plasticity in a variety of experimental models, ranging from sensory cortices to the hippocampus and subcortical brain areas. Notably, EE has been shown to positively affect the physiological status of the aged brain, a phenomenon that is accompanied by the induction of neural plasticity. It has been recently demonstrated that the plasmatic levels of the chemokine ccl11/eotaxin increase during the aging process. Moreover, ccl11 has been clearly shown to be a negative regulator of plasticity. Thus, a higher concentration of ccl11 could account for the lower cognitive performance displayed by aged animals in comparison to younger subjects. Based on this evidence, we reasoned that a reduction in ccl11 plasmatic concentration could be induced by exposure to EE during aging. To address

this issue, aged mice were reared in EE for one month and we found that this manipulation induces a significant decrease in plasmatic ccl11. Thus, we hypothesized that lower ccl11 levels could be the crucial mediator of the beneficial effects of EE on the aged brain. To demonstrate this point, we treated aged mice with ccl11 injections while exposed to EE (EE-ccl11 group), in order to counteract the decrease in its plasmatic levels. The cognitive performance of this experimental group was then compared with vehicle-injected mice either exposed to EE (EE-veh group) or maintained in standard rearing (SC-veh group), by testing on the Morris Water Maze. We found that ccl11 injection correlates with ablation of the improvement in short- and long-term memory retention that is otherwise caused by EE. Taken together, our findings point to the decrease in ccl11 plasmatic levels as a key phenomenon responsible for the improved neural plasticity and cognitive performance observed in aged mice exposed to EE.

Title: Effects and mechanisms of ADDLs on AMPA receptors trafficking and cognitive deficits

Authors: J.-R. HAO, N. SUN, L. LEI, X.-Y. LI, K. SUN, *C. GAO;
Jiangsu Key Lab. of Anesthesiol., Xuzhou Med. Col., Jiangsu, China

Abstracts: It is widely accepted that ADDLs (Aβ-derived diffusible ligands) play a prominent role in triggering the early cognitive deficits that constitute Alzhimer's Disease (AD). However, the mechanisms for its effects on synaptic plasticity are not fully understood. Regulation of a-amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA) receptor trafficking in and out of excitatory synapses is important for controlling the strength of excitatory synapses in long-term potentiation (LTP), long-term depression (LTD) and other forms of synaptic plasticity. So

targeting AMPA receptors trafficking and its regulation is a new strategy for AD early treatment. We used primary hippocampal cultures and APP/PS1 transgenetic mice to test the hypothesis that ADDLs influence synaptic plasticity by modulating AMPA receptor subunit GluA1 trafficking. Three hours exposure of ADDLs decreased surface expression of GluA1-containing AMPA receptors by decreasing their rate of externalization at extrasynaptic sites. LTP was also inhibited in hippocampal slice. This was mediated mainly by protein kinase A (PKA), which could phosphorylate S845 of GluA1. *l*-Stepholidine (l-SPD), which belongs to the tetrahydroprotoberberines elicits D1 agonistic activity while acts as D2 receptor antagonist. *l*-SPD not only rescued the phosphorylation of GluA1 and surface expression in hippocampal cultures but also protected the LTP in hippocampal slice induced by ADDLs. PKA agonist SpcAMP and D1 agonist SKF81297 had similar effects, while PKA antagonist RpcAMP or D1 receptor antagonist SCH23390 diminished the effects of *l*-SPD on GluA1 trafficking and LTP. Furthermore, *l*-SPD partialy rescued both the hippocampal-dependent memory and surface expression of GluA1 in hippocampus in APP/PS1 mice. These results demonstrated that D1-PKA singal pathway plays an important role in early dysfunction of synaptic plasticity in AD. Elucidating the molecular mechanisms that ADDLs affect AMPA receptors surface expression and disrupt synaptic plasticity for triggerring memory malfunction and cognitive deficits will provide new strategy for early treatment of AD and shed light on new target for drug discovery.

Title: Behavioral phenotypes in the 5xFAD mouse model of Alzheimer's disease and their relation to amyloid-beta plaque load

Authors: *J. J. MATYAS[1,2], A. RECHENBERG[1,3], S. A. LOWRANCE[1,3], J. ROSSIGNOL[1,4], G. L. DUNBAR[1,2,3,5];

Abstracts: Alzheimer's disease (AD) is a progressive, neurodegenerative disorder affecting millions of aging adults. It is characterized by the trademark physiology of intracellular tau tangles, amyloid beta plaque formation, cortical inflammation, and neuronal atrophy, which are each thought to contribute to the loss of cognitive function. The 5xFAD mouse model of AD replicates aggressive plaque formation as early as two months of age, though there is much disagreement among studies regarding the magnitude of its effect on behavior. The present study explored a variety of behavioral tests in the 5xFAD mouse at three time points, and compared findings with final histological measures in an attempt to validate previous observations within the model. 5xFAD mice demonstrated progressive motor deficits when compared to wild type (WT) control, as well as decreased anxiety as measured by the elevated plus maze, but no significant changes in learning and memory behavior were observed when assessed by water T-maze, Y-maze for spontaneous alternation, or an operant alternation paradigm. Histological analysis of AD and WT brains revealed dramatically elevated amyloid beta-42 (Aβ-42) levels in the cortex, hippocampus, lateral septum, and olfactory bulb regions, as well as increased neural inflammation in the cortical region, with trends toward increased inflammation in the hippocampal regions, though cortical density was not affected. These findings suggest that cognitive deficits in 5xFAD mice are as robust as expected, despite evidence for an increased plaque load. These results provide further support for other findings showing a dissociation between plaque load and learning deficits.

Title: Effect of aging and repeated testing on performance of mice in the continuous alternation test

Authors: *L. VER DONCK[1], H. DUYTSCHAEVER[2], R. WILLEMS[2], L. MERTENS[2]; [1]Neurosci., Janssen Res. & Development, A Div. of Jans, Beerse, Belgium; [2]Neurosci., Janssen Res. & Development, A Div. of Janssen Pharmaceutica NV, Beerse, Belgium

Abstracts: Spontaneous alternation (SA) is an innate tendency of mice to avoid visits to previously explored locations. It can therefore serve as a measure of spatial exploratory behavior, defined as a visit to the other of the two goal arms of a triangular maze from the arm visited before. In order to alternate or avoid a revisit, a mouse must use spatial orientation. The information about the previous arm-visit is stored in the spatial working memory. The SA-test is therefore suited to assess the effects of cognition enhancing and impairing experimental manipulations. OBJECTIVE: To evaluate the effect of aging and of repeat testing on SA-performance of mice. METHODS: The setup consisted of 3 square plastic boxes (15x15x15cm) each with a ∞3cm hole in one wall; the latter were placed to face each other thus creating a triangular centre. Mice were placed in the centre and explored the setup for 8 min. Sessions were recorded by a video camera and images were analysed using EthoVision XT to determine distance traveled by the mouse, number of entries into the boxes (visits), number of alternations from one box to another and % spontaneous alternations (%SA: mouse enters the three boxes sequentially one after the other, relative to total number of visits). Six groups (n=16 each) of male 2 month old C57BL6J mice (Janvier) were housed in IVC cages. Five groups started their experimental series at either 3, 6, 9, 12 or 15 months of age respectively (effect of age), followed by testing once a week for 4 weeks (weekly repeat testing). Group 6 was tested in SA once every 3 months (3-monthly repeat testing). RESULTS: Naive mice showed reduced performance from 6 months onward on all parameters, while the group with 3-month repeat testing showed reduced performance at each age tested. Performance of the latter was less than naive animals at ages ≥6 month. Weekly repeated testing at each age was decreased for all parameters measured, except for %SA which remained constant. CONCLUSION: Aging and repeated testing decreased performance of mice on most parameters in the continuous alternation test, but %SA remained constant throughout.

Title: Effects of environmental enrichment in a mouse model of Alzheimer's pathology

Authors: *K. E. STUART[1], A. KING[2], M. J. SUMMERS[3], J. C. VICKERS[2];
[1]Wicking Dementia Res. & Educ. Ctr. / Uni, Hobart, Australia; [2]Wicking Dementia Res. & Educ. Ctr., Hobart, Australia; [3]Sch. of Med., Launceston, Australia

Abstracts: Objective Environmental enrichment (EE) has been proposed to reduce the risk of developing dementia in conditions such as Alzheimer's disease (AD). The current project investigates the potential of different forms of later-life EE to ameliorate cognitive deterioration in ageing in wildtype (WT) mice as well as in a transgenic model (APP/PS1) of early-stage AD. **Method** Male transgenic (APPswe, PSEN1dE9) and WT mice entered differential housing from 6 – 12 months of age. Mice entered standard (SH) or EE housing. EE housing comprised a cage double the size of the SH cage, with various enrichment objects. A sub-set of EE mice (EE+) received additional stimulation by spending several hours a week in a larger cage with novel objects. Working memory (Y maze) was tested at 6 months, before entering differential housing, and at 9 and 12 months. At 12 months, mice were also tested for their long-term memory function on the Barnes maze. **Results** At 6 months, APP/PS1 mice demonstrated inferior Y maze performance compared to WT mice ($n = 75$, $p < .001$). After 3 months of differential housing, WT performance declined to the level of TG mice, and a combined effect of housing and genotype on Y maze performance was detected ($p = .01$). Post-hoc tests demonstrated that WT mice exhibited similar levels of performance regardless of housing condition, however TG EE mice demonstrated improved Y maze performance compared to SH mice ($p < .01$). After 6 months of differential housing, this effect dissipated ($p = .76$). Significantly longer latency on the Barnes maze was demonstrated by TG mice ($p = .01$). Housing condition did not predict long-term memory function on the Barnes maze in TG mice, however, WT animals exposed to EE made less errors on the Barnes maze than those in SH ($p = .03$). **Conclusions** The results indicate that EE confers differential beneficial effects to cognitive function. The results also suggest there is no additive effect of more complex, novel stimulation on memory function above that of standard EE. Results from cognitive testing data will be correlated with pathological brain alterations, including β-Amyloid plaque load and synaptic alterations.

Title: Whole life environmental enrichment impacts hippocampal oscillatory activity in CA1 of aged rats

Authors: ***F. FUCHS**[1,2], A. BARBELIVIEN[1,2], K. HERBEAUX[1,2], C. KELCHE[1,2], C. MATHIS[1,2], M. MAJCHRZAK[1,2], R. GOUTAGNY[1,2,2];
[1]CNRS UMR 7364, Strasbourg, France; [2]Univ. de Strasbourg, Strasbourg, France

Abstracts: Whereas a prominent cognitive decline is commonly described with aging, some old subjects perform as well as young. According to the "cognitive reserve" hypothesis, some individual characteristics either innate and/or related to life experience (e.g. level of education, professional and leisure activities) limit cognitive alterations in aged subjects. In rats, lifelong environmental enrichment attenuates deleterious effects of aging on spatial memory, suggesting that it may allow the constitution of such a reserve. To assess whether preserved hippocampal oscillatory activity contributes to the enrichment-induced maintenance of spatial memory in aging, local field potentials were recorded throughout the dorsoventral axis of CA1 in adult rats submitted to standard environmental condition and in old rats reared until 24 months in enriched or standard environment. During paradoxical sleep, in the *stratum radiatum* there was no difference in theta (4-12 Hz) and slow and fast gamma (25-50 and 60-140 Hz respectively) power between the three groups. However, theta-gamma coupling, a mechanism thought to play an important role in cognitive functions, was different in old rats. Whereas theta-slow gamma coupling was lower in older animals whatever their rearing conditions, theta-fast gamma coupling was lower specifically in aged enriched animals. Moreover, they also presented a

significantly lower theta-fast gamma coupling during active wake state and spatial novelty exposition. These results show that environmental enrichment during the whole life may modify the hippocampal oscillatory activity, particularly the theta-fast gamma coupling, suggesting that aged enriched rats process notably spatial information in a different way. How this may explain their better spatial capabilities needs to be explored.

Title: Senile or sage? Improved memory and sensitivity to cognitive priming accompany aging in male rats

Authors: D. L. KOROL[1], L. A. NEWMAN[1], *P. E. GOLD[2];
[1]Biol., [2]Dept of Biol., Syracuse Univ., Syracuse, NY

Abstracts: Aged rats exhibit impairments in several cognitive tasks, particularly those designed to be solved using spatial cues or to require memory across delays. Findings like these suggest that decreased hippocampal functions develop with age. Interestingly, in young adult rats, diminished hippocampal function can result in enhanced learning of tasks associated with non-hippocampal learning and memory systems, as seen in demonstrations of competition across multiple memory systems. Here we examined the possibility that striatum-sensitive learning and memory improve with age, such that aged rats might be superior to young rats when trained on striatum-sensitive tasks. Young adult (3-mo-old) and aged (24-mo-old) Fischer-344 rats were trained on two versions of the same maze, a place version that is hippocampus-sensitive and a

response version that is striatum-sensitive. These mazes have the same motivational (food) and locomotor (arm entry) requirements and differ mainly in the rule used to solve the maze, i.e. leave the start arm and go to a place in the room for place learning or turn in a specific direction for response learning. The findings revealed a slight impairment in place learning in the aged compared to the young rats. However, the aged rats were significantly better than young rats at learning the response maze, suggesting that cognitive decline with age is not a unitary process. Moreover, these results support the idea that aging brains are quite plastic. We recently found that cognitive priming with a spatial working memory task, spontaneous alternation, enhanced later maze learning in young adult rats. Here we tested whether cognitive priming with spontaneous alternation one hour prior to learning would enhance subsequent learning in old rats. Spontaneous alternation testing administered to 24-mo-old rats one hour before place learning improved their rate of learning to that of young adult rats. This suggests that any hippocampal dysfunction in the aged rats is not irreversible and that the hippocampus may retain sufficient plasticity to handle spatial learning even into senescence. Based on our recent findings in young adult rats, we are currently testing whether BDNF signaling and lactate delivery to neurons from astrocytic glycogen are mediators of the age-related shifts in learning abilities across memory systems and the priming by cognitive activity.

Title: Evaluating aged mice in two touchscreen tests that differ in visual demands: Impaired cognitive function or declining visual abilities?

Authors: N. BUSCHER, P. VAN DORSSELAER, *T. STECKLER, J. C. TALPOS;
CNS Resch & Devel Europe, Johnson & Johnson PRD, B-2340 Beerse, Belgium

Abstracts: Aging is associated with cognitive decline mediated by changes in hippocampal and prefrontal function, decreases in hippocampal LTP, and changes to cell size and density in neuronal populations. Accordingly, aged rodents have been proposed as a model of cognitive impairment for research into potential symptomatic treatments of Alzheimer's disease (AD). However, a short-coming of this approach is that aging is also associated with impaired vision

that may impact performance on cognitive tasks. We have recently established that rats with impaired vision can complete a hippocampus-dependent touchscreen-based Automated Spatial Search Task (ASST; inspired by the CANTAB Spatial Working Memory Test) that requires no or only limited visual acuity, despite showing clear impairments on acquisition and reversal of a visually more demanding visual discrimination (VD). Here we test aged mice on the acquisition of VD and performance of ASST to evaluate age-related cognitive decline, while also investigating the effects of age on visual acuity. Two cohorts of male mice (C57BL/6N, aged 6-8 or 18-20 months) were trained on touchscreen (MedAssociates; K Limbic Software, Conclusive Solutions) VD or ASST. In VD, the mice learned to discriminate between two complex visual stimuli displayed simultaneously on a touchscreen, one of which was correct (S+; rewarded), and the other incorrect (S-). In ASST, mice learned to find the location of a rewarded area on the screen (S+). The location of S+ was not indicated otherwise, but remained in the same location for 10 trials and then shifted to a new area, requiring the mouse to search for and then maintain the memory for the new location (4 locations per session). Visual acuity was assessed using an animal's ability to detect a moving vertical grey scale sine wave and measured in terms of cycles per degree (Virtual Optomotor System, Cerebral Mechanics). Aged mice were impaired in VD acquisition (reduced % correct responses and increased response latencies). Moreover, aged mice showed impaired spatial performance in ASST, requiring more trials to find a rewarded location, while rate of responding was unaltered. There was also an age-dependent decline in visual acuity, but that was not correlated with performance in AST or VD in the old mice, suggesting that the age-related decline in VD performance was at least in part unrelated to visual acuity. Thus, both touchscreen tests may be of utility to assess age-related cognitive deficits in C57BL/6N mice.

Title: Curcumin as a dietary intervention improves functional outcomes in middle- aged and senescent male and female c57bl/6 mice

Authors: *M. SARKER[1], S. F. FRANKS[2], N. SUMIEN[3], F. FILIPETTO[2], M. J. FORSTER[3]; [2]Family Med., [3]Pharmacol. and Neurosci., [1]UNT Hlth. Sci. Ctr., Fort Worth, TX

Abstracts: Curcumin, a component of the Indian spice turmeric, has antioxidant, anti-inflammatory and anti-angiogenic effects that are hypothesized to benefit impaired cognitive and psychomotor performance related to normal aging. The results reported here are from an ongoing study of dietary curcumin supplementation alone and in combination with caloric restriction, testing functional and biochemical outcomes in late middle age (15 months) and senescent (20 months) C57BL/6J male and female mice after 16 weeks of treatment. Mice were assigned in groups to receive: (i) base diet ad libitum (AL), (ii) weight stable caloric restriction (WSCR), (iii) curcumin in the base diet (7200 mg/kg diet (CURCAL) or (iv) curcumin plus WSCR. Beginning 8 weeks after the initiation of the treatments, all mice received a battery of behavioral tests for psychomotor and cognitive function (Sumien et al., 2006) that included a test of spatial memory performance and one for cognitive flexibility. Both initial learning and cognitive flexibility, tested for by a discriminated avoidance, serial reversal task, was significantly better for mice under CR, CURAL and CURCR compared to AL, when measured by the number of trials required to reach criterion. In addition, the food intake of mice in the CURAL group was higher when compared to AL, though there was not a significant difference in body weight between CURAL and AL after 16 weeks of treatment which could be attributed to improved metabolic activity in CURAL mice. The results indicate dietary intake of curcumin has positive effects on frontal cortical functions in both genders, in mice of middle and more advanced age. Sumien et al. Title: Investigation of the neuroprotective potential of bone marrow mesenchymal stem cells in an *in vitro* model of Alzheimer´s disease

Authors: *M. GODOY, L. M. SARAIVA, A. VASCONCELOS-DOS-SANTOS, H. J. V. BEIRAL, C. V. BRAGA, C. A. A. SILVA, R. B. LEAL, L. R. P. CARVALHO, A. P. C. LIMA, A. VIEYRA, F. G. DE FELICE, S. T. FERREIRA, R. MENDEZ-OTERO;
Univ. Federal Do Rio De Janeiro, Rio De Janeiro, Brazil

Abstracts: Alzheimer's disease (AD) is a neurodegenerative disease with high prevalence and morbidity, for which there are no effective therapies. Soluble oligomers of the amyloid-β peptide (Aβ) or ADDLs (Aβ-derived diffusible ligands) are the main neurotoxins involved in the early synaptic dysfunction and oxidative stress associated with the disease. The therapeutic potential of bone marrow mesenchymal stem cells (MSCs) has been investigated in several models of neurological diseases and the main mechanism of action of these cells is based on paracrine signaling, through the release of trophic or neuroprotective factors. The aim of the current study was to evaluate the neuroprotective actions of MSCs against the deleterious effects caused by exposure of rat hippocampal neurons to Aβ oligomers. We have also investigated the interaction of ADDLs with MSCs and possible mechanisms of neuroprotection. We established a model of indirect coculture of neurons and MSCs and our results indicate that the ADDLs do not alter the viability (LIVE/DEAD), proliferation (Ki67 expression) and respiration of MSCs (Oroboros oxygraph) *in vitro*. However, presence of MSCs in coculture protected neurons against oxidative stress generated by exposure to ADDLs (preventing the increase of 3 times in the levels of reactive species) or hydrogen peroxide (reducing by half the increase of ~ 8 x in the levels of reactive species), and preserved the integrity of synapses, evaluated by the expression of pre and post synaptic proteins. We also found a reduction in the concentration of exogenously added ADDLs in the culture medium after increasing periods of incubation with MSCs. In addition, we found that ADDLs are internalized by MSCs (reducing about 10 times their concentration in the medium, after 24 hours), which could partially explain the neuroprotection actions of MSCs. These data suggest that mesenchymal stem cells may constitute a novel therapeutic alternative for the treatment of Alzheimer's disease.

Title: The inhibition of histone deacetylase rescues synaptic plasticity and memory function in aged mice

Authors: *G. RAMIREZ MEJIA[1,2], P. MORENO-CASTILLA[2], L. RODRIGUEZ-DURAN[2], M. L. ESCOBAR[2], F. BERMUDEZ-RATTONI[2];
[1]Inst. De Fisiologia Celular, Div. De Neuro, Mexico DF, Mexico; [2]UNAM, Mexico City DF 04510, Mexico

Abstracts: Aging is an irreversible process that affects heterogeneously all body's cells leading them to morphological and functional deterioration. Brain aging is marked by a gradual decline in cognitive function, linked to deterioration of synaptic function in brain regions crucial for memory formation and consolidation. Epigenetic regulation, including histone acetylation plays an important role in many physiological conditions, including aging. Increasing histone acetylation by inhibition of histone deacetylase (HDAC) enhances gene transcription and improves hippocampal long-term potentiation (LTP) and memory function in several experimental models, but the effect of HDAC inhibitors in non-hippocampal plasticity and memory has not yet described. The aim of this work was to determine whether the histone deacetylase inhibitor MS-275 could restore memory performance and cortical synaptic function affected by aging. We used B6129SF2/J young and aged mice. For synaptic function evaluation, we used LTP in anesthetized animals receiving intracerebral injections of MS-275 at IC prior to LTP induction in the basolateral amygdala-insular cortex (BLA-IC) projection. High frequency

stimulation was applied into the BLA, responses were then measured at IC. The effect of the HDAC inhibitors in memory performance was evaluated in aged animals administered with MS-275 or vehicle, bilaterally in the IC prior to acquisition of conditioned taste aversion (CTA) or prior to object recognition memory (ORM). We found that aged mice presented *in vivo* synaptic dysfunction in the BLA-IC pathway and deficiencies in memory performance of CTA and ORM tasks. Cortical acute administration of MS-275 in aged mice reestablished the induction of LTP and improved memory function. Our findings suggest that chromatin histone acetylation modifications by HDAC inhibitors could be a promising strategy to improve cognitive alterations during brain aging.

Title: Age-related changes in the behavior and neuronal morphology of Diversity Outbred mice

Authors: *L. C. ANDERSON, L. C. HOERTZ, W. N. FERM, Jr., E. J. CHESLER;
The Jackson Lab., Bar Harbor, ME

Abstracts: The Diversity Outbred (DO) mouse population is a genetic mapping resource with high precision, genetic polymorphism, and phenotypic diversity. The DO provides a powerful tool for identifying genetic loci that influence behavioral and neuroanatomical changes that occur in the aging process. In a cross-sectional design we assayed 200 male and female DO mice of three age groups (~6, ~12, and ~18 months). Behavioral assays consisted of the Open Field (OF), hippocampal dependent T-Maze, Novel Object Recognition (NOR), and the Tail Suspension Test (TST). Behavioral measures are correlated with measures of spine density and type from pyramidal neurons in the CA1 hippocampal subfield. General linear models were used to test

effects of age, sex, and age x sex interactions for each behavior. In the OF older mice showed lower anxiety than younger mice as measured by fecal boli, latency to periphery of arena, and center time. For the NOE and NOR we observed a significant decrease with age on distance traveled and time spent exploring objects. Time spent exploring the objects on Day 1 was correlated with the time spent with the objects on Day 2 but was not predictive of novel object preference. Chi^2 analysis showed an age effect on the number of poorly performing mice (lower quartile of all groups combined) on novel object recognition among 18 month old males but not females. No difference was found among the top performers (in the first quartile), indicating that the proportion of older mice of both sexes displaying spared cognition are indistinguishable from younger mice. T-Maze behavior varied across age as measured by the percent of correct transitions and distance traveled. There was no age or sex effect on TST. The correlation between dendritic spine density of CA1 pyramidal neurons and cognitive performance on the T-maze varied in magnitude across ages. There were no significant correlations of spine type or density on the TST or the cognitive aspects of the NOR. The behavioral results reflect age-related changes in activity, anxiety, and cognition related phenotypes. Future quantification will provide data on neuronal arborization. By combining these data with neurological, physiological, and genetic information obtained from the same mice we will be able to uncover genetic mechanisms and pathways of age related behavioral variation.

Title: The effect of parity on olfactory acuity and spine density in the piriform cortex

Authors: *S. BELGRAVE[1], M. FRANKFURT[3], V. LUINE[2];
[2]Dept. of Psychology, [1]Hunter Col., New York, NY; [3]Dept. of Sci. Educ., Hofstra North Shore LIJ Sch. of Med., New York, NY

Abstracts: Cognitive decline as a result of aging can be attenuated in females that have been through the motherhood experience, parity. Previous studies show multiparous females exhibit preservation of spatial memory ability past the time that females actively care for young. The attenuation of cognitive decline is accompanied by morphological changes because apical spine density on pyramidal cells in the CA1 region of the hippocampus is the same as that of young adult females. Given that spatial memory, an important maternal behavior, is preserved by parity we hypothesized that parity may induce long lasting effects in other behaviors and brain areas related to maternal behavior. Olfaction is a necessary component of the maternal ability to identify offspring and is interconnected with the limbic system, which form part of the memory and emotion centers in the brain, making it a prime candidate for study in the context of parity. Previous studies have found that anxious behavior is also attenuated by parity, but other studies have found no differences. In this study we utilized three groups of female F344 rats (young virgins, retired breeders and middle-aged virgins). Olfactory ability was tested using an olfactory acuity task and an olfactory habituation/dis-habituation task. The anxiety measures used were a latency to approach a novel object task, open field and plasma corticosterone level measurement after an acute stress. No significant difference was found in the latency to approach the object task and the olfactory acuity task. Middle aged females exhibited rearing ($p< .05$) and wall climbing ($p<.05$) behaviors significantly more than other groups. There was significant difference between retired breeders and aged females ($p< .05$) in corticosterone levels. For the habituation/dis-habituation task all groups are able to do the task successfully, but on the test trial, the retired breeder group did not spend as much time with the novel scent as the other two groups. These results suggest that the retired breeders have difficulty distinguishing between the habituation odor and new odors. This result was unexpected in comparison with effects of parity on spatial memory. Spine density of the semi-lunar cells in layer II/III of the piriform cortex was assessed using Golgi impregnation. No significant differences were found in spine density. Though parity mitigates the spatial memory decline that accompanies age, as well as some anxious behaviors the preservation benefits do not seem to extend to olfactory acuity behaviors and the semi-lunar cells of the piriform cortex.

Title: Glutamatergic regulation prevents age-related spatial memory decline through dendritic spine clustering

Authors: *A. C. PEREIRA[1], H. LAMBERT[2], Y. GROSSMAN[3], W. JANSSEN[3], B. MCEWEN[2], J. MORRISON[3];

Abstracts: The devastating cognitive decline that accompanies Alzheimer's Disease (AD) results primarily from degeneration of neurons that furnish glutamatergic corticocortical connections that subserve memory and cognition. While neuron death is minimal in the absence of AD, age-related cognitive decline does occur in animals as well as humans, and it decreases quality of life and independence for elderly people. Age-related cognitive decline has been linked to specific synaptic alterations that impair function in regions such as hippocampus and prefrontal cortex. These synaptic alterations are likely reversible, such that maintenance of synaptic health in the face of aging is a critically important therapeutic goal. Here we show that riluzole can protect against some of the synaptic alterations in hippocampus that are linked to age-related memory loss in rats. Riluzole increases glutamate uptake through glial transporters and is thought to decrease glutamate spillover to extrasynaptic NMDA receptors while increasing synaptic glutamatergic activity. Treated aged rats were protected against age-related hippocampal cognitive decline displayed in non-treated aged animals. Memory performance correlated with density of thin spines on apical dendrites in CA1, though not with mushroom spines. Furthermore, riluzole treated rats had an increase in clustering of thin spines that correlated with memory performance and was specific to the apical dendrites of CA1. Clustering of synaptic inputs along dendritic branches has been shown in electrophysiological studies and computational models to allow non-linear summation of synaptic strength. These findings further elucidate mechanistic neuroplastic changes in glutamatergic neural circuits with aging and advance therapeutic development to prevent and treat age-related cognitive decline.

Title: The role of specific receptors for corticotropin-releasing factor CRF1 and CRF2 from basolateral and central nuclei of amygdala in tonic immobility behavior in guinea pigs

Authors: B. B. DE PAULA[1], J. R. M. M. COELHO[2], R. L. SPINIELI[1], *C. R. LEITE-PANISSI[2];
[1]Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Ribeirão Preto, Brazil; [2]Dept MFPB, Ribeirao Preto Dent. Sch. - USP, Ribeirao Preto, Brazil

Abstracts: The behavioral response of Tonic Immobility (TI) occurs under extreme dangerous and inescapable situations, such as the predator attack. This response is characterized by loss of righting reflex and the relative lack of responsiveness to environmental stimuli. Consistent studies have demonstrated the involvement of different brain areas to modulate this defensive behavior, including the periaqueductal gray matter, hypothalamus and amygdala. Whereas the amygdala in particular, studies have shown the involvement of receptors for corticotrophin-releasing factor (CRF) of the central (CeA) and basolateral (BLA) nuclei of amygdala in TI modulating. Indeed, in recent decades, several evidences suggest that CRF is closely correlated with emotional behavior associated with fear and anxiety. While it is clear the involvement of CRF receptors in the modulation of fear, and specifically in the TI modulation, it is still unclear the involvement of different subtypes of CRF receptor in this response. Hence, the aim of this study was evaluated the involvement of specific receptors for corticotrophin-releasing factor, CRF1 and CRF2, in TI behavior in guinea pigs (Cavia porcellus). Male guinea pigs (CEUA 12.1.1393.53.0, n=105) received unilateral administration of CP-376395 (CP37) and Astressin 2B (ASTR2B), both at doses of 0.8 μg/0.2 μl, either intra-basolateral (BLA) or intra-central (CeA) nucleus of amygdala. As well, these drugs were administered at the doses of 0.4 μg/0.2 μg before the administration of CRF at dose of 0.2 μg/0.2 μl in the same nuclei. The results showed that CP37 in BLA or CeA reduced the duration of TI per se (BLA-$F_{6,27}=6.987$, $p=0.003$; CeA-$F_{6,27}=8.629$, $p=<0.001$) and antagonized the increase of TI induced by CRF administration into

same site (BLA-F6,27=6.026, p=0.005; CeA- F5,23=8.482, p=0.002). Again, ASTR2B reduced the TI response either in BLA or CeA per se (BLA-F4,19=10.800, p=0.001; CeA- F4,19=4.575, p=0.023) and blocked the increase of TI duration induced by CRF (BLA- F6,27=3.360, p=0.033; CeA- F5,23=8.430, p=0.002). In addition, the drugs used in this study did not alter motor activity. These findings suggest that the antagonism of CRF1 and CRF2 receptors in BLA and CeA can reduce the duration of TI behavior, an innate fear behavior. Title: The dorsal raphe nucleus is integral to negative prediction errors in Pavlovian fear

Authors: *M. A. MCDANNALD[1], G. SCHOENBAUM[2], B. A. BERG[2];
[1]Dept. of Psychology, Boston Col., Chestnut Hill, MA; [2]Natl. Inst. on Drug Abuse, Baltimore, MD

Abstracts: Prediction errors are central to modern learning theories. While brain regions contributing to reward prediction errors have been uncovered, the sources of prediction errors in Pavlovian fear remain largely unknown. Here we used probabilistic and deterministic reinforcement procedures, followed by extinction, to examine the contribution of the dorsal raphe nucleus to negative prediction errors in Pavlovian fear. Rats with dorsal raphe lesions were able to acquire fear and reduce fear to a non-reinforced, deterministic cue. However, dorsal raphe lesions impaired the reduction of fear to a probabilistic cue and fear extinction to a deterministic cue - both of which involve the use of negative prediction errors. The results point to an integral role for the dorsal raphe nucleus in negative prediction error signaling in Pavlovian fear.

Title: Increased Egr-1 expression in the prefrontal cortex correlates with context-shock association in the context pre-exposure facilitation effect (CPFE) in adult rats

Authors: *T. CHAKRABORTY, A. ASOK, M. E. STANTON, J. B. ROSEN;
Psychology, Univ. of Delaware, Newark, DE

Abstracts: The context pre-exposure facilitation effect (CPFE) is a fear-conditioning paradigm that temporally separates the context acquisition and context-shock association phases of learning and can be used to investigate differential contributions of brain regions in each of these phases of learning. We previously found differential expression of *Egr-1 (Zif268)*, an inducible transcription factor associated with learning and synaptic plasticity, in the prefrontal cortex (PFC), dorsal hippocampus (dHC), but not the lateral nucleus of the amygdala (LA) during the CPFE in adolescent rats (Asok, et. al., 2013; Schreiber et. al., under review). In the present study we extended this work to adults. Adult male Long Evans rats were trained in the CPFE over 3 days. On the first day, animals were either left in their homecage (HC) as controls or preexposed to context A (Pre) or context B (Alt). Brains were collected from a third of the rats 30 min post-exposure. Another third of the rats were run in the context-shock association phase 24h after preexposure. Pre and Alt rats were given an immediate shock in Context A, and an additional novel context (NC) group was placed in context A but not shocked. Rats were sacrificed 30min post-training and their brains were collected. The last cohort of rats was tested for fear conditioned freezing in context A during a retrieval phase 24 h later. Pre rats displayed contextually conditioned freezing, but the Alt rats did not, indicating fear conditioning in Pre, but not Alt rats. *Egr-1* expression after the context preexposure and context-shock training phases was assayed by *in situ* hybridization in the PFC, dHC, and LA. After pre-exposure, increased *Egr-1* expression was found in all regions of the PFC in both the Pre and Alt groups compared to HC. No differences were found in the dHC or LA. After training, the Pre, Alt, and NC groups once again expressed higher *Egr-1* levels compared to HC. Importantly, a differential increase in *Egr-1* was found in the Pre group compared to the Alt and NC groups in the PFC. Alt and Pre groups also expressed increased *Egr-1* expression compared to the HC and NC groups in the dHC. The results indicate that differential activation of *Egr-1* in the PFC correlates with fear

learning during the context-shock association phase. Animals that were not preexposed to the conditioned context (Alt) exhibited the immediate shock deficit and had less expression of *Egr-1* in the PFC. The data from adult rats are similar to previous findings with juvenile rats. They suggest that the PFC, and *Egr-1* may play a role in contextual fear conditioning when a prior incidentally learned context is subsequently associated with an aversive US.

Title: Effects of CB1 receptor agonism and antagonism on fear and stress responses in adult male rats

Authors: *J. J. SIMONE[1], M. R. GREEN[2], T. E. HODGES[2], C. M. MCCORMICK[2];
[1]Biol. Sci., [2]Psychology, Brock Univ., St. Catharines, ON, Canada

Abstracts: The endogenous cannabinoid system (ECS) is a retrograde messenger system involved in the regulation of a wide variety of behavioural and physiological processes. ECS signalling occurs through two main receptor subtypes, cannabinoid receptor type 1 (CB1) and type 2 (CB2). Studies in rodents have revealed a role of the ECS in fear and stress responses; increasing ECS signalling decreases, whereas inhibiting ECS signalling increases fear and stress responses. Many studies administering systemic injections, however, use non-specific CB1/CB2 agonists and, as such, the specific contributions of each receptor to fear and stress responses are not well known. Using the highly selective CB1 receptor agonist ACEA and inverse agonist AM251, we investigated the effects of CB1 receptor activity on fear and stress responses in adult male rats. CB1 receptor effects on unconditioned fear were assessed using elevated plus maze, and open field testing, whereas conditioned fear was analyzed using a classical auditory fear conditioning paradigm. As CB1 is known to elicit changes in intracellular signalling cascades implicated in fear behaviours, we performed an additional study investigating the effects of

ACEA on hippocampal ERK1/2 and Akt signalling. When tested on the elevated plus maze both ACEA (0.5 mg/kg) and AM251 (3 mg/kg) decreased time spent on the open arm relative to vehicle ($p = 0.07$ and 0.004, respectively). When tested on an open field, ACEA (0.1 and 0.5 mg/kg) and AM251 significantly decreased the time spent in the center of the field compared to vehicle (all $p < 0.04$). Although neither AM251 nor ACEA affected freezing to a conditioned fear, AM251 impaired, and ACEA enhanced, fear extinction. After exposure to the conditioned stimulus, corticosterone concentrations were higher in rats given ACEA (0.5 mg/kg) and AM251 than those given ACEA (0.1 mg/kg) or vehicle. To determine the effects of ACEA on ERK1/2 and Akt signalling, rats were injected and brains harvested at various post-injection time points. ACEA (0.5 mg/kg) decreased pERK1/2 expression in the dorsal hippocampus 30 minutes post-injection ($p = 0.013$), and increased pERK1/2 expression in the ventral hippocampus 60 minutes post-injection ($p = 0.048$). There was no effect of ACEA on pAkt expression in either region at any of the time points examined. These results are consistent with reports of fear-enhancing effects of the inverse agonist, and add to evidence that relatively low doses of CB1 agonists can have both fear-enhancing and fear-reducing effects, depending on the measure. The results suggest ERK1/2 signalling may be involved in the behavioural effects of ACEA.

Title: Activity of the interoceptive insular cortex during expression of conditioned fear

Authors: P. CASANOVA, M. AGUILAR, M. RODRIGUEZ, *F. TORREALBA;
P. Univ. Catolica de Chile, Santiago, Chile

Abstracts: The insula is the cortical component of the interoceptive pathway. This cortex has been involved in regulating internal states and emotional responses. A growing body of evidence

suggests that learned fear may be related to the activity of the interoceptive Insular Cortex. Preliminary data from our laboratory show that the inactivation of the primary interoceptive Insular Cortex (pIC) of the rat markedly reduced fear expression to an auditory conditioned stimulus (CS). In the present study we tested the activity of single neurons from the pIC during expression of auditory conditioned fear in freely moving rats. The rats were implanted with an array of 6 tetrodes under general anesthesia and left in their homecages for a week. On experimental day 1, the rats received 5 auditory CS (5 kHz, 20 sec, 80 dB) that co-terminated with a mild footshock (0.5 sec, 0.5 mA). On day 2, the rats were placed in a different box located in a different room, and received 15 CS in the absence of footshock, while we recorded from the pIC. We calculated firing rate 20 sec before (baseline) and 20 sec after CS onset for the first 3 CS, and z-scored the data. Then we obtained average change in z-score for each cell during CS compared to baseline. CS elicited significant changes (Z-Score > 1.96) in 19.2 % of recorded 99 neurons: 10.1 % showed an increase and 9.1 % a decrease in their firing rate. These data suggest that the electrical activity of neurons from the pIC is associated to fear expression.

Title: Changes in the orexin (hypocretin) system in rats following footshock exposure

Authors: H. WANG[1], S. LI[1], G. LIU[1,2], *G. J. KIROUAC[3];
[1]Oral Biol., Univ. of Manitoba, Winnipeg, MB, Canada; [2]Intl. School, Guangdong Food and Drug Vocational Col., Guangzhou, China; [3]Oral Biol. and Psychiatry, Fac. of Dent., Winnipeg, MB, Canada

Abstracts: Orexins (hypocretins) are peptides produced by neurons located exclusively in the hypothalamus. Orexin neurons project to many areas of the brain known to be important for

regulating arousal levels. A number of studies have also shown that orexin neurons are activated by stressful conditions and that these neurons play a role in the physiological and behavioral responses to stress. Post-traumatic stress disorder (PTSD) is an anxiety disorder triggered by traumatizing and stressful events. Similarly, rats exposed to an acute episode of moderately intense footshocks display long lasting fear and anxiety. Work in our laboratory has demonstrated that a subset of shocked rats which showed a high level of acute fear to a novel tone the day after the footshock experience (high responders; HR), showed high levels of anxiety that last for several weeks. Previous work in our laboratory has also shown that systemic treatment of HR with an orexin antagonist has an anxiolytic effect in these rats. The present study examined if the mRNA levels for prepro-orexin (ppOX), orexin 1 receptor (OX1R) and orexin 2 receptor (OX2R) are increased in rats exposed to footshocks. On day 1, shocked rats were exposed to footshocks (5 × 2 sec episodes of 1.5 mA with an inter shock period of 10-50 s presented randomly over 3 min), whereas nonshocked (NS) rats were placed in the shock chamber for the same amount of time. On day 2, rats were placed in a novel chamber and the time that each rat spent immobile during the presentation of a novel tone was scored. Based on the immobility to the novel tone, shocked rats were assigned to the HR (rats spent > 60% of the time immobile) or low responders (LR; rats spent < 40% of the time immobile) groups. On day 14, the rats were anesthetized and the posterior hypothalamus, dorsal midline thalamus and locus coeruleus/parabrachial region were removed for analysis using real-time RT-PCR. The level of ppOX mRNA was increased in the hypothalamus of HR compared to the LR and NS. In addition, the level of OX1R mRNA was found to be increased in the hypothalamus of HR compared to NS. No difference was observed in OX2R mRNA levels in the hypothalamus between the 3 groups. There was no difference between groups in the level of OX1R and OX2R in samples of the midline thalamus and locus coeruleus/parabrachial region. Protein expression levels for the OX1R and OX2R are being quantified using Western blot and will be presented at the meeting. The results of the present study indicate that changes in orexin and OX1R synthesis occur in a subset of rats exposed to footshocks. These results may provide a better understanding of the brain mechanisms contributing to hyperarousal and anxiety in PTSD.

Title: Predator Exposure, but not footshock, produces a noradrenergic-dependent flashbulb memory in rats

Authors: *L. A. BULLARD[1], C. R. PARK[1,2], D. M. DIAMOND[1,2];
[1]Psychology, Univ. of South Florida, Tampa, FL; [2]Res. and Develop., VA Hosp., Tampa, FL

Abstracts: A primary component of flashbulb memories in people is the enhancement of memory for incidental events occurring close in time with an arousing experience. We theorized that a flashbulb memory-like effect should occur in rats that are given a stressful experience. We have assessed the effects of two kinds of arousing stimuli, footshock or predator (cat) exposure, on a rat's memory for an incidental (emotionally neutral) event.We hypothesized that either form of arousing stimulus (shock or cat) would enhance incidental memory, but only when the arousing event occurred close in time to the neutral experience. Adult male SD rats were habituated to an open field (OF) on 3 consecutive days. On Day 4 (training), the rats were placed in the OF which contained two identical objects. All behavioral manipulations occurred prior to or after OF exposure on Day 4. Memory retrieval was assessed on Day 5, when the rats were returned to the OF, which contained an identical (familiar) object and a novel object. Increased time spent around the novel, relative to the familiar, object was an index of enhanced memory. We have found that 2 min of cat exposure, either immediately before or after training (on Day 4), enhanced novel object memory on Day 5. The memory enhancement effect occurred only if the onset of cat exposure occurred within 2 min, but not 30 min, before or after training. We also found that the 2 min cat-induced enhancement of memory was mimicked by injection of epinephrine (0.1 mg/kg, ip) immediately before or after training, and was blocked by propranolol (beta antagonist). Administration of CPP (5.0 mg/kg, ip) blocked the memory enhancement produced by 2 min cat exposure. In contrast, we found that footshock had no effect on novel object memory, despite generating fear memory (freezing) to the context in which the shock occurred. That is, memory for the shock, itself, was indicated by freezing behavior to the context, but this stimulus did not enhance memory for the incidental stimuli occurring close in time to the shock. These findings indicate that predator exposure exerts a qualitatively different effect on memory processing than footshock, suggesting that a life-threatening experience gains greater access to trauma memory processes than does a painful stimulus. These findings may prove to be relevant toward enhancing our understanding of the neurobiology of traumatic memory processing.

Title: Amygdala PKM zeta increases with functional emergence of amygdala-dependent fear learning in rat pups

Authors: *P. A. SERRANO[1], L. MICHELSON[2], R. M. SULLIVAN[2];
[1]Dept of Psychology, Hunter Col. and City Univ. of New York, NEW YORK, NY; [2]Child & Adolescent Psychiatry, Nathan Kline Institute, New York Univ., New York, NY

Abstracts: During infancy rapid learning associated with attachment and orientation to a caregiver is essential to survival. This developmental period also prevents the acquisition of avoidance learning. In rodent models this developmental time window occurs prior to post-natal day 10 (PND 10), during which pups display heightened preference learning accompanied by decreased aversion learning. PND 10 rats presented with odor-shock pairings fail to avoid the odor associated with shock, and show a preference for the paired odor. Older pups (PND-12) given odor-shock pairings develop an aversion to the odor at subsequent test. Even though pups at any age find the shock itself aversive, as measured by vocalizations and overall activity. One key developmental mechanism that appears to direct the change from a preference for the odor associated with shock to an aversion, involves the activation of the amygdala by corticosterone. Corticosterone is low in pups during the sensitive period and increases at PND 10. We investigate synaptic markers which may be important for establishing the avoidance memory and that are likely activated by corticosterone. Recently, protein kinase M zeta (PKMζ), which is important for late-phase LTP and long-term memory, is also upregulated during stress (Sebastian et al 2013, PLoS One, vol 8, e79077). Therefore, we investigated the role of PKMζ in avoidance vs preference learning in rat pups using the paired odor-0.5mA shock fear-conditioning paradigm. PND 8 and PND 12 pups were given either paired (simultaneous odor and shock) or unpaired (shock 2 min after odor) training and tested 24hr later on a Y maze with one arm containing the conditioned stimulus (CS) odor and the other a familiar odor. Immediately after Y maze test, pups were sacrificed and amygdalae were harvested. The tissues were separated into cytosolic and synaptic cellular fractions. Each fraction was analyzed by Western blots. Pups in

the unpaired condition showed no preference for either arm. PND 8 paired pups in the paired condition preferred the CS odor and PND 12 pups avoided the CS odor ($p<0.01$). PND 12 in the paired condition had higher cytosolic PKMζ in the amygdala compared to unpaired pups ($p<0.05$) with no change in synaptic PKMζ. PN8 paired did not show any changes in cytosolic or synaptic PKMζ. Thus, increased PKMζ expression following the sensitive period plays a role in the activation process of the amygdala and the formation of aversive memories.

Title: Lack of neuroendocrine and behavioral habituation after repeated predatory threat in mice

Authors: ***K. S. GOMES**[1], A. C. CIPRIANO[1,2], R. L. NUNES-DE-SOUZA[1];
[1]Univ. Estadual Paulista, Araraquara, Brazil; [2]Joint Grad. Program in Physiological Sci., Ufscar/UNESP, Brazil

Abstracts: Predator exposure is a naturalistic stressor of high ethological relevance. As such, determining mechanisms underlying predator-related stress responses are valuable to understand how endogenous stress-related disease processes are initiated and perpetuated. Here we evaluate the impact of chronic predator exposure on the behavior and corticosterone levels of mice. Male Swiss mice (n=7-9) were repeatedly exposed to a toy or to a predator on the rat exposure test (RET) paradigm for seven days. Independent groups were sacrificed 5, 20 or 50 minutes after beginning of the exposure and trunk blood was collected for corticosterone quantification. The RET comprises a prey-predator based model that provides a home chamber connected via tunnel to a surface area in which a wire mesh prevents the predator (rat) from approaching or contacting the mouse subject. During a 10-min session in the RET, mice were exposed to a rat and the frequency of entries and time (in seconds) spent on each compartment of the apparatus, risk

assessment behavior (stretched attend postures, SAP), immobility, defensive burying (from the home chamber towards tunnel), as well as contact and climbing the wire mesh were scored. Compared to the toy-exposed group, mice repeatedly exposed to a rat exhibited a higher corticosterone level after 5 minutes (21 vs. 12 μg/dL, $p<0.05$) but not after 20 or 50 minutes from beginning of stress ($p>0.05$). Furthermore, the behavioral analysis revealed that the mice exposed to a rat spent more time on distal compartments of the RET apparatus compared to the control group, as well as exhibited more risk assessment behavior (time and frequency) and immobility time and less time in contact or climbing the wire mesh ($p<0.05$). The results show that, unlike other chronic homotypic stress regimens (e.g. repeated restraint stress), repeated rat exposure facilitated corticosterone secretion after the 7th day and indicate that predator stress engages a unique pattern of neuroendocrine activation that may contribute to long-lasting changes in brain stress responsivity. Moreover, the behavioral data also show that there is no habituation to the predatory threat after successive exposures. Further experiments are being conducted to determine the pattern of neural fos activation in areas of the brain defense system.

Title: Role of Neurokinin B-expressing neurons in the basolateral amygdala in fear and fear extinction

Authors: *R. O. TASAN[1], G. LACH[1], J. WOOD[1], D. VERMA[2], S. WEGER[3], R. HEILBRONN[3], G. SPERK[1];
[1]Inst. of Pharmacology, Med. Univ. Innsbruck, Innsbruck, Austria; [2]Inst. of Physiol. I (Neurophysiology), Westfälische Wilhelms-Universität, Münster, Germany; [3]Inst. of Virology, Charité - Univ. Med., Berlin, Germany

Abstracts: Anxiety disorders constitute a major burden for the society and are characterized by pathological expression of anxiety and fear. Among the different brain areas involved in the encoding and modulation of fear memories the amygdala plays an exceptionally important role. Intrinsic and extrinsic amygdala connections are predominantly mediated by glutamate and GABA, but the resulting behavioral response is fundamentally shaped by various neuromodulators, including different neuropeptides. Despite extensive investigations, the role of many of these neuropeptides is still poorly understood. Among the neuropeptide family of tachykinins, substance P is promoting anxiety-related behavior, whereas the role of neurokinin B (NKB) that is abundantly expressed in different amygdala nuclei is not clear yet. Thus, we wanted to investigate the role of NKB and NKB-expressing neurons in the amygdala in fear conditioning and extinction. To test the specific role of NKB-expressing neurons in the basolateral amygdala (BLA), Tac2-Cre mice were locally injected into the BLA with a Cre-dependent rAAV-vector expressing tetanus-light-chain (TeLC) or rAAV-hM3Dq for specific and local permanent silencing or for transiently activating NKB neurons, respectively, followed by Pavlovian fear conditioning two weeks later. Pavlovian fear conditioning was used as a simple form of associative learning by pairing a tone with a mild electric food shock. Fear extinction was performed the following day by repetitive exposure to the tone without foot-shock. Inhibition of NKB-expressing neurons in the BLA did not affect fear acquisition or context fear but resulted in reduced expression of tone-induced freezing and facilitated extinction learning. This change was also observed in extinction recall, demonstrating a persistent effect of NKB neuron inhibition in the BLA. Interestingly, inhibition of all GABA-ergic neurons in VGAT-Cre mice resulted in increased fear and delayed extinction, indicating a highly specific function of NKB neurons in the BLA. Together our data indicate that inhibition of NKB-expressing neurons in the BLA reduces the expression of fear while facilitating fear extinction. Further studies will clarify the exact mechanism and the contribution of NKB itself in this process.

Title: Protein synthesis inhibitor (anisomycin) microinjected into medial prefrontal cortex, amygdala or dorsal hippocampus disrupts the consolidation of step-down inhibitory avoidance in mice

Authors: *L. CANTO DE SOUZA[1], R. MATTIOLI[2];
[1]Univ. de Sao Paulo, Araraquara, Brazil; [2]Univ. Federal de São Carlos, São Carlos, Brazil

Abstracts: Several studies using inhibitory avoidance models have demonstrated the importance of limbic structures as the amygdala, dorsal hippocampus and medial prefrontal cortex on emotional memory. On the other hand, there are few studies assessing the involvement of these limbic structures on the emotional memory of mice exposed to step-down inhibitory avoidance. Therefore we aimed to investigate the role of the medial prefrontal cortex, amygdala and dorsal hippocampus, through bilaterally microinfusions of anisomycin (ANI-40µg/µl; a protein synthesis inhibitor), on the modulation of emotional memory in mice subjected to the step-down model. We observed that microinfusions of anisomycin into the medial prefrontal cortex, amygdala and dorsal hippocampus prevent the increase in latency observed in control groups during the test. We suggest that protein synthesis in the medial prefrontal cortex, amygdala and dorsal hippocampus of mice is independently necessary for the consolidation of emotional memory of mice in the step-down inhibitory avoidance model, and that step-down inhibitory avoidance task is also an interesting model to infer emotional memory in mice.

Title: Release of glutamate from ventral tegmental inputs into the lateral habenula elicits aversive conditioning

Authors: *D. H. ROOT[1], C. A. MEJIAS-APONTE[2], M. MORALES[2];
[1]Natl. Inst. On Drug Abuse, Baltimore, MD; [2]Neuronal Networks Section, Natl. Inst. on Drug Abuse, Baltimore, MD

Abstracts: Ventral tegmental area (VTA) activity is involved in the detection and prediction of rewarding stimuli. However, VTA has been shown to also be activated by aversive stimuli. Though the circuits involved in VTA participation in aversion are unclear, activation of glutamatergic inputs to VTA from lateral habenula (LHb) elicits conditioned aversion. Here we show that a glutamatergic input to LHb from VTA also elicits conditioned aversion. Channelrhodopsin2-eYFP (ChR2) or eYFP was expressed in VTA vesicular glutamate transporter 2 neurons of VGluT2::Cre mice. Bilateral optical fibers or cannulae were implanted dorsal to LHb. Using a place conditioning procedure, mice traversed a three chamber maze over several sessions. During training, when mice entered a randomly assigned Paired chamber, light was continuously delivered (473 nm, 5-10 mW, 10 ms duration, 50 ms period) until mice exited the Paired chamber. Light was not delivered in any other chamber. During training, ChR2-eYFP mice but not eYFP mice, spent more time in the Unpaired chamber in which light activation of ChR2 mesohabenular axon terminals did not occur. In the absence of light stimulation, ChR2-eYFP mice demonstrated a conditioned place aversion to the Paired chamber that was previously associated with light delivery. Following the reverse of Paired and Unpaired chamber light-delivery contingencies ChR2-eYFP mice, but not eYFP mice, spent more time in the chamber that did not result in light delivery. During a Reversal Test in which light was not delivered, ChR2-eYFP mice spent more time in the chamber that was not associated with light delivery, demonstrating the formation of a new conditioned place aversion. eYFP mice never formed conditioned place preference or aversion. To determine if LHb glutamate receptors participate in light-elicited aversion, another group of ChR2-eYFP mice was tested in the following manner. The chamber in which mice spent more time during baseline in the absence of light delivery was selected as the Paired chamber. A mixture of AMPA and NMDA antagonists (CNQX and AP5), or vehicle, was injected into LHb prior to being placed in the maze and light was delivered to LHb when mice entered the Paired chamber. Glutamate receptor antagonist injection in LHb resulted in no significant change from baseline time spent in any chamber. aCSF injection in LHb resulted in ChR2-eYFP mice spending more time in the Unpaired chamber and less time in Paired chamber, demonstrating that aversion elicited by light activation of ChR2 terminals from VTA VGluT2 neurons is dependent on LHb glutamate receptors. We conclude that a glutamatergic pathway from VTA to LHb plays a role in aversion and its conditioning.

Title: Gabaergic activation in the basomedial amygdala reduces the tonic immobility response in guinea pigs: A innate fear behavior

Authors: ***B. B. DE PAULA**, J. R. MELO, R. L. SPINIELI, C. R. A. LEITE-PANISSI; Morphology, Physiol. and Pathology Basic, Univ. of São Paulo, Ribeirão Preto, Brazil

Abstracts: The defensive behavior of tonic immobility is associate with intense danger. In laboratory, this response is easily induced, and it may represent a model for study of the innate fear. Also, the amygdala has a critical role in the emocional mean of the sensory stimuli and modulation of the unconditioned and conditioned fear. In particular, the basomedial nucleus of the amygdala (BMA) participates in fear modulation, being responsable, together with lateral nucleus of the amygdala, by integration of the cognitive processing of the predator presence. In this context, GABAergic neurons exert a tonic control on neural substrates involved in expression of defensive reactions. The aim of this study was evaluated the involvement of GABAA and GABAB receptors of BMA in tonic imobillity response in guinea pig. Guinea pigs (n = 77, CEUA: 12.1.202.53.7) were anesthetized and submitted to surgery for guide canulla implate into the BMA. Afterward, guinea pigs were divided in groups for administration intra-BMA of Bicuculline (BIC; GABAA antagonist; 0.1µg/0.2µl and 0.5µg/0.2µl), Muscimol (MUS; GABAA agonist; 0.1µg/0.2µl and 0.5µg/0.2µl), MUS (0.5µg) preceded by BIC (0.1µg), Baclofen (BAC, GABAB agonist, 0.1µg/0.2µl and 0.5µg/0.2µl), Faclofen (FAC; agonist GABAA; 0.1µg/0.2µl and 0.5µg/0.2µl), FAC (0.5µg) preceded by BAC (0.1µg). Immediately after the treatment, the animals were submitted to TI response or the open field test (OF). Statistical analysis (One-Way ANOVA) was applied followed by Tukey test, with $P < 0.05$. The MUS and BAC reduced TI duration ($F_{6,4}=14.16$, $P < 0.001$ and $F_{5,29}=11.678$, $P < 0.001$, respectively) when compared with their respective controls ($P < 0.05$, Tukey). In contrast, BIC and FAC increased TI response ($F_{6,34}=5.827$, $P=0.002$ and $F_{5,29}=10.828$, $P<0.001$) compared to their respective controls. Further, BIC and FAC blocked the decrease in TI induced by MUS or BAC ($F_{4,24}=6.646$, $P=0.002$ and $F_{4,24}=5.445$, $P=0.006$). Furthermore, in the OF test, activation or blockade of GABAA and GABAB receptors into BMA did not alter the locomotion in guinea pigs, at the doses that were effective to produce changes in TI response. These results suggested that GABAA and GABAB receptors activation into BMA reduced TI responses, probably due to reduced innate/unconditioned fear. This reduce was not due to altered spontaneous motor activity, which may non-specifically affect TI behavior.

Title: Evidence for the thalamic targets of the medial hypothalamic defensive system mediating emotional memory to social defeat

Authors: *M. J. RANGEL, JR, N. S. CANTERAS;
Univ. De São Paulo/Instituto De Ciências Biomédicas, São Paulo, Brazil

Abstracts: We have documented that the medial hypothalamic defensive system is involved in processing defensive behavior to social defeat, and that the dorsal premammillary nucleus (PMd) represents a key hypothalamic site for the expression of defensive behaviors to social threats. Anatomical findings suggest that the PMd is also in a position to modulate memory processing through a projecting branch to the ventral part of the anteromedial nucleus (AMv). In the present study, we investigated the role of this thalamic target in mediating emotional memory to social defeat. Using NMDA iontophoretic lesions, three experimental groups were analyzed: AMv lesioned animals; Reuniens (RE) lesioned animals and intact animals. During social attack by the aggressor (resident male), intruder animals from all experimental groups exhibited intense defensive responses remaining most of the time freezing and avoiding the aggressive co-specific. ANOVA analysis revealed that during exposure to the environment previously associated with the social defeat, the animals with bilateral AMv lesions (n=7) presented significantly less contextual fear responses, such as as risk assessment (29.3 ± 8.1; p=0.00009), and spent significantly more time in the resident cage (176.8 ± 41.1; p=0.00003), when compared to animals with RE lesions (n=4; risk assessment: 168.0 ± 45.2; time spending in resident cage: 85.2 ± 33.7) and intact animals (n=7; risk assessment: 177.8 ± 15.4; time spending in resident cage: 22.9 ± 10.3). Overall, the present results support the idea that the AMv, one of the main thalamic target of the medial hypothalamic system, is critically involved in the emotional memory processing related to social defeat.

LABEX BRAIN (ANR-10-LABX-43)

Title: CB1 receptors in the medial habenula control emotional behavior

Authors: *E. SORIA[1], A. MEHIDI[2], A. BUSQUETS-GARCIA[2], L. ROUX[2], L. ALONSO[2], I. LOUIT[2], T. WIESNER[2], D. VERRIER[2], A. CANNICH[2], F. GEORGES[3], G. MARSICANO[2]; [1]INSERM U862, Bordeaux, France; [2]INSERM, Bordeaux, France; [3]CNRS, Bordeaux, France

Abstracts: The habenula (Hb), divided in lateral (LHb) and medial (MHb) subregions, is involved in the regulation of emotion. Particularly, the projections from the MHb to the interpeduncular nucleus (IPN) play an important role in anxiety and fear responses. However, the molecular mechanisms participating in these processes are poorly understood. Many of the functions mediated by the MHb-to-IPN circuit, such as the control of anxiety, are also known to be under the control of the endocannabinoid system (ECS). The expression of CB1 receptors in this circuit suggests that ECS could mediate the functions of this brain region. However, no studies have addressed this issue so far. The presence of cannabinoid receptors (CB1) on habenular cells is the prerequisite for the definition of the impact of the ECS on the functions of this brain region. In this work we showed that CB1 receptors are functionally expressed in the MHb-to-IPN circuit, participating in the control of fear expression potentially by selectively modulating cholinergic transmission in the IPN.

Title: Connections between the hippocampus, amygdala and prefrontal cortex: Circuits that drive fear learning and extinction

Authors: *P. SAH[1], R. MAREK[2];
[1]Queensland Brain Inst., St Lucia, Australia; [2]Queensland Brain Institite, The Univ. of Queensland, Brisbane, Australia

Abstracts: The hippocampus, amygdala, and medial prefrontal cortex (mPFC) form a tripartite neuronal circuit are key players in fear learning and extinction. Activity within the infralimbic medial prefrontal cortex (IL) has been shown to enhance fear extinction through synaptic connections to the amygdala. Moreover, the ventral hippocampus (vHPC) sends unidirectional projections to the mPFC. Lesioning of the vHPC alters IL activity and disrupt the encoding of fear extinction. Using retrograde tracers and optogenetics, combined with whole-cell recordings *in vitro* we have studied the neural circuits within the mPFC and their connections with the amygdala and vHPC. We describe the intrinsic connections with the mPFC and show that connections between the prelimbic medial prefrontal cortex (PL) and IL are unidirectional with L5/6 neurons in PL projecting to similar neurons in the IL. We show that vHPC projections to the mPFC largely target the IL. The PL receives moderate projections from the vHPC that show a rostro-caudal organisation. vHPC input is strongest onto fast spiking interneurons, which in turn produce large disynaptic inhibitory potentials in pyramidal neurons in both L2/3 and L5/6 pyramidal neurons, some of which send projection to the amygdala. This large inhibition shows adaptation to low frequency stimulation, and is capable of increasing the firing threshold of pyramidal neurons in the IL. These data show that vHPC-driven feed-forward inhibition controls the excitability of IL pyramidal neurons, and suggests a neural mechanism for the context dependency of extinction.

Title: Cross-fostering between Hatano high and low active avoidance rats altered emotional reactivity of male offspring

Authors: *Y. HORII[1,2], R. OHTA[3], K. TAKAHASHI[1], Y. SATO[1], K. SATO[1], S. NAKAJIMA[1], Y. SHIRAISHI[1], M. KAWAGUCHI[1];
[1]Meiji Univ., Kanagwa, Japan; [2]Natl. Inst. of Genet., Shizuoka, Japan; [3]Hatano Res. Inst., Kanagawa, Japan

Abstracts: It is important to develop a better understanding of how brain development and behavior are influenced by environmental stimuli such as maternal care, through these stimuli effects on epigenetic programming. For instance, rat offspring reared by high- licking and grooming (LG) dams are less fearful and show more modest hypothalamic-pituitary-adrenal (HPA) responses to stress than those reared by low-LG dams. Inbred strains of Hatano high- (HAA) and low- (LAA) active avoidance rats, which were originally selectively bred on the basis of respective high or low avoidance performance in an active avoidance task, show no strain differences in maternal LG behavior. However, in a preliminary experiment male HAA offspring reared by LAA dams showed reduced emotional reactivity in an elevated plus maze (EPM) test than HAA offspring reared by HAA dams. The aim of the present study is to confirm this earlier finding and to investigate detailed characteristics of maternal behavior. We prepared 4 experimental groups: HAA and LAA pups reared by unrelated HAA and LAA dams, respectively (in-fostering), and HAA and LAA pups reared by LAA and HAA dams (cross-fostering). First, we compared emotional reactivity of the male offspring using the EPM test and found both genetic and foster dam strain effects on emotional reactivity of male offspring. The HAA offspring showed higher anxiety-like behavior than the LAA offspring, regardless of the foster dam strain. Cross-fostering by HAA and LAA dams respectively increased or decreased emotional reactivity of the offspring. These results suggest that some maternal characteristics of each strain affected the development of emotional reactivity. Next we observed 18 types of maternal behavior, including LG, during the first 10 days postpartum. We found no differences in frequencies of LG or any of the other types of maternal behavior between the experimental groups. Thus these results suggest that some other maternal characteristics may influence the development of emotional reactivity of male offspring.

Title: Chronic treatment with fluoxetine enhances antinociception and up-regulates 5-HT1A and 5-HT2C receptors within the periaqueductal gray in mice

Authors: *D. B. SOUZA[1], R. NUNES-DE-SOUZA[2], A. CANTO-DE-SOUZA[1];
[1]Univ. Federal De São Carlos, São Carlos, Brazil; [2]Pharmacol, FCF/Unesp/Araraquara, Araraquara, Brazil

Abstracts: AIM: It has been demonstrated that selective serotonin reuptake inhibitors (SSRI) attenuate pain response in human beings and animals. In addition, we have observed that the confinement of mice in the open arm of the elevated plus-maze (EPM) elicits antinociception (OAA). Besides to increase the levels of serotonin in the synaptic cleft, fluoxetine can also interact with 5-HT1A and 5-HT2C receptors. Here, we investigated the effects of chronic treatment with the SSRI fluoxetine on OAA, and on 5-HT1A and 5-HT2C receptors levels in the periaqueductal gray matter (PAG) of mice. METHODS AND RESULTS: Exp. 1: Male Swiss mice (n=7-9/group) were treated with fluoxetine (FLU: 0, 5, 10 and 20 mg/kg, s.c.) for 21 consecutive days. On 21th day, each mouse received an intraperitoneal injection of 0.6% acetic acid (0.1 ml/10g weight; nociceptive stimulus) and was then confined to either the open arm (OA) or enclosed arm (EA) of the EPM for 5 minutes, when the number of writhes was recorded. Two-way ANOVA (Factor 1: place of confinement x Factor 2: treatment) followed by Duncan's test confirmed that the OA confinement induced antinociception in comparison to EA-confined animals and revealed that FLU (20 mg/kg) enhanced this type of environmentally induced pain inhibition [Factor 1: $F(7,54) = 76.34$, $P<0.05$; Factor 2: $F(7,54) = 9.39$, $P<0.05$]. Exp. 2: Male Swiss mice (n=6-9/group) were treated with fluoxetine (FLU: 0, 5 or 20 mg/kg, s.c.) for 21 consecutive days. On 21th day, 40 minutes after the last FLU injection, the animals were sacrificed and their brains removed for analysis of the 5-HT1A and 5-HT2C receptors levels in the PAG through the Western Blotting assay. ANOVA followed by Duncan's test confirmed that FLU (5 and 20 mg/kg) increased 5-HT1A [$F(2,18) = 12.49$, $P<0.05$] and 5-HT2C receptor levels [$F(2,23) = 16.40$, $P<0.05$] compared to control group. CONCLUSION: Taken together, these results (i) confirm that the OA confinement induces antinociception, (ii) indicate that FLU (20 mg/kg) enhances OAA and (iii) suggest that chronic FLU increases 5-HT1A and 5-HT2C

receptor levels within the PAG, probably facilitating the OAA. FINANCIAL **SUPPORT:** UFSCar, CNPQ, FAPESP (2009/17938-6).

Title: The affective component of pain: The role of prostaglandins

Authors: *A. K. SINGH, M. FRITZ, A. M. KLAWONN, D. ENGBLOM;
Dept. of Clin. and Exptl. Med., Linköping Univ., Linköping, Sweden

Abstracts: Pain is characterized by two major components: the sensory (localization, intensity and quality) and the affective component (unpleasantness). The neural circuits and molecular mechanism underlying pain sensation have been extensively studied, but we are only now beginning to understand those responsible for the affective component. In the present study, we have investigated the role of prostaglandins in the affective component of pain. To study the affective component of pain we used a formalin-induced conditional place aversion (CPA) paradigm in mice. Normal mice showed a robust pain-induced aversion. The aversion was blocked by genetic or pharmacological inhibition of cyclooxygenase 2 (COX2) whereas inhibition of COX1 had no major effect. Deletion of COX2 in myeloid cells had no effect but COX2 deletion specific to the nervous system strongly attenuated the aversion. Mice lacking microsomal prostaglandin E synthase 1 (mPGES1) also showed an attenuated aversion indicating that prostaglandin E2 is the critical prostaglandin involved. Finally, we observed attenuation in the aversion of mice lacking EP2 prostaglandin E2 receptors while there was no change of CPA in mice lacking EP1 receptors. To determine if peripheral pain signaling is affected in the mutant mice, Fos-induction in the dorsal horn of the spinal cord will be measured. Overall, our results suggest that the discomfort and aversion induced by pain is controlled by neuronal COX2, mPGES1, and EP2 receptors.

Title: Role of TRPV1 channels of the dorsal periaqueductal gray in the modulation of phasic and tonic pain in mice

Authors: *D. C. MASCARENHAS[1,2], K. S. GOMES[1], R. L. NUNES DE SOUZA[1,2]; [1]Sch. of Pharmaceut. Sciences/ UNESP, Araraquara, Brazil; [2]Joint Grad. Program in Physiological Sci., Sao Carlos, Brazil

Abstracts: Previous findings have suggested that the TRPV1 channels located within the periaqueductal gray (PAG) play a role in the modulation of acute pain in rats. For instance, intra-PAG capsaicin (a TRPV1 agonist) increased the nociceptive responses assessed in the tail-flick and plantar tests. As far as we know there are no studies investigating the role of the TRPV1 channels of the PAG in the modulation of tonic pain. This study attempted to elucidate the role of TRPV1 channels within the dorsal PAG (dPAG) in the modulation of the phasic (assessed in the tail-flick test) and tonic (assessed in the formalin test) types of pain. Male Swiss mice (n=5-8) were surgically implanted with guide cannula targeted to the dPAG and five days later they received local injection of capsaicin (0, 0.01, 0.1 or 1 nmol/0.2 μL) or capsazepine (0, 10, 30 or 60 nmol/0.2 μL), TRPV1 agonist and antagonist, respectively, and were individually subjected to either the formalin or tail-flick tests. Results showed that both capsaicin (1 nmol; $F_{3,14}=10.31$) and capsazepine (60 nmol; $F_{3,16}=4.34$) attenuated the time spent licking the formalin-injected paw ($p<0.05$). Also, two-way ANOVA followed by Duncan test revealed that intra-dPAG capsaicin dose-dependently increased the latency of nociceptive response assessed in the tail-flick test [treatment ($F_{3,18}=42.09$, $p<0.05$); analgesia index ($F_{6,108}=31.34$, $p<0.05$); interaction ($F_{18,108}=13.96$, $p<0.05$)]. In contrast, intra-dPAG capsazepine decreased the tail-flick latency in mice [treatment ($F_{3,14}=9.45$, $p<0.05$); analgesia index ($F_{6,84}=7.16$, $p<0.05$); interaction ($F_{18,84}=2.5$, $p<0.05$)]. Our results suggest that activation (with capsaicin) of TRPV1 channels located within the dPAG leads to antinociception assessed in acute and tonic tests of nociception in mice. Curiously, the blockade of these channels with intra-dPAG capsazepine (60 nmol)

produces pro-nociceptive and antinociceptive effects in mice exposed to the tail-flick and formalin tests, respectively. Although further studies are needed to clarify these apparently inconsistent effects provoked by capsazepine, we cannot neglect that they may be due to the activation of distinct neural circuitry induced by different types of nociceptive stimuli [thermal stimulus (tail-flick test) × chemical stimulus (formalin test)].

Title: Role of amygdala, insula and anterior cingulate cortex in the modulation of nociceptive response and pain empathy in mice

Authors: *A. CANTO-DE-SOUZA[1,2,3], V. PELARIN[1,3], D. BAPTISTA-DE-SOUZA[1,3]; [1]Psychobiology Group, Dept of Psychology, UFSCar, Sao Carlos, Brazil; [2]Grad. Program in Psychology, UFSCar/São Carlos, Brazil; [3]Joint Grad. Program in Physiological Sci., UFSCar/UNESP, Brazil

Abstracts: It has been suggested that limbic structures [e.g., amygdala (Amy), anterior cingulate cortex (ACC) and insula (Ins)] play a role in the modulation of pain and empathy in human beings. Previous studies have indicated that rodents also express pain empathy to a conspecific. Here, we investigated the role of Amy, ACC and Ins in the modulation of nociceptive response in mice living together with a cagemate with chronic pain. Male Swiss mice were housed in groups (Experiment 1) or in pairs (Experiment 2). The role of the brain areas in the modulation of the nociceptive empathy was assessed through the local injection of cobalt chloride ($CoCl_2$), which produces synaptic non-selective inactivation. In Experiment 1, mice received bilateral intracerebral injection of saline (0.1 µl) or $CoCl_2$ (1mM/0.1 µl) and, 10 min later, were subjected to the writhing test [intraperitoneal (i.p) injection of 0.6% acetic acid, nociceptive stimulus]

during a 5-min period, when the number of writhes was recorded. On the dyads (Experiment 2), animals lived together for 28 days since weaning. On 14th day, one animal of each pair was surgically subjected to a sciatic nerve constriction (SNC) or not (sham). On 24th day, the cagemate underwent a stereotaxic surgery to implant guide cannulae in the Amy, ACC or Ins. On 28th day, each mouse received intracerebral injection of saline or $CoCl_2$ and, 10 min later, was subjected to the writhing test, as described in Experiment 1. While inactivation of the Amy increased the number of writhes, inhibition of the ACC or Ins did not alter nociception, suggesting a distinct modulatory role of these structures on the sensorial compound of pain (Exp. 1). In Experiment 2, mice living together with a SNC-cagemate expressed higher frequency of abdominal writhing induced by 0.6% acetic acid i.p. in comparison to the control group (living with sham-operated mouse), suggesting that this experience activates the circuitry of neural representation of pain on the observer mouse (state of 'priming'). Inactivation of Ins and Amy produced opposite effects on nociception i.e. it decreased and increased, respectively, the abdominal contortions in those animals that lived together with a SNC cagemate mouse. ACC inactivation did not alter writhing behavior. Our results suggest that Amy and Ins differentially modulate pain empathy in mice.

Title: Role of neuronal nitric oxide synthase neurons located in the medial prefrontal cortex on restraint-induced long lasting anxiety in rats

Authors: *F. S. GUIMARAES, C. VILA-VERDE, A. Z. MARINHO, A. B. SONEGO; Pharmacol., Sch. Med. Ribeirao Preto-Usp, Ribeirao Preto, Brazil

Abstracts: Neurons expressing the neuronal isoform of the nitric oxide synthase (nNOS) enzyme are located in brain areas related to defensive responses such as the dorsolateral periaqueductal grey, dorsal premammilary nucleus, medial amygdala and medial prefrontal cortex (mPFC). Rats exposed to a live predator (a cat) show increased anxiety and expression of nNOS neurons in the mPFC one-week later. The present study aimed at investigating if restraint stress, another procedure known to induce long-lasting anxiogenic effects, would also be associated with increased nNOS expression in the mPFC. In addition, we also verified if inhibition of this enzyme in the mPFC would be anxiolytic in restrained animals. Male Wistar rats were forced restraint for 3-h. Twenty-four or 7 days later they were tested in the elevated plus maze. Immediately after, their brains were removed and nNOS expression in the mPFC was evaluated by immunohistochemistry. Independent groups of animals had bilateral cannulae implanted into the prelimbic (PL) mPFC. Five to seven days after surgery the animals were forced restraint (3-h) and tested in the EPM 24-h later. Ten min before the test they received bilateral microinjections of the selective nNOS inhibitor n-propyl-l-arginine (NPL, 0.04 nmol) or vehicle (saline, 0.2 μL). Restraint stress increased (28% to 49%) the number of neurons expressing nNOS in the prelimbic, but not in the infralimbic, mPFC both 24-h and 7 days after restraint. The number of nNOS neurons was negatively associated with the percentage of open arm entries in the EPM (r=-0.702 and -0.539). Restraint stress decreased open arm exploration 24-h later (percentage of open arm entries, control: 36.2 ± 4.6, restraint:19.8 ± 7.6). This effect was prevented by intra-PL microinjection of NPL (drug versus stress interaction, $p<0.05$). The results suggest that nNOS expression changes in the prelimbic mPFC could be related to the long-lasting anxiogenic effects of inescapable stressors such as forced restraint.

Title: Tempol protects anxiogenic drug induced anxiety-like behavior in rats

Authors: *G. D. PATKI, A. SALVI, H. LIU, F. ATROOZ, S. SALIM;
Univ. of Houston, Houston, TX

Abstracts: We have published that pharmacological induction of oxidative stress (OS) causes anxiety-like behavior in rats. We also have established that psychological stress induces OS and leads to anxiety-like behavior in rats. All evidence points towards a causal role of OS in anxiety-like behavior. In this study we have examined whether anxiety-like behavior induced directly via anxiogenic drugs can be prevented using agents (adenosine receptor agonist, caffeine, 50mg/kg or the partial inverse agonist of the GABAA receptor, FG-7142, 7.5mg/kg) that minimize OS. Osmotic pumps were either filled with antioxidant tempol or saline. The pumps were attached to the catheter leading to the brain cannula and inserted into the subcutaneous pocket in the back of the rat. Continuous i.c.v. infusion of saline or tempol in the third ventricle of the brain (4.3mmol/day) was maintained for 1 week by attachment of the infusion cannula to an osmotic pump. On the test days rats were injected i.p. with either saline vehicle or the anxiogenic drugs. Each of these drugs have been reported to cause increased vigilance and arousal behaviors in rat's home cage environments from 2-3 hr following drug administration compared with vehicle-injected controls. Two hours following drug injection all groups were subjected to behavioral assessments. Anxiety-like behavior tests (open-field, light-dark and elevated plus maze) suggested that tempol prevented anxiogenic drug-induced anxiety-like behavior in rats. Biochemical data suggests significant differences in the levels of stress (assessed via corticosterone assay) and oxidative stress (analyzed via 8-isoprostane and protein carbonylation) in rats.

Title: Differential analgesic and anxiolytic effects of neuropeptide Y into periaqueductal gray of rat

Authors: *P. V. LEÓN[1,2], J. PACHECO-ROSADO[2], L. MENDOZA-RUIZ[2], A. MIRANDA-PÁEZ[2];
[1]Colonia Prohogar, Distrito Federal, Mexico; [2]Fisiology, Inst. Politécnico Nacional, Mexico City, Mexico

Abstracts: Neuropeptide Y (NPY) which is highly conserved across animal species, is the most abundant neuropeptide in the central nervous system of mammals, is located mainly in the hypothalamus, septum, nucleus accumbens and periaqueductal gray (PGA). The PAG has gained importance due to their relation to analgesic mechanisms, immobility response, aggressive reactions, fear and fight or flight, all of which can be considered as integrated defensive behaviors. In the current study the differential effects of NPY in the dorsal and the ventrolateral columns of the PAG on analgesia, defensive behavior and anxiety were assessed. Adult male Wistar rats were used and subjected to stereotactic surgery to insert one guide cannula aimed at the dorsolateral or ventrolateral PAG columns for microinjection of NPY [Leu31, Pro34] dissolved in ISS (0.0, 0.23, and 0.47 nmol). The effect of NPY was assessed by testing tail flick (TF), immobility response by clamping the neck (IRCN), elevated plus maze (EPM) and defensive burying (DB). The NPY microinjected in VL-PAG or D-PAG exerts a significant analgesic effect because the tail flick latency was increased at all doses. The NPY injected in the VL-PAG significantly reduces the IRCN at both doses used, and into the D-PAG only with the dose of 0.47 nmol/1 µl compared between columns of PAG. NPY has a significant anxiolytic effect produced by the injection of 0.23 nmol/ 1 µl into the VL-PAG because it increases the dwell rate in open arms of EPM; oppositely, NPY applied into D-PAG has an anxiogenic effect at 0.47 nmol/1 µl, since it significantly reduces the dwell rate in open arms. It was confirmed in the DB test that NPY has an anxiolytic effect when injected into the VL-PAG at both doses; and within the D-PAG it has an anxiogenic effect only at a dose of 0.23 nmol / 1 µl; however, at 0.47 nmol/ 1 µl, its effect turns anxiolytic. NPY has a significant analgesic effect either ventral and dorsal PAG assessed through tail-flick test; NPY decreases IRCN probably due to an anxiolytic effect at this level and has a potent anxiolytic effect which is more apparent within the VL-PAG when assessed through aimed tests of EPM and DB.

Title: Deep brain stimulation of the ventral striatum attenuates avoidance but not approach behaviors in rats

Authors: *T. J. BANASIKOWSKI, A. A. GRACE;
Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstracts: Approximately two-thirds of people with OCD exhibit compulsions that are performed to protect them from negative consequences, even though they cognitively know the fear is irrational. Such avoidance behaviors rely on environmental triggers that are linked to aberrant frontal-cortical-limbic-basal-ganglia circuit activity - implicated in impulse control, reward learning and approach behaviors. Recently, deep brain stimulation (DBS) of the ventral striatum (VS) was shown to reduce refractory OCD symptoms while increasing the effectiveness of "extinction with response prevention (EXT-RP)" therapy, a process modeled after patient exposure therapy where compulsion triggers are devalued of salience. Using a rodent model of OCD-like behavior we hypothesized that DBS of VS during EXT-RP will strengthen the reevaluation of no longer salient events, thus leading to subsequent attenuation of compulsive avoidance behavior in test. Using the platform-avoidance task originally conceived by Gregory Quirk and colleagues, we trained rats to lever-press for food and avoid a shock that was predicted by a 30 second tone. The shock could be avoided if a rat stepped on a safety platform located opposite from the sucrose-delivering lever. During EXT-RP training, the platform was present but obstructed and the tones were no longer punished with a shock (stimulus devaluation/reevaluation). On the test day, rats again had access to the platform to examine if tones continued to elicit avoidance behavior (now compulsive). Bilateral DBS stimulation of VS significantly enhanced devaluation of avoidance-triggering stimulus (tone) during EXT-RP compared to non-stimulated animals. The decrease in avoidance following EXT-RP was not associated with changes in approach behaviors as demonstrated by lack of significant difference in lever-press suppression ratios between DBS and non-stimulated animals. This effect was further confirmed by rats trained to lever-press for sucrose on a progressive ratio schedule in that they showed no significant change in lever-presses and break-points in sessions when DBS was given. Our findings suggest that therapeutic effects of DBS in ventral striatum are most likely due to a decrease in avoidance behaviors and not due to an increase in approach behaviors as animals failed to significantly alter their effort to obtain desirable rewards.

Title: Anxiolytic properties of protium copal in rats

Authors: ***C. CAYER**[1,2,3], D. KOLMOGOROVA[3], Z. MERALI[1], J. T. ARNASON[2]; [1]Behavioral Neurosci., IMHR / Univ. of Ottawa, Ottawa, ON, Canada; [2]Biol., Ctr. for Advanced Res. in Envrn. Genomics / Univ. of Ottawa, Ottawa, ON, Canada; [3]Psychology, Univ. Of Ottawa, Ottawa, ON, Canada

Abstracts: Introduction: The main goal of this study was to determine whether copal, an aromatic resin derived from the Protium Copal tree, elicited anxiolytic-like behavior in rats. Despite the extensive Central and South American use of this resin, there are currently no known scientific behavioral studies done with this resin and the behavioural effects of this substance are largely speculative. Background: Burning of herbs and the herbal resins has always been common to most cultures around the world. Mayan people have traditionally used copal as incense and during sweat lodge ceremonies since pre-Columbian times. Many South American cultures continue practicing these traditions today. It is generally described that copal, when burned, is mentally uplifting and calming. Methods: Behavioral measurements in rats were assessed with the elevated plus maze (EPM), social interaction (SI) and conditioned emotion response (CER) paradigms. Rats were exposed to burning copal (100 mg) over 5 minutes in smoking chamber apparatus using a unique technique and then immediately tested for each behavioral paradigm. Quantification of triterpenes in the copal resin was compared to different types of sage by analysis using mass spectrometry. Results: Copal resin smoke exposure significantly reduced anxiety-like behavior in the SI and CER tests. Moreover of the anxiolytic time window of copal resin inhalation seems short and within 10 minutes and was more profound in the social interaction context. Phytochemical analysis revealed that copal has markedly more α- and β-amyrins compared to several types of sage. Conclusion: This study shows that copal incense from Protium copal does indeed elicit some anxiolytic-like effects in rats and possibly its high α and β-amyrin content may offer us a clue to an active ingredient.

Title: The effects of acute vagus nerve stimulation on anxiety in rats

Authors: *L. J. NOBLE, C. K. MCINTYRE;
Univ. of Texas At Dallas, Dallas, TX

Abstracts: Anxiety disorders, such as posttraumatic stress disorder (PTSD) and obsessive compulsive disorder, are typically treated with cognitive behavioral therapy. In one form of cognitive behavior therapy, exposure therapy, patients are repeatedly exposed to the cues that elicit conditioned fear or maladaptive behavioral responses. Over time, conditioned responses are extinguished. Because successful extinction requires learning of new associations with conditioned cues, many studies have examined the effects of memory enhancing drugs as adjuncts to exposure therapy. Although this approach is highly effective in fear conditioned rats, results in humans with PTSD have been somewhat inconsistent. One possible explanation for

this discrepancy is, when the conditioned response is not sufficiently extinguished, memory-enhancing drugs could reinforce the association between the cue and the inappropriate fear response. Optimal anxiety disorder treatments should reduce the anxiety produced by the conditioned cues while enhancing consolidation of fear extinction. Unfortunately, most anxiety-reducing drugs impair memory consolidation and thus interfere with progress in exposure therapy. Vagus nerve stimulation (VNS) is an FDA-approved treatment for the prevention of seizures. Recent research indicates that VNS enhances memory consolidation in rats and humans, and training-induced cortical plasticity and rehabilitation in animal models of stroke and tinnitus. We recently found that VNS pairing with unreinforced exposure to conditioned cues enhanced extinction of conditioned fear in rats. This effect could be due to enhanced consolidation of fear extinction. Alternatively, or additionally, VNS may facilitate extinction learning by reducing anxiety during exposure to the conditioned cues. Reduced anxiety has been observed in humans and rats following chronic VNS. However, whether VNS has immediate anxiolytic effects remains unknown. The objective of this study was to examine the effect of acute VNS administration on anxiety in male Sprague-Dawley rats. VNS was administered 10 min before or during exploration on an elevated plus maze. Because rats are neophobic, VNS was administered 1 time/day for 3 days prior to testing in some groups. Results indicate that animals given VNS with habituation spent significantly more time in the open arms of the elevated plus maze and corticosterone levels were significantly reduced in this group compared to sham-stimulated controls. These findings suggest that, following habituation, VNS reduces anxiety in rats.

Title: Lending a helping paw: GABAergic mechanisms in empathy and pro-social behaviors in rats

Authors: *B. CAMPBELL, J. E. MEYERS-MANOR, N. D. MATHEWS, E. P. WIERTELAK; Neurosci. Studies, Macalester Col., Saint Paul, MN

Abstracts: Non-human animals, here specifically rats, are capable of both pro-social behavior and responses implicating emotional contagion. The current studies set out to: 1) determine whether rats may demonstrate the ability to recognize a conspecific's distressed state from a non-distressed state, through patterns of behavior indicative of differential levels of accord with an empathetic response., and 2) Examine the role that GABAergic mechanisms may play in such responsivity. The activation of GABAergic mechanisms is highly correlated with relief from anxiety-related symptoms in humans; the question here was whether alterations in GABAergic activity might affect the performance of empathy-related activity in rats. Physiological symptoms of anxiety and distress originate in activation of brain areas associated with the limbic system. Administration of chlordiazepoxide, a prototypical GABAergic benzodiazepine agonist results in decreased levels of such responsivity. To examine whether activation of limbic system structures and GABAergic mechanisms are necessary for the emotional contagion involved in empathetically motivated behavior, in study 1, subjects from two groups of rats were placed in individual plexiglas restraining apparatuses; one habituated to the restrainer, one non-habituated (and therefore distressed). A free-roaming cagemate was then placed into the open-field containing the restrainer, which offered the option of opening the restrainer and freeing their cage-mate. Here, rats released the distressed cagemate at a greater rate on the first day of testing than those in the habituated, non-distressed group. In study 2, non-habituated distressed group received either 2 mg/kg of chlordiazepoxide or vehicle to evaluate the impact of benzodiazepines on pro-social behavior.

Title: Effect of anxiety on spontaneous activity of the prefrontal cortex and its neuronal correlates of the extra-dimensional set-shifting task performance

Authors: *J. PARK[1], C. O. BONDI[1], A. DEL ARCO[2], J. WOOD[1], B. MOGHADDAM[1]; [1]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Complutense Univ. of Madrid, Madrid, Spain

Abstracts: Anxiety is a debilitating disorder for approximately one-third of the population at some point in their lives, and it is a common symptom of many psychiatric disorders including PTSD, GAD, OCD, major depression, schizophrenia and addiction. Human and animal studies indicate that pathological manifestations of anxiety are associated with the PFC neuronal dysfunction. However, little is known about the prefrontal neuronal substrates of sustained anxiety. In this study, we first investigated the modulation of spontaneous PFC population activity in anxiety using *in vivo* electrophysiology from freely behaving rats in their home cage. The systemic administration of anxiogenic compound FG-7142 induced sustained suppression of PFC population activity, as the majority of PFC single units decreased their firing rates. We then examined how rats' cognitive task performance and its PFC neuronal correlates are modulated during the pharmacologically induced state of anxiety. Rats were trained and tested with an extra-dimensional set-shifting task that requires responses according to two discrimination rules, each involving a distinct perceptual dimension, spatial position and location of a light stimulus, to acquire food reward. The rats' task performance was bidirectionally modulated by the anxiogenic drug injection, as the response accuracy increased in trials guided by the location of a light stimulus, whereas the accuracy decreased in trials guided by the spatial position, regardless of the light stimulus. This suggests that anxiety may be associated with the response pattern biased to the sensory stimulus, but reduced cognitive control of behavior based on the task rule. The PFC single unit activities were recorded during the set-shifting task performance. Consistent with the home cage recording data, the baseline firing rates of single units tended to be lower after drug injection compared to vehicle injection. However, the PFC units tended to increase their firing rates with a greater magnitude in the peri-response period. In addition, their peri-response activity patterns differed in the two discrimination rules during performance after the drug injection, which may underlie the bidirectional modulation of response accuracy. Together, these suggest that anxiety is associated with disrupted spontaneous and task-related PFC neuronal activities that may lead to alterations in cognitive behavior.

Title: Ketamine microinjected in the prelimbic (PL) region of the PFC blunts the behavioral and neurochemical effects of inescapable stress (IS), but the PL is not necessary for systemic ketamine to blunt the effects of IS

Authors: *K. H. KUBALA[1], J. AMAT[2], R. M. ALEXSEJEV[2], J. KIM[2], L. R. WATKINS[2], S. F. MAIER[2];
[1]Psychology, [2]Univ. of Colorado, Boulder, CO

Abstracts: Sub-anesthetic doses of ketamine have been shown to have potent and rapid antidepressant and anti-stress effects, and these effects likely involve the prefrontal cortex. We have reported (SFN, 2013) that ip ketamine given 2 hrs before inescapable tail shocks (IS) blunts the increase anxiety and the increase in basolateral amygdala (BLA) levels of 5-HT typically produced by IS. Here we tested whether the prelimbic (PL) region of the prefrontal cortex is involved in such protective effects of ketamine. In the first experiment, adult Sprague Dawley rats, were microinjected with a range of ketamine doses (1, 10, 100 & 1000 ng, in 0.5 microliters) into PL, 1 hr before IS. Twenty-four hrs later exploration of a juvenile in a novel environment was measured to assess anxiety. The 10 ng dose was the only dose that prevented the increased anxiety (decreased exploration) produced by IS. Consistent with this result, PL microinjection of 10 ng ketamine prevented the increase in BLA 5-HT usually produced by IS, and did so as robustly as systemic administration of ketamine. Given this result, we tested whether the PL region is necessary at the time of stress for the protective effect of systemic ketamine. Rats received an ip injection of ketamine and 90 min later muscimol was microinjected into PL. 30 min later subjects received IS. Contrary to expectation, inhibition of neuronal activity in the PL region did not prevent the IS protective effect of systemic ketamine. In conclusion, ketamine microinjected in the prelimbic region appears to be sufficient to block the anxiogenic effect of IS, but inactivation of this prefrontal cortex region at the time of stress does not appears to prevent the protective effect of systemic ketamine.

Title: Activation of group II metabotropic glutamate receptors exerts an anxiolytic-like effect in ovariectomized female rats

Authors: *C. PINEYRO RUIZ[1], L. RIVERA ROMAN[3], S. GONZALEZ[3], N. PEREZ-ACEVEDO[2];
[1]Anat. & Neurobio., [2]Univ. of Puerto Rico Med. Sci. Campus, San Juan, PR; [3]Univ. of Puerto Rico Rio Piedras Campus, San Juan, PR

Abstracts: Anxiety disorders affect 40 million adults in the United States. Generalized anxiety disorder (GAD), one type of anxiety disorders, affects females twice more than males. It is possible that this predisposition might be due to differences in metabolite concentration such as estradiol. In hippocampal cells, estrogen receptors at the plasma membrane regulate metabotropic glutamate receptors (mGluRs). mGluRs have been also linked to anxiety modulation. 1S,2S,5R,6S)-2-Aminobicyclo[3.1.0]hexane-2,6-dicarboxylic acid (LY354740), a potent and selective group II mGluRs agonist, produces anxiolytic effects in male rodents. However, whether LY354740 produces the same effect in female rats, and whether estradiol might modulate anxiety through mGluRs interaction is still unknown. We hypothesized that the anxiolytic effect of LY354740 will be higher in ovariectomized female rats containing estradiol implants (OVX-EB) than animals containing empty implants (OVX). We evaluated GAD using the elevated plus-maze (EPM). We also evaluated risk assessment behaviors (RABs) within the EPM. RABs include flat back approach (FBA), stretch attend postures (SAP) and head dipping. We also analyzed freezing, grooming and sniffing. A Two-Way ANOVA was performed to evaluate the effect of LY354740, estradiol and the interaction between LY354740 + estradiol. We administered LY354740 (10 mg/kg) intraperitoneal 30 minutes prior to the EPM. Preliminary data shows that LY354740 significantly decreased closed arms entries in OVX-EB but not OVX female rats ($p = 0.039$). LY354740 significantly reduced FBA in OVX-EB and OVX female rats ($p = 0.001$) and SAP in OVX female rats only ($p = 0.006$). Our preliminary results suggest that in GAD, the anxiolytic-like effect of LY354740 is selective to OVX-EB female rats, suggesting an interaction between mGluRs and estrogen receptors. On the other hand, the anxiolytic-like effect of LY354740 in RABs seems to be independent upon estradiol treatment in female rats in the EPM, suggesting that the effect is due to group II mGluRs activation. Further experiments need to be done to evaluate these results.

Title: Novel acetylcholine detectors reveal that habenula cholinergic neurons regulate anxiety via nicotinic acetylcholine receptor signaling

Authors: *X. PANG[1], J. NGOLAB[1], L. LIU[1], R. ZHAO-SHEA[1], J. M. MCINTOSH[2], P. D. GARDNER[1], A. R. TAPPER[1];
[1]Umassmed, Worcester, MA; [2]George E. Wahlen Veterans Affairs Med. Ctr., Salt Lake City, UT

Abstracts: Anxiety disorders are associated with increased cigarette consumption and decreased smoking cessation, although the underlying neuroanatomical bases and molecular underpinnings of this association are unclear. Recently, the cholinergic neuron-rich habenulo-interpeduncular circuit has been implicated in modulation of anxiety. Interestingly, cholinergic neurons of the medial habenula (MHb) that project to the interpenduncular nucleus (IPN) robustly express nicotinic acetylcholine receptors (nAChRs), ligand-gated cation channels that are activated by the excitatory neurotransmitter, acetylcholine (ACh), as well as nicotine, the addictive component of tobacco smoke. To test the hypothesis that signaling through nAChRs expressed in either the MHb or IPN regulates anxiety-like behavior, we infused the nAChR receptor antagonist, mecamylamine into each region and measured anxiety-like behavior. Blockade of nAChRs in the MHb, but not the IPN, reduced anxiety-like behavior in both the elevated plus maze and marble burying test. To test the hypothesis that MHb nAChRs specifically in cholinergic neurons regulated anxiety, we expressed novel nAChR subunits that render nAChRs hypersensitive to ACh (ACh detectors) selectively in MHb cholinergic neurons of adult mice. Mice expressing ACh detector nAChR subunits exhibited increased baseline anxiety-like behavior compared to control animals. In addition, increased anxiety was alleviated by blockade of mutant receptors with a nAChR antagonist. During chronic nicotine exposure, nAChRs in MHb cholinergic neurons were functionally up-regulated. Selective blockade of these up-

regulated nAChRs in the MHb during withdrawal alleviated anxiety. Together, these data indicate that MHb cholinergic neurons regulate anxiety via nAChR signaling and point toward nAChR in the MHb as targets for novel anxiolytic and smoking cessation therapeutics.

Title: The dopamine D2 receptor is involved the anxiety-like behavior in light and dark choice test

Authors: *Y. IIDA[1], T. KOJIMA[2], H. NAGAYAMA[2], S. YAMAMORI[2], M. ITAKURA[2], T. SASAOKA[3], H. MIYAOKA[1], M. TAKAHASHI[2];

Abstracts: Anxiety disorders are one of the most frequent psychiatric illnesses and have a life-time prevalence of 15-20%. To overcome anxiety disorders, neuronal basis of anxiety should be clarified. Although it has been well documented that serotonin was one of the critical factor for anxiety disorders, a role of dopamine has not been evaluated. In the present study, we examined effects of quinpirole, a selective dopamine D2/D3 receptor agonist, on anxiety-like behaviors of mice. To evaluate anxiety-like behavior, we conducted open field test and light and dark preference test. Since the mice having increased anxiety show thigmotaxis in open field test, and a preference of dark room in light and dark preference test, we measured a percentage of time spent in the central area in open field test, and a percentage of time spent in the dark room in light and dark test. These typical anxiety-like behaviors as well as a reduction of locomotor activity were observed in both open field test and light and dark test after intraperitoneal injection of quinpirole to C57BL/6 mice in dose-dependent manners. A co-administration of haloperidol, a selective antagonist of dopamine D2/D3 receptor, with quinpirole markedly attenuated the anxiety-like behavior in light-and dark test, but not in open field test. Intraperitoneal injection of quinpirole to D2 receptor-deficient knock-out mouse still induced thigmotaxis in open field-test and a reduction of locomotor activity in open field test and light

and dark test, however no reduction of a percentage of time spent in the dark room in light and dark test was observed. From these results, we concluded that there are several distinct mechanisms for the expression of anxiety, and dopamine D2R participate at least in the expression of anxiety-like behavior in light and dark test.

Title: Chemical stimulation and inhibition of the right (but not the left) medial prefrontal cortex changes the anxiety-like behavior in mice

Authors: *R. L. NUNES-DE-SOUZA[1], N. S. COSTA[2], T. T. MIGUEL[3], M. A. VICENTE[2]; [1]Univ. Estadual Paulista, UNESP, Araraquara, Brazil; [2]Pharmacol., São Paulo State University, UNESP, Araraquara, Brazil; [3]Pharmacol., Federal Univ. of Uberlândia, Uberlândia, Brazil

Abstracts: Several brain areas (e.g., amygdala, hypothalamus, periaqueductal gray) play a role in the modulation of defensive responses. Recently, the medial prefrontal cortex (mPFC) has also been suggested as an important structure that processes emotional reactions induced by aversive stimuli. **Objectives:** This study investigated the effect of chemical stimulation [with NOC-9, a nitric oxide (NO) donor] or inhibition [with cobalt chloride ($CoCl_2$)] of the mPFC on the behavior of mice exposed to the elevated plus-maze (EPM), a widely used animal test of anxiety. **Materials and Methods**: Male Swiss mice (n=9-12) received unilateral injection of vehicle or

NOC-9 [6-(2-hydroxy-1-methyl-2-nitrosohydrazino)-N-methyl-1-hexanamine; 37.5 nmol/0.2 µl] or $CoCl_2$ (0.1 mM/0.1 µl) into the left (L) or right (R) mPFC. Five minutes later, each mouse was exposed to the EPM to record the conventional measures of anxiety (percentage of open-arm entries and percentage of open-arm time: %OE and %OT) and locomotor activity (frequency of closed-arm entries: CE) for a period of 5 minutes. **Results**: Unilateral injection of NOC-9 into the L mPFC did not change anxiety indices [%OE (t=-0.44 p=0.66); %OT (t= -0.32; p=0.74]. However, when injected into the R mPFC NOC-9 (37.5 nmol) provoked an anxiogenic-like effect, reducing the open arm exploration [%OE (t= 2.5; p< 0.05); %OT (t= 2.4; p< 0.05)]. Neither intra-LmPFC nor intra-RmPFC injections of NOC-9 changed general activity [CE; LmPFC (t=1.12; p=0.24); RmPFC: (t= -1.8; p= 0.09)]. While intra-LmPFC injections of $CoCl_2$ did not change the behavior of mice exposed to the EPM [%OE (t=1.10; p=0.28); %OT (t=1.13; p=0.27)]; CE (t=0.80; p=0.43)], intra-RmPFC CoCl2 provoked an anxiolytic-like effect, increasing the open arm exploration [%OE (t=-3.7; p<0.05); %OT (t=-2.05; p<0.05)] without changing locomotor activity [CE (t=0.91; p= 0.37)]. **Conclusions:** While chemical stimulation or inhibition of the LmPFC does not change anxiety-like behavior, intra-RmPFC injections of NOC-9 and CoCl2 increase and attenuate, respectively, open arm avoidance in the EPM. **T**hese results are suggestive that the mPFC plays a functional lateralization in the modulation of anxiety-like behavior in mice exposed to the EPM.

Title: Urocortin III injected into the amygdala does not change anxiety-like behavior in mice exposed to the elevated plus-maze

Authors: *A. C. CIPRIANO[1,2], K. GOMES[2], R. L. NUNES-DE-SOUZA[2,1];
[1]Joint Grad. Program in Physiological Sci. UFSCar/UNESP, Araraquara, Brazil; [2]Sch. of Pharmaceut. Sciences, São Paulo State University, UNESP, Araraquara, Brazil

Abstracts: We have recently observed that injections of low doses of corticotrophin-releasing factor (CRF) into the amygdala produce anxiogenic-like effects in mice exposed to the elevated plus-maze (EPM). The hypotheses that CRF plays an anxiogenic-like role at CRF receptor type 1 (CRF1) in this limbic area was strengthened by a marked anxiolytic-like effect provoked by local injection of CP376395, a highly selective CRF1 receptor antagonist. However, the role of CRF2 receptors located within the amygdala in the modulation of anxiety remains to be determined. Here, we investigated the effects of intra-amygdala injections of urocortin III, a selective CRF2 agonist, on behavior of mice exposed to the EPM. Adult male Swiss mice (N = 10-14/group) received bilateral intra-amygdala microinjections of saline or urocortin III (4, 8 or 16 pmol/ 0.1µl), and 10 min later, were individually placed to the EPM to record the conventional indices of anxiety [percentage of open-arm entries (%OE) and percentage of open-arm time (%OT)] and locomotor activity (closed-arm entries: CE) for a period of 5 minutes. One-way ANOVA revealed that urocortin III did not significantly change any behavior of mice in the EPM [%OE ($F_{3,45} = 0.25$); %OT ($F_{3,45} = 0.48$); CE ($F_{3,45} = 0.26$); $p > 0.05$]. Taken together, these results suggest that the activation of CRF2 receptors within the amygdala does not change the behavior of mice exposed to EPM. However, present results do not rule out the hypotheses that the CRF2 receptors located within the amygdala of mice play a modulatory role on anxiety assessed in the EPM.

Title: Genetic mutations in GluN2A serine and tyrosine phosphorylation sites controlled by PKC decrease anxiety-related behaviors in mice

Authors: *D. BALU[1], J. LARSON[2], J. V. SCHMIDT[1], J. P. LEONARD[1];
[1]Biol. Sci., Univ. of Illinois - Chicago, Chicago, IL; [2]Psychiatry, Col. of Medicine, Univ. of Illinois at Chicago, Chicago, IL

Abstracts: Activity-dependent plasticity in neuronal synapses could be regulated by phosphorylation of specific protein subunits that are involved in synaptic transmission. NMDAR-activation dependent long-term potentiation is a well-studied phenomenon of synaptic plasticity. Heterotetrameric NMDA receptors are composed of two GluN1 subunits and two of four different GluN2 subunits (A-D). The subunit composition of the receptor renders different physiological properties (such as activation kinetics, gating, post-synaptic protein clustering). The long C-terminal domain (CTD) of the NMDAR contains a number of serines and tyrosine residues which could be phosphorylated by a number of kinases. Currents through GluN2A-containing NMDAR were found to be diminished when specific Ser and Tyr residues in the CTD were mutated to Ala and Phe respectively. Thus, it was established that the phosphorylation of the serines (S1291 and S1312) directly by Protein Kinase C (PKC) and tyrosines (Y1292 and Y1387) indirectly via PKC activation of Src Tyrosine Kinase positively modulate the receptor currents. To understand the behavioral and physiological consequences of phosphorylation at those sites, we employed a gene targeted replacement strategy and generated *Grin2adeltaPKC* mice. *Grin2adeltaPKC* mice have site-directed mutations in two Ser and two Tyr residues (S1291A, Y1292F, S1312A and Y1387F) in the CTD of GluN2A. These mice have similar expression levels of *Grin2a* mRNA compared to their littermate controls. These mice also have similar locomotor activity and spatial working memory in a plus maze. However, they show decreased alternation (lower than chance level alternation) in a T-maze continuous alternation task which might be related to the sensitivity of the behavioral paradigm. When these mice were subjected to anxiety-associated tasks, they exhibited reduced anxiety-related behaviors such as increased time spent in the center of an open field, increased time in light side of light/dark box, and increased entries and dwell times in the open arms of an elevated plus maze. Interestingly, LTP induced by theta burst stimulation of Schaffer collateral-CA1 synapses in hippocampal slices from *Grin2adeltaPKC* mice was not impaired and in fact may have been enhanced. Presynaptic mechanisms were not involved in the impairment since there were no significant differences in input-output curves and paired-pulse facilitation between the mutant and control mice. Thus, these results suggest that PKC phosphorylation of at least one of those sites regulates NMDAR-mediated signaling that modulates anxiolytic behaviors and possibly long-term potentiation in hippocampus.

Title: Cortical projections to the amygdala in mouse

Authors: *Q. WANG, L. NG, J. A. HARRIS, S. W. OH, A. BERNARD, A. M. HENRY, M. T. MORTRUD, B. OUELLETTE, J. J. HOHMANN, C. KOCH, H. ZENG;

Abstracts: The mammalian amygdala is subdivided into several groups of nuclei. Its basolateral and centromedial nuclear groups play a pivotal role in fear-conditioned learning and emotional behavior. Recently, advantage has been taken from mouse amygdala to characterize the function of different cell types linked to these behaviors. Although cortical inputs to amygdala are important sensory sources, a comprehensive effort of brain-wide cortical inputs to mouse amygdala has not been done. Here we systematically analyzed the projections from various cortical regions to mouse amygdala using the data generated in the Allen Mouse Brain Connectivity Atlas, with viral tracer AAV as an anterograde tracer. We find that different cortical areas project bilaterally and/or ipsilaterally to different nuclei of the amygdala with different strengths. The primary auditory cortex has sparse ipsilateral projections to LA. The dorsal auditory cortex has bilateral projections to LA and ipsilateral projections to BLA. The ventral auditory cortex has ipsilateral projections to LA, BLA and medial amygdala nucleus (MEA). The primary and secondary motor cortices have bilateral projections to BLA and central amygdala nucleus (CEA). The primary somatosensory cortex has bilateral projections to LA and CEA. The supplemental somatosensory cortex has bilateral projections to BLA and CEA, and ipsilateral projections to LA. The ventrolateral orbital frontal area has ipsilateral projections to BLA and CEA. The medial orbital frontal area has bilateral projections to BLA and CEA, and ipsilateral projections to LA, basomedial amygdalar nucleus (BMA), MEA, anterior amygdala area (AAA) and cortical amygdala area (COA). The lateral orbital frontal area has bilateral projections to BLA, and ipsilateral projections to CEA, MEA, COA and AAA. The infralimbic area has bilateral projections to BLA and MEA, and ipsilateral projections to BMA, COA and AAA. The prelimbic area has bilateral projections to BLA and CEA, and ipsilateral projections to MEA, COA and AAA. The perirhinal cortex has bilateral projections to LA and BLA, and ipsilateral projections to BMA, MEA CEA, COA and piriform-amygdala area. The posterior part of the agranular insular area has bilateral projections to BLA, and ipsilateral projections to LA. The dorsal part of the agranular insular area has bilateral projections to LA, BLA and CEA, and ipsilateral projections to COA and AAA. These results show the convergence of cortical input in amygdala, and will help further explore how different cortical regions influence behaviors through the emotional gateway of the amygdala.

Title: Chronic anxiety response - effects of diazepam, amphetamine and H4R antagonist

Authors: *R. M. ABUHAMDAH[1,2], S. ABUHAMDAH[4], P. L. CHAZOT[3], A. ENNACEUR[5]; [1]Univesity of Jordan, Amman, Jordan; [2]Sch. of Medicine, Pharm. and Hlth., [3]Sch. of Biol. & Biomed. Sci., Durham Univ., Durham, United Kingdom; [4]Fac. of Pharm., Univ. of Jordan, Amman, Jordan; [5]Dept. of Pharm., Univ. of Sunderland, Sunderland, United Kingdom

Abstracts: Most current tests of anxiety proved inappropriate for assessing chronic anxiety as they are limited to a single test session. In the present report we describe a novel behavioral test in which fear and anxiety response can be observed over a number of test sessions. This test consistently discriminates between anxious and non-anxious strains of mice and distinguishes between diazepam and amphetamine. When exposed to an unfamiliar elevated platform with downward steep slopes attached on two opposite sides, BALB/c, C57BL/6J, and CD-1 mice spent a large amount of time in the areas adjacent to the slopes than in any other parts of the platform. C57BL/6J, C57BL/6N and CD-1 crossed onto and explored the slopes while BALB/c mice remained the entire 12 min session on the platform. Repeated exposure (3 sessions/24hr intervals) to the test did not affect the difference between these strains of mice. In another configuration of the test, the two slopes were tilted upward. At the end of each slope there was a stand. Mice needed to climb the slope to reach the stand. In this configuration, all 4 strains of mice were able to climb onto the slopes but only C57BL/6J, C57BL/6N and CD-1 mice crossed onto the stand. Repeated exposure (3 sessions/24hr intervals) to the test did not affect the difference between these strains of mice. The above observations suggest that repeated exposure to the elevated platform induced fear and anxiety which was elevated in BALB/c mice and reduced in C57BL/6J, C57BL/6N and CD-1 mice. Diazepam facilitated crossing onto the slopes while amphetamine and H4R antagonist (JNJ7777120) had no effects. Repeated exposure (6 sessions/24hr intervals) to the test did not reduce anxiety in Balb/c mice.

Title: Anxiety-like behavior in crayfish is controlled by serotonin

Authors: P. FOSSAT[1], J. BACQUE-CAZENAVE[1], P. DE DEURWAERDERE[2], J.-P. DELBECQUE[1], *D. CATTAERT[1];
[1]Univ. Bordeaux & CNRS - INCIA - UMR 5287, Talence, France; [2]Univ. Bordeaux & CNRS - IMN - UMR 5293, Bordeaux, France

Abstracts: Anxiety is a behavioral adaptation to stress and is a sustained apprehension about future uncertainties that prepares individuals to detect and address threats. Although this complex emotional state has been exclusively described and analyzed in humans and higher mammals, the question can be raised as to whether lower animals, including invertebrates, also express anxiety-like behaviors. Here, we show that crayfish that are stressed by repetitive exposure to electric fields subsequently adapt their behavior even when placed in a different context: in an aquatic dark/light plus-maze, the crayfish avoided aversive light arms. This avoidance was completely abolished by an injection of chlordiazepoxide, which is a benzodiazepine anxiolytic drug. Avoidance is associated with increases in brain serotonin (5HT) in stressed animals. In unstressed crayfish, 5HT injections induced avoidance, and chlordiazepoxide prevented this effect. The striking similarities between the behavioral

adaptations displayed by crayfish and rodents after exposure to stressful situations, the involvement of 5HT, and the suppressive effects of a benzodiazepine clearly indicate that crayfish can express a primitive form of anxiety and that the underlying mechanisms have undoubtedly been conserved during evolution. Analyses of this ancestral form of behavior in a simple model reveal a new route to understanding anxiety and may alter our conceptions of the emotional statuses of invertebrates.

Title: Stress enables serotonergic tuning of fear memory consolidation

Authors: *M. V. BARATTA[1,2,3,4], J. YAO[2,4], M. D. WEBER[1], B. GISABELLA[2,4], P. E. MONAHAN[2,3,4], N. PETROSSIAN[2,4], E. S. BOYDEN[2,3,4,5], K. A. GOOSENS[2,4]; [1]Psychology & Neurosci., Univ. of Colorado Boulder, Boulder, CO; [2]McGovern Inst. for Brain Res., [3]MIT Media Lab., [4]Dept. of Brain and Cognitive Sci., [5]Dept. of Biol. Engin., MIT, Cambridge, MA

Abstracts: Serotonergic systems play a critical role in the regulation of emotion, and its dysregulation is associated with stress-related vulnerability to anxiety disorders such as post-traumatic stress disorder. Prior work from our laboratory and others suggest that the serotonergic dorsal raphe nucleus is critical for mediating the impact of stress on aversive processing. Here we investigated the role of serotonin 2C ($5\text{-}HT_{2C}$) receptors in the basolateral amygdala (BLA), a

target area in the fear network that receives serotonergic innervation from the dorsal raphe. As in prior studies, repeated immobilization stress prior to auditory fear conditioning enhanced long-term fear memory without impacting freezing levels during acquisition or during a short-term memory test. Intra-BLA administration of the highly selective 5-HT_{2C} receptor antagonist SB242084 (0.4 μg/0.4 μl) immediately following fear acquisition completely blocked the stress-induced enhancement of fear without impacting basal levels of fear in unstressed animals. Post-conditioning serotonin levels in the BLA did not differ between Stress and No Stress groups. In contrast, western blot analysis revealed that stress elevated the membrane expression of BLA 5-HT_{2C} receptors without altering whole cell levels of these receptors. Since edited forms of the 5-HT_{2C} receptor exhibit less internalization from the membrane surface, we examined expression of the editing enzyme for the 5-HT_{2C} receptor, adenosine deaminase acting on RNA 1 (ADAR1). Following fear training, we found that BLA ADAR1 protein levels were increased in subjects exposed to repeated stress. Taken together, these data show that stress bolsters the consequences of aversive reinforcement not by simply enhancing the neurobiological signals used to encode fear in unstressed animals, but rather by engaging a distinct serotonergic mechanism. Our results also point to 5-HT_{2C} receptors as a promising therapeutic G-protein target for restoration of normal, adaptive levels of threat processing in mood disorders.

Title: Evaluating CF 50 kHz USVs as an indicator of anxious state

Authors: *J. O. TAYLOR, S. B. KEGLEY, A. LEMKE, C. M. URBANO, B. G. COOPER; TCU, Fort Worth, TX

Abstracts: Adult rat ultrasonic vocalizations (USVs) are a valuable tool for noninvasively assessing an animal's emotional state. USVs are produced in one of two frequency ranges, 22 kHz or 50 kHz. Within the 50 kHz range, one subtype of USV, constant frequency 50 kHz (CF 50 kHz) calls, is not viewed as a call signaling a particular emotional state. The current study tested the hypothesis that CF 50 kHz calls are an indicator of anxiety using behavioral and

pharmacological manipulations. Animals were injected (i.p.) with an anxiolytic (diazepam, 1 mg/kg), an anxiogenic (pentylenetetrazole, 10 mg/kg), or saline 30 min prior to behavioral testing. USVs were recorded while animals received a repeated sequence of mild, unsignaled footshocks to elicit anxiety; or animals were evaluated for anxiety using an elevated plus maze (EPM) without acute stressors. To determine whether previous aversive experience modulated anxiety, animals that received control injections in the unsignaled footshock paradigm were subsequently tested on the EPM . A low dose of diazepam decreased the rate of CF 50 kHz calling immediately following the initial unsignaled footshocks compared to saline- and PTZ-treated animals. Animals with previous footshock experience were more likely to produce CF 50 kHz calls on the EPM, and were significantly more anxious than experimentally naïve animals. The pattern of CF 50 kHz call production during both behavioral tests supports the novel interpretation that the production of CF 50 kHz calls is an indicator of anxiety in rats. These results suggest that anxiety state can be noninvasively measured by recording USVs and recording these USVs may aid the development of animal models of anxiety.

Title: Reward signaling in the dorsal raphe nucleus

Authors: *Z. LIU, J. ZHOU, Y. LI, F. HU, Q. FENG, J.-E. ZHANG, D. WANG, J. ZENG, J. BAO, M. LUO;
Natl. Inst. of Biol. Sciences,Beijing, Beijing, China

Abstracts: Reward processing is critical for animal's survival in a dynamic environment. The dorsal raphe nucleus (DRN) is a center of serotonin (5-hydroxytryptamine; 5-HT) neurons and has long been implicated in mood regulation. Although 5-HT has been theorized to encode punishment by opposing the dopamine system, the role of DRN in reward processing remains largely elusive. Here, combining optogenetics, *in vitro*/vivo physiology, immunohistochemistry

with a series of behavioral tests, we show that DRN neurons actually signal reward directly by releasing glutamate and serotonin. Glutamate contributes most of the reward motivation while 5-HT sustains this high motivation even in more challenging & complicated conditions. Furthermore, Ventral Tegmental Area (VTA) and Nucleus Accumbens (NAc) might be the downstream targets involved in the reward effects mediated by DRN. These results uncover the pivotal role of DRN in the brain reward system which has long been neglected before and have multiple implications on reward theory and 5-HT functions in mood & emotion regulation.

Title: Sonic hedgehog signaling pathway is important in the maintenance and function of adult dopaminergic neurons

Authors: X. ZHOU[1], Y. JIN[1], E. FILICHIA[1], K. JIN[2], *B. J. HOFFER[3,1], Y. LUO[1]; [1]Neurolog. Surgery, Case Western Reserve Univ., Cleveland, OH; [2]Dept. of biomedical engineering, Univ. of Rochester, Rochester, NY; [3]Scientist Emeritus, NIDA/NIH, Lyndhurst, OH

Abstracts: During development, sonic hedgehog (shh) induce precursor cells to differentiate into dopaminergic (DA) neurons. However, whether shh signaling is also required in the maturation or maintenance of DA neurons is unknown due to the lethality of traditional shh knockout models. We utilized the cre-loxP system to achieve stage and cell type-specific deletion of shh or its receptor, smoothened (smo), in DA neurons during the late developmental stage (E15.5) by crossing DATcre (dopamine transporter) mice with loxP-shh or loxP-smo mice. Our results show that DATcreshh knockout (ko) mice demonstrate hyperactivity compared to wild type (wt) mice at 3 months and 5-6 months. TH positive neuron cell counts in substantia nigra (SN) showed that, at 7 months, there is no difference between wt and shh ko mice. However, in aged mice (20 months), there are significantly less TH-positive neurons in shh ko mice (110.625 ± 6.78 per section) as compared to wt mice (141.5 ± 8.17 per section, $p = 0.019$). In DATcresmo knockout mice, similar hyperactivity was found in 4-5 month old mice. TH positive neuron cell count

using unbiased stereology showed substantially fewer cells in 7 month old smo ko mice (6245.16 ± 71.44) than in wt mice (7361.72 ± 362.55, p = 0.039). In lesion studies of smo ko versus wt mice, we found no difference in survival of DA neurons in the classic unilateral striatal 6-OHDA lesion modeling Parkinson's disease. DATcreshh and DATcresmo mice also display differential response when exposed to psychostimulant and addictive drugs. In summary, our data demonstrate that shh signaling pathway plays critical role in maintaining the function of dopaminergic system in adulthood in mice.

Title: Encoding reward signals by dorsal raphe 5-ht neurons of freely behaving mice

Authors: ***Y. LI**[1,2], W. ZHONG[1,2], Z. LIU[1], J. ZHOU[1], D. WANG[1], J. ZENG[1], Q. FENG[1], J. BAO[1], C. JIA[1], M. LUO[1,3];

Abstracts: The dorsal raphe nucleus (DRN) is the major source of serotonin (5-HT) in the forebrain, although a substantial number of neurons here are known to release other neurotransmitters such as glutamate, GABA, and dopamine. These neurons exhibit diverse correlations with different phases of reward-related behaviors, but it remains unclear how 5-HT neurons in the DRN encode reward signals in freely behaving animals. We carried out recordings of DRN 5-HT neurons from freely behaving Sert-Cre mice that underwent a simplified sucrose foraging behavioral task. 5-HT neurons were identified by selectively expressing ChR2 and then optical tagging with optetrodes. Our experiments reveal that 5-HT neurons exhibit low basal firing rate (~2Hz), become gradually activated in anticipation of sucrose delivery (~8 Hz), and fire burst of action potentials (>20 Hz) at the early phase of reward consumption. In contrast, a

substantial number of GABAergic neurons exhibit high basal firing rates and are inhibited during reward anticipation and consumption. Moreover, mouse poking behavior during reward anticipation phase is increased by optogenetic stimulation and reduced by optogenetic inhibition of DRN 5-HT neurons, respectively. These results strongly demonstrate that DRN 5-HT neurons encode reward-seeking signals with tonic and then bursting activation pattern, suggesting an important role of these neurons in reward processing during freely behaving states.

Title: Qualitative reward prediction errors and dopamine during reward reversal

Authors: *V. MARTINEZ[1], L. M. BURGENO[2], P. E. M. PHILLIPS[2];
[1]Rehabil. Med., Univ. of Washington, SEATTLE, WA; [2]Psychiatry and Behavioral Sci., Univ. of Washington, Seattle, WA

Abstracts: Phasic dopamine transmission in the nucleus accumbens core (NAC) has been implicated in the formulation of quantitative reward prediction errors. Using fast-scan cyclic voltammetry (FSCV) we examined phasic dopamine responses in the NAC during performance of a Dual Reward Discrimination (DRD) task. Rats were simultaneously deprived of food and water to elicit motivated task performance for food and water rewards. Sessions were comprised of 90 trials (30 food trials, 30 water trials and 30 choice trials) with all trial types evenly interleaved across each session. Operant performance requires that rats respond to cues (light flashes) that predict specific rewards (food or water) which are contingent on their spatial location (left-cues predict food and right-cues predict water). Rats were trained exclusively using this reward contingency until they reached performance criteria; at this time rats performed a 'Reversal' session that was accompanied by FSCV recordings. The first 30 trials of Reversal sessions were presented using standard reward contingencies (left=food; right=water); however during trials 31-90 reward contingencies were reversed so that the left responses now yielded water and right responses, food. This was done to elicit reward prediction errors that resulted from changes in reward identity, while leaving the quantity of rewards unchanged. Baseline

performance on choice trials indicated equal preference for food and water rewards; therefore, prediction errors elicited by reward reversal aren't necessarily ‘positive’ or ‘negative’, but rather reflect qualitative discrepancies in reward identity. Performance accuracy and number of omissions did not differ substantially following reversal. Peak dopamine concentrations were taken from distinct time periods associated with cue onset, lever extension and reward delivery. Preliminary voltammetric data indicated that food and water trials elicited phasic signals of equal magnitude when rats performed under standard reward contingencies. Interestingly, following reward reversal, phasic dopamine signals were augmented for both trial types relative to baseline. We interpret these findings to suggest that unforeseen contingency reversals alter the predictive values of cues based on their prior history and render subsequent rewards as qualitatively-unexpected.

Title: Brain structures involved in the reinforcement omission effects modulation

Authors: *T. TAVARES, D. M. JUDICE-DAHER, J. L. O. BUENO;
Univ. de São Paulo, Ribeirão Preto, Brazil

Abstracts: Studies developed in our laboratory have showed that amygdala is involved in the modulation of the reinforcement omission effects (ROEs). For instance, rats with large amygdala lesions, trained to respond on a fixed-interval with a limited hold signaled schedule of reinforcement (FI LH signaled), failed to increase response rates in intervals following nonreinforcement. However, rats with lesions of the basolateral complex of amygdala (BLA), trained to respond on the same schedule of reinforcement, were more responsive to occasional reinforcement omission than rats of the sham-operated group. The view that amygdala lesions block ROEs is supported by evidence implicating the amygdala in responses correlated

motivational and attentional processes. However, these processes depend on the operation of separate amygdala areas, through their connections with other brain systems. We are investigating whether the ROEs may be modulated by different brain structures linked to the amygdala, like nucleus accumbens (NAC), medial pre-frontal cortex (mPC), orbitofrontal cortex (OFC), substantia nigra pars compacta (SNc) and tegmental ventral area (VTA). For example, recent experiments developed in our laboratory showed that nucleus NAC and mPC, but not OFC, also are involved in the modulation of ROEs. Thus, the present study aimed to verify if the neurotoxic lesions of the SNc interfere on ROEs modulation. Rats were trained on a FI 12 s LH 6 s signaled schedule in which correct responses were always followed by reinforcement (100% reinforcement schedule). After the training the rats were submitted to SNc lesions. In the test, the training was changed from 100% to 50% reinforcement schedule. The results showed that SNc lesions did not impair the ROEs. Rats of SNC lesioned group present ROEs as well as rats of the sham-operated group: the response in intervals following nonreinforcement was higher than in intervals following reinforcement. Furthermore, there were no differences among both groups. Together, the results obtained in our laboratory support the hypothesis that not only amygdala, but also NAC and mPC are related to ROEs modulation. However, the OFC and SNc do not seem to be involved in this process. Studies have showed that the dynamic interaction of BLA with the NAC, mPC and also VTA may be important to incentive motivational processes. Thus, it is possible that VTA could also be involved in the ROEs modulation.

Title: Hedonic reward and incentive salience in rats exposed postnatally to the polybrominated diphenyl ether commercial mixture DE-71

Authors: *L. L. DRISCOLL[1], E. BECKETT[2], J. BOESE[2], J. WATTS[2], J. SPERRY[2], R. KASEMODEL[2];
[1]Colorado Col., COLORADO SPGS, CO; [2]Neurosci., Colorado Col., Colorado Springs, CO

Abstracts: Polybrominated diphenyl eithers (PBDEs) are environmentally ubiquitous and bioaccumulative flame retardants used in the manufacturing of polymer products. Exposure to PBDEs in food, dust, and air can have endocrine (thyroid and sex hormone) and neurobehavioral (especially learning and attention) effects, particularly if exposure occurs in the perinatal period. Neurobehavioral assessments of PBDE exposure effects have not, to date, included measures of motivation or reward. The purpose of this study was to determine the effects of postnatal exposure to the PBDE commercial mixture DE-71 on sucrose water consumption, which is a measure of hedonic tone, and on a progressive ratio (PR) lever pressing task, which measures the amount of effort the subject is willing to exert to earn a reward. Male and female rat pups received daily oral doses of DE-71 (0, 30, or 60 mg/kg) in corn oil from postnatal days 6-12; half of the DE-71-exposed rats also received oral doses of 6 μg/kg/day levothyroxine sodium (LT4) to determine if thyroid hormone supplementation could "rescue" the impacts of DE-71 on behavior. All DE-71 exposed groups demonstrated a greater preference for sucrose water than did controls; this effect was present in both sexes. In contrast, PR lever press performance was relatively unaffected by DE-71, except that the 60 mg/kg exposed rats showed a sexual dimorphism in the number of lever presses completed (males more than females), whereas the other groups did not. LT4 supplementation had no effect on sucrose consumption or PR performance, suggesting that the alterations in hedonic tone due to DE-71 exposure are not secondary to toxin-induced hypothyroidism. Taken together, these results show that postnatal DE-71 exposure increases hedonic drive in both males and females, but it does not seem to impact motivated responding for rewards under a PR schedule.

Title: Reward prediction error signals in major depressive disorder

Authors: *R. B. RUTLEDGE, M. MOUTOUSSIS, T. HERLT, L. HRYNKIEWICZ, J. LAM, O. OUSDAL, P. FONAGY, R. J. DOLAN;
Univ. Col. London, London, United Kingdom

Abstracts: Dopamine neurons are believed to represent a reward prediction error (RPE) signal, the difference between experienced and predicted rewards. In healthy subjects, RPE signals have been measured from dopamine projection areas including the ventral striatum using functional neuroimaging. Subjects suffering from major depressive disorder have been found to have deficits in reward learning tasks and to lack normal RPE signals in the striatum. We tested whether RPE signals are represented in the striatum of depressed subjects in a task that does not require learning. We used an axiomatic model of the dopaminergic RPE hypothesis to formally test whether neural responses satisfied necessary and sufficient conditions for the class of RPE models. The axioms will be satisfied if activity: 1) increases with prize magnitude, 2) decreases with lottery expected value, and 3) is the same for outcomes from all lotteries with a single possible outcome. We tested medicated, unmedicated, and healthy subjects on a decision making task in which they chose between lotteries with different probabilities of monetary gains and losses and the outcomes of chosen lotteries were shown after a brief delay. Task earnings and reaction times did not differ between subject groups and all groups responded more quickly to choose the best than the worst option. Neural responses in the ventral striatum and in the ventral medial prefrontal cortex in depressed subjects satisfied all three conditions of the axiomatic model, demonstrating that there are intact neural RPE representations in subjects suffering from major depressive disorder.

Title: Pattern analysis of low-frequency power predicts stopping behavior in human subthalamic nucleus

Authors: *J. M. PEARSON, P. T. HICKEY, S. P. LAD, M. L. PLATT, D. A. TURNER; Neurobio., Duke Univ. Med. Ctr., DURHAM, NC

Abstracts: Pharmacological treatment of Parkinson's Disease (PD) with dopaminergic drugs can lead to impulse control disorders such as compulsive gambling, hypersexuality, and punding. Recent evidence suggests that these disorders may also be evoked by deep brain stimulation (DBS). Studies in humans and animals indicate that the subthalamic nucleus (STN), the typical target for DBS treatment of PD, may be necessary for inhibiting prepotent motor responses, particularly those linked to reward, but little is known about other types of motivational information encoded by this area. We recorded neurons from the deeper part of STN (<3mm from ventral border, adjacent to substantia nigra) of patients undergoing DBS implantation for the treatment of PD while awake. Subjects performed an interactive task during the recordings, using a variant of the balloon analogue risk task (BART), a decision making paradigm used to assess impulsivity in humans. Here, instead of inhibiting a motor response, subjects were required to terminate the inflation of a balloon presented onscreen before it popped. Successfully terminating the inflation resulted in a reward proportional to the final balloon size, while a popped balloon resulted in no reward. Pop times were random, with balloon color signaling risk level. On control trials, balloons inflated to a predetermined size indicated onscreen by a gray circle before stopping; subjects simply initiated inflation. Balloons never popped on control trials, though some balloons (colored gray) resulted in 0 reward. Using multi-electrode arrays, we recorded 32 simultaneous channels of local field potentials (LFP) in a subset of patients. We found that low-frequency LFP power in the 0-10 Hz range rose in seconds in advance of stopping decisions, and that this pattern was absent on trials where subjects did not respond in time. A classifier analysis based on a regularized regression model successfully predicted stop decisions within 1 second, with area under the ROC curve measures of > 0.6 in multiple subjects. These results suggest that local activity in STN carries a mixture of motivational and motor preparatory behavior, and that machine learning methods might be useful in predicting impulsive behavior via monitoring of signals at the DBS electrode.

Title: Different monetary incentive delay neural profiles in high and low risk social drinkers

Authors: M. DIBARTOLO[1], X. ZHU[1], J. SCHACHT[2], *B. FROELIGER[1], R. ANTON[2], J. JOSEPH[1];
[1]Neurosciences, [2]Psychiatry, Med. Univ. of South Carolina, Charleston, SC

Abstracts: The monetary incentive delay (MID) task is an effective probe for isolating neural circuitry in the human brain associated with incentivized motivation. Individuals at risk for substance abuse have been shown to exhibit differences in incentive elicited neural activation. This study examined whether or not young adults at high- or low- risk for alcohol dependence would show different neural activation patterns related to reward or loss-avoidance of high and low monetary values. It was hypothesized that high-risk social drinkers would exhibit attenuated reward sensitivity or hypersensitivity to loss. 30 young adults (ages 18-25, 15 male) were categorized as being at high- (N=12, 7 male) or low-risk (N= 18, 8 male) for future alcohol dependence based on the Alcohol Use Disorders Identification Test (AUDIT). Scores for the high-risk group ranged from 8-13, scores for the low-risk group ranged from 2-7, and no subjects had previous or current alcohol use disorder treatment. Subjects performed the MID task while undergoing functional magnetic resonance imaging. Five incentive levels were used (- $5, - $,5, 0, + $.5, + $5) in the MID task. We found that neurobehavioral MID profiles were different in high- and low-risk social drinkers. Neural activation in several frontal regions was consistently higher in low-risk drinkers than high-risk drinkers during the feedback stage, independent of incentive level. Of particular interest was the activation pattern in the left superior frontal gyrus: during the cue phase, the high-risk group showed greater activation during high loss trials than low risk group, but similar activation during high reward trials. During the feedback stage the opposite effect was observed: the low-risk group showed greater activation during high reward trials than the high risk group, but showed similar activation during the high loss trials. The left superior frontal cortex has been linked to working memory and complex executive functioning as well as to processes that are related to value determination and motivation. The present findings suggest that high-risk drinkers may engage in more elaborative, higher-level processing for potential negative outcomes whereas low-risk drinkers devote the same type of processing to positive outcomes.

Title: Neural encoding of incentive salience in the ventral pallidum of rats during Pavlovian conditioned approach

Authors: ***A. M. AHRENS**, T. E. ROBINSON, J. W. ALDRIDGE;
Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

Abstracts: Individual differences in the neural representation of incentive salience may be an important factor that predisposes certain individuals to addiction. Incentive motivation can be modeled in rats using a Pavlovian conditioned approach procedure, in which the presentation of a discrete cue (the conditioned stimulus, CS) is consistently followed by food reward (the unconditioned stimulus, US) in a response-independent manner. In this procedure there are clear individual difference in the form that conditioned behavior takes; with some rats approaching and interacting with the cue itself ("sign trackers", STs), some rats approaching the food cup ("goal trackers", GTs), and other rats alternating between the CS and the food cup ("intermediates", INs). The attraction to the CS seen in STs, but not GTs, is thought to reflect the attribution of incentive salience to the CS. The goal of the present study was to determine how these individual differences are represented in the neural firing patterns of the ventral pallidum, a mesolimbic structure that encodes both the predictive and incentive value of reward-paired cues. We used single-unit *in vivo* electrophysiology to record neural activity in the ventral pallidum of freely-moving ST, GT, and IN rats during the expression of Pavlovian conditioned approach behavior. We found that all rats showed clear increases in neural activity in response to both the onset of the CS and the delivery of the US. However, the STs showed heightened CS responses, both in terms of the percentage of responsive neurons and the magnitude of cue responses, compared to the GTs and INs. These results show that individual difference in approach behavior

are reflected in mesolimbic reward circuitry, and that by utilizing the ST/GT model it is possible to distinguish between the predictive and incentive value attributed to a reward-paired cue.

Title: Interaction between inhibition of monoamine transporter function and environmental enrichment or social isolation on responding for conditioned reinforcement in mice

Authors: *C. BROWNE[1], P. J. FLETCHER[2], F. D. ZEEB[2];
[1]Univ. of Toronto/CAMH, Toronto, ON, Canada; [2]Biopsychology, Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

Abstracts: Stimuli associated with primary rewards can acquire motivational value through incentive motivational processes, as demonstrated by their ability to function as conditioned reinforcers. The expression of incentive motivation is regulated in large part by the activity of brain monoamine neurotransmitters. Environmental enrichment (EE) and isolation rearing can alter both monoamine function and motivational processes such as cue-induced reinstatement of reward seeking. This suggests that environmental factors may interact with the incentive value of reward-associated stimuli through altered monoamine function. Thus, the present experiments examined the effects of rearing condition on responding for a reward-associated stimulus serving as a conditioned reinforcer (CR) in environmentally enriched (EE), pair housed (PH), and single housed (SH) mice. We also determined how responding was affected by blocking the serotonin (SERT), norepinephrine (NET), and dopamine (DAT) transporters, with citalopram (CIT), atomoxetine (ATO) and GBR12909 (GBR), respectively. At post-natal day 21, male C57BL/6 mice were separated into EE, PH, and SH groups for the duration of the study (all groups n=12). PH and SH mice were housed in standard conditions, while EE mice were housed 6 to a large cage in an enriched environment. In adulthood, mice were tested on a conditioned reinforcement

procedure involving a Pavlovian conditioning phase followed by an operant conditioning phase. During the Pavlovian phase, water-restricted mice received 30 pairings of a conditioned stimulus (CS) prior to the delivery of saccharin over 14 sessions. No group differences were seen in learned approach to the reward location upon CS presentation. In the operant phase, mice were able to respond on a lever to obtain only the stimulus previously paired with saccharin (now a CR). Baseline levels of responding for the CR were similar between PH and EE mice, while SH mice showed significantly higher responding. Subsequently, the effect of the CIT (10, 20 mg/kg), ATO (0.3, 1, 3 mg/kg), and GBR (2.5, 5, 10 mg/kg) on responding was examined. For all groups, both doses of CIT decreased responding for the CR, whereas ATO decreased responding only at the highest dose tested. In contrast, GBR increased responding for the CR only in EE mice at the highest dose. These results suggest that mice in impoverished conditions (SH) may attribute greater incentive value to reward-associated stimuli, and that PH and EE mice do not differ greatly in responding for a CR. Further, blockade of SERT and NET produce decreases in CR responding in general, while EE mice show a susceptibility to the response enhancing effect of DAT blockade.

Title: Resting state and functional connectivity of the nucleus accumbens with rewards regions in overweight and obese women

Authors: K. COVELESKIE[1], A. GUPTA[1], *L. A. KILPATRICK[1], E. D. MAYER[1], C. ASHE-MCNALLEY[1], J. STAINS[1], J. S. LABUS[1], E. A. MAYER[1,2];

[1]Oppenheimer Family Ctr. for Neurobio. of Stress, UCLA, LOS ANGELES, CA; [2]David Geffen Sch. of Med., University of California Los Angeles (UCLA), CA

Abstracts: Background: Neuroimaging studies in obese subjects have identified abnormal activation of key regions of central reward circuits, including the nucleus accumbens (NAcc), in response to food related stimuli. We aimed to examine if subjects with elevated body mass index (BMI) show structural, and resting state (RS) functional connectivity alterations within regions of the reward network. Methods: 50 healthy, premenopausal women, 19 overweight and obese (high BMI=26-38 kg/m2) and 31 lean (BMI=19-25 kg/m2) were studied. Structural and RS functional scans were collected using a Siemens Allegra 3T magnetic resonance imaging (MRI) scanner. Group differences in grey matter volume (GMV) of the NAcc, oscillation dynamics of intrinsic brain activity, and functional connectivity of the NAcc to regions within the reward network were examined. Results: GMV of left NAcc was significantly greater in the high BMI group than in the lean group (p=0.031). Altered frequency distributions were observed in women with high BMI compared to lean in the left NAcc, right and left anterior cingulate cortex (ACC) and ventro-medial prefrontal cortex (vmPFC). Additionally, subjects with high BMI had greater connectivity of the left NAcc with bilateral ACC and right vmPFC in specific frequency bands. Conclusions: Overweight and obese women in the absence of food related stimuli show structural and functional alterations in reward related brain networks which may play a role in altered ingestive behaviors.

Title: Prenatal exposure to stress in combination with adolescent exposure to marijuana results in sexually dimorphic cognitive and physiological effects

Authors: *R. J. KEELEY, J. TROW, B. LOWRY, R. J. MCDONALD;
Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstracts: Adolescent marijuana exposure is associated with disruptions in cognitive function in some but not all animal models. In addition, human exposure to marijuana during adolescence can increase the risk of development of psychiatric illness. However, some populations are more at risk than others to the long-term consequences of adolescent marijuana use. One possible factor that could predispose an individual to the negative consequences of marijuana is early-life stress, particularly given the relationship between the endogenous cannabinoid system and the hypothalamic-pituitary-adrenal axis. Therefore, this research study examined the long-term consequences of exposure to the psychoactive component of marijuana, Δ9-tetrahydrocannabinol (THC), in rats prenatally exposed to stress. This prenatal stress paradigm has been shown to alter stress responses, anxiety behaviour as well as has epigenetic consequences for the offspring. Following adolescent exposure to THC, rats were aged to adulthood and exposed to a battery of behavioural tasks, including elevated plus maze, the Morris water task and discriminative fear-conditioning to context. Following a minimum 2 week acclimation period following the fear-conditioning task, blood was taken before and 30 minutes after a restraint stress. No differences were observed in anxiety-related behaviour in the elevated plus maze or spatial learning in the Morris water task. In the discriminative-freezing to context task, a sex-specific effect was observed such that only males showed any impairment in discriminative freezing or active avoidance with the administration of THC. Finally, basal corticosterone was unaltered with treatment conditions. However, sexually dimorphic effects of THC or just a vehicle injection were observed. Females showed altered corticosterone responses following restraint stress if they had been exposed to vehicle or THC in adolescence in comparison to a handled control group. Male corticosterone responses were less clear, such that THC may have returned corticosterone levels to that of controls in comparison to the vehicle group. This research project highlights the importance of considering at risk groups for the administration of THC and that these effect may be sexually dimorphic.

Title: Effects of chronic oral methylphenidate exposure on behavior and brain metabolism in female rats

Authors: *L. S. ROBISON[1], M. VITALE[1], M. MICHAELOS[1], J. GANDHI[2], S. PAENG[3], J. LEE[4], E. MIAO[1], M. HADJIARGYROU, Ph.D.[6], D. KOMATSU[5], P. K. THANOS[1]; [1]Psychology, [2]Physiol. & Biophysics, [3]Biol., [4]Chem., [5]Orthopedics, Stony Brook Univ., Stony Brook, NY; [6]Life Sci., New York Inst. of Technol., Old Westbury, NY

Abstracts: Methylphenidate (MP; marketed as Ritalin) is a commonly prescribed stimulant used to treat Attention Deficit Hyperactivity Disorder (ADHD). MP has received attention for its possible abuse potential and side effects that may persist after cessation of treatment. Previously, we found that chronic MP treatment has significant effects on locomotor behavior, emotionality, and neurochemistry in male rats. In the current study, female Sprague-Dawley rats were split into 3 groups (n=24/group) at 4 weeks of age: control (water), low dose MP (LD), high dose MP (HD). A dual bottle 8-hour limited access drinking paradigm was utilized, which produces an MP pharmacokinetic profile similar to treated patients: 4 mg/kg MP (LD) or 30 mg/kg MP (HD) during hour 1, and 10 mg/kg (LD) or 60 mg/kg MP (HD) hours 2-8. Half of the rats in each group were treated for 13 weeks, while the other half were treated for 13 weeks then went through a one month abstinence period (given water for the 8h drinking period). Food and fluid intake and body weight were recorded daily for the duration of the experiment. Rats were tested for open field activity weekly throughout treatment and abstinence. Circadian activity testing was performed during weeks 1, 2, 4, 8, and 13 of treatment, as well 1, 2, and 5 weeks into the abstinence period. Novel object recognition (NOR) and social interaction tests were performed during the last weeks of treatment and abstinence. Brain metabolic effects of MP were assessed with [18F]FDG microPET scans at the end of treatment. HD MP increased food intake but decreased body weight, likely due to dramatic increases in energy expenditure. Open field tests revealed that MP dose-dependently increased general activity levels during treatment. These effects were greatest in later weeks of treatment, suggesting sensitization, and were corroborated by increased circadian activity levels in the dark cycle only. MP also increased rearing and center activity in the open field throughout treatment, suggesting increased exploratory behavior and reduced anxiety. MP had no significant effect on novel object recognition memory or social interaction. Preliminary PET findings reveal that MP resulted in alterations in neural activity in prefrontal, striatal, thalamic, and midbrain regions, as well as regions involved in memory & sensory processing. Collection of data during abstinence is ongoing.

Title: Persistent inhibitory circuit deficits emerge following chronic prenatal exposure to exogenous cannabinoids

Authors: *G. A. VARGISH, C. J. MCBAIN, K. A. PELKEY, X. YUAN, D. COLLINS;
Lab. of Cell. and Synaptic Neurophysiol., NIH/NICHD, Bethesda, MD

Abstracts: *In utero* exposure to exogenous cannabinoids (CBs) is correlated with cognitive defects in humans. However, the mechanism underlying these defects remains unknown. Disruption of cholecystokinin expressing interneuron (CCK INTs) development is a prime candidate as CCK INTs express cannabinoid receptor 1 (CB1R) embryonically and comprise much of the CB1R expression in the cortex and hippocampus. Further, endocannabinoid (eCB) signaling has been implicated in aspects of development such as proliferation, migration and circuit integration. As CB1R expressing CCK INTs proliferate and migrate beginning around embryonic day 10.5 (E10.5) in mice, maternal intake of CBs could interfere with CCK INT eCB signaling *in utero*. Thus, we examined the outcome of chronic prenatal exposure to CBs by comparing the offspring of pregnant mice treated from E10.5 to birth with CBs (Δ9-THC or WIN55,212-2 (WIN), a CB1R agonist) or a vehicle control (VH). Immunohistochemical characterization revealed a dramatic reduction in CCK INT density in mice prenatally exposed to WIN when compared to VH controls (55.5% decrease). This deficit was specific to CCK INTs as the density of cells expressing other INT markers was comparable between the two groups. Recordings of spontaneous inhibitory postsynaptic currents (sIPSCs) in the dentate gyrus support anatomical findings as there is a reduction in basal sIPSC amplitude in mice prenatally treated with WIN (VH=63pA, n=64; WIN=54pA n=61). To assess the specific contribution of CCK INTs we applied ω-conotoxin (CTx), an N-type Ca2+ channel antagonist. As CCK INTs rely solely on N-type Ca2+ channels for transmitter release, CTx should specifically reduce CCK INT mediated IPSCs. CTx significantly reduced sIPSCs in VH but not WIN-treated animals (VH=28%, n=20; WIN=7%, n=17). sIPSCs in WIN-treated animals also showed a reduced sensitivity to acute WIN application compared to VH (VH=29%, n=11; WIN=12%, n=9). Further, recordings of disynaptically evoked feedback inhibition in CA1 of WIN treated animals exhibit a significantly reduced sensitivity to acute WIN application when compared to VH

(VH=54% n =20; WIN=30% n=17; p=0.01). Finally, recordings of connected CCK INT-pyramidal cell pairs in WIN treated mice show that the synaptic properties of residual CCK INTs remain intact, suggesting CCK INT loss accounts for the observed inhibitory deficits. Overall, our data reveal deficits in CCK INT mediated inhibitory drive following *in utero* exposure to CBs. These deficits could precipitate a significant change in excitation/inhibition balance, allowing us to understand, at a cellular level, the cognitive defects associated with prenatal CB exposure.

Title: Chronic peripubertal WIN55212-2 administration is associated with changes in fear conditioning, amygdalar volume, and synaptic proteins

Authors: P. DELUCA, M. BOUDREAULT, J. ANDREWS, N. LANDRY, S. HILL, C. JESSO, M. J. SAARI, *A. C. WEEKS;
Nipissing Univ., North Bay, ON, ON, Canada

Abstracts: Although cannabis and its associated derivatives are the predominant illicit substances consumed by young people, experimental research regarding long-term adverse neurological effects of its chronic use is limited for this age group. This research is particularly important since the age when marijuana is first used in North America is steadily decreasing with the younger aged users being the fastest growing population. It has recently been demonstrated that, in animal models, chronic cannabinoid administration during the peripubertal period is uniquely capable of causing neurological damage. In this way the youngest age groups may be at the highest risk for long-term detrimental effects of cannabis consumption. Research has also indicated that increased levels of anxiety may be associated with cannabis use. For this reason, the amygdala, which has long been implicated in anxiety and fear responses, was the focus of the neurological examination in the current study. This experiment involved chronic administration

of the cannabinoid agonist WIN55212-2 mesylate to peripubertal male Wistar rats. Following chronic injections, experimental and control rats went through a standard auditory fear conditioning procedure to determine whether the drug treatment altered fear-learning. Neurological effects were examined by measuring co-localized synaptic protein density in the lateral and central amygdaloid nuclei (LA and CE respectively) using a confocal microscopic approach. Co-localizations were determined by applying primary antibodies to the synaptic proteins SV2 and PSD-95. Specific fluorophore-conjugated secondary antibodies were then applied and synapses were defined by the unique colour produced when both proteins co-localized. The behavioural results confirmed normal fear conditioning in both groups but indicated that the drug condition rats were more likely to show a fear response to the tone only (no shock). Preliminary synaptic results did not show any significant differences but there was a significant change in neural volume where the LA in the drug group was significantly larger than in the vehicle controls. Taken together, these results suggest that chronic cannabinoid use during adolescence results in a heightened level of emotional response and changes in amygdalar volume.

Title: Expectation of specific therapeutic effects induces generalized placebo improvement of both pain and pleasure

Authors: *D.-M. ELLINGSEN[1], S. LEKNES[2], C. TRISCOLI[3], H. OLAUSSON[4], J. WESSBERG[1];

Psychology, University of Oslo, Norway; [3]Univ. of Gothenburg, Inst. of Neurosci. and Physiol., Goteborg, Sweden; [4]Dept. of Clin. and Exptl. Med., Linköping Univ., Linköping, Sweden

Abstracts: Placebo improvement of negative symptoms, like pain, is often thought to arise from an "unconscious decision" that the pain is less important, because of an impending treatment that is believed to be efficient. We have recently shown that placebo improvement of positive (pleasant touch) and negative (pain) hedonic feelings rely on activation of a similar modulatory circuit. Here, we investigated whether suggestion of treatment benefit on either touch pleasantness or pain unpleasantness can bring about placebo improvement of both pleasure (hyperhedonia) and pain (analgesia). Forty-seven healthy volunteers participated in a crossover design, where they self-administered a nasal spray suggested to either (1) improve the pleasantness of touch (HYP group) or (2) reduce pain unpleasantness (ANA group). To strengthen the participants' expectations of treatment benefit, they were shown one out of two brief video documentaries that summarized scientific findings supporting either treatment-induced improvement of pain (ANA group) or touch pleasantness (HYP group). The video documentary was presented immediately before nasal spray treatment. Next, they rated pleasantness/unpleasantness and sensory intensity of gentle stroking touch and moderate heat pain. After placebo treatment, relative to a control condition without treatment, both the HYP and the ANA groups reported increased touch pleasantness and reduced pain unpleasantness. There was a similar placebo-induced improvement of sensory intensity, whereby pain intensity was reduced and touch intensity was increased, in both the HYP and the ANA groups. The results are consistent with a view of placebo responses as a generalized mechanism of reward prediction, by which a placebo-induced "motivational state" affects both positive and negative hedonic feelings.

Title: Animal model of adolescent cannabis abuse exhibits permanent deficit in the endocannabinoid system signaling

Authors: *A. CORCHES, J. W. LOVELACE, A. HIROTO, E. KORZUS;
Univ. of California, Riverside, Riverside, CA

Abstracts: Whereas current data link adolescence cannabis abuse to increased risk for dependence on other drugs, depression, anxiety disorders and psychosis, the mechanism underlying these adverse effects remains controversial. Here we show that mouse model of adolescent cannabis abuse shows deficits in an endocannabinoid (eCB)-mediated signaling and plasticity at adult central glutamatergic synapses in prefrontal cortex. Blockade of the monoacylglycerol lipase, the primary enzyme responsible for degrading the endocannabinoid 2-arachidonoylglycerol, with the specific inhibitor JZL184 amelioratesthese deficits. The observed deficit in cortical eCB-dependent signaling may represent a neural maladaptation underlying network instability and abnormal cognitive functioning.

Title: A longitudinal analysis of changes in accumbens and dorsolateral striatal drug processing across protracted cocaine self-administration

Authors: *D. J. BARKER[1], K. COFFEY[2], N. GAYLIARD[2], J. KULIK[2], M. WEST[2];
[1]Rutgers Univ., Ellicott City, MD; [2]Rutgers Univ., New Brunswick, NJ

Abstracts: One of the most important hallmarks of substance dependence is addicts' perseverative drug seeking behavior. Indeed, once drug abuse has become chronic, drug-seeking behaviors often persist despite an overwhelming array of negative consequences associated with continued use. For this reason, it is important to understand changes in neural activity that

develop as drug abuse transitions from acute to chronic use and critical to examine drug-related processing in the dependent subject. Theories of addiction have suggested that long-term changes in striatal activity may be responsible for the transition from goal-directed drug seeking behaviors to automatic or habitual responding. Goal-directed behaviors are those whose responding is outcome driven, while habitual responding develops over repeated stimulus-response associations such that responding becomes stimulus elicited (i.e., insensitive to changes in the outcome). Evidence supporting these theories includes the data demonstrating that neural activity gradually shifts from the ventromedial striatum (i.e. nucleus accumbens) to the dorsolateral striatum across chronic drug self-administration. Nevertheless, a thorough longitudinal study of changes in striatal firing has yet to be conducted. Thus, the goal of the present study was to record neurons in the ventral striatum (accumbens core and shell) and dorsolateral striatum across 24 sessions of long-access cocaine self-administration and to examine changes in the processing of drug-seeking behaviors across this period.

Abstracts: Dopamine (DA) is a neurotransmitter involved in reward learning and drug addiction. Therefore, monitoring DA *in vivo* is critical in investigating DA activity related to these behaviors. Fast-scan cyclic voltammetry (FSCV) at the carbon fiber microelectrode has long been an indispensable tool in monitoring real-time DA signaling. Previously, glass-housed DA electrodes have limited this technique to short-term DA monitoring (hours) *in vivo*. Development of polyimide fused silica-encased microelectrodes has advanced the technique for

long-term DA monitoring (months) *in vivo*. In this study, we electrically stimulated and recorded DA signals at silica-encased microelectrodes long-term (months) in effort to characterize the recovery time and electrode stability after implantation. Silica-encased recording, bipolar stimulating, and silver chloride reference electrodes were surgically implanted and affixed in the dorsomedial striatum (+1.0 AP, +2.0 ML, -5.0 DV) of male Sprague-Dawley rats (~400 g). Electrically evoked (60Hz, 60p, 300 μA) DA signals were obtained during surgery and biweekly for four months post-surgery. Recorded DA signals were subsequently modeled by kinetic analysis to resolve parameters describing DA release ($[DA]_p$; the concentration of DA release per stimulus pulse) and uptake (V_{max}; maximal rate of DA uptake). Preliminary data suggest that peak amplitude of evoked DA signals (DA_{max}) has an initial decrease after surgery and then stabilizes several weeks later. The same trend holds for parameters describing DA release and uptake determined by kinetic analysis. The results of this study indicate that once recovered, electrically evoked DA signals recorded at the silica-encased microelectrode, and resulting kinetic parameters describing DA release and uptake, are stable long-term (months).

Title: Combinations of housekeeping genes for normalization of qPCR data in cerebral age-related transcriptomic studies

Authors: *G. BRUCKERT, M. HEBERT, D. VIVIEN, F. DOCAGNE, B. ROUSSEL; INSERM U919, Caen, France

Abstracts: Numbers of studies use quantitative PCR (qPCR) for investigating gene expression because of its precision and accuracy to treat many samples. Internal and external controls are needed to set up qPCR experiments including normalization processes with housekeeping genes.

Nowadays more than one housekeeping gene is recommended that do not vary with experimental paradigms. This point is particularly important in age-related cerebral studies in which standard "housekeeping" genes are usually highly variable. Because of this limitation, such studies usually use only one housekeeping gene to normalise their specific gene expression or use the direct Ct values. Altogether, this implies a major approximation of the results which could lead to possible interpretation mistakes. In the present study, we tried to develop a more rigorous approach for analysing qPCR data during aging and thus in different mouse brain areas. To address this question, we used the geNorm algorithm (QBase+ software) for the identification of a set of relevant housekeeping genes which should allow us to normalized aged-related qPCR data. As controls, we first investigated the expression of 8 genes largely used as housekeeping genes (pPIB, HMBS, RPL13A, actin, HPRT, pPOX, SDHA, Polr2a) in studies performed from hippocampus, striatum, cerebellum and cortex of C57Bl/6J mice aged from 8 weeks to 22 months old. In each of these structures, although none of these putative housekeeping genes displayed a stable expression from 8 weeks to 22 month old, we proposed a combination of at least two of them allowing an acceptable normalization. Our data revealed a unique combination of housekeeping genes that are specific of each of the brain structures analysed, that could be useful for normalization procedure of qPCR data in cerebral age-related transcriptomic studies.

Title: Genetically-Directed sparse and stochastic labeling of striatal direct-pathway neurons in mice: Application to study neurodevelopment and neurodegeneration

Authors: *X. LU, X. W. YANG;
Dept Psychiatry & Biohav Sci., Ctr. For Neurobehavioral Genetics, Semel Inst., LOS ANGELES, CA

Abstracts: To tackle the complexity of brain, tools for sparse and random labeling of individual neurons are needed to study neuronal development, connectivity, plasticity, physiology and pathology. Current reagents are limited by their availability for use in multiple cell types and developmental stages, the time consuming process of generating and combining the necessary mouse alleles (usually bi-, or tripartite system), and the inability to perform genetic-based tagging of endogenous proteins in single defined neuronal cell types. We have developed a simple and versatile method (i.e. MORF) to label single neurons. We generated a dopamine D1 receptor (Drd1a) bacterial artificial chromosome transgenic mice (D1-bacMORF) to demonstrate such method. The D1-bacMORF mice reveal fine dendritic structures of the sparse and stochastic labeled neuronal cell types normally expressing dopamine D1 receptor, including the striatal direct pathway medium spiny neurons (D1-MSNs), hippocampal and cortex pyramidal neurons. By crossing with D1-BAC-TdTomato mice, we showed D1-bacMORF mice selectively labels about 1% of the D1-MSNs. As a demonstration of the functional utility of such method, we used D1-bacMORF mice to reveal the increasing elaborated dendritic morphology of D1-MSNs during postnatal ages between P0 and P90. Furthermore, we crossed D1-bacMORF mice with a Huntington's disease knock-in mice and was able to show age-dependent, progressive dendritic pathology in D1-MSNs of HD mice but not wildtype control mice. Together, our study established a novel and powerful transgenic method to confer genetically-directed sparse and stochastic expression of a marker protein in specific neuronal cell types, and the resulting "Golgi-like" morphological details of the molecularly-defined neurons in intact mouse brains may help to greatly facilitate the study of development, function and dysfunction of the mammalian central nervous system.

Title: A transgenic mouse model expressing a luficerase-based sensor to study proteostasis *in vivo*

Authors: *E. SCHULZ-TRIEGLAFF, R. KLEIN, I. DUDANOVA;
Molecules - Signaling - Develop., Max Planck Inst. of Neurobio., Munich, Germany

Abstracts: The decline in protein homeostasis (proteostasis) mechanisms is believed to be a major cause of age-related neurodegenerative disorders, such as Alzheimer's, Parkinson's or Huntington's disease. It has been shown that modulating the proteostasis machinery protects from or enhances pathological changes in cellular and animal models of neurodegenerative diseases. However, proteostasis has not been monitored during the course of disease of mammalian models *in vivo*. To study the chronological sequence of proteostasis impairment, protein aggregation and neuropathological and functional changes in the brain, we are using protein sensors, which consist of firefly luciferase (Fluc) fused to GFP. Fluc is a metastable protein that requires chaperone assistance for proper folding and full enzymatic activity. A decrease in protein folding capacity of a cell can be detected by decreased enzymatic activity of Fluc and changes in GFP distribution in the cytoplasm, as the sensor forms inclusions when not folded correctly. Point mutations have been introduced into this protein, leading to sensor proteins with increased sensitivity to disturbances of proteostasis (Gupta R, et al. 2011. Nature methods 8: 879-84). We first tested the sensor variants` sensitivity and effectiveness in murine cortical cultures by applying different stress paradigms to transfected primary neurons. Either application of a proteasome inhibitor or co-expression of aggregating proteins leads to the formation of GFP+ inclusions in transfected neurons. Subsequently, we have generated transgenic mice expressing the sensor under a pan-neuronal promoter, to drive expression in the nervous system. Promising founder lines show expression in several brain regions, including cortical layer V pyramidal neurons, thalamus, hypothalamus, ventral tegmental area and cerebellar granule cell layer. We are currently characterizing the properties of the sensor in neuronal cultures of these transgenic animals. We plan to cross these sensor mice to different disease models to assess proteostasis in *ex vivo* fixed tissue and in cultures of dissociated neurons. In addition, luciferase activity could be visualized *in vivo* in anesthetized mice in a noninvasive manner, providing the opportunity for studies of disease progression in the same animal. Our sensor mice represent a tool to monitor proteostasis status in the living animal, an important basis for developing new therapies based on improved proteostasis.

Title: Isolation of DNA from genetically-defined populations of neurons

Authors: *P. S. LAMBETH, B. A. NEWMYER, D. M. WARTHEN, E. PEREZ-REYES, M. M. SCOTT;
Dept. of Pharmacol., Univ. of Virginia, Charlottesville, VA

Abstracts: A clear description of how epigenetic and transcriptional changes occur in defined populations of neurons is crucial to understanding how stimuli modify neuronal function. Currently, no method exists for both flexibly and efficiently tagging nuclei for either genetic or epigenetic analysis. To address this shortcoming, we have developed a broadly applicable method of tagging neuronal cells in a Cre-dependent manner. Sun2 is a protein anchored in the inner nuclear membrane and has redundancy with Sun1, therefore it is an ideal target as it has been shown that manipulations to one of the pair do not affect function. By fusing the myc epitope tag to the C-terminus of Sun2 and inserting it into a DIO (double floxed inverted) adeno-associated viral vector, we have developed a way to limit nuclear tag expression to genetically defined cell types that express Cre recombinase. In the development of this technique, we report on our ability to isolate whole nuclei and to separate genetically distinct populations of cells from heterogeneous cortical tissue. We anticipate combining this approach with other methods that permit the isolation of mRNA from defined cell types through the Cre recombinase dependent expression of HA-tagged or GFP-tagged ribosomal proteins. Consequently, this approach will allow for an analysis of how genetic or epigenetic changes correlate with transcriptional changes in defined populations of neurons. We envision our approach being suitable for a wide variety of downstream applications, including ChIP-seq and multiple forms of DNA methylation analysis.

Title: Generation of a bacterial artificial chromosome transgenic rat line for specifically expressing Cre recombinase and channelrhodopsin in dopamine neurons

Authors: *Y. LU, S. FREY, P. WANG, J. U. FREY;
Lab. of Functional Plasticity, Learning and Memory (BBDI), Georgia Regents Univ., Augusta, GA

Abstracts: Dopamine is known for its importance in many cognitive functions and neurodevelopmental processes. Understanding of mechanisms regulating and regulated by dopaminergic neurons lags however, partially because of shortage of genetic tools to selectively and precisely manipulate these neurons. Comparing with mice, rats offer several advantages both in behavioral tests and electrophysiology. The dopamine transporter (DAT) is only expressed in a subpopulation of dopaminergic neurons to regulate the extracellular dopamine levels. Comparing with the more widely expressed tyrosine hydroxylase (TH) gene, DAT expression is more selective for dopaminergic neurons. Here we generated a transgenic rat line expressing a codon-improved Cre recombinase (iCre), and bicistronically a red shifted chimeric channelrhodopsin (C1V1) using the self-cleaving 2A peptide derived from porcine teschovirus-1 (p2A). These two genes were placed under the control of a large genomic regulatory sequence of DAT gene in a bacterial artificial chromosome (BAC). This DAT-C1V1-p2A-iCre BAC transgenic rat line could present a unique tool allowing genetic manipulations using the Cre/LoxP system and simultaneously an optogenetic control of the DA neuron activity.

Title: Cell-type specific control of gene function in *Drosophila* melanogaster

Authors: *Y. E. FISHER[1], D. M. GOHL[2], T. R. CLANDININ[1];
[1]Stanford Univ., Stanford, CA; [2]Univ. of Minnesota Genomics Ctr., Univ. of Minnesota, Minneapolis-St Paul, MN

Abstracts: The ability of a neuron to perform a specific computational role within a circuit is tightly shaped by its gene expression profile. Therefore, a common experimental goal is to disrupt a gene of interest in a cell-type specific manner. Due to its immense genetic toolkit, *Drosophila* is a powerful model system for the study of circuit function. However, current conditional gene disruption techniques often only incompletely reduce gene activity or require time-consuming genome engineering. We have developed FLP-STOP, a conditional gene disruption tool for *Drosophila* that uses a targeted insertional mutagenesis strategy that takes advantage of a large collection of existing transposable elements targeting most genes. In this approach, a transgenic animal is created in which a recombinase-dependent STOP-cassette is placed within an intron of the gene of interest. By design, this cassette will only disrupt gene function when it is in one of two possible orientations. The cassette is flanked by recombinase recognition sites (creating a FLEx switch) such that it becomes inverted in the presence of FLP recombinase (Schnutgen et al. 2003). We demonstrate that intronic insertions of the STOP-cassette in the neutral or "non-disrupting" orientation retain normal gene function while the "disrupting" orientation is sufficient to severely impair gene function and can even produce null alleles. Cassette inversion is highly efficient and can be achieved when FLP recombinase is expressed using a heatshock promotor or under GAL4/UAS control, demonstrating compatibility with existing tools for targeting and manipulating neuronal populations. We present progress toward a tool kit of transgenic tools for manipulating genes that target GABAergic, glutamatergic and cholinergic transmission as well as various voltage-gated ion channels. This tool facilitates experiments that investigate the interaction between genes and circuit function.

Title: Profiling of midbrain dopamine neuron projections to the striatum using Retro-TRAP

Authors: ***A. R. NECTOW**[1], M. I. EKSTRAND[1], K. N. LATCHA[1], J. M. FRIEDMAN[2]; [1]Dept. of Mol. Genet., Rockefeller Univ., New York, NY; [2]Dept. of Mol. Genet., Rockefeller University/HHMI, New York, NY

Abstracts: Translational profiling methodologies have allowed for the systematic characterization of neural circuitry in health and disease states. We have recently developed a methodology, Retro-TRAP, for profiling neurons based on their connectivity utilizing an anti-GFP nanobody fused to ribosomal protein Rpl10a (NBL10). This approach can be further extended to be cell-type-specific by restricting NBL10 expression to Cre-expressing populations of neurons through viral-mediated gene transfer (AAV-FLEX-NBL10), allowing for molecular interrogation of genetically-defined neurons based on connectivity. Building on these methods, we added an N-terminal 3xFLAG tag to our construct (AAV-IV-NBL10), allowing for normalization to the whole Cre-expressing population to identify projection-specific marker genes within a molecularly defined population. We used these approaches to comprehensively profile and compare mesolimbic and nigrostriatal projections, with a particular focus on dopamine neurons. Through comparative analysis of high-throughput RNA sequencing (RNA-seq) data generated from each of these populations, we've identified a number of projection-specific marker genes differentiating these two populations, some of which were confirmed via immunohistochemistry, FISH, and/or the Allen Brain Atlas. Importantly, the current approach is generalizable to neural circuitry throughout the central and peripheral nervous system, allowing for comprehensive molecular profiling of defined cell-types based on their connectivity.

Title: Quantification of protein levels in single cells *in vivo*

Authors: C.-A. LO[1], I. KAYS[1], F. EMRAN[2], T.-J. LIN[2], V. CVETKOVSKA[1], *B. E. CHEN[1]; [1]Ctr. for Res. in Neurosci., McGill Univ., Montreal, QC, Canada; [2]Ctr. for Res. in Neurosci., Res. Inst. of the McGill Univ. Hlth. Ctr., Montréal, QC, Canada

Abstracts: Accurate measurement of the amount of specific protein a cell produces is important for investigating basic molecular processes of the cell. The current methods for determining protein amounts have poor cellular resolution and are inherently destructive to cells, limiting the accuracy and relevance of the measurements. We have developed a technique that allows for quantitation of protein levels in single living cells. This Protein Quantitation Ratioing (PQR) technique uses a genetic tag that produces a stoichiometric ratio of a fluorescent protein reporter and the protein of interest during protein translation. The fluorescence intensity (i.e., brightness of the cell) is directly proportional to the number of molecules produced of the protein of interest, and thus is used to determine the relative protein amount within the cell. Using quantitative imaging and electrophysiology, we demonstrate that PQR can produce stoichiometric separations and linear relationships between different genes. Using the circadian system, we demonstrate cyclical changes in fluorescence in small lateral ventral neurons in the *Drosophila* brain. We use genome editing techniques to insert Protein Quantitation Reporters into endogenous genomic loci in three different genomes for quantitation of endogenous protein levels. Fluorescence quantification of endogenous RPL13A protein levels in a neuron can be used to normalize across experimental and optical conditions, such as spherical aberrations, optical distortions, calcium imaging, and imaging depths during *in vivo* imaging. The Protein Quantitation Ratioing technique allows for measurements of endogenous or exogenous protein

amounts in single living cells *in vivo*, to relate cellular phenotypes as a function of protein concentrations.

Abstracts: The introduction of plasmid DNA into cells with the aim to manipulate the protein expression is a widely used method in cell biology research. Several transfection methods are available, although all methods do not suit all cellular systems. Specifically, many primary cell types, such as neurons, have proven to be difficult to transfect with high efficiency and viability. We have developed a protocol for in-situ electroporation of primary dorsal root ganglion (DRG) neurons from adult rats using the Cellaxess Elektra Discovery Platform. The Elektra platform utilizes a capillary electroporation concept that can be applied for gene transfer to primary cultures in 384-well plates. The focused electrical field delivered by the platform minimizes electrochemical toxicity and joule heating, compared to conventional cuvette-based electroporation methods. The platform has the capability to transfect neuronal cells, e.g. rat, mouse & IPS-derived human neurons, with excellent viability and retained morphology, and the method is well-suited for high content readouts. Importantly, as the transfection procedure is performed directly in 384-well HCA compatible plates, the protocol is ideally suited for a screening workflow where additional manipulations, such as microscopy-based readouts or other follow-up assays, are easily accomplished without additional cell processing. With the Elektra platform, we were able to develop stable protocols for transfection of rat DRG neurons with a high degree of viability and a retained and healthy morphology. Using a CopGFP-plasmid a transfection efficiency of 40-60% was achieved and cultures could be transfected at different

time points after plating in a straightforward manner. In our lab, we use primary DRG neurons in culture as a cell model for chronic pain. These neurons retain their sensory functionality after transfection and remain responsive to thermal, mechanical and functional stimuli, and when supplemented with nerve growth factor (NGF), they can be used to mimic peripheral sensitization. Through the use of the transfection protocol described here, we now have the capability to knock in, and/or knock out, gene targets of interest in these cells to further refine and enhance the relevance of our disease models.

Title: Intravascular administration of an AAV vector to neonatal macaques results in widespread gene transduction into neurons throughout the primate brain

Authors: ***K. INOUE**[1], K. KIMURA[1,2], R. YASUKOCHI[1], N. SUGAWARA[1], Y. OKUDA[1], M. FUJIWARA[1], M. TAKADA[1];
[1]Systems Neurosci. Sec., Primate Res. Inst., Kyoto Univ., Inuyama, Japan; [2]Dept. Neurol. and Stroke Med., Sch. of Medicine, Yokohama City Univ., Yokohama, Japan

Abstracts: Recombinant adeno-associated virus (rAAV) vectors constitute a powerful tool for delivering target genes into the brain. Previous studies reported that serotype 9 of AAV (AAV9) was able to cross the blood-brain barrier, and that systemic application of a self-complementary AAV9 vector to neonatal mice, rats, and cats yielded efficient gene transduction into neurons. However, gene transduction into neurons of neonatal non-human primates has not yet been performed successfully. Here we show that intravascular administration of a single-stranded AAV9 vector to neonatal macaques resulted in widespread gene transduction into neurons

throughout the brain. We injected 1.0 x 10^{14} viral genome/kg of the AAV vector expressing green fluorescent protein (GFP) under CMV promoter control through the saphenous vein. Robust GFP expression was found in both neurons and glia over the cerebral cortex, subcortical regions, and cerebellum. Neuronal tropism and transduction efficiency varied depending on the brain structure and cell type. Purkinje cells in the cerebellar cortex exhibited the highest transduction efficiency. The present data indicate that systemic delivery of the AAV9 vector in neonatal macaques is a potential methodology to transduce target genes efficiently throughout the primate brain and is useful in creating genetically manipulated primate models of neuropsychiatric disorders and developing their gene therapeutic approaches.

Title: Improved and expanded Q-system toolkit for transgene expression

Authors: *O. RIABININA[1], D. LUGINBUHL[3], E. MARR[1], S. LIU[2], M. N. WU[2], L. LUO[3], C. J. POTTER[1];
[1]Dep of Neuroscience, SOM, [2]Dep of Neurology, SOM, Johns Hopkins Univ., Baltimore, MD; [3]Howard Hughes Med. Inst., Stanford Univ., Stanford, CA

Abstracts: The Q-system is a binary transcription factor system for expression of transgenes *in vivo*. The system was originally developed for use in *Drosophila* (Potter et al, 2010), and has since been adapted for *C. elegans* (Wei et al, 2012) and D. rerio (Subedi et al, 2014). In its original form, the transcriptional activator of the Q-system QF appeared to be toxic when

expressed pan-neuronally or ubiquitously in *Drosophila*. To solve the toxicity problem, we created a number of chimeric transactivators by combining functional subunits (DNA binding domain, middle domain and activation domain) of QF, GAL4 and the third *Drosophila* expression system, LexA. We discovered that the middle domain of QF is chiefly responsible for its toxicity. By removing the middle domain we developed the second-generation version of QF, named QF2. By introducing a mutation in the activation domain, we also generated QF2w, a weaker variant useful in cases of very broad QF2 expression. Both QF2 and QF2w are non-toxic, can drive strong expression and are QS-suppressible. QF2 and QF2w function equally well in the range of temperatures (18-29C), typically used in *Drosophila* experiments. For use in the nervous system, we generated transgenic *Drosophila* that express QF2 and QF2w pan-neuronally under the control of a strong synaptobrevin promoter. To extend the use of the Q-system beyond nervous system, we also generated fly lines where QF2/QF2w are expressed ubiquitously by actin and tubulin promoters. These lines can be used to express high levels of reporter genes in nervous system, imaginal discs and muscles of larva, and various tissues in adult flies. In the course of our study, we also developed two chimeric transactivators, GAL4-QF and LexA-QF, that bind the UAS and LexAop, respectively, and are QS-suppressible. Pairwise combinations of all new transactivators and GAL4 functions effectively during pan-neuronal expression, thus allowing greater flexibility in intersectional studies that make use of the Q, GAL4/UAS and LexA systems.

Title: Cas9 nickase increase efficiency in producing transgenic human embryonic stem cell lines

Authors: ***J. CAO**, Y. CHEN, M. XIONG, Z. DU, S.-C. ZHANG;
Waisman Center, Univ. of Wisconsin Madison, Madison, WI

Abstracts: The ability to precisely modify mammalian genome has revolutionized biomedical researches over the past decades. Nevertheless, generation of genetically modified human stem cells with traditional transgenic tools has been challenging. The RNA-directed sequence-specific Cas9 endonuclease enables homology-directed repair (HDR) in the presence of a template, making it possible to produce genetically modified human stem cell lines. The newly developed Cas9 nickase system further improves the specificity of sgRNA-guided targeting on a DNA locus. However, it is not known whether the nickase system affects the HDR efficiency, especially in human pluripotent stem cells (PSCs). By using the Cas9 system to target Ago2 and Sox2 in human embryonic stem cells (ESCs), we found that the HDR efficiency is enhanced from 1.3% in the regular Cas9 system to 55.8% in the nickase system at Ago2 locus. Similarly, the HDR efficiency is improved from 21.8% to 67.8% by the nickase system at Sox2 locus. Importantly, we also observed an increased homozygous HDR ratio by Cas9 nickase (is from 0% to 20% for Ago2 and from 2.3% to 16.1% for Sox2). Interestingly, when we tested the genomic DNA cleavage efficiency by regular Cas9 or nickase, we found that nickase has a lower cleavage efficiency than regular Cas9. Our results thus indicate that Cas9 nickase increasesthe HDR efficiency and homozygous HDR ratio in human ESCs, suggesting that Cas9 nickase system is

ideal for producing transgenic human ESC lines, including knockout lines that require targeting both alleles.

Title: Fluorescence-activated sorting of fixed nuclei (FAST-FIN): A general method to study nuclei from specific cell populations that preserves post-translational modifications

Authors: L. MARION-POLL[1], E. MONTALBAN[1], A. MUNIER[2], D. HERVÉ[1], *J.-A. GIRAULT[1];
[1]UMR-S 839, Inserm UPMC Inst. du Fer A Moulin, Paris, France; [2]Cell Imaging and Flow Cytometry facility, UPMC, Paris, France

Abstracts: A major difficulty in the study of transcriptional changes and epigenetic modifications comes from the cellular heterogeneity of brain tissue. A promising approach is to directly purify identified nuclei. Using mouse striatum we have developed a rapid and efficient method to isolate cell type-specific nuclei from fixed adult brain (fluorescence-activated sorting of fixed nuclei, FAST-FIN). The protocol we describe can be performed within one or two days. Animals are quickly perfused with a formaldehyde fixative that stops enzymatic reactions and maintains the tissue in the state it was at the time of death. Tissue is subsequently dissociated with a Dounce homogenizer and nuclei prepared by centrifugation in an iodixanol density gradient. The purified fixed nuclei can then be immunostained with specific antibodies and either analyzed or sorted by flow cytometry. Simple criteria allow identification of neurons. Immunolabeling and transgenic mice that express fluorescent proteins can be used to identify specific cell populations, and the nuclei from these populations can be efficiently isolated, even rare cell types such as parvalbumin-expressing interneurons. This method allows the preservation and study of dynamic and labile post-translational protein modifications. FAST-FIN should be applicable to other tissues and species.

Title: Brain-specific delivery of rabies virus glycoprotein modified nanoparticles as a function of route of administration

Authors: ***A. PRAKAPENKA**[1,2,3,5,6], R. L. MCCALL[6], R. W. SIRIANNI[6,4], H. A. BIMONTE-NELSON[5,3,6];
[2]Sch. of Life Sci., [3]Dept. of Psychology, [4]Dept. of Biomed. Engin., [1]Arizona State Univ., Tempe, AZ; [5]Arizona Alzheimer's Consortium, Phoenix, AZ; [6]Brain Tumor Res. Center, Barrow Neurolog. Inst., Phoenix, AZ

Abstracts: The efficacy of hydrophobic drugs in the central nervous system (CNS) is limited by poor solubility, rapid clearance, and inefficient delivery to target tissue. Nanoparticles composed of poly (lactic co-glycolic) acid (PLGA) release drugs over a time period of days to weeks, sustaining the presence of drug in tissue to improve efficacy. By modifying the surface of the nanoparticle, it may be possible to achieve tissue-specific targeting. For instance, rabies virus glycoprotein (RVG) is a 26-amino acid peptide from the coat protein of the rabies virus that plays a crucial role in its penetration of the CNS. This study examined the biodistribution of both plain PLGA and RVG modified PLGA nanoparticles using encapsulated fluorescent hydrophobic dye. The nanoparticle formulations were administered to mice by intravenous, intraperitoneal, and subcutaneous routes. Tissue was extracted at 30 minutes, 2 hours, 6 hours, and 24 hours after injection and homogenized to measure fluorescent signal. Results showed that total dye concentration in the brain was highest following intravenous administration, with a 40% concentration increase at 2 hours using RVG modified PLGA relative to plain PLGA. An increase in brain concentration with RVG modified PLGA was also seen with intraperitoneal (at 2 hours) and subcutaneous (at 6 hours) administration relative to plain PLGA. These results suggest that the brain-targeting effect of RVG modification is maintained across administration techniques, but that the kinetics of delivery are a function of the route of administration. That is, intravenous administration of nanoparticles produced the highest payload delivery to the brain.

These data will be helpful to identify drug delivery strategies that are capable of producing the highest accumulation of encapsulated payload in the brain while reducing peripheral exposure. In particular, we are developing surface-modified nanoparticles to study brain-specific effects of estrogen on cognitive performance.

Title: Two-key recombinase system for neural ensemble labeling and manipulation of ventral striatal D1R- and D2R-MSN neural ensembles encoding primary appetitive and aversive stimuli

Authors: *D. M. OPLAND, C. W. BOND, D. S. ABRAMOV, R. J. DILEONE;
Mol. Psychiatry, Yale Univ., New Haven, CT

Abstracts: The ventral striatum is known to take part in encoding information relative to both primary appetitive and aversive stimuli, a component of its role in mesocorticolimbic reward processing. Previous research has elucidated the role of D1R-containing medium spiny neurons (MSNs) in encoding appetitive stimuli and potentiating behavior ("Go" neurons). Conversely, D2R-MSNs encode aversive stimuli and attenuate behavior ("No-Go" neurons). However, recent evidence suggests that there might be encoding of aversion within D1R-MSN populations and encoding of reward within D2R-MSNs. These populations represent an understudied subset of striatal neurons that potentially contribute significantly to reward-mediated behaviors. Limits of molecular genetic labeling techniques prevent sufficiently identifying and manipulating functionally relevant subsets of active neural ensembles. Recent studies have used c-Fos or Arc IEG promoter driven Cre recombinase mediated expression of fluorophore labels in order to label activated neural ensembles participating in discrete behaviors. We have developed a similar IEG-mediated neuronal ensemble labeling technique that uses two different recombinase

enzymes (a 2-key system) which allows for both labeling (flourophore-tagging) and manipulation (optogenetically with hChR2) of active neural ensembles restricted by a population-specific marker (in this case a Cre-driver transgenic mouse line). This construct uses Arc as a marker for neural activity and tamoxifen as a means of restricting the labeling window. Using this new molecular tool we are able to specifically label in D1R-Cre and D2R-Cre mouse lines the relative response of each type of MSN to either primary appetitive or aversive stimuli as well as how each contribute to the modulation of behavior. This strategy allows labeling, and ultimately manipulation, of specific subsets of active neurons within brain regions.

Title: Towards nontoxic monosynaptic transduction

Authors: *I. R. WICKERSHAM;
McGovern Inst., MIT, CAMBRIDGE, MA

Abstracts: Monosynaptically restricted transsynaptic tracing using rabies viral vectors has become a widely used technique, allowing identification of synaptically connected neurons and expression of transgenes within them. However, this technology has so far been used almost exclusively for anatomical experiments because of its rapid cytotoxicity. Solving the toxicity problem would be a major advance, allowing the monitoring and manipulation of identified synaptically connected neuronal networks in the context of long-term behavioral experiments.

Here I present an approach to identifying and expressing transgenes within monosynaptically connected neurons while leaving them alive and physiologically normal indefinitely.

Title: ApoE-mediated lipid nanoparticle delivery of RNA for loss-of-function and gain-of-function studies in primary neurons *in vitro* and *in vivo*

Authors: *E. RAMSAY, C. WALSH, A. ANSARI, A. THOMAS, K. OU, A. WILD, T. LEAVER, R. J. TAYLOR, D. ZWAENEPOEL;
Precision Nanosystems Inc., Vancouver, BC, Canada

Abstracts: Objective To demonstrate Apolipoprotein E (ApoE)-mediated Lipid Nanoparticle (LNP) delivery of RNA modulates gene expression in primary neurons *in vitro* and *in vivo* providing a rapid and simple mechanism to manipulate gene regulation. Methods RNA-LNP were prepared using a proprietary microfluidic-based manufacturing platform (SUB9KITS™). For uptake studies, fluorescent RNA-LNP (100 ng - 1000 ng RNA/mL) were incubated (24 h) with primary hippocampal neurons grown +/- astrocyte feeder layer. A mixed culture of primary cortical neurons (PCN) were treated with siRNA-LNP targeted against phosphotensin homolog 1 (PTEN). Gene knockdown was determined by mRNA (qPCR) and protein (western blot (WB)). Neuron viability was assessed using the lactate dehydrogenase (LDH) assay. A single dose of siRNA-LNP (500 nL at 5 mg/mL siRNA/10mins) was directly injected into the somatosensory cortex. Acute cortical slices (5 days post injection) were assessed for siRNA-LNP uptake and PTEN gene knockdwon *in vivo*. Gene expression was assessed in PCN using GFP mRNA-LNP

(500 ng/mL mRNA). GFP expression was measured using flow cytometry 72 h post-transfection. Results RNA-LNP were avidly taken-up (>98%) by primary hippocampal neurons grown on an astrocyte feeder layer. Neurons cultured without astrocytes had minimal uptake. Addition of ApoE4 recovered RNA-LNP uptake. ApoE delivers essential lipids, e.g. cholesterol to neurons via LDLR. PCN incubated with PTEN siRNA-LNP (100 ng/mL siRNA) for 72 h showed > 90% knockdown (qPCR, WB). Gene knockdown was sustained for 21 days after a single treatment. PTEN siRNA-LNP (100 ng/mL) mediated > 80% knockdown in PCN (DIV 6, 9, 13 and 16) at 72 h (qPCR). PCN incubated with 500 ng/mL GFP mRNA-LNP for 72h showed > 95% GFP positive neurons (Flow cytometry). The tested RNA-LNP were well tolerated (no difference in LDH signal compared to untreated control). A single intracortex of siPTEN-LNP (500nL at 5mg/mL siRNA/10mins) mediated > 85% knockdown in cortical slices 5 days post-injection (Western Blot). Conclusion RNA-LNP (SUB9KITS™) demonstrated ApoE-enhanced rapid uptake by neurons, which mediated effective, sustained and widespread modulation of a target gene expression both *in vitro* and *in vivo*, with no detectable toxicity at concentrations tested. This technology offers a a rapid and simple mechanism to manipulate gene regulation.

Abstracts: The Cre/loxP recombination system is one of the conditional chromosomal mimics to investigate systemic function of targeted genes (Rabbitts et al., 2001), and has been adopted to examine a function of specific gene. For *in vivo* experiments, rat offers potential advantages of larger body size and progressed ability to accomplish more complex behavioral task as compared to mouse. Here we evaluated a conditional reporter rat line which has red fluorescent protein (tdTomato) gene in the downstream of loxP-flanked STOP cassette. Firstly we injected AAV-Cre into striatum, hippocampus and cerebellum of the reporter rats to test the conditional expression of tdTomato. Each Cre-immuno-positive cells sparsely located in the injection part and merged with tdTomato. Secondly, site-specific expression was evaluated by *in utero* electroporation of AcGFP-NCre plasmid. Cortical layer 2/3 neurons were visualized by tdTomato fluorescence in the newborn pup. Thirdly, we evaluated this reporter system using *phox2b*-Cre driver rat, which specifically expresses Cre in cells of several hindbrain regions involved in the autonomic nervous system including neurons that are responsible for respiratory rhythm generation. When the double transgenic rats with *phox2b*-Cre and *floxed* tdTomato were examined at embryonic day (E)12.5, tdTomato was expressed in the neurons of parafacial respiratory group (pFRG), epibranchial ganglia, the forming oculomotor/trochlear nuclei and autonomic ganglia. The neuronal projection fibers were clearly visualized by tdTomato signal. It is suggested that the tdTomato was strongly expressed in neurons including Cre with high specificity. Our reporter rat would facilitate the neurophysiological studies and the connectomics of identified neurons which express Cre under a certain promoter. All animal procedures were

conducted in accordance with the guiding principles of Physiological Society of Japan and NIH.

Abstracts: Alzheimer's disease (AD) is a devastating neurodegenerative disease for which there is currently no cure. We previously demonstrated that expression of the *epsilon2* allele of human apolipoprotein E (*APOE*) via intraventricular injection of adeno-associated virus serotype 4 (AAV4) can reduce pathological processes in transgenic mouse models of AD slowing down the

progression of amyloid deposition and alleviating A-associated neurotoxicity *in vivo*. As an alternative preclinical approach to further enhance the safety and efficacy of this strategy, we engineered a novel self-complementary AAV9, scAAV9-GFA', designed to drive expression of a transgene specifically in astrocytes after peripheral intravascular infusion. Intravenous delivery of scAAV9-GFA' encoding green fluorescent protein led to robust and long-lasting transduction of astrocytes throughout the entire cerebral tissue, in the absence of neuronal transduction or more than trivial levels of peripheral expression of the transgene. scAAV9-GFA' led to transduction of ~10% of cortical astrocytes, two orders of magnitude higher levels than the comparable traditional ssAAV9 serotype. Both GFAPactivated and resting astrocytes expressed the reporter gene. These data suggest the potential of scAAV9-GFA' as a system to drive expression of therapeutic genes specifically in astrocytes of the CNS.

Title: Understanding the genetic basis for functional heterogeneity in telencephalic interneurons

Authors: A. B. MUNOZ-MANCHADO, A. ZEISEL, S. LINNARSSON, *J. HJERLING LEFFLER, Dr;
Karolinska Institutet, STOCKHOLM, Sweden

Abstracts: The overarching goal is to discover and characterize the distinct transcriptional states that generate most of the distinct interneuron cell types in the mammalian neocortex. Despite a century of efforts, we have only a broad understanding of the cell types that make up the mammalian forebrain. For example, GABAergic interneurons are often classified by their expression of neurochemicals such as parvalbumin, somatostatin, calretinin and NPY, yet these classes overlap in complex patterns and still are not enough to describe the known functional diversity. During development the GABAergic interneurons are ventrally derived from the ganglionic eminences in the embryonic brain, which can be anatomically divided into lateral, medial and caudal parts (LGE, MGE and CGE respectively). The two latter regions give rise to non-overlapping cortical interneuron populations and the developmental origin remains the only unequivocal way to group cells. Nonetheless, there are distinct functions described for more than five different classes of interneurons and we are asking whether functional heterogeneity is reflected in reproducible gene-expression patterns. Furthermore, we know very little about the transcriptional states and chromatin organization that create and maintain distinct cell types. This lack of knowledge stymies efforts at large-scale brain connectivity mapping, since we do not fully understand the properties of the connected nodes and reduces reproducibility of experiments between labs. Recent progress in single cell RNA sequencing allow us to describe each cell individually in terms of RNA expression and thus address many of the questions mentioned above. We focus our effort in studying the cellular make up of interneurons from the somatosensory cortex and the striatum in p21-28 mice using the method described by the Linnarsson group (Islam et al., Nat Methods, 2012). We are validating our findings with immunohistochemistry and/or *in situ* hybridization. The cortical interneurons constitute a minority of all cortical cells, and to address this heterogeneous population in more detail, we use FACS isolation of, genetically labelled interneurons, based on developmental origin and/or the expression of markers. In order to infer functionality we will validate our findings using single-cell RT-PCR on electrophysiologically recorded neurons.

Title: Characterization of a transgenic rat expressing Cre recombinase from the dopamine transporter promoter

Authors: *Y.-J. ZHANG[1,2], C. T. RICHIE[1], L. R. WHITAKER[1], A. F. HOFFMAN[1], C. E. SPIVAK[1], C. R. LUPICA[1], H. A. BALDWIN[1], J. J. HINKLE[1], G. YEH[1], C. MEJIAS-APONTE[1], M. MORALES[1], S. M. UNDERHILL[3], J. C. SMITH[4], J. M. PICKEL[3], B. T. HOPE[1], B. K. HARVEY[1];
[1]NIDA IRP, Baltimore, MD; [2]NIAAA, Rockville, MD; [3]NIMH IRP, Bethesda, MD; [4]NINDS IRP, Bethesda, MD

Abstracts: The dopamine transporter (DAT) protein is a target of the widely abused psychostimulants cocaine and amphetamine, and loss of DAT expressing cells is often a marker of neurodegeneration associated with Parkinson's disease and methamphetamine abuse. Given the relevance of DAT-expressing neurons to rat models of addiction and neurodegeneration, we have generated and characterized three lines of transgenic Long Evans rats expressing Cre recombinase under the DAT promoter (DAT::iCre). The tissue-specific expression of Cre can be used in combination with Cre-dependent transgenes to obtain selective transgenesis in DAT(+) neurons. A bacterial artificial chromosome (BAC) containing the rat DAT gene was recombineered to replace the start codon of DAT with Cre recombinase. Pronuclear injections of DAT::iCre BAC into fertilized rat eggs ultimately resulted in three independent, phenotypically positive DAT::iCre lines. All three lines were immunoreactive for Cre recombinase in the midbrain and Cre-immunoreactivity colocalized with tyrosine hydroxylase-immunoreactivity (TH-IR), a marker for dopaminergic neurons. Injection of adeno-associated viral (AAV) vectors expressing Cre-dependent mCherry reporter protein resulted in expression restricted to TH-IR cells in the midbrain. *In situ* hybridization for DAT mRNA also colocalized with the Cre-driven mCherry. When DAT::iCre rats were crossed to DIO-mCherry (Cre-dependent) reporter rats, mCherry expression was primarily restricted to TH-IR cells in midbrain with few mCherry-labelled cells sparsely distributed in cortical regions including hippocampus. We also examined the effects of the genomic integration of the DAT::iCre transgene on endogenous DAT function and dopaminergic neuron phenotype. The presence of DAT::iCre did not alter endogenous levels of TH protein or TH-immunoreactivity in the striatum and midbrain compared to wild-type (WT) rats. Both basal levels of DAT and amphetamine-induced internalization of DAT in the midbrain were similar for WT and DAT::iCre rats. Fast-scan cyclic voltammetry was performed in brain slices from WT and DAT::iCre rats and no significant difference was observed in evoked dopamine release,dopamine uptake or concaine sensitivity in the dorsal striatum. *In vitro* intracellular recordings revealed no significant difference in firing and membrane properties of midbrain dopamine neurons from WT and DAT::iCre rats. The development of transgenic rat lines for targeting transgene expression to midbrain DAT-expressing neurons provides a promising approach to selectively asses the function of these neurons in animals models of drug abuse and neurodegeneration.

Title: Identification of astrocytes derived from neural progenitor cells by high-throughput screening using a live cell mRNA detection technology

Authors: *D. WELDON, V[1], Y. WILLIAMS[1], A. KO[1], V. KOONG[1], W. JASTROMB[2]; [1]EMD Millipore, Temecula, CA; [2]Nikon, Melville, NY

Abstracts: Neural progenitor cells (NPCs) contain the capability to differentiate into neuronal and glial cell lineages, and have been used by researchers to develop ways to repair the central nervous system following damage. One example is the derivation of astrocytes from NPCs, which is effective in generating functional terminally differentiated neuronal cells that can then be subjected to molecular and biological assays. Currently, astrocytes are mainly identified using intracellular antibody staining of proteins such as GFAP, which prevents those characterized cells from use in further experiments, due to the need to permeabilize the cells for successful staining. Here, we successfully demonstrate the detection of intracellular GFAP mRNA during the NPC-to-astrocyte differentiation process using a novel probe-based live-cell RNA detection technology, which can specifically measure RNA expression in whole cells without altering cell viability, function, or integrity. This allows researchers to not only monitor the regulation of specific mRNA during the course of the differentiation protocol, but also enables interrogated cells to be used in downstream cell-based functional assays. Here, we employed a high-throughput screening (HTS) method to screen our NPC-derived astrocytes expressing GFAP mRNA, which retained their biological function as evident in a subsequent migration assay. This enabled the quick and accurate identification of highest GFAP mRNA expressing cells, thus maximizing the likelihood of success in our downstream assay. The ability to monitor gene expression during NPC differentiation to astrocytes in a live cell setting not only removes the need to set up extra duplicate wells for downstream studies, but also enhances the relevance of

the data generated, due to the fact that the same cell is being tracked throughout the entire experimental workflow. Using live-cell RNA detection probes in HTS experiments not only enables researchers to vastly increase the number of cells that can be accurately interrogated at a time, but also allows them to retain their best candidate live samples for use in downstream functional assays, something that is not currently possible using traditional antibody-based methods.

Title: Dissecting multiple neuronal pathways in mammalian brain using Avian sarcoma and leukosis virus envelope-receptor pairs

Authors: *M. MATSUYAMA[1,2], Y. OHASHI[1], T. TSUBOTA[1], M. YAGUCHI[1], K. MAMADA[1], S. KATO[3], K. KOBAYASHI[3], Y. MIYASHITA[1];
[1]Dept. of Physiol., Univ. of Tokyo Sch. of Med., Tokyo, Japan; [2]JSPS Res. Fellow, Tokyo,

Japan; [3]Dept. of Mol. Genetics, Inst. of Biomed. Sciences, Fukushima Med. Univ., Fukushima, Japan

Abstracts: Methods for manipulating specific neural pathways are a powerful way to disentangle complex neural systems; however, conventional genetic tools (e.g., Cre/loxP and Tet system) cannot control gene expression in more than two neural pathways simultaneously. To overcome this limitation, we developed a "Gate-Tag vector system" using modified avian sarcoma and leukosis virus (ASLV) receptors and envelopes; this system simultaneously can be used to deliver three different genes into three separate cell targets. The vector system comprises two elements: a Gate vector expressing a specific receptor "Gate" on the target-cell surface and a Tag vector that enters the target-cell through the Gate. The specificity of the Gate-Tag vector system was confirmed by demonstrating the selective expression of fluorescent proteins only for specific receptor/envelope pairs both *in vitro* (>97% in HEK293T cells) and *in vivo* (>98% in rat brain). Moreover, when combined with highly efficient retrograde gene transfer (HiRet) (Hirano et al., 2013), this vector system achieved three distinct pathway-specific gene transfers of three different fluorescent genes into rat thalamocortical neurons. This system can be easily adapted to manipulate the function of selected neuronal pathways by expressing other genes such as those encoding neurotoxins and opsins. Thus, the Gate-Tag vector system is an independent, simultaneous, and specific genetic tool that can be used to dissect multiple neural pathways *in vivo*.

Title: RiboTag: A novel method for measuring gene expression within discrete populations of primary neuronal cultures

Authors: *A. J. LESIAK, J. F. NEUMAIER;
Psychiatry and Behavioral Sci., Univ. of Washingotn, Seattle, WA

Abstracts: Measurement of dynamic changes in gene expression within cellular sub-types from a diverse cellular milieu has been a significant challenge in neuroscience; however recent techniques have been developed to resolve this issue. The HA-tagged RPL22 ribosomal protein (RiboTag) construct was originally developed for translational profiling in animal models and allows for the isolation of ribosome-bound mRNA transcripts specifically within the cells in which the RiboTag construct is expressed; however it may also be a useful tool for numerous *in vitro* applications. Primary neuronal cultures are a commonly used tool for the study of a variety of neurophysiological processes, but experimental analysis of gene expression within these cultures is often confounded by low transfection efficiency and co-culturing with non-neuronal cell types. To determine if RiboTag expression can address this problem, we prepared primary cultures and co-transfected RiboTag plasmids and various experimental plasmids using lipofection. 24-48 hours later, sample lysates were collected, and a small portion of this lysate was reserved as an in-well representation of mRNA within the entire sample (input sample) prior to isolation of RiboTag complexes using magnetic bead immunoprecipitation (pull-down sample). RiboTag pull-down yielded a significant enrichment of co-transfected genes relative to the input control. When a neuron-specific promoter was used to drive RiboTag expression selectively in neurons, mRNA recovered by RiboTag pull-down was enriched for neuronal markers and absent of glial markers, while the input samples contained both neuronal and glial transcripts. Co-transfection of RiboTag with sh-RNA constructs was also used to quickly and easily confirm sh-RNA knockdown of endogenous genes despite low transfection rates. Lastly, we demonstrate how RiboTag can be used to measure the transcriptional and translational effects of pharmacological and cell signaling events using DREADD-receptors, which are selectively activated by clozapine-N-oxide (CNO), an otherwise inert ligand. Treatment of neurons with forskolin induced an equivalent increase in cFos expression in both the pull-down sample and input sample relative to unstimulated controls; however, in Gs-coupled DREADD expressing neurons cFos expression was induced specifically in the pull-down sample but not in the input sample following CNO-treatment. In summary, RiboTag represents a convenient but powerful tool to isolate mRNA within a specific sub-set of cultured cells, and provides a tool for analyzing the translational profile accompanying a variety of neurophysiological events.

Title: The creation and characterization of Cre Rat Drivers

Authors: Z. LIU, *X. CUI;
Res. & Develop., SAGE Labs, Saint Louis, MO

Abstracts: The Cre-loxP system has been widely applied in the mouse, providing accurate spatiotemporal control of gene expression. Yet its adaptation in the rat, the preferred model system for neuroscience research, has been hindered by technical challenges until the recent but rapid development of nuclease-mediated site-specific genome editing technologies, such as zinc finger nucleases and CRISPR/Cas9, allowing efficient site-specific insertion of Cre expression cassette and loxP sites (Brown et al., 2013). Cre rat drivers will undoubtedly be of greatly impact, especially on the fast rising field of optogenetics. However, few Cre rats have been generated to date, preventing the rat from reaching their full potential as research models. We have reported previously the creation and preliminary characterization of two Cre rats: Th-Cre and Dat-Cre. Here we present further characterization of these two lines, including demonstration of the neuron-specific expression of Cre in different lines by using a combination of immunohistochemistry and mRNA fluorescence *in situ* hybridization (FISH) as well as the confirmation of Cre-dependent excision of the floxed alleles in cells harvested with laser-assisted microdissection and discuss breeding strategies. Additionally, we report our progress on the effort to expand the Cre-loxP rat tool box by creating six more Cre driver rats and three reporter lines. In the Cre rats, 2A-Cre will be under the control of Tph2, Sst, Slc32a1, Calb2, VIP and HTR3A promoters from each respective endogenous locus. A conditional fluorescent reporter and two conditional opsin (excitatory channelrhodopsin2 or inhibitory Halorhodopsin) expression cassettes will each be inserted to the readily targetable rat Rosa26 locus to obtain Cre-dependent expression. We hope these rat lines will not only provide the research community useful tools but encourage researchers to join force to make more Cre rats. Title: Improvement of gene transduction efficiency for neuron-specific retrograde gene transfer lentiviral vector with a novel fusion envelope glycoprotein

Authors: *K. KOBAYASHI[1], S. KATO[1], K. KOBAYASHI[2];
[1]Dept Mol Genet., Fukushima Med. Univ., Fukushima 960-1295, Japan; [2]Sec Viral Vector Dev, Natl. Inst. Physiol Sci., Okazaki 444-8585, Japan

Abstracts: Viral vectors for retrograde gene transfer mediate the delivery of transgenes into neuronal cell bodies innervating the region around the injection site of the vectors. Pseudotyping of a human immunodeficiency virus type 1 (HIV-1)-based lentiviral vector with different types of fusion envelope glycoproteins composed of rabies virus glycoprotein (RVG) and vesicular stomatitis virus glycoprotein (VSVG) domains produces a high efficiency of retrograde gene transfer. The vector for neuron-specific retrograde gene transfer (NeuRet) is a pseudotype of HIV-1 vector with fusion glycoprotein type C (FuG-C), which consists of the N-terminal region of the extracellular domain of RVG and a short C-terminal part of the extracellular domain (membrane proximal region) and the transmembrane/cytoplasmic domains of VSVG. The NeuRet vector has a high efficiency of retrograde gene delivery and transduces only neuronal cells around the injection site. In the present study, we tested gene transfer of HIV-1 lentiviral vectors pseudotyped with various types of fusion glycoproteins, in which the junction of RVG/VSVG segments diverged in the C-terminal portion of their extracellular domain. We found a novel type of fusion glycoprotein, termed type E (FuG-E), that displayed improved efficiency of retrograde gene transfer compared with the NeuRet vector having FuG-C. This FuG-E-pseudotyped vector transduced selectively neuronal cells around the injection site, showing the property of the NeuRet vector. Our NeuRet vector system with FuG-E will provide a powerful tool for gene therapeutic trials of neurological and neurodegenerative diseases and for the study of the mechanisms of neural networks underlying a variety of brain functions.

Title: A novel method to uniquely label transcripts for massively parallel functional dissection in the mammalian brain

Authors: *T. BJORKLUND[1], M. DAVIDSSON[1], O. SCHWICH[1], P. ALDRIN-KIRK[1], P. DIAZ-FERNANDEZ[1], M. TORROBA CALVO[1], L. QUINTINO[2], C. LUNDBERG[2]; [1]Mol. Neuromodulation, Wallenberg Neurosci., Lund, Sweden; [2]CNS Gene Therapy, Wallenberg Neurosci. Ctr., Lund Univ., Lund, Sweden

Abstracts: Sequencing by synthesis technologies have enabled cost-effective deep transcriptome sequencing and has also triggered the development of novel molecular technologies to prepare and amplify mRNA from a single cell. We have taken these technologies and utilized them to develop a novel platform for massively parallel functional dissection *in vivo*. Through the implementation of linear insertion of unique identifiers (a.k.a barcodes) in viral vector plasmids, we can identify and quantify large numbers (≈3E5 unique clones) if functionally different vector clones in the same animal. This has been combined with a novel technology to randomly fragment a longer genetic fragment and insert each subfragment into either a lentiviral or AAV backbone. We here show that the barcodes in libraries produced through this technique are entirely orthogonal and that thus multiple libraries can be studied in the same animal (up to four studied in parallel to date). This platform can potentially be utilized to dissect a plethora of biological functions such as promoter and enhancer regions, 3' and 5' UTRs and more. Here we will present a proof-of-principle study where both lentiviral and AAV vectors are barcoded and utilized to study mRNA processing and trans-splicing in the mouse and rat brain.

Title: Trans-synaptic retrograde transportation of Cre recombinase

Authors: K. SHIMIZU[1], A. INUTSUKA[2], A. INUI[2], S. OHNISHI[1], *A. YAMANAKA[2]; [1]Dept. of Med., Nagoya Univ., Nagoya, Japan; [2]Res. Inst. of Envrn. Medicine, Nagoya Univ., Nagoya, Japan

Abstracts: Past studies have identified specific neuronal populations in the brain according to their genetic property such as expressing neurotransmitters. However, these genetically identified neuronal populations sometimes consist of subpopulations which have distinctive projections and functions. Although it is easy to trace forward axons from specific neuronal populations, it is difficult to trace back the upstream neurons and manipulate their activity selectively. In this study, we developed Cre recombinase fused with tetanus toxin fragment C (Cre-TTC) which can be expressed by adeno-associated virus (AAV) vectors. TTC is used for neuronal tracing, taking its advantage of retrograde trans-synaptic transport. To examine their retrograde transport, we selected dopamine neurons in the ventral tegmental area (VTA) and the substatia nigra pars compacta (SNc). It is known that dopamine neurons in the VTA project to the nucleus accumbens (NAc), while dopamine neurons in the SNc project to the caudate putamen (CPu). When we injected Cre-TTC vector in the CPu and FLEX-GFP vector in the VTA-SNc region, we detected GFP only in the SNc not in the VTA. On the other hand, when we injected Cre-TTC vector in the NAc and FLEX-GFP vector in the VTA-SNc region, we observed GFP only in the VTA not in the SNc. These findings show that Cre-TTC is trans-synaptically and retrogradely transported from projected neurons and induce Cre-dependent gene expression in upstream

projecting neurons. Our new tool provides projection pathway selective tracing and manipulation.

Title: Rapid and ultra-sensitive single-cell transcript profiling with Droplet Digital PCR - application to neuronal differentiation

Authors: ***C. LITTERST**, S. WANG, T. LEGLER, N. KLITGORD, E. HEFNER, Y. JOUVENOT, G. KARLIN-NEUMANN;
DBC Bio-Rad, Pleasanton, CA

Abstracts: Single-cell transcript profiling is undoubtedly the ideal approach for gene expression analysis in neuronal tissues composed of various cell types. However, the robust detection of transcripts in isolated single cells or cytoplasm samples is technically challenging. Droplet Digital PCR (ddPCR) developed at Bio-Rad Digital Biology Center directly counts individual molecules with superior precision and reproducibility. The ddPCR-based single-cell gene expression protocol measures transcripts at molecular levels with minimal sample processing for defined targets. Furthermore, ddPCR is performed in 96-well plates and is well-suited to high throughput studies of focused sets of genes in large numbers of single cells. In this work, we demonstrate the single-cell gene expression analysis of *in vitro* differentiated neuronal cells. We present a simple and robust workflow for profiling multiplexed, transcript targets in flow-sorted, neuronal single-cells. We characterize a panel of validated assays targeting stem cell, proliferation and differentiation marker genes including nanog, p21, and Synapsin, respectively. We compare expression levels of these genes in non-differentiated versus differentiated single cells and bulk RNA preparation from the same cell populations prior to sorting. We demonstrate that ddPCR provides absolute counts of transcripts from >100,000 copies to <10 copies per cell. Our findings are discussed with current data in the literature.

Title: Co-opting fluorescent proteins for cell-specific gene manipulation

Authors: ***C. TANG**[1,2], T. SZIKRA[3], Y. KOZOROVITSKIY[1,2], M. TEXEIRA[3], B. SABATINI[1,2], B. ROSKA[3], C. CEPKO[1,2];
[1]Harvard Med. Sch., Boston, MA; [2]Howard Hughes and Med. Inst., Chevy Chase, MD; [3]Neural Circuit Laboratories, Friedrich Miescher Inst. for Biomed. Res., Basel, Switzerland

Abstracts: Detailed understanding of neural circuits and dynamics underlying animal behavior would be greatly facilitated by the ability to manipulate gene expression and neural activity in any desired cell type. However, it remains a challenge to achieve cell-specific gene manipulation in many model systems, especially the mouse nervous system. Fluorescent proteins are commonly incorporated into transgenic organisms for labeling specific cell populations, but the unmodified forms cannot control biological activities. Using GFP-binding proteins derived from Camelid antibodies, we co-opted GFP as a scaffold for inducing formation of biologically active complexes, developing hybrid transcription factors and split-Cre recombinases that control gene expression only in the presence of GFP or its derivatives. The modular design of the hybrid transcription factors allows for variation in key properties such as DNA specificity, transcriptional potency, and drug dependency. Production of GFP controlled cell-specific gene expression and facilitated functional perturbations in the mouse retina. Further, retrofitting existing transgenic GFP mouse and zebrafish lines for GFP-dependent transcription enabled applications such as optogenetic probing of neural circuits. This work establishes GFP as a multifunctional scaffold and opens the door to selective manipulation of diverse GFP-labeled

cells across transgenic lines. This approach may also be extended to exploit other intracellular products as cell-specific scaffolds in multicellular organisms.

Title: *In vivo* bioluminescence-driven optogenetics for neuronal activation and inhibition

Authors: *K. A. CLISSOLD, K. BERGLUND, M. E. KLEIN, V. PREVOSTO, M. KOVAL, Z. M. ABZUG, M. A. SOMMER, H. H. YIN, U. HOCHGESCHWENDER;
Psychology and Neurosci., Duke Univ., Durham, NC

Abstracts: Chemical genetic approaches for neuronal manipulation are advantageous for their minimal invasiveness and their ability to influence entire neuronal populations in large brain structures, while optogenetic approaches are advantageous for their ever-expanding diversity and temporal precision. To combine and complement the advantages of each technique, we recently developed a hybrid technology that allows control of a neuron by both chemical genetic and optogenetic means: luminescent opsins. These “luminopsins” are an engineered chimeric fusion of a light-generating enzyme (luciferase) to a light-activated opsin. Luminopsins enable tonic activation or silencing of neurons by bioluminescence upon application of a BBB-permeable substrate, coelenterazine (CTZ), while maintaining the ability to control the neurons rapidly with conventional light sources such as lasers. Here we investigated this approach for its efficacy *in vivo*. To activate a population of neurons, we developed an AAV vector containing a human Synapsin promoter-driven Gaussia luciferase fused to Volvox channelrhodopsin 1 (VChR1). To inhibit neurons, VChR1 was replaced by a light-driven proton pump, Maculans opsin (Mac). Virus was unilaterally injected into the substantia nigra pars reticulata (SNr) of the mouse. After incubation of 4-6 weeks, CTZ was applied directly to the SNr via micro-injections or injected peripherally in tail veins. Effects were compared to laser activation through an optic fiber implanted in the SNr. Upon activation or inhibition of SNr neurons by bioluminescence, the mice

showed ipsilateral or contralateral turning behavior, respectively. These results are consistent with previous research on the motor effects of unilateral activation or inhibition of the SNr. Using the same virus, we also evaluated the efficacy of luminopsins in non-human primates, Macaca mulatta, whose brain size has been the major obstacle for conventional optogenetics. These results demonstrate the first *in vivo* applicability of bioluminescence-driven excitation and silencing of neurons utilizing Gaussia luciferase.

Title: Conventional invasive and next-generation non-invasive optogenetic modulation of the thalamic reticular nucleus

Authors: *B. HIGASHIKUBO[1,2], S. CRANDALL[1], B. CONNORS[1], U. HOCHGESCHWENDER[3], C. MOORE[1];
[1]Brown Univ., Providence, RI; [2]MIT, Cambridge, MA; [3]Duke Univ., Durham, NC

Abstracts: The thalamus relays sensory information from the periphery to the cortex, and thalamocortical dynamics are central to normal perception and to a number of pathological states. The thalamic reticular nucleus (TRN) provides inhibitory input to thalamic relay nuclei and is thus poised to gate the transmission of sensory information and to modulate activity in the thalamocortical circuit. The involvement of the TRN in diverse processes like sleep and epilepsy makes it an attractive target for modulation in experimental and clinical contexts. We have developed techniques for manipulating TRN activity using conventional optogenetics as well as a novel, non-invasive method using bioluminescence to drive optogenetic elements. In order to

characterize the response of TRN neurons to standard optogenetic drive, we combined optical stimulation and extracellular recording in a transgenic mouse expressing the light-sensitive ion channel ChR2 in GABAergic neurons. In a population of ~100 well isolated TRN units, we parametrically mapped the influence of stimulus duration on spike and burst probability. In addition, we characterized the influence of stimulus variation on the generation of persistent oscillatory activity in the thalamocortical circuit. Subsequent work utilized a non-invasive method of stimulating optogenetic elements using bioluminescent light production. In this preparation, a "luminopsin" protein consisting of Gaussia luciferase tethered to Volvox channelrhodopsin-1 was virally expressed in the TRN of wild-type mice. This luminopsin enables optogenetic activation with application of the luciferase substrate, coelenterazine (CTZ). *In vitro* whole cell recordings in brain slices showed consistent small depolarization in expressing cells when CTZ was applied to the bath. *In vivo* multielectrode recordings showed an increase in TRN spike rate after systemic CTZ delivery. Simultaneously recorded putative relay neurons decreased overall firing rate, while still firing bursts. This work is proof of concept for the use of luminospins to modulate neural activity, and could provide a means to optogenetically influence thalamocortical circuits without external light delivery.

Title: Development of Tango system for the monitoring of 5-HT2CR activity

Authors: *Y. WATANABE, A. TSUJIMURA, M. AOKI, K. TAGUCHI, M. TANAKA; Basic Geriatrics, Kyoto Pref. Univ. Med., Kyoto, Japan

Abstracts: 5-HT2C receptor (5-HT2CR) is a member of the seven transmembrane-spanning G-protein coupled receptors (GPCRs) and couples to Gq/11 that subsequently activates

phospholipase C. It is widely distributed in the central nervous system and is involved in the regulation of anxiety, mood, and feeding. 5-HT2CR is known to undergo RNA-editing at five sites of second intracellular loop by adenosine deaminases acting on RNA (ADARs). 5-HT2CR RNA-editing leads to decrease in 5-HT potency, agonist binding affinity, constitutive activities, and G protein coupling activity. To date, the measurement of 5-HT2CR activity has been performed by G-protein dependent functional assays, such as inositol-1,4,5-trisphosphate (IP3) production assay and calcium flux assay. Although these assays are excellent methods, they are not appropriate for high-throughput drug screening (HTS) and application to *in vivo* live-imaging. Now, we are developing a novel method of 5-HT2CR monitoring to solve these problems. Tango system is a powerful tool for GPCRs assays based on ligand binding to a specific GPCR that triggers desensitization, a process mediated by the recruitment of arrestin to the activated receptor. For validation of 5-HT2CR Tango system, we constructed the following plasmids: pEF1_5HT2CR-TEVc-LexA-2A-arrestin-TEVp and pLexOP-EGFP. A cleavage site (TEVc) fused to the C-terminus of 5-HT2CR is cleaved by the TEV protease-tagged arrestin (arrestin-TEVp), resulting in the release of LexA transcriptional factor. Released LexA is translocated to the nucleus and induces EGFP-expression driven by the LexA promoter. These two plasmids were transfected into 293 cells, and EGFP expression was monitored with a fluorometer. We verified that 5-HT induced the expression of reporter gene in a dose-dependent manner and that its expression was inhibited by the 5-HT2CR antagonist SB242084. Moreover, this system was able to detect the difference of 5-HT2CR activities among RNA-editing isoforms (VGV and INI). These results suggest that our system will be useful for live-imaging of 5-HT2CR activity and HTS for drug discovery.

Abstracts: Specific, targeted control of neural systems to establish causality between neuronal activity and behavior has remained difficult to achieve until the recent advancements in optogenetics, which introduces light sensitive proteins (opsins) into neurons that regulate transmembrane ion conductance. Electrophysiological studies have shown that optical excitation or inhibition of neuronal activity is correlated with behavior, but to date, very few studies have examined neurotransmitter release combined with optical stimulation. We have combined our expertise of direct electrochemical measurements of neurotransmitter release (glutamate) *in vivo* with optogenetics in order to examine glutamate dynamics in the CNS. We infused (1 µl/each) AAV5-Syn-ChR2-EYFP into the right dentate gyrus (DG) of the hippocampus and the left infralimbic (IL) region of the frontal cortex. Histological analysis using yellow fluorescence revealed that, 5 weeks post-infusion, EYFP was present throughout the left frontal cortex and right hippocampus. There was also some evidence of bilateral distribution. We attached an optical fiber (200 µm o.d. ~200 µm from the recording sites) to our ceramic-based microelectrode array (MEA) configured to directly record tonic and phasic glutamate transients and lowered the assembly in DG or IL. We used constant light activation (DC: 488 nm, 1 to 10 mW) or pulses (train (TR): 10 ms; 40 Hz) to directly observe light-dependent glutamate release. Glutamate dynamics were in the same range as we have previously reported using other forms of stimulation (high potassium, drug induced or behavior). We observed glutamate release in the range of 1 to 70 µM and uptake rates of 0.1 to 10 µM/sec. These results show the feasibility of directly measuring glutamate release *in vivo* while controlling glutamatergic systems using optogenetics.

Title: High level expression of genetic tools with improved cell type specificity

Authors: *L. MADISEN[1], A. GARNER[1], A. CHUONG[2], N. KLAPOETKE[2], L. LI[1], A. CHENG[1], B. TASIC[1], H. GU[1], M. MILLS[1], T. NGUYEN[1], T. KNÖPFEL[3], E. BOYDEN[2], R. C. REID[1], H. ZENG[1];
[1]Allen Inst. for Brain Sci., SEATTLE, WA; [2]MIT, Cambridge, MA; [3]Imperial Col. London, London, United Kingdom

Abstracts: The ongoing development of increasingly sensitive optical molecules allows for probing and perturbing neuronal states with unprecedented control. Despite their evident potential, the practical utility of such tools relies on their high-level expression in restricted cell populations. We previously generated a Rosa26-targeted expression platform that directs Cre-dependent expression of functionally high levels of fluorescent reporters, biosensors and actuators in transgenic mice. Although this system enables study and manipulation of Cre-driver defined cell populations, sporadic or transient expression of the Cre-driver during development and/or expression of the driver in multiple cell types in the adult often preclude limiting transgene expression to singular cell types. In addition, for optimal application of some genetic tools, even higher levels of expression than reached in our Rosa26 reporters would be advantageous. Accordingly, we continue to work on strategies to generate genetic tools with increased specificity and level of expression. As intersectional approaches for gene regulation offer the potential for increased specificity, we've generated Rosa26-targeted reporters that require co-expression of multiple site-specific recombinases, as well as a Cre-dependent reporter targeted to the neuronally-limited Snap25 locus. Analyses of informative double and triple transgenic mice demonstrate that both approaches achieve more precise expression of transgenes than previously obtainable. To achieve higher levels of reporter expression, we've targeted alternative genomic loci with constructs of various designs, including a Cre and tetO regulated reporter based in an alternative genomic locus known as TIGRE. Notably, we've found that our new TIGRE reporter directs robust expression of fluorescent markers, voltage and calcium sensors, and novel optogenetic tools to levels higher than those obtained using our comparable Rosa26-based reporters. Functional characterizations of TIGRE lines carrying different types of optical tools under Cre and tetO control demonstrate their utility for high performance studies of neuronal activity, both in tissue slices and *in vivo*. Our data establish this new reporter strategy as

a useful foundation for robust and highly-regulated transgene expression, enabling more effective labeling, activity monitoring, and activity control.

Title: Recent developments for neurotransmitter analysis

Authors: M. EYSBERG, *L. M. VAN HEERWAARDEN, H.-J. BROUWER, N. REINHOUD; Antec, Zoeterwoude, Netherlands

Abstracts: In the field of neurotransmitter analysis, there is a continuing demand for faster and more sensitive analyses. -Concentrations of some neurotransmitters from particular brain regions are very low. -There is a demand for measurements in ever smaller sample volumes. -In each sample the levels of many components are of interest. The recent development of a new electrochemical detector (DECADE Elite) and a new electrochemical flow cell (Sencell) in combination high efficiency separation columns makes it possible to improve the methods for neurotransmitter analysis. We present an overview these methods for analyzing neurotransmitters in microdialysate samples with the ALEXYS Neurotransmitter Analyzer. The DECADE Elite with an increased data rate and high temperature fully supports fast UHPLC separations. The Sencell from Antec has an Adjustable Spacer Technology (ATS) that enhances the sensitivity and improves detection limits. Optimized applications have been developed for the following neurotransmitters in microdialysate samples: -Monoamines -Acidic metabolites -Acetylcholine -Amino acids glutamate and GABA The ALEXYS Neurotransmitter Analyzer is a versatile and flexible UHPLC system dedicated to analyzing a wide range of neurotransmitters in very small samples and at low concentrations.

Title: Optogenetics manipulation of cortical and subcortical neurons in the macaque monkey. Assessing expression of excitatory and inhibitory opsins

Authors: *B. W. CORRIGAN[1], R. A. GULLI[2], J. C. MARTINEZ[2], A. SACHS[3];
[1]Physiol., McGill Univ., Montreal, ON, Canada; [2]Physiol., McGill Univ., Montreal, QC, Canada; [3]Neurosurg., The Ottawa Hosp., Ottawa, ON, Canada

Abstracts: Electrical stimulation has been the gold standard for control of neural circuits in clinical practice such as deep brain stimulation (DBS) in the treatment of Parkinson's Disease and depression. Optogenetics is an alternative method of manipulation of neural circuits, with the added benefits of targeting genetically and spatially defined cell groups, and avoiding the use of immunoreactive metal electrodes in favour of inert optic fibres. Using this method, it is possible to either excite or inhibit different light-sensitive opsins and proton pumps with millisecond time resolution. Research using this technique for treatment of clinically relevant rodent models is progressing rapidly, but much more research is needed in primate models before therapeutics can be developed for humans. We carried out injections in three different *Macaque* monkeys, targeting both cortical and subcortical areas and compared results of optical stimulation/electrophysiological recording, and transfection. In one female *Macaca fascicularis*, we conducted visually guided injections under anaesthesia of the excitatory opsin ChR2 (*Lenti-hThy-1-ChR2(H134R)-eYFP*) into the prefrontal cortex. During *in vivo* recordings, we measured increases in firing rates of up to 70 times above baseline. We also transfected the prefrontal cortex of a male *Macaca mulatta* with the inhibitory opsin ArchT (*AAV2-CaMKIIa-ArchT-eYFP*). These injections were done through a recording chamber in the awake, behaving monkey using a microinjectrode, allowing for electrophysiological identification of target region. During subsequent recordings, target neurons were effectively silenced during optical stimulation. We

carried out transfection of deep brain structures using a frameless stereotax system to target the MR-identified regions of a female *Macaca fascicularis,* including the basal ganglia: the striatum (*Lenti-hThy-1-ChR2(H134R)-eYFP*) and the medial septum(*Lenti-hThy-1-eNpHR3.0-eYFP*). Despite the similarity of the delivered viral envelopes, immunohistological analyses of these regions showed different transfection patterns, suggesting that different brain structures can express different patterns when the same viral vector is used. We are currently using this frameless stereotaxic system to transfect neurons of the subthalamic nucleus (STN) of a female *Macaca fascicularis* using *AAV2-CaMKIIa-ArchT-eYFP* and *AAV2-CaMKIIa-hChR2(H134R)-EYFP*. We will also test the effects of optical excitation and inhibition of the STN on behaviour by measuring saccade accuracy and latency. This is an important structure in the pathology of Parkinson's disease and an important target for DBS.

Title: Development of a new fast-response GCaMP3 family for monitoring calcium flux *in vivo*

Authors: *N. HELASSA[1], E. ESPOSITO[2], I. CONTE[1,3], T. CARTER[1,3], J. BRADLEY[2], D. OGDEN[2], K. TOROK[1];
[1]St George's Univ. of London, London, United Kingdom; [2]Lab. de Physiologie Cérébrale, CNRS and Univ. Paris Descartes, Paris, France; [3]MRC-National Inst. for Med. Res., London, United Kingdom

Abstracts: Green Fluorescent-Calmodulin Proteins (GCaMPs) have been the reporters of choice for visualizing neuronal network activity *in vivo* as they can monitor Ca^{2+} flux that accompanies membrane depolarisation and action potentials. GCaMPs are based on a circularly permutated EGFP molecule (cpEGFP) flanked at the N and C termini by the smooth muscle myosin light chain kinase derived RS20 peptide and calmodulin (CaM), respectively. Upon Ca^{2+} binding, the

formation of a tight complex between RS20 and CaM, stabilises the deprotonated form of cpEGFP inducing a fluorescence enhancement. However, the slow Ca^{2+}-response kinetics of the current GCaMPs does not make them suitable for measuring high frequency Ca^{2+} transients e.g. action potentials. To accelerate the Ca^{2+}-response kinetics of GCaMP3, we decreased the binding affinity of the Ca^{2+}.CaM.RS20 complex by point mutations in the EF-hands of CaM[1] (mutants EF-1 to EF-4) and in the RS20 target peptide sequence[2] (mutant RS-1). Newly engineered GCaMP3 proteins were characterised in terms of dynamic range, two-photon cross-section, Ca^{2+} affinity and association and dissociation kinetics. Ca^{2+} responses and dynamic range *in vivo* were tested in endothelial cells (HUVEC) stimulated by ionomycin. Dissociation constants (K_d) for Ca^{2+} obtained from the equilibrium Ca^{2+} binding experiments were in the μM range (0.5-5.6 μM) with Hill coefficients from 2 to 5. The fastest mutant GCaMP3 RS-1 EF-3 showed half times ($t_{1/2}$) for Ca^{2+} decay decreasing with temperature ($t_{1/2}$ of 10.1 ms at 20°C to $t_{1/2}$ of 2.5 ms at 37°C), which is 52-fold faster than GCaMP3. Fluorescence changes on Ca^{2+} association were highly cooperative and characterized by a rate limiting conformational change. The association rates of GCaMP3 wild-type were not temperature-dependent ($t_{1/2}$ for Ca^{2+} rise of 36.0 ± 1.0 within the 20-37°C range). However, GCaMP3 RS-1 EF-3 showed $t_{1/2}$ for Ca^{2+} rise from 4.5 ms at 20°C to 0.9 ms at 37°C, which is 38-fold faster than GCaMP3. Two-photon cross-sections and fluorescence responses to Ca^{2+} influx of mutated GCaMPs in endothelial cells were comparable to those of GCaMP3 wild-type. The systematic mutations employed accelerated the Ca^{2+} response kinetics of GCaMPs to be suitable for monitoring fast, high frequency Ca^{2+} transient, and the principles established can be applied to develop new GCaMPs with fast-response and low affinity properties. Title: Elucidating input-output relations of VTA dopamine neurons

Authors: K. BEIER[1], K. MIYAMICHI[2], L. SCHWARZ[2], R. C. MALENKA[3], *L. LUO[2]; [1]Stanford University, Stanford Univ. Sch. of Med., STANFORD, CA; [2]Stanford Univ., STANFORD, CA; [3]Stanford Univ. Sch. of Med., STANFORD, CA

Abstracts: The ventral tegmental area (VTA) has been suggested to contain functionally heterogeneous dopamine (DA) neurons encoding signals that include reward, novelty, salience, motivation, and aversion. While initial studies suggested that DA neurons themselves were a homogenous population that exhibited phasic excitation in response to rewards and cues that signaled rewards, subsequent research showed that subpopulations of VTA DA neurons that project to different target areas exhibit different anatomical, molecular and electrophysiological properties. A thorough investigation of these subpopulations has been hampered by a paucity of tools capable of granting genetic access to anatomically-defined neural populations intermingled in heterogeneous brain structures. This limitation has made it challenging to definitively identify functional roles for distinct VTA DA neuron populations in signaling reward and aversion *in vivo*. Particularly useful would be the ability to concurrently map both input and output connectivity of each subpopulation. Classic neuroanatomical techniques have provided invaluable information about the connectivity of the brain, but are limited by an inability to identify direct synaptic connections or distinguish cell types. Recent rabies virus tracing experiments have identified direct synaptic input onto VTA DA neurons originating from over fifty distinct anatomical structures, suggesting that DA neurons receive input from surprisingly broad and diverse populations. In addition, more recent studies suggest that unique VTA neuron subtypes, defined by projection site, receive distinct inputs. However, the global connectivity of unique neuron types in the VTA has not been examined. Here, we employed a novel technique we developed called TRIO (trace the relationships between input and output) to more thoroughly study the connectivity of VTA DA neurons. TRIO combines rabies virus mediated retrograde transsynaptic tracing with a helper virus that is transduced via the axon terminals, such that we can examine input to VTA DA neurons that project to a specific brain region. We will report our systematic examination of global similarities and differences in input connectivity between VTA DA neuron subpopulations defined by their output sites. This approach has the potential to yield fundamental insights into the architecture of the midbrain dopamine system.

Title: Imaging cortical sensory dynamics in a transgenic mouse expressing a voltage indicator

Authors: *D. SHIMAOKA[1], L. ROSSI[1], T. SATO[1], A. BENUCCI[1], T. KNÖPFEL[2], L. MADISEN[3], H. ZENG[3], M. CARANDINI[1];
[1]Univ. Col. London, London, United Kingdom; [2]Imperial Col. London, London, United Kingdom; [3]Allen Inst. for Brain Sci., Seattle, WA

Abstracts: Genetically-encoded voltage indicators (GEVIs) enable chronic imaging of selected neuronal populations across large portions of cortex, with fine temporal resolution. GEVIs, however, have hitherto required viral delivery or *in utero* electroporation, which are invasive and result in local expression. The Allen Institute recently developed a transgenic mouse (Ai78) that promises to overcome these limitations, as it expresses a FRET-based GEVI, VSFP-Butterfly 1.2. To test these new transgenic mice we imaged their cortical responses using wide-field optical imaging. Using a dual recombinase intersectional approach, we crossed Ai78 mice with Camk2a-tTA and Rasgrf2-Cre lines to express VSFP-Butterfly 1.2 in excitatory neurons of layer 2/3. For comparison, we also imaged the cortical responses of C57BL/6 mice electroporated *in utero* at E15.5 with the same VSFP construct. We implanted the adult mice with a head plate and a coverslip over thinned skull, and then repeatedly imaged the underlying cortex while the mice were head-fixed and awake. We exposed a large region of dorsal part of cortex (8x6 mm) to image somatosensory, auditory, and visual cortex. Voltage signal was estimated by taking the ratio between signals from the acceptor (594 nm) and the donor (543 nm) fluorophores on a single-trial basis. The transgenic mice showed similar voltage response amplitude (S/N = 8.5 ± 1.8 (S.E.), n = 3) compared to the electroporated mice (S/N = 5.5 ± 0.5, n = 3), and the signal could be obtained in a broader region of cortex including visual, auditory, somatosensory and motor areas. By presenting visual flickering bars we mapped the retinotopic organization in visual areas V1, LM, and AL. Trains of tones revealed tonotopic organization in at least 2 auditory areas. Trains of air puffs directed to the whiskers revealed activation in both barrel cortex and motor cortex, consistent with studies based on classical voltage-sensitive dyes. Response latency was examined by analysing the phase of oscillatory responses to the visual flickering bars or trains of air puffs or trains of tones. Visual latencies were in the order of 50 ms, with earliest responses seen in V1 and later responses in higher visual areas. Much shorter latencies were seen in somatosensory cortex (~5 ms) and in auditory cortex (~10 ms). We conclude that Ai78 mice provide a promising transgenic tool for GEVI imaging. This tool allows for noninvasive, genetically targeted monitoring of neuronal voltage activity at mesoscopic spatial scales and millisecond temporal scales.

Title: High temporal resolution method for glutamate quantification in hippocampal slices

Authors: *C. L. LOPEZ VALENZUELA[1], K. PARDO-PEÑA[2], A. MORALES-VILLAGRÁN[2];
[2]Biología celular y molecular, [1]Univ. De Guadalajara, Guadalajara, Mexico

Abstracts: Neurotransmitters quantification in specific regions of the central nervous system provides important information for linking specific regions with chemical and electrophysiological events. The available methodologies do not have the needed temporal resolution. Therefore, it is essential to design a method for accurately measurement of these compounds in brain tissue with high specificity and temporal resolution. We developed a method for accurate measurement of glutamate (Glu) in brain slices microregions that can be correlated to simultaneous electrical recordings. We obtained hippocampal slices of 400 micron thick of brains Wistar male rats. The slice was placed and stabilized in a dual superfusion chamber and DL-TBOA (DL-Theobenziloxyaspartate) 10 mM was administered, Glu concentrations and the electrical activity were simultaneously evaluated. This method consists in continuous collection of samples every 200 milliseconds from the hippocampal slice with a tubing probe (200 μm diameter). Sample collection was simultaneously mixed with an enzymatic reactor prepared to measure Glu concentration. The mixture was introduced into a fused silica tubing that was inside of an incubation chamber at 37 °C to carry out the reaction. A fluorescence cell was placed at the end of the tubing. The resorufin obtained as a product of reaction was excited with a laser beam (532 ηm). Fluorescent signal was taken at 590 ηm. Signal intensity was correlated with Glu concentration. Data show that DL-TBOA administration produces and increased of 25.00% in glutamate concentrations in the hippocampal slice compared to the basal concentration. With respect to the electrical recordings an increase of 217% in the amplitude after DL-TBOA administration appeared. The frequency remained without any evident change. The Glu increase

was directly correlated with the change in electrical activity produced by DL-TBOA administration. It can be concluded that using this technique, it is possible to quantify glutamate concentrations in a near real time resolution way that can be correlated with changes in the electrical activity.

Abstracts: An attractive way to study brain function is to use optical imaging techniques such as Confocal and Two-Photon Microscopy, which allow simultaneous sampling of hundreds of fluorescently tagged neurons. Recently, genetically encoded calcium indicators of the GCaMP family have been synthetized. When expressed in excitable cells of the brain, these molecules fluoresce upon calcium binding, becoming a visible marker of neural activity. While these molecules can be delivered to discrete areas of the brain via local injection of a viral vector, it would be extremely valuable to create a transgenic animal in which these molecules were expressed ubiquitously in neurons all over the brain. The common marmoset (Callithrix jacchus) is an important nonhuman primate animal model in neurophysiological research because its brain organization resembles that of humans. Lately, the successful generation of transgenic marmosets with germline transmission of the transgene has boosted the attractiveness of this species as a valuable animal model for biomedical research. In this work, we aimed to develop

transgenic marmosets expressing GCaMP for imaging neural activity *in vivo*. High-titer lentiviral vectors expressing GCaMP5G and GCaMP6S under control of the CMV promoter were designed. Previously, we determined that these vectors, when injected stereotaxically in the brain, produced high levels of expression and mostly expressed in neurons. For non-surgical embryo collection and transfer, female marmosets greater than two years old were used. Ovarian cycles were controlled by a prostaglandin F2 alpha analogue and monitored by measurements of serum progesterone. We recovered up to 81.6% (31/38) of the ovulated embryos and repeated the flushing up to 10 times in the same animals. Repeated uterine flushing did not affect the integrity of the reproductive tract as well as quality or quantity of the embryos produced. Lentiviruses encoding EGFP, GCaMP5G or GCaMP6S were injected into the perivitelline space. Injected embryos were transferred to 2, 4 and 6 surrogate mothers, respectively. Four of them (one EGFP, two GCaMP5G, and one GCaMP6S) were diagnosed to be pregnant by ultrasonography around 21 days after embryo transfer. The EGFP recipient had a miscarriage around day 40 of pregnancy. The other three recipients are doing well and we are waiting for the pups to be born in GCaMP5G and GCaMP6S group. These results are important steps in developing the transgenic marmosets that robustly express calcium sensors for functional optical imaging of neural activity.

Title: A novel upright low-dose brain imager: A new tool in neuroscience and its potential applications

Authors: *C. BAUER, J. BREFCZYNSKI-LEWIS, J. W. LEWIS, M.-B. MANDICH, S. MAJEWSKI;
West Virginia Univ., Morgantown, WV

Abstracts: Positron Emission Tomography (PET) is traditionally used to image patients in the supine or prone position, and only few research devices allow for upright, brain dedicated imaging. Here, we present a novel device that allows for functional brain imaging in a freely-moving upright individual. This imager is extremely compact and fits tightly around the head, allowing for both the usage of lower radiation dose and the potential for longitudinal imaging. **Methods:** Four (4) individuals already scheduled for F^{18}-FDG PET/computed tomography (CT) imaging as part of their standard diagnostic package volunteered to also be imaged with the Helmet_PET wearable imager. In order to simulate the lower injected dose that this device can tolerate, the Helmet_PET imaging was performed 4 hours post F^{18}-FDG injection (lower dose by radioactive decay). Brain images were first obtained while patients were seated comfortably, and then when they rotated their head continuously by +/- 45^0. **Results:** The obtained images showed reasonable agreement with standard PET images with respect to the FDG distribution pattern in pronounced brain regions. In our ROI analysis, it was shown that there was only a 9.9% (Head of Caudate/Putament), 8.55% (Thalamus), and 4.74% (Medial Occipital) difference between the clinical images and the images obtained by Helmet_PET in the indicated ROI's (averages among patients). In addition, the metabolic activation recorded by Helmet_PET also corresponded to the anatomic structure as shown by standard CT. **Conclusion:** The results presented in this pioneer upright brain imaging study show that low-dose PET pattern imaging in the upright position is feasible. Implications of this study suggest that low-dose longitudinal PET brain imaging in the upright position is possible, which could produce numerous research or clinical opportunities. In regards to the clinical perspective, this type of imager could assess the progress of post-stroke patients to see how well they have regained function over a series of time points. Different types of rehabilitation modalities could be compared for improvement efficacy, as well as neural plasticity, connectivity, or neurotransmitter modulation as measured by PET. On the basic research side, the motion tolerance of the device would allow one to better elucidate neural mechanics of motor and posture-related processes. In addition, we would be able to image less predictable emotional states without needing to return to baseline or to suppress related motion (e.g. laughter, crying, facial expression), and with the participant more naturally engaged in social and emotional scenarios in real or virtual reality settings.

Title: Sweetie: An optimized genetically-encoded fluorescent sensor for glucose

Authors: *J. P. KELLER[1], J. MARVIN[2], E. SCHREITER[2], L. L. LOOGER[2];
[1]Janelia Farms Res. Campus, Ashburn, ; [2]Janelia Farms Res. Campus, Ashburn, VA

Abstracts: Because of glucose's central role as the primary physiological source of energy, it is difficult to overstate the need for a clear and detailed understanding of glucose trafficking and usage to all branches of biological and medical sciences. To address this need, we created, optimized, and benchmarked several versions of genetically-encoded fluorescent protein sensors, all with large dynamic ranges and high specificity for glucose. We describe herein the methods used for initial design of both intracellular and extracellular versions of the sensor with both ratiometric and non-ratiometric capabilities, as well as strategies for optimization of dynamic range, tuning of affinity (Kd), and improvement of membrane targeting of the extracellular version of the sensor. Regarding specificity, assays for cross-reaction with glucose-related compounds determined that the highest affinity among them was galactose, whose affinity was ~100-fold weaker than that of glucose, thus demonstrating the sensor's high specificity for glucose. Regarding dynamic range, the df/f of the sensor was found to be ~3, which was robustly detectable in all of experimental settings tested. To further broaden the sensor's utility, we used targeted mutations to produce sensors with Kd's of approximately 10 uM, 250 uM, and 3 mM, allowing for measurements across a broad range of glucose concentrations. The last of these is intentionally approximately equivalent to the physiological serum glucose concentrations in many organisms, thus enabling continuous glucose monitoring (CGM) in living subjects when the extracellular version of the sensor is used. To improve this extracellular version, we optimized its membrane targeting through the insertion of endoplasmic reticulum export tags, which significantly improved targeting in all cell lines tested. Beyond *in vitro* benchmarking experiments, we also present herein examples of *in vivo* real-time imaging of glucose fluctuations, thus demonstrating the utility of the sensor in living subjects. We believe that these genetically-encoded glucose sensors will prove valuable tools for the scientific, medical, and pharmaceutical communities, especially when used in concert with the increasingly-powerful genetic manipulation techniques coming to fore.

Title: Optogenetic control of seizures through the nigrotectal pathway

Authors: *P. A. FORCELLI, C. SOPER, C. KULICK, S. GUTHERZ, J. ACCARDI, K. GALE;
Dept of Pharmacol., Georgetown Univ., WASHINGTON, DC

Abstracts: Optogenetic methods offer high levels of spatiotemporal, cell-type specific, and pathway specific methods for neuronal stimulation and silencing. Previous studies examining optogenetic methods of seizure control have focused on suppressing activity at the site of seizure initiation. Clinically, however, the site of seizure initiation is often unknown or multifocal. For this reason, exploiting brain networks that have broad-spectrum anticonvulsant effects (e.g., endogenous circuits that can impede pathological network synchronization) is an important new direction. For this purpose, we examined the nigrotectal pathway; pharmacological suppression of activity within substantia nigra pars reticulata (SNpr) or enhancement of activity within the deep and intermediate layers of superior colliculus (DLSC) has been previously shown to suppress a wide variety of seizure types. However, pharmacological manipulations do not allow for a high degree of temporal resolution, nor do they allow for an analysis of the contributions of specific terminal fields. To test the efficacy of optogenetics manipulations of this circuit, we injected rAAV-hSyn-ChR2 into DLSC to mediate activation or rAAV-hSyn-ArchT into SNpr into SNpr to mediate silencing. Fiber optic cannula were placed either at the site of virus injection (DLSC or SNpr) or in DLSC after virus injection into SNpr. Seizures were evoked by either: pentylenetetrazole (which activates both forebrain and hindbrain seizure networks), focal disinhibition of area tempestas (a site in piriform cortex that selectively evokes forebrain seizures), or by gamma butyrolactone (a drug that triggers thalamocortical, absence-like spike and wave seizures). Recordings of multi-unit activity within DLSC were used to confirm the efficacy of optogenetic activation. We found that activation of DLSC at high frequencies (constant stimulation or 100Hz stimulation) or low frequency (5Hz) was highly effective at reducing all seizure types examined. Similar patterns of seizure protection were found after optogenetic silencing of SNpr. Finally, preliminary results suggest that selective silencing of nigrotectal terminals within DLSC is sufficient to attenuate evoked seizure responses. These data demonstrate that optogenetic manipulation of the nigrotectal pathway can be exploited *in vivo* to control seizures evoked from diverse brain networks. This raises the prospect that optogenetic manipulation of endogenous seizure-controlling circuitry may hold promise for therapeutic intervention in epilepsy.

Title: Optimization of micropattern geometry for long-term culture of isolated neurons and identification of excitatory-inhibitory cell types

Authors: *H. YAMAMOTO[1,2], S. KONO[4], T. KUSHIDA[4], A. HIRANO-IWATA[2], M. NIWANO[3,2], T. TANII[4];
[1]Frontier Res. Inst. for Interdisciplinary Sci., [2]Grad. Sch. of Biomed. Engin., [3]Res. Inst. of Electrical Communication, Tohoku Univ., Sendai, Japan; [4]Sch. of Fundamental Sci. and Engin., Waseda Univ., Shinjuku-ku, Tokyo, Japan

Abstracts: Using a micropatterned substrate as a culture scaffold, single neurons can be arrayed with controlled axon-dendrite orientation [1,2]. The neurons can further be wired *in vitro* using laser-assisted surface modification techniques [3]. Such surface engineering will allow us to construct a small neuronal network with pre-defined signal propagation direction. One major obstacle that hindered the progress of this work was the early death of neurons isolated on micropatterns. Thus we studied the geometrical factors that accelerate death of neurons and optimized the pattern geometry for long-term culture. Micropatterns of cell-permissive polylysine were fabricated in a polyethylene glycol background on a glass substrate by electron-beam lithography. A micropattern consisted of a circular island for soma adhesion, a single long pathway, and three short pathways: this pattern has been successful in directing axon-dendrite polarity of a single neuron, with the axon growing on the longest pathway [2]. Embryonic rat hippocampal neurons or cortical neurons were cultured on the patterned substrate, and axon lengths of each cell were monitored from 2 to 7 DIV. After 7 days, the cells were fixed and doubly stained for MAP2 (neuronal marker) and GAD67 (GABAergic neuron marker) to identify excitatory and inhibitory neurons. We found that constraint of axon elongation and soma

spreading was the primary cause of accelerated cell death, and that ~70% viability can be achieved at 7 DIV by optimization of micropattern geometry. Taking advantage of this pattern, we studied axon growth rate of micropattered cortical neurons to find that excitatory and inhibitory cells can be identified based on axon length by setting an appropriate threshold length. Title: Toward efficient production of transgenic marmosets

Authors: *J. OKAHARA[1], H. OKANO[2], E. SASAKI[3];
[1]Central Inst. For Exptl. Animals, Kanagawa, Japan; [2]Dept. of Physiol., Keio Univ. Sch. of Med., Tokyo, Japan; [3]Central Inst. for Exptl. Animals, Kanagawa, Japan

Abstracts: The common marmoset (marmoset) is a non-human primate, which is able to generate transgenic non-human primate with germ line transmission, which would be a useful and powerful experimental animal for neuroscience as well as human neuronal disease models. Moreover, their small body size, easier handling than macaque and fecundity are useful characteristics as a lab animal. Currently, 10 independent transgenic marmoset lines have been generated by lenti-viral vector method. In this method, to avoid obtaining non-transgenic animals by transgene integration failure, fluorescent protein marker gene is introduced with objective transgene, the fluorescence from which is to be confirmed around 8 cell stages before transplantation into the uterus of surrogate mother. While producing 10 transgenic marmoset lines including high cognitive disorder disease models it seemed that the promoters and fluorescent proteins showed tendencies to affect embryonic development. In this study,

influences of promoters and fluorescent proteins on the marmoset embryonic development were analyzed. Five promoters, EF1α (Elongation Factor1α), CAG (a modified chicken beta-actin promoter with CMV-IE enhancer), CMV (Cytomegarovirus), Synapsin (Syn), EOS (Early Transposond Sox2 enhancers), and 5 fluorescence protein markers, Green Fluorescent Protein (GFP), Venus, Kusabira Orange (KO), monomeric Red Fluorescent Protein (mRFP) and mCherry, were analyzed for influences on the embryonic development. The data set of total 444 transferred embryos to surrogate mothers and 23 newborn babies were used for Chi-square test analysis. As the results, the efficiency of generation rates of transgenic marmoset pups were 2.6% (EF1α), 7.0% (CMV), 4.1% (EOS), 8.8% (CAG) and 7.7% (Syn), respectively. The Chi-square showed that birth rates were no differences among the promoters. On the other hand, the efficiency of birth rate of transgenic marmoset pups in each fluorescence proteins marker was 9.4% (GFP), 7.7% (Venus), 5.4% (KO), 1.6% (mRFP) and 0% (mCherry) respectively. This result indicated that the transgenic birth rates were affected by fluorescent protein ($P< 0.05$). From these results, selection of fluorescent protein markers would be one of critical point for efficient transgenic marmoset production for neuroscience models.

Title: Dopamine kinetics in discrete larval *Drosophila* brain regions

Authors: *E. PRIVMAN, J. VENTON;
Dept. of Chemistry, Univ. of Virginia, Charlottesville, VA

Abstracts: Dopamine has many evolutionarily conserved functions and neurotransmission mechanisms. Nanomolar concentration of monoamine neurotransmitters such as dopamine can be detected at a millisecond time scale in the *Drosophila* melanogaster central nervous system using an electrochemical technique known as fast scan cyclic voltammetry (FSCV). This study

uses a newly described modified channelrhodopsin called CsChrimson to stimulate release from dopaminergic neuronal subpopulations. CsChrimson is activated by red light avoiding the heat, tissue damage, and electrode surface changes caused when using conventional blue-light activated channelrhodopsins. Dopamine release is stimulated with 4 ms red light pulse trains to mimic the physiological phasic burst firing patterns of neurons. FSCV is used to monitor real time extracellular dopamine concentrations at the tip of an implanted 7 um carbon fiber electrode. The release of dopamine at a pulse frequency range of 10 to 120 Hz is tested in the protocerebrum and ventral nerve cord (VNC) of an *ex vivo* larval central nervous system (CNS) preparation. The subsequent uptake is modulated using the amine transporter blocker nisoxetine and uptake changes are quantified using Michaelis-Menten kinetics. Increasing the number and frequency of red light pulses predictably increased the extracellular dopamine concentration. We found that Vmax and Km are significantly different in the protocerebrum and ventral nerve cord of the larval *Drosophila*, as is seen with different brain regions in mammals. Nisoxetine was shown to act as a competitive inhibitor at the *Drosophila* dopamine transporter, as it does for its proposed evolutionary relative the human norepinephrine transporter. This novel combination of optogenetic and electrochemical techniques allows us to study the effects of basic pharmacological and genetic manipulations on dopamine neurotransmission in disparate brain regions of the *Drosophila*.

Title: The sinusoidal probe- towards translation in the non-human primate

Authors: *H. SOHAL[1,2], F. YOSHIDA[1,2], N. P. BICHOT[1], K. PAYER[3], G. RIGGOT[3], E. S. BOYDEN[2,1], R. DESIMONE[1];

Abstracts: Micromotion, attributable to the modulus mismatch between the moving brain and electrode materials, is a fundamental phenomenon contributing to generalized electrode failure for chronic brain implants. This failure hampers our ability to dissect neural circuits over chronic experimental paradigms and the ability to produce reliable signals for invasive brain-machine interfaces. We have recently shown that the sinusoidal probe is effective as a chronic implant, providing high fidelity, stable, neural recordings for up to two years with reduced overall gliosis when compared to conventional electrodes (Sohal et al, 2014), perhaps due to its flexibility, and thus intrinsic micromotion reducing measures. Such measures included a rounded recording tip, a sinusoidal shaft and a polyimide ball-anchor. The sinusoidal shaft accommodates the brain movement, while the recording sites are anchored in place with the ball anchor. All measures attempt to restrict electrode recording site movement relative to the surrounding brain tissue. The original probe was a proof-of-concept therefore comprised of a limited number of electrode recording sites and restricted to certain lengths. Further, the probes were optimized for chronic recordings in rodents, rather than non-human primates. Now, we have designed and microfabricated the next generation of the sinusoidal probe, substantially increasing the number of recording sites and allowing for multi-depth recording. Lengths of these novel probes, based on the original design, vary from 3-30 mm allowing for the specific targeting of brain regions in both rodents and non-human primates in highly customizable, 3D arrangements. Further, we have optimized insertion procedures, which may allow for the implantation of more sinusoidal probes using a single carrier, hence minimizing vasculature damage during the insertion process due to repeated brain penetrations. Here we report data from initial bench testing and implantation for the sinusoidal probe in the non-human primate. The initial results suggest that the sinusoidal probe can be successfully translated from rodents to accommodate the technological challenges associated with successfully implanting and chronically recording from the non-human primate brain with flexible devices. Title: Imaging from the inside out: A design of an implantable probe for imaging of single-cell physiological dynamics in deep brain tissue at large scales

Authors: *M. A. HENNINGER[1], Y.-G. YOON[1], J. DEGUCHI[1,2], J. SCHOLVIN[1], A. ZORZOS[1], R. HORSTMEYER[3], R. RASKAR[1], E. S. BOYDEN, III[1];
[1]MIT Media Lab., MIT, Cambridge, MA; [2]Toshiba Corp., Kawasaki, Japan; [3]Caltech, Pasadena, CA

Abstracts: We present the design of a system to image the neural activity of many individual neurons simultaneously, at arbitrary locations in the brain. We use numerical simulations to estimate the proposed system's performance, and predict how future advances would improve performance. Simulating widely available fluorescent reporters and current CMOS pixel designs, our results indicate that a microprobe shank (e.g., 10 microns thin, 60 microns wide) placed in the cortex could image the activity of many hundreds of neurons. While fluorescent indicators of physiological activity are powerful tools for monitoring brain activity, it remains difficult to use them to image the activity of individual cells at high speeds, especially in deep tissue. We propose a lensless microimager that is thin enough to implant with minimal tissue displacement. An array of such probes can record from many arbitrary sites in the mammalian brain. The system consists of a silicon probe that is densely arrayed with CMOS imaging pixels. On top of the CMOS pixels are a standoff layer, a light-modulating mask layer, and fluorescence emission

filters. This probe is implanted in conjunction with an excitation light delivery mechanism--such as a waveguide or optical fiber–to excite the fluorescent signal to be recorded. Whereas the lenses in a traditional imager alter the angles of incoming light such that the recorded image contains purely spatial information, our mask causes the imager to collect spatial and angular information, sampling from the 4D light field. The recorded angular information allows us to determine depth information; the imager records a full 3D image every frame. This reduces problems related to out of focal plane light without requiring techniques like confocal or two photon microscopy. While our technique does not allow diffraction-limited resolution, it does allow resolving to within a few microns, which is sufficient to correctly assign fluorescence to its cell of origin in most brain structures. Reconstructing the 3D volume from the recorded image can be cast as a straightforward linear algebra problem. While this problem appears to be underconstrained, there are several techniques for introducing additional information—such as sparsity, knowledge of cell locations, or positive-definiteness—that allow us to constrain the problem to a single valid solution. The end result is an activity trace for each neuron in the probe's field of view. We characterize the correlation between the fluorescent activity and the probe recording, and find that with full fluorescent labeling in the cortex, a single probe would record hundreds of neurons with over 90% fidelity to the underlying signal.

Abstracts: Optogenetic tools have been used with considerable success in mammalian model organisms, but visual and thermal artifacts induced by activation light have limited their use in *Drosophila*. Here we introduce two new optogenetic reagents in *Drosophila*: CsChrimson and Jaws. CsChrimson is a red-shifted channelrhodopsin, a chimera between the N-terminus of CsChR and the transmembrane domain of Chrimson. It is 100 times more sensitive to orange light than the most sensitive variant of channelrhodopsin-2 previously used in *Drosophila*. With CsChrimson, we were able to activate neurons inside the brain of freely behaving flies through the cuticle. We have also used CsChrimson for other applications, including coarse functional connectivity mapping, triggering endogenous biogenic amine release, and neural stimulation using deep-red light (720nm) without visual-system-mediated behavioral artifacts. Jaws, a newly derived efficient red-shifted cruxhalorhodopsin, provides a complementary tool for neural inactivation. With CsChrimson and Jaws, the *Drosophila* research community now has a basic set of optogenetic tools for neural activation and inhibition with significantly higher temporal resolution than traditional thermogenetic tools such as dTrpA1 or Shibire(ts).

Title: *In vivo* experimental testing of scalable 3-d microfabricated electrode array neural recording in mammalian brain

Authors: *J. P. KINNEY[1], J. BERNSTEIN[1], J. SCHOLVIN[1], C. MOORE-KOCHLACS[1,2], N. KOPELL[2], E. BOYDEN[1];
[1]MIT, Cambridge, MA; [2]Boston Univ., Boston, MA

Abstracts: We have developed (Scholvin et al., SFN 2012) 3-D micromachined silicon electrode arrays with ultradensely packed electrodes, targetable to defined sites distributed throughout the mammalian brain, and compatible with simultaneous use of optogenetic neural circuit perturbation. In order for such *in vivo* probes to be utilized in a scalable fashion, we have invented (Kinney et al., SFN 2012) a novel minimalist computer architecture for performing scalable neural signal acquisition, storage, and processing, appropriate for extracellular neural recording at large scale (i.e., in head-fixed animals in virtual reality environments). Finally, to enable the analysis of neural dynamics thus recorded, we have devised automated data analysis methods that can automatically spike sort -- unmixing signals acquired on our ultradense electrode arrays into well defined spike times attributed to individual source neurons, without human intervention, and with zero false positives, as assessed using modeled neural activity (Moore-Kochlacs et al., SFN 2013). Here we present the integration, and validation, of these three technologies - ultradense electrode arrays, minimalist computers for scalable data acquisition, and automated spike sorting -- into a scalable neural recording system for live mammals. We characterize the performance of our system to record neural activity on large numbers of densely packed electrodes simultaneously (e.g., aiming for 1000 channels of neural recording or more) in head fixed mice, aiming for both locally dense recording as well as recording from multiple sites at once. We also present strategies for optimally implanting and utilizing such probes, as well as strategies for technology dissemination to the neuroscience community.

Title: Mechanical and geometric principles of interfacing to the nervous system via the vasculature

Authors: *C. LINGHU[1], A. N. ZORZOS[1], G. T. FRANZESI[1], H. S. SOHAL[1], C. T. WENTZ[1], N. GROSSMAN[1], P. BLINDER[2], E. S. BOYDEN[1];
[1]Media Lab., MIT, Cambridge, MA; [2]Dept. of Neurobio., Tel-Aviv Univ., Tel Aviv, Israel

Abstracts: Building a minimally-invasive chronic interface for recording and stimulating cells of the nervous system is of great importance to a broad range of topics in both basic neuroscience research and clinical treatment. In principle, threading electrodes through blood vessels could enable less invasive access to neurons. Many questions emerge from such a proposal: how much of the nervous system is accessible via introduction of probes into blood vessels? How many turns must probes make, and how much distance must they travel, to reach desired targets in the body from a given entry point? Should probes be actively steered or passively guided to targets? The answers to these questions could guide the development of practical probes for neural interfacing via the blood vessel network. Here we performed a theoretical analysis of the mechanical and geometrical constraints on neural interfacing via the vasculature. Using digitized structural data of neural vasculature and positional data of the neurons, we analyzed the statistical distribution of neuronal somata relative to vascular structures, as well as what fraction of the cells can be accessed from probes introduced at specific points in the vascular network. Based on fluid dynamic models of devices in the bloodstream, we performed Monte Carlo simulations to study the mechanical behavior of devices in the vasculature, as well as their influences on blood flow in vessels. These statistical and Monte Carlo simulations provide important mechanical and geometric constraints on how neurons could be interfaced to, via the vasculature.

Abstracts: Simultaneously measuring the activities of all neurons in a mammalian brain at millisecond resolution is a challenge beyond the limits of existing techniques in neuroscience. Entirely new approaches may be required, motivating an analysis of the fundamental physical constraints on the problem. We outline the physical principles governing brain activity mapping using optical, electrical, magnetic resonance, and molecular modalities of neural recording. Focusing on the mouse brain, we analyze the scalability of each method, concentrating on the limitations imposed by spatiotemporal resolution, energy dissipation, and volume displacement. Based on this analysis, all existing approaches require orders of magnitude improvement in key parameters. Electrical recording is limited by the low multiplexing capacity of electrodes and their lack of intrinsic spatial resolution, optical methods are constrained by the scattering of visible light in brain tissue, magnetic resonance is hindered by the diffusion and relaxation timescales of water protons, and the implementation of molecular recording is complicated by the stochastic kinetics of enzymes. Understanding the physical limits of brain activity mapping may provide insight into opportunities for novel solutions. For example, unconventional methods for delivering electrodes may enable unprecedented numbers of recording sites, embedded optical devices could allow optical detectors to be placed within a few scattering lengths of the measured neurons, and new classes of molecularly engineered sensors might obviate

cumbersome hardware architectures. We also study the physics of powering and communicating with microscale devices embedded in brain tissue and find that, while radio-frequency electromagnetic data transmission suffers from a severe power-bandwidth tradeoff, communication via infrared light or ultrasound may allow high data rates due to the possibility of spatial multiplexing. The use of embedded local recording and wireless data transmission would only be viable, however, given major improvements to the power efficiency of microelectronic devices.

Title: Time course of subthreshold activity preceding spike generation in awake behaving mouse hippocampus

Authors: *A. C. SINGER[1], G. TALEI FRANZESI[1], S. B. KODANDARAMAIAH[1], M. TSITSIKLIS[1], S. SHARMA[1], D. BOZIC[1], S. BATIR[1], I. R. WICKERSHAM[1], G. L. HOLST[2], C. R. FOREST[2], C. BÖRGERS[3], N. J. KOPELL[4], E. S. BOYDEN[1];

Abstracts: Neurons are often thought of as coincidence detectors that respond selectively to highly synchronized inputs. Indeed, research *in vitro* (e.g. in brain slices) has characterized how coincident synaptic inputs sum together within a neuron to drive well-timed spiking, and *in vivo* highly synchronized spiking across multiple presynaptic neurons is often assumed to drive activity in downstream neurons. However, patterns of inputs and intrinsic activity are very different between neurons *in vitro* and in awake behaving animals, leaving a major gap in our understanding of how neurons integrate incoming inputs and intrinsic activity to produce a spike in the awake brain. Accordingly, we have examined the time course of subthreshold depolarization preceding spiking in CA1 neurons in awake behaving mice. We performed whole cell patch clamp recordings using an optimized patch clamp robot (Awake Autopatcher) in head-fixed mice navigating through a virtual reality environment. We found that subthreshold depolarizations ramped up over extended periods - as much as fifty to a hundred milliseconds or more -- preceding the time of actual spike generation. Because these extended depolarizing ramps bring cells close to threshold, they could allow subsequent small inputs to rapidly result in spiking. Furthemore, these results may provide insight into the neural network patterns that drive individual neurons to fire in the living brain. (Singer and Talei Franzesi are co-first authors.)

Title: Next-generation multiphoton optogenetic control via opsin engineering and computer generated holography

Authors: *E. RONZITTI[1], R. CONTI[1], N. KLAPOETKE[2], A. J. FOUST[1], E. PAPAGIAKOUMOU[1], E. S. BOYDEN[2], V. EMILIANI[1];
[1]Univ. Paris Descartes - CNRS UMR8250, Paris, France; [2]Departments of Biol. Engin. and Brain and Cognitive Sci., MIT Media Lab. and McGovern Inst., Cambridge, MA

Abstracts: The ability to perturb and manipulate the flow of excitation and inhibition, enabled by a rapidly developing repertoire of optogenetic actuators, is essential for elucidating causal relationships between neural circuit activity and function. Optogenetic tools have spurred a parallel revolution in optical technology to realize their full potential for brain circuit interrogation, specifically through the development of methods for light patterning. An ideal light delivery method should be: efficient, robust to scattering, span multiple spatial scales, and feature high spatial (micron) and temporal (millisecond) resolution. To accomplish these goals, the Emiliani laboratory utilizes computer generated holography (CGH), generalized phase contrast (GPC), and temporal focusing (TF) to send shaped single- and two-photon (2P) excitation volumes into neural tissue. Specifically, we have shown that wave front shaping, accomplished with a liquid crystal matrix, enables dynamic control of the light at the sample plane matching the geometry of structures or circuits of interest with micrometer lateral and axial resolution. Using these approaches we demonstrated efficient 2P optogenetic stimulation of single and multiple cell expressing ChR2, in culture and brain slices. One challenge to implementing parallel illumination methods for neural circuit stimulation is that available laser power is divided among selected targets. As a result, the number of opsin-expressing cells that can be stimulated in parallel is determined by a combination of total laser power, sensitivity and expression level of the specific opsin. Therefore, any improvement to opsin sensitivity can increase the number of cells that can be independently and simultaneously actuated with CGH patterns and reduce the total amount of light necessary for patterned photostimulation. The Boyden laboratory has recently demonstrated a series of new sensitivity-enhanced opsins including Chronos, Chrimson and CoChR. Here we characterize, in cultured cells and brain slices, the 2P action spectra and on/off kinetics of these new opsins under 2P holographic illumination and laser scanning excitation. We demonstrate that 2P CGH, combined with these new opsins, enables efficient generation of 2P photocurrents, highlighting the potential of this technology for *in vivo* cellular resolution optical stimulation of multiple targets in large 3D volumes.

Title: Hearing the light: Perceptual and neurophysiological encoding of optogenetic stimulation delivered to the auditory midbrain

Authors: *A. E. HIGHT[1,2], W. GUO[1,5], J. X. CHEN[1,3], N. C. KLAPOETKE[6], B. G. SHINN-CUNNINGHAM[5], E. S. BOYDEN[6], D. J. LEE[1,4], D. B. POLLEY[1,5,4];

Abstracts: Optogenetics provides the means to manipulate specific neural circuits with high temporal precision. Neurons in the central auditory pathway encode temporal modulation of acoustic signals with submillisecond precision at rates as high as hundreds - or even thousands - of Hertz. Thus, to faithfully reconstruct auditory representations in the CNS, optogenetic stimulation must provide excitation that is both precise and fast. In this study, we used viral constructs to infect neurons in the mouse central nucleus of the inferior colliculus (ICc) with two types of channelrhodopsins: standard channelrhodopsin-2 (ChR2) or Chronos, an opsin recently demonstrated to have enhanced photosensitivity and rapid channel activation kinetics (Klapoetke 2014). *In vivo* extracellular recordings of ChR2+ ICc neurons revealed rapid spike adaptation to

stimulation rates > 40 Hz. By contrast, Chronos+ neurons synchronized spike timing to pulse rates as high as 140 Hz, with less synchronized, non-adapting responses at higher pulse rates. To address how these temporal coding differences might translate to perception, we trained mice having previously received ICc injections of ChR2+, Chronos+ or saline on a simple behavioral task in which they crossed sides of a shuttle box upon detecting pulse trains of acoustic or laser stimuli presented at various rates and amplitudes. As expected, the acoustic detection probabilities in all three groups were similar to one another and strictly dependent upon sound pressure level. Although saline-injected mice could not behaviorally detect the ICc photostimulation, we were surprised to discover that optogenetic detection functions between ChR2+ and Chronos+ mice were similar across amplitudes and pulse rates. To address how the psychometric functions derived from ChR2+ and Chronos+ mice could be so similar, yet their ICc spike coding be so different, we are now characterizing the downstream effects of ChR2 and Chronos activation in ICc on pulse rate encoding in the auditory cortex. Our preliminary findings suggest the precisely synchronized midbrain coding has been reformatted to a simplified rate code in the cortex that appears grossly similar between the two opsins, which may explain the similar behavioral detection functions. Our ongoing experiments address the hypothesis that the cortical encoding of ICc optogenetic stimulation with either opsin can predict the behavioral detection functions in individual mice.

Title: Optogenetic tool operation with extracellular vs. intracellular ionic sources

Authors: A. YANG, *Y. K. CHO, E. S. BOYDEN;
Media Lab, McGovern Inst., Dept. of Biol. Eng., Dept. of Brain and Cog. Sci., MIT, Cambridge, MA

Abstracts: We recently showed (Perea et al., 2014) that optogenetic tools not only transport ions across the plasma membrane, between the outside and inside of the cell, but also can drive release of ions from intracellular stores. Astrocytes in brain slices or in culture, upon intracellular calcium store depletion via thapsigargin application, no longer showed channelrhodopsin-2 (ChR2)-mediated calcium responses. Others have also shown that optogenetic tools can operate in intracellular organelles, for example altering mitochondrial function and metabolism through altering proton exchange (Hara et al., 2013). Given that channelrhodopsins transport many ionic species, including Na+, K+, Ca+2, and H+, we recently generated a channelrhodopsin ChromeQ (which stands for channelrhodopsin that omits Ca+2 and H+, quadruple mutant), that presents ~10x lower Ca+2 and H+ currents than wild-type, while preserving Na+ and K+ conductances. We show that ChromeQ, upon expression in astrocytes, does not result in light-driven intracellular store release of calcium. Thus, for some applications where calcium- and proton-dependent effects, ranging from plasticity to changes in cell survival to changes in cell signaling, are undesired, ChromeQ may present a useful reagent for the study and engineering of cellular membrane potential.

Title: Super-resolution microscopy across arbitrary scales

Authors: *F. CHEN, P. W. TILLBERG, E. S. BOYDEN;
MIT, Cambridge, MA

Abstracts: With existing super-resolution microscopy methods, there are fundamental tradeoffs between imaging volume, imaging speed, and resolution. Furthermore, existing methods also can be difficult to implement, requiring expensive or complex optical components and/or specialized fluorophores (e.g. capable of photoswitching). Here we report a novel super-resolution imaging method which is potentially capable of imaging large volumes, at high speeds, with excellent resolution. Our method can achieve ~60 nm lateral and ~200 nm axial resolution, imaging at a rate of 2.5*10^6 super-resolved voxels per second (i.e., a 50 μm x 50 μm x 1 μm sample volume can be imaged in ~1 second). This method is relatively inexpensive to implement, and requires relatively modest computational resources, compared to previous microscopes. We anticipate that our new method may enable nanoscopic investigation of neural structures across essentially arbitrarily large sample volumes.

Platform Quantum Phenomena & Nanoscale Biol. Systems (QuNaBioS), Univ. of Vienna, Vienna, Austria

Abstracts: 3D functional imaging of neuronal activity of entire organisms at the single cell level and on physiologically relevant time scales poses a major challenge in neuroscience. Here, using light-field microscopy in combination with 3D deconvolution, we demonstrate intrinsically simultaneous volumetric functional imaging of neuronal population activity at single neuron resolution for an entire organism, the nematode Caenorhabditis elegans, at up to 50Hz. This owes to a system-level optimized light field microscope, a fast deconvolution algorithm, and an appropriate genetically-encoded calcium indicator (GECI). This data combined with the full wiring diagram, or connectome, of *C. elegans* may allow the study of the nervous system at the circuit level in a systematic way. By performing whole-brain imaging of neural activity in larval zebrafish, we demonstrate the ability of our technique to capture dynamics of spiking neurons in volumes of ~700x700x200µm at 20Hz. The optical resolution for this volume is below single neuron resolution, but computational techniques based on independent component analysis enabled us to extract the activity of large numbers of neurons. The simplicity of our technique makes it an attractive tool for high-speed volumetric calcium imaging, and potentially voltage imaging, of neural activities in intact neural networks. (Prevedel and Yoon are co-first authors; Vaziri and Boyden co-corresponding authors).

Title: Optogenetic inactivation of the frontal eye field (FEF) increases error rates during all epochs of the memory-guided saccade task

Authors: ***L. ACKER**, E. BOYDEN, R. DESIMONE;
MIT, Cambridge, MA

Abstracts: Pharamacological inactivation studies have shown that the frontal eye field (FEF) is critical for executing saccades to remembered locations. Additionally, neurons within the FEF increase their firing rate during all three epochs of the memory guided saccade task: visual stimulus presentation, the delay interval, and motor preparation. It is unclear, though, whether FEF activity is necessary during all of those times for memory-guided saccade execution. A red-shifted halorhodopsin (JAWS) and a novel large-volume tissue illuminator were used in two rhesus macaques to inactivate part of the FEF at different times during a memory-guided saccade task. Neuronal recordings showed that the inactivated tissue volume spanned several cubic millimeters, which is consistent with histological findings. Error rates (e.g., failures to execute

memory-guided saccades to the proper target location) increased in both subjects with inactivation during either the target, delay, or motor period for targets in the inactivated receptive field. This implies that FEF neuronal activity contributes to performance throughout the memory-guided saccade task.

Abstracts: Many molecular, synaptic, and cellular mechanisms have been discovered and explored *in vitro* (e.g., in brain slices) or in anesthetized animals. Whether these mechanisms play a role in awake brain functions, however, often remains to be determined, in part because

performing intracellular recordings in awake behaving animals - necessary for verifying the real-time contribution of a specific synaptic or ionic conductance to a specific network function, for example - is technically challenging. Accordingly, we recently developed an awake autopatching robot to perform whole cell patch clamp recordings in awake behaving animals. We are now working on strategies for automatically exploring whether specific types of cellular mechanisms observed *in vitro*, also contribute to neural computations in the awake behaving animal. To achieve this, we are building informatics approaches to mine complex patterns of subthreshold and suprathreshold activity within single neurons undergoing whole cell patch clamp *in vivo* via our autopatcher robot. We can then mine the recordings that emerge for specific subthreshold patterns of synaptic activity or intrinsic conductance in an unbiased fashion, applying pharmacological (and even optogenetic) perturbation as needed to validate the findings. For example, one question amenable to this approach is the investigation of the fundamental timescales over which subthreshold activity patterns might be observed to repeat in a stereotyped fashion. By taking patch clamp recording traces, and cross-correlating each part of a trace with other parts, we can in an unbiased fashion survey whether specific patterns of activity repeat over time. These automated and unbiased methods of recording and analyzing intracellular activity in awake behaving animals may yield important insights into the computations that occur within neurons and neural networks. Moreover, combined with automated methods for feedback and causal hypothesis testing, as well as automated pharmacology and optogenetic approaches, this approach could enable rapid and systematic exploration in the awake brain of the specific roles played by the vast number of mechanisms identified *in vitro*. (Talei Franzesi, Singer, Kolb, and Sharma are co-first authors.)

Sci. and Technol., Harvard MIT, Cambridge, MA

Abstracts: We are developing a robot capable of patch-clamp whole cell neural recording of many cells at once (the "multipatcher"), in the waking and anesthetized brain, in order to reveal the synaptic and ion channel conductances that generate neural dynamics that support different brain states. Building from our past work (Kodandaramaiah et al., Nature Methods, 2012), we are both perfecting the technology and applying it to a major question: investigating the cellular mechanisms of general anesthesia. Despite its clinical importance, as well as its importance in basic-science studies of consciousness, perception, awareness, arousal, and other brain functions, little is known about how anesthetics act on specific cell types in the live brain, despite overt similarities in anesthetized behavioral states arrived at through administration of different drugs. In this study we are using our multipatching robot to study neural responses to multiple kinds of anesthetic drug: ketamine, an NMDA receptor antagonist; dexmedetomidine, an alpha-2 adrenoceptor agonist; and propofol, a GABA-A receptor agonist. We have performed single and multiple whole-cell patch clamp recordings in the somatosensory cortex of awake head-fixed mice, while tracking the changes in membrane potential and spiking activity as the awake animals transition into sedated states. We observe that the membrane potential of both inhibitory and excitatory cortical neurons in awake animals are characterized by slow oscillations during quiet wakefulness, interspersed by persistent depolarization during movement. Systemic infusion of both ketamine and dexmedetomidine results in the abolishment of the persistent depolarization, with the slow oscillation remaining. These membrane potential slow oscillations

are highly coherent across nearby (<200 microns) and more distant neuron pairs (200-500 microns). However, infusion of propofol produces a strong, constant hyperpolarization of the membrane potential. Our results indicate that ketamine and dexmedetomidine which are two very different drug classes have similar effects on the membrane potential of cortical neurons, possibly through their actions in brainstem arousal nuclei; whereas propofol might be inducing inhibition, perhaps in part by enhancing GABA-mediated chloride currents in pyramidal neurons in the cortex.

Abstracts: One of the critical questions in neuroscience is how brain neural networks perform computations necessary for higher level cognitive functions. To answer this question one needs to record electrical activity of individual neurons with synaptic resolution. The tool best suited to address this question is the whole-cell patch clamp technique with which multiple aspects of excitatory and inhibitory synaptic currents, cellular excitability, and interneuronal connectivity can be characterized. However, this method is slow and currently requires the high level of expertise of the experimenter to achieve good recordings. We have developed a new image-guided Autopatcher system for brain slices and primary neuronal cultures, extending the “blind” *in vivo* automated whole-cell patch clamp prototype published previously. The system presented

here is an image-guided whole-cell patch clamp electrophysiology suite for analyzing synaptic currents and electrophysiological properties of single neurons *in vitro*, and can be combined with Channelrhodopsin-Assisted Circuit Mapping (CRACM) to map functional connectivity in different brain areas.

Title: High-throughput fully-automated patch clamp robot for in-vivo electrophysiology and morphology

Authors: *G. HOLST[1], S. B. KODANDARAMAIAH[3], I. KOLB[2], W. STOY[2], I. WICKERSHAM[4], A. SINGER[3], L. LI[5], E. S. BOYDEN[3], H. ZENG[5], C. R. FOREST[1]; [1]Mechanical Engin., [2]Wallace H. Abstracts: Patch clamp recording is the gold-standard for measuring single ion channel currents, synaptic inputs, and whole cell currents in neurons. However, patch clamp recordings are still

something of an art form requiring great skill to record from only a few cells per day. For the last 20 years patch clamping was only performed by highly skilled technicians who have undergone months of training. Kodandaramiah et. al. recently developed a robot and neuron detection algorithm to autonomously record from neurons in-vivo. This robot, called the autopatcher, performs the skilled tasks previously performed by trained technicians and enables autonomous simultaneous recordings that have historically been extremely difficult to obtain. This work demonstrates the use of the autopatcher combined with a pipette exchange robot to obtain high-throughput in-vivo whole cell recordings in a fully automated fashion. To use the system, the operator only needs to prepare the mouse and perform the craniotomy at the correct stereotaxic location. After the mouse is placed in the robot, the operator locates the craniotomy with the first pipette and the autopatcher performs all the steps to obtain a gigaseal. Next, the pipette changing robot controls the automated break-in process by applying pulses of suction or voltage and assessing the quality of the seal after a whole cell configuration is obtained. Upon obtaining a successful recording, the robot waits for the experimental protocol to run and assesses the quality of the seal between repeats of the experimental protocol. After the recording has been completed or the seal with the cell has failed, the robot replaces the pipette for another recording attempt. For simultaneous biocytin staining, the robot slowly retracts the pipette after the recording has completed to reform the gigaseal for a high quality fill. The pipette exchange robot stores up to 20 pipettes that can be used as necessary throughout the experiment. For example, if a pipette is broken or clogged after being lowered into the brain, the robot detects it and immediately exchanges it with a fresh pipette without any human interaction. This kind of automated troubleshooting and correction throughout the experiment eliminates the need for constant supervision of the operator and enables parallel operation of multiple robots. We will also report progress of a large experiment (n>30 cells) using this robot to record both electrophysiology and morphology data on single cells in the visual cortex of mice. This data may begin to determine metrics for differentiating between types of neurons based on their intrinsic properties, morphology, and some basic visual stimulus protocols.

Title: Optimizing unsupervised spike sorting using heuristic spike sort tuner

Authors: *D. A. BJANES[1], R. A. GAUNT[2,3], D. J. WEBER[3,2];
[1]Electrical and Computer Engin., [2]Physical Med. and Rehabil., [3]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstracts: Extracellular microelectrodes frequently record neural activity from multiple sources in the vicinity of the electrode. Spike sorting generally describes the process of labeling each recorded spike waveform with the identity of its source neuron, which is required to conduct any further analysis of the neuronal spiking patterns. This process for spike sorting or isolating neural activity is often approached from an abstracted mathematical perspective such as calculating the Euclidean distance between spike waveform features in some lower dimensional space or using probability distributions to describe the isolation of neural activity or recorded spikes. However, these approaches ignore neurophysiological realities and result in the loss of important information that could improve the accuracy of these methods. Furthermore, standard algorithms typically require manual selection of at least one free parameter, which can have significant effects on the ultimate quality of the spike sorting and all resulting neurophysiological inferences. We describe a Heuristic Spike Sorting Tuner (HSST), a spike sorting framework which can determine the optimal choice of the set of free parameters for any given spike sorting algorithm. A set of heuristic metrics computes a neurophysiologically-based qualification score of an algorithm's output across a range of parameters. This qualification score measures unit isolation and signal discrimination, allowing HSST to select the best set of parameters for a sorting algorithm, resulting in high sort quality. With simulated datasets, we compare performance of many existing sorting algorithms, while using HSST to select their free parameters. We show HSST's ability to reliably select the optimal set of free parameters, demonstrating robust performance over varied data (signal-to-noise ratio, number of units, relative size of units to each other, etc). Surprisingly, simple algorithms such as K-Means (when HSST is selecting its parameters) are shown to out-perform more complex supervised algorithms. Rather than being a spike sorting algorithm in its own right, HSST is a general framework that can incorporate any existing spike sorting algorithm, has an extendable set of heuristics and can be integrated in any existing neural signal processing stream. HSST makes use of known neurophysiological priors while simultaneously taking advantage of the power of abstract mathematical tools. We believe that this approach enables unsupervised spike sorting that exceeds the performance of previous methods, thereby enabling principled processing of large data sets without the significant confound of human intervention.

Title: MATLAB-based automated patch clamp system for awake behaving mice

Authors: *N. S. DESAI, J. J. SIEGEL, R. A. CHITWOOD, D. JOHNSTON;
Ctr. for Learning and Memory, Univ. of Texas at Austin, Austin, TX

Abstracts: Automation has been an important part of biomedical research for decades; and the use of automated and robotic systems is now standard for such tasks as DNA sequencing, microfluidics, and high-throughput screening (including *in vitro* electrophysiology in cell lines). Recently, Kodandaramaiah and colleagues (Nat. Methods, 2012) demonstrated, using anesthetized animals, the feasibility of automating blind patch clamp recordings *in vivo*. Blind patch is a good target for automation because it is a complex but highly stereotyped process that revolves around analysis of a single signal (electrode impedance) and movement along a single axis. Here, we introduce an automated system for blind patch clamp recordings from awake behaving mice running on a wheel. In its design we were guided by three requirements: easy-to-use and easy-to-modify software; simple integration of behavioral signals and online data acquisition and analysis; and efficient use of time (important because of the typically short durations of intracellular recordings in moving animals). The resulting system employs equipment that is either standard for patch recording rigs, moderately priced, or simple to make. It is written entirely in MATLAB, a programming environment that has an enormous user base in the neuroscience community and many available resources for analysis and instrument control. The system includes not only components for obtaining patch recordings *in vivo* but a complete data acquisition system suitable for current clamp, voltage clamp, and field potential recordings; image acquisition for MATLAB-compatible cameras; and triggering signals for behavioral equipment. In pilot studies, we obtained 6 recordings (~40 attempts) from deep-layer neurons in prefrontal cortex of 8-9 week old mice, which ran at speeds between 0 and 20 cm/sec. Our procedures are still being optimized, but the success rate (~15%) is already comparable to that of experienced electrophysiologists working manually. The recordings were good by several criteria: membrane potential (-59.6 ± 2.3 mV), input resistance (48.7 ± 8.0 MΩ), and

spontaneous firing rate (0.3 ± 0.1 spikes/sec). The durations averaged 5.7 ± 1.0 min, but we have yet to explore several straightforward options for improving stability. Together with complementary approaches, this system should be useful to many cellular electrophysiologists who wish to study (head-fixed) mouse behavior. The system is general enough that it could be used as is in a variety of brain areas and with a variety of behaviors, but, written in a simple and familiar language, it also allows individuals to tailor procedures for the particulars of their own experiments.

Title: Automated intracellular recording with multiple sharp micropipettes

Authors: *G. F. COLLINS, S. N. BAKER;
Inst. of Neurosci., Newcastle Univ., Newcastle-upon-Tyne, United Kingdom

Abstracts: Intracellular recording from neurons allows access to sub-threshold potentials and permits the characterisation of single cell properties. Using multiple electrodes, synaptic and gap-junctional connections between cells can be characterised. Such recordings are made using either patch or sharp pipette electrodes. Advantages of patch electrodes are low access resistance and high seal resistance. Several groups have recently reported automated systems for patching neurons, either 'blind' or under visual guidance. However, patch electrodes can only be used once; after a cell has been successfully recorded, pipettes must be replaced. By contrast, sharp electrodes have higher access resistance and form less effective membrane seals but can be repeatedly driven into and out of cells, allowing many neurons to be recorded over the course of a single track, thereby increasing the data yield. We have built a novel system to automate recording with sharp micropipettes. Brain slices (450μm) are maintained in an interface chamber at 34°C, perfused with artificial CSF and exposed to 95% O_2/5% CO_2. Six micropipettes (resistance 50-100MΩ) are positioned over the slice using three-axis manual micromanipulators. Z-axis movement is provided by piezoelectric microdrives (Newport PZA12) with 12.5mm

travel and 30nm resolution under computer control. Pipettes are connected to bridge amplifiers (NPI, model BA03X), the output of which are digitised by a data acquisition card (National Instruments). A microcontroller-based circuit provides computer control of current pulses delivered to each bridge amplifier, as well as the 'buzz' and electrode impedance measurement functions. Software written in the Dephi environment provides real-time display of recordings, and control of pipette movement. With one click, pipettes may be driven down until they just touch the surface of the slice (detected by the sudden change in offset potential). Height is then zeroed, and electrode offset nulled. Automated cell finding then commences. Electrodes are advanced in small steps (~2μm); after each step, the electrode is buzzed. Cell penetration is detected by a reduction in membrane potential, and appearance of spikes in response to a depolarising current step. Electrodes continue until either a cell is found, at which point movement is stopped, or a maximum travel limit is reached. Once cells have been located, screens within the software guide the user through measurement of intracellular properties. We are now applying this system to record from primate brain slices, where the high value of tissue especially benefits from the increased yield which an automated approach provides.

KOCH, H. ZENG, *A. BERNARD;
Allen Inst. Brain Sci., SEATTLE, WA

Abstracts: The Allen Institute has initiated a multi-year program to understand the diverse neuronal cell classes in both human and mouse. We expect the properties of these cell classes to provide a foundation for the understanding of higher cortical function. To this end, we are investigating one of the most fundamental aspects of neuronal behavior - intrinsic electrophysiological properties. To develop a comprehensive electrophysiological classification of neuronal populations from both mouse and human, we have established a core platform to perform *in vitro* electrophysiology at scale. This platform will integrate and optimize technical expertise, instrument engineering, data acquisition standards and information management to maximize data output and quality. Quality control standards and systematic experimental workflows are under development to ensure that the datasets are reproducible and robust. Initial scientific objectives include gathering data from broad populations of cortical neurons from adult mouse and explanted human tissue from surgical specimens. A core set of electrophysiological stimuli suitable for a range of computational analysis, from detailed biophysical to generalized linear models, has been implemented using a custom acquisition software package. Ultimately, a data-driven cell classification scheme will be developed using features extracted from subthreshold and action potential waveforms as well as model parameters. Neurons will be labeled with biocytin while recording and the subsequent image acquisition and stereological analysis will provide for the pairing of morphological and electrophysiological data. Once established, this robust platform for gathering intrinsic electrophysiological properties from slice recordings should allow for the acquisition of ever more complex cell classification attributes, including paired cell recordings and post-hoc transcriptional profiling. Data, analysis tools, and model parameters will be made accessible via an online portal.

Title: A minimally invasive method for the analysis of sleep/wake behavior in rats

Authors: *J. BAUTISTA[1], D. H. MALIN[1], H. L. MATHEWS[2], D. M. NGHIEM[1], J. J. IZYGON[1], J. C. SHAHIN[1], C. A. MADISON[1], D. MCGHIEY[1], C. P. WARD[1];
[1]Psychology, Univ. of Houston Clear-Lake, Houston, TX; [2]Inst. for Behavioral Genet., Univ. of Colorado Boulder, Boulder, CO

Abstracts: Electroencephalography (EEG) is a procedure routinely used in sleep research to measure sleep-wake behavior. Non-invasive techniques are available for both humans and larger mammals. However, in rodents, long-lasting, invasive surgical procedures are required to implant screw electrodes for EEG recording purposes. This method uses a novel minimally invasive procedure (using surface electrodes). Specifically, the objective of this project is to minimize the invasiveness of the standard surgery. Adult Sprague-Dawley rats (n=3) were briefly anesthetized (isoflurane) and fitted with a spandex jacket attached to a cable tether. During a four-day period prior to polysomnography (PSG) recordings, rats were habituated to the jackets. During this period, rats were monitored for weight and locomotor activity. At the end of the fourth day, six customized electrodes were pasted on the scalp of each rat with a customized, plastic-made, protective cap glued on top of the EEG electrodes in order to prevent tampering. Each electrode was individually connected to a tethering cable affixed to the back of each rat jacket. In order to test the relative effectiveness of the minimally invasive procedure, the sleep/wake behavioral states of each rat were scored using polysomnographic recordings based on EEG and electromyography (EMG) data for a period of 24 hours. Following the recording period, data was analyzed using sleep-scoring software (SleepSign for Animals). The habituation data suggests that there was no fluctuation in weight or locomotor activity after the four-day recording period. Results from PSG data analysis show that over 24 hours there was a 49.9 % of total time spent in wake (W), 40.6 % of total time spent in NREM sleep, 4.8 % of total time spent in REM sleep. This was compared to control rats (n=6) using standard surgical methods to attached electrodes to the skull. Controls spent 48.90 % in W, 43.45 % in NREM, and 7.59 % in REM over 24 hours. Wake and NREM sleep was not significantly different between the two techniques ($t(7)=0.430$, $p<.05$ and $t(7)=0.289$, $p<.05$ respectively). There was significantly more REM scored in control rats ($t(7)=0.0231$, $p<.05$). In addition, there was a total of 4.6 % of unscorable epochs using surface electrodes due to mainly to artifacts occurring during W period as indicated by EMG patterns.

Title: Automated neuronal spike detection and discrimination

Authors: *E. B. MONTGOMERY JR[1], H. HUANG[1], A. BARBORICA[2], F. HAER[3]; [1]Greenville Neuromodulation Ctr., Greenville, PA; [2]FHC Europe, Bucharest, Romania; [3]FHC, Inc., Bowdoin, ME

Abstracts: Objective: Neuronal spike train analysis is fundamental to neurophysiology. Electrode arrays vastly increases the amount of electrophysiological data that can be simultaneously collected, risking overwhelming the investigator. Particularly difficult are distinguishing neuronal spike from noise and artifact and discriminating different signals that can be attributed to individual neurons in the recording. Novel algorithms, initially developed for remote intraoperative neurophysiological monitoring during surgery, are presented that automate this process. Methods: The statistical analyses derive from the fact that noise is the largest portion of the recording and dominates the statistical distributions of signal amplitudes. The amplitude of a subsequent signal relative to the prior signal should follow the principle of regression towards the mean (1). A signal amplitude near the maximum of the noise likely would be followed by a signal amplitude closer to the mean. If the signal amplitude is just above the noise and not at the maximum of the true signal, the next signal amplitude will not regress towards the mean of the noise but towards the mean of the signal. A new algorithm developed plots the distribution of the difference between the ith and the ith+n amplitudes and should show a Gaussian distribution except at the tails. This distribution can be compared to the distribution where the order of amplitudes were randomized. The difference determines the amplitudes that distinguish the signal from the noise. Waveforms of the neuronal signals are discriminated by using a set of six heuristics previously described (1) where the value of the heuristics are plotted in a six dimensional space and unsupervised n-dimensional cluster analyses (2) is able to partition the waveforms into discrete clusters that can be assigned to individual neurons. The methods were applied to neuronal spike trains recorded during intraoperative neurophysiological monitoring. Recording were modified to create differing signal-to-noise ratios to determine the sensitivity of neuronal detection. Spike discriminations were tested by both auto-correlograms and cross-correlograms between simultaneously recorded neurons Results and Conclusions: The completely automated system (Distance Expert) was highly effective in detecting neuronal activity from noise and in discriminating neuronal waveforms attributable to individual neurons.

Title: Electrophysiological properties of neurons in the mouse claustrum

Authors: *N. L. PETTIT, A. M. PACKER, S. CHUN, M. HAUSSER;
Wolfson Inst. for Biomed. Res., Univ. Col. London, London, United Kingdom

Abstracts: The claustrum is a thin nucleus lateral to the striatum that may be involved in inter-hemispheric coordination of cortical processing. Modern studies of the mouse connectome have confirmed widespread connectivity between the claustrum and the cortex and highlight the need for a more thorough investigation of the claustrum's internal elements. To address this, we have employed retrograde tracing from mouse primary visual cortex (V1) to reliably identify the claustrum in acute slices and carry out whole-cell patch-clamp recordings from confirmed

claustral neurons *in vitro* at physiological temperatures. Recovery of cell morphology with biocytin staining allowed us to assign electrophysiological properties to morphologically-defined claustral cell types. We observed substantial variability in passive membrane properties, action potential waveforms, and degree of spike-frequency adaptation, consistent with previous intracellular recordings in the claustrum of anaesthetized rats. We have also expressed C1V1, a red-shifted opsin, in motor cortex and performed subsequent retrobead injections and targeted *in vitro* claustral recordings to investigate the potential of channelrhodopsin-based cortico-claustral circuit mapping. The heterogeneity in the firing properties of recorded claustral neurons suggests the presence of functionally distinct subtypes of principal claustral neurons.

Title: The Real-Time eXperiment Interface: A closed-loop data acquisition system with sub-millisecond latencies for electrophysiology

Authors: *A. GEORGE[1], Y. PATEL[2], F. ORTEGA[1], J. WHITE[3], D. CHRISTINI[1], A. DORVAL[3], R. BUTERA[2];
[1]Weill Cornell Med. Col., New York, NY; [2]Georgia Inst. of Technol., Atlanta, GA; [3]The Univ. of Utah, Salt Lake City, UT

Abstracts: To understand causal interactions between neural activity and function, both function and neural activity need to be monitored with timing precision at the sub-millisecond scale. This requires enabling of closed-loop real-time technologies that are capable of controlling stimulation (optogenetic, electrical, thermal, etc) dependent upon some functional measure (behavior, motor action, etc) within a deterministic period. While monitoring neural activity at precise time scales is commonplace, there is an important unmet need in a cost-effective sub-millisecond closed-loop real-time framework capable of interacting with neural activity and function at the appropriate timescales. To enable investigation of neural activity and function at these time scales, we have developed the Real-Time eXperiment Interface (RTXI) - a versatile

interface based off of real-time Linux that enables deterministic closed-loop monitoring, stimulation, and control of single-cell, network, animal, and human electrophysiology experiments. RTXI is a free and open source platform currently employed by over 65 labs around the world. Essential modules such as a high-speed oscilloscope, signal generators, and common filters are included in the base of RTXI. An expanding library of community-developed modules is maintained and available for all users to enable resource sharing and maximizing reproducibility of experimental setups and results. In its present state, the RTXI allows for up to 32 16-bit I/O channels, with worst-case jitter of 10 microseconds relative to the input, and enables control of a wide variety of stimulation methods (optical, electrical, thermal, etc). Current and future development is focused on interfacing with Intan bioaquisition headstages to enable higher channel counts as well as scaling of hardware. Addtional information is available on our website (http://www.rtxi.org), and our code repository is open on GitHub (https://github.com/RTXI).

Title: Differentiation induction of neural stem cell microfibers

Authors: ***H. ONOE**[1,2,3], M. KATO-NEGISHI[2,3], S. TAKEUCHI[2,3];
[1]Keio Univ., Yokohama-Shi, Kanagawa, Japan; [2]The Univ. of Tokyo, Tokyo, Japan; [3]ERATO, JST, Tokyo, Japan

Abstracts: Cell-laden hydrogel microfibers have recently studied for scaffolds or building blocks for 3D tissue constructions. One of the attractive targets using these cell-laden hydrogel microfibers is artificial reconstruction of 3D neural network *in vitro* for tissue engineering and regenerative medicine. As a standpoint of such practical applications, (i) the use of stem cells and (ii) the control of differentiation induction are essential factors. Here we report differentiation induction of mouse primary neural stem cells (NSCs) in a fiber-shaped three-

dimensional (3D) microenvironment created in a core-shell hydrogel microfiber. Formation of NSC-encapsulating core-shell hydrogel fiber (inner diameter: ~100 μm, length: > meter) was conducted by using double coaxial microfluidic device. The NSC microfibers were composed of the core of NSCs with collagen matrix and the shell of mechanically stable calcium alginate. The differentiation of the fabricated NSC-encapsulating hydrogel microfibers was induced by controlling growth factors in medium. We successfully demonstrated the differentiation of NSCs to neurons and glial cells in the fiber-shaped 3D microenvironment where the diameter of the core NSC cells and the shell of calcium alginate were varied. We found that the spatial configuration of the differentiated neurons is not uniform: neurons were clustered and localized at the surface of the fibers. These results indicate that our technology would provide a confined fiber-shaped 3D microenvironment as a tool for neural stem cell biology and also could provide differentiated fiber-shaped neural tissues that can be applicable to tissue engineering and medical transplantation.

Title: A scalable system for large spherical treadmills

Authors: *A. K. LEE, N. J. SOFRONIEW, K. SVOBODA, J. COHEN;
HHMI Janelia Farm Rsrch Campus, ASHBURN, VA

Abstracts: Recent advances in the use of the awake, head-fixed preparation for small rodents (e.g., rats and mice) have led to an array of new interactive tools for studying mammalian brain and behavior. Here we present a method for creating large, lightweight spherical treadmills of arbitrary size. In order to accommodate different treadmill sizes, we provide a point-based floatation mechanism that is highly scalable. Moreover, its simple, sparse features leave the treadmill surface quite accessible for motion-tracking and other potential manipulations. For mice (8-12 wk, 20-30 g), we employ a 16” (40.64 cm, approx. 70 g) diameter spherical treadmill. For young-adult rats (3-6 wk, 60-150 g), we employ a 24” (60.96 cm, approx. 225 g) diameter sphere. We show that with little-to-no training, rodents are able to comfortably perform a variety of simple behaviors on these large spheres, such as running, walking, grooming, resting, and

sleeping. In addition, we demonstrate that this behavioral apparatus can be used in conjunction with sensitive electrophysiological and optical imaging techniques to obtain high-quality, long-duration recordings. Examples shown include long-duration multichannel extracellular and whole-cell patch-clamp recordings in the hippocampus of young-adult rats and adult mice behaving in visual-based virtual environments, and optical imaging of the somatosensory cortex of mice behaving in a tactile virtual reality.

Title: Evaluation of positive allosteric modulators on ligand gated ion channels using automated electrophysiology and fast fluidic exchange

Authors: J. WEBBER[1], A. YEHIA[2], J. COSTANTIN[1], *X. JIANG[1];
[1]Mol. Devices, LLC, SUNNYVALE, CA; [2]Fluxion Biosci., South San Francisco, CA

Abstracts: Ligand gated ion channels (LGICs) mediate fast synaptic transmission in the nervous system, and they represent a class of highly attractive drug targets due to the pivotal role they play in many physiological functions. At the molecular level, the binding of ligands such as neurotransmitters to LGICs transduce chemical signals into electrical signals, by enabling the passage of ions across the membrane. Functional impairment of these LGICs represents a variety of disease states, and positive allosteric modulators (PAMs) are proven therapeutic tools which alter the function of LGICs. Such modulation includes altering the channel conductance or the gating properties in the presence of ligand. After activation, many LGICs quickly enter a desensitized state, often within milliseconds. The transient nature of the LGIC activation and subsequent desensitization is crucial for fast synaptic signaling. Over the last decade automated electrophysiology has become an indispensable tool for analyzing ion channel activities. Here we evaluate the fluidic performance envelope in automated patch clamp, and its impact on LGIC assays both in the presence and absence of PAMs. We examined three ligand gated ion channels: acid sensing ion channel 1a (ASIC1a), gamma aminobutyric acid (GABA A), and nicotinic alpha 1. CHO-K1 cells stably expressing pore-forming subunit of human ASIC1a channel, HEK293 cells stably expressing GABA A, and TE671 cells with endogenous expression of nicotinic alpha

1 were used for these experimental models. In one series of experiments, we examined the speed of tonic ligand wash-in and wash-out to examine the activity and kinetics of ion channels, as well as multiple channel modulators and compared these results to those obtained with historical data generated from a conventional patch clamp. Next, we examine recovery from desensitization using a paired ligand application method. The interval between first and second application of ligand is varied and the amplitude of the second ligand application is compared to the first. In conclusion, we demonstrated the fluidics performance envelope in automated electrophysiology, and its successful applications in high-throughput LGIC assays offering a high throughput, robust platform for LGIC screening in drug discovery.

Title: Functional measures of synaptic transmission in stem cell-derived neurons intoxicated with Clostridial neurotoxins: An ultra-sensitive cell-based platform with shared pathophysiologies to *in vivo* intoxication

Authors: *P. H. BESKE, A. B. BRADFORD, M. E. LYMAN, P. M. MCNUTT;
US Army Med. Res. Inst. of Chem. Def., Aberdeen Proving Ground, MD

Abstracts: Following internalization into presynaptic termini, the two families of Clostridial neurotoxins (CNTs), botulinum neurotoxin (BoNT) and tetanus neurotoxin (TeNT), cleave SNARE proteins associated with synaptic vesicle release, preventing the exocytosis of neurotransmitters. To date, no cell-based model used in CNT research has been shown to form

functioning synapses, limiting the ability to conduct target discovery or therapeutic screening. Stem cell-derived neurons have recently been proposed as a next-generation cell-based platform for neurotoxicity research. We have shown that mouse embryonic stem cell-derived neurons (ESNs) replicate the unique neuronal responses to intoxication that occur *in vivo*, including serotype-specific persistences, activity-enhanced intoxication, and differential serotype potencies. ESNs are highly sensitive to TeNT and the seven classical BoNT serotypes, with EC_{50} values that are similar to primary neurons. Whole-cell patch clamp electrophysiology indicates that ESNs develop mature electrical responses and form a complex, synaptically coupled network with an excitatory:inhibitory balance by 18 days *in vitro* (DIV). Using RNAseq, electrophysiology and immunocytochemistry, we show that ESNs produce exclusively glutamatergic (75%) and GABAergic (25%) synapses and demonstrate abundant spontaneous miniature excitatory and inhibitory post-synaptic currents, indicative of monosynaptic activity. Hypothesizing that synaptically coupled ESNs may undergo inhibition of synaptic transmission in the presence of CNTs, we evaluated the effects of intoxication with BoNT/A through BoNT/G as well asTeNT on functional measurements of synaptic activity at DIV 24. We found that electrophysiologic-based measurements of mEPSC frequency provided a more sensitive metric of CNT intoxication compared to immuno-based assays for SNARE protein cleavage. Collectively, these studies demonstrate that intoxicated ESNs exhibit the same pathophysiology that manifests as clinical intoxication, suggesting that they are suitable models for therapeutic screening. Additionally, this approach suggests that electrophysiological characterization of trans-synaptic activity may comprise a novel, rapid screen for the presence of functional toxin in forensic, pharmaceutical, environmental and/or food samples, as well as provide an *in vitro* model for central neuron research involving CNT induced synapse silencing. Disclaimer: The views expressed in this abstract are those of the authors and do not reflect the official policy of the Department of Army, Department of Defense, or the U.S. Government.

Title: Spatial tracking and volume reconstruction for *in vivo* blind whole cell patch-clamp recordings

Authors: *D. C. CHAN, H. KO, W. YUNG;
Sch. of Biomed. Sci., The Chinese Univ. of Hong Kong, Hong Kong, China

Abstracts: The *in vivo* application of the whole cell patch-clamp technique is fundamental to understanding the subthreshold computational dynamics of individual neurons in an ethologically relevant setting. Recordings of deep cortical and subcortical neurons typically employ a blind patch approach, in which spatial resolution is lost due to variability in pipette fabrication and mounting. We developed an automated tracking system that rapidly registers the micromanipulator position of each freshly mounted pipette relative to a fixed reference frame, prior to insertion into brain tissue. Biocytin labelling of recorded neurons and subsequent volume reconstruction enables us to match neuron morphology with recordings in a post-hoc fashion. Accurate localization of the pipette tip also enables us to approach a volume of interest in close proximity (~30μm), and derive local spatial relationships in microcircuit computation. We demonstrated the system in anaesthetized as well as awake and mobile head-fixated C57BL/6 mice, with the latter conducted on a one-dimensional treadmill paradigm. We performed whole cell patch-clamp recordings and volume reconstruction in the hippocampus, and the caudal forelimb area (CFA) and hindlimb area (HA) of the primary motor cortex (M1), and demonstrated specific micromanipulator trajectories to record from intracolumnar and local intralaminar volumes relative to neocortical layer V pyramidal neurons.

Title: Fast scan cyclic voltammetry in *Drosophila* melanogaster for dopamine measurement

Authors: R. FRANCONVILLE[1], E. PRIVMAN[2], B. BARBARITS[1], P. AHAMMAD[1], M. BARBIC[1], V. JAYARAMAN[1], T. HARRIS[1], J. VENTON[2], *S. KIM[1];
[1]Janelia Farm Res. Campus / HHMI, Ashburn, VA; [2]Dept. of Chem., Univ. of Virginia, Charlottesville, VA

Abstracts: The amount of dopamine released by dopaminergic neurons is not a simple function of their activity level. Thus, neither electrophysiological recordings nor calcium imaging of dopaminergic neurons is sufficient to monitor dopamine concentration in the brain. In mammals, Fast Scan Cyclic Voltammetry (FSCV) has been successfully used to measure dopamine concentration *in vivo*, but, in *Drosophila*, the large size of carbon fiber probes relative to the size of the fly brain have limited their use. Here, we successfully apply FSCV in the adult *Drosophila* brain using a positioning technique with improved z-resolution, and a sharp carbon fiber electrode small enough to be placed inside tiny compartments of the *Drosophila* brain. We used a two-photon laser-scanning microscope to precisely position the electrode in the peduncle or the medial bulb of the mushroom body in an isolated brain. We optogenetically stimulated CsChrimson-expressing dopamine neurons with orange light (590nm) and used FSCV to measure dopamine concentration. We were able to detect dopamine concentration as low as 10nM at a temporal resolution of 10Hz. Combined with 2-photon calcium imaging, our new technique will provide a more detailed and fine-grained understanding of dopaminergic modulation in the fly brain during behavior.

Title: Simultaneous multi-scale electrophysiological measurement and optical manipulation of *in vivo* cortical networks

Authors: *K. BOUCHARD[1], P. LEDOCHOWITSCH[4], L. MULLER[2], E. A. K. PHILLIPS[3], B. SEYBOLD[3], M. M. MAHARBIZ[5], A. HASENSTAUB[3], C. E. SCHREINER[3], E. F. CHANG[1]; [1]Neurosurg. and Physiol., [2]Neurosurg., [3]Otolaryngology, UCSF, San Francisco, CA; [4]Allen Brain Inst., Seatle, WA; [5]Electrical Engin. and Computer Sci., UCB, Berkeley, CA

Abstracts: Here, we describe an electrophysiological recording system that combines micro-eletrocorticography (μECoG) to record neural activity from the cortical surface over extended areas with mesoscale spatial resolution, with laminar polytrodes to densely record neural activity across cortical layers with microscale spatial resolution. Combining these high-temporal resolution, multiscale electrophysiological recordings with optical manipulations of neural activity further allows causal inference into the role of specific neural populations in local and distributed cortical computations. We highlight this system in the context of auditory cortex recordings from anesthetized rats and mice. We demonstrate that μECoG arrays placed on the surface of rodent auditory cortex record sound evoked field potentials with high signal-to-noise ratio primarily in the 70-170 Hz range (high-gamma) but extending up to 300-800Hz. Examination of recorded signals >1kHz reveals neural events with timing and amplitude characteristics indicative of multi-unit action potentials evoked by sounds. Focusing on the activity in the high-gamma range, we demonstrate that μECoG recorded field potentials have sufficient spatial resolution and selectivity to derive functional organization of rat auditory cortex (tonotopy), and thus provide a method for rapid, non-destructive mapping of cortical function. We show that auditory evoked high-gamma responses provide sufficient temporal resolution to derive spectro-temporal receptive fields that are qualitatively similar to those derived from multi-unit spiking activity. Direct recordings of action potentials with laminar polytrodes inserted through perforations in the μECoG array suggest that functional tuning derived from μECoG (70-170Hz) reflects a spatial average of multiunit spiking activity immediately beneath the μECoG contacts. Finally, we combined our multiscale electrophysiological recording system with optogenetic manipulation of neural activity in mice. Preliminary results in PV-Cre x AI32 animals, in which parvalbumin-positive (PV+) interneurons are activated by light, demonstrate the ability of μECoG to record mesoscale changes in sound-evoked neural activity with high temporal resolution during optical manipulation of specific neuronal populations. Together, these results demonstrate high-temporal resolution, multi-scale electrophysiological measurements with simultaneous optical manipulation of *in vivo* cortical networks. Translating this system to behaving animals promises to reveal mechanisms of distributed cortical processing underlying complex tasks.

Title: Longitudinal evaluation of the safety and reliability of peripheral nerve electrode technologies

Authors: *S. VASUDEVAN, C. WELLE;
Office of Sci. and Engin. Laboratories, Div. of Physics, FDA, Silver Spring, MD

Abstracts: There are over a million amputees in the United States alone, many of whom can benefit from neuroprosthetic devices. Human studies have shown the ability to translate signals from the peripheral nerves into motor commands even after chronic amputation. However, the long-term performance, both safety and reliability, of peripheral nerve interface technology remains to be fully demonstrated. To investigate peripheral nerve electrode technologies, we have developed surgical, electrophysiological, behavioral, histological and data analysis protocols to characterize peripheral nerve-machine interface technology using established rodent models. Utilizing existing research electrode technology including intraneural floating multi-electrode arrays (Microprobes), life arrays and Utah-style arrays (Blackrock) and extraneural cuff electrodes (Microprobes, Ardiem), implanted in the rat sciatic nerve, we obtained neural signals. Connectors were anchored onto the back of the animals using 3D printed custom pedestals. Beginning two weeks after surgical implantation, electrophysiological recordings and impedance spectroscopy were performed weekly for the study duration. The quality and temporal dynamics of the recorded electrophysiological signals were compared for extraneural and intraneural electrode types. Upon obtaining stable recordings from the implanted electrodes, electrode impedance characteristics were correlated with electrophysiology recording metrics. To study the extent of motor and sensory deficits associated with electrode implantation, we used

walking track analysis and sensory stimulation thresholds measured bi-weekly over the course of the experiment. These behavioral and functional assessments were used to demonstrate recovery trajectory following electrode implantation. Following termination of the *in vivo* experiment, we harvested nerve tissue for assessment using histology and histomorphometry. Using histological techniques, the average axonal distance from the recording electrodes and the total number of myelinated axons were quantified across electrode type. This regulatory science research study serves as a test platform to understand the principles that influence peripheral nerve interface device performance. Title: A fully implantable ECoG recording device WIMAGINE® for human BCI applications: Toward a clinical trial

Authors: ***G. CHARVET**, C. MESTAIS, F. SAUTER, M. FOERSTER, A. LAMBERT, N. TORRES-MARTINEZ, T. COSTECALDE, D. RATEL, A. BENABID;
CEA/LETI/CLINATEC - MINATEC Campus, Grenoble, France

Abstracts: The WIMAGINE® implant (Wireless Implantable Multi-channel Acquisition system for Generic Interface with NEurons) was developed to record ECoG (ElectroCorticoGram)

signals for long term clinical applications, such as BCI. The implant is composed of an array of 64 biocompatible electrodes, a hermetic titanium housing including the electronic boards and biocompatible antennae for wireless transmission of data and remote power supply. During the surgical procedure, the implant will be inserted into a 50 mm craniotomy so that the electrode array is in contact with the dura mater, and the implant recovered by the skin. The design of the WIMAGINE® implant takes into account all the constraints of long term implantable medical devices: low power, miniaturization, safety and reliability. WIMAGINE® was designed to satisfy the Essential requirements of the European Medical Device Directives 93/42/CEE and 90/385/EEC. A risk analysis according to ISO 14971 standards has been conducted, and risk management actions were set up. The implant manufacturing was achieved according to a qualified industrial process under ISO certification 13485. In order to increase the reliability, all electronic boards undergo a burn-in procedure to avoid early in-use system failures, and functional tests. The electronic board is encapsulated into a dedicated titanium packaging with hermetic feedthrough. The hermeticity is achieved by laser welding and tested in terms of helium leakage and yield 10-9 bar.cm3.s-1. Then, each implant is tested, cleaned and sterilized according to a validated process. The first qualification tests of the implant according to standards were achieved by certified bodies. In particular mechanical and electrical test according the ISO 45502-1 were successfully achieved such as resistance to mechanical forces, vibrations and shocks, electrodes leakage current less than 1µA, ElectroStatic Discharge (ESD) immunity, heating at the surface of the implant less than 2°C. Likewise, the electrical security tests and electromagnetic compatibility (EMC) tests according to the EN 60601-1 were performed on the implant and its external unit. Finally, the long-term biocompatibility has been evaluated according to the ISO 10993, in particular consisting of the local tolerance and systemic effects after 26 weeks contact duration in animals. The next step is the submission of the protocol for clinical trial authorization to the French authorities (ANSM) in the context of Brain Computer Interface for tetraplegia. Other neurological applications requiring wireless ECoG recording such as presurgical evaluation of epilepsy, or post stroke rehabilitation can be addressed.

Abstracts: Graphene has recently emerged as the most investigated 2D material, owing to its superior electrical, mechanical and thermal properties. Graphene's flexibility, transparency, its excellent electrical conductivity and low noise characteristics make it attractive for neural sensing and stimulation applications. Transparency of graphene is particularly important for developing neural electrode arrays that enable simultaneous functional optical imaging and electrophysiological recording from the same population of neurons. Combining high spatial resolution of calcium imaging with high temporal resolution of electrical recording, neuronal circuit dynamics can be studied with high spatiotemporal resolution. We demonstrated that hippocampal slices can be imaged through transparent graphene electrodes by confocal microscopy, while the neural activity was simultaneously recorded by the graphene electrode. Both excitation and emission light penetrated through the graphene electrode without causing any light induced artifacts in the electrical recordings. Recordings by the graphene electrode and calcium transients measured by the confocal microscopy were found to be consistent, showing short population bursts during induced epileptic form of activity. The temporal resolution of the recordings with the graphene electrode enabled detection of high frequency population discharges, which could not be resolved by the calcium fluorescence responses. In contrast, calcium imaging was able to capture complex network contributions of individual neurons which were not evident in the electrical recordings. Experiments with the slices have shown that the graphene electrode was able to measure very fast population spikes with durations less than 5 ms, as well as slow field potentials that were not detectable by calcium imaging.

Title: Assessing novel materials to improve chronic cortical implants

Authors: *D. G. MCHAIL[1], H. CHARKHKAR[2], G. L. KNAACK[1], H. S. MANDAL[3], J. S. KASTEE[3], J. F. RUBINSON[4], J. J. PANCRAZIO[3], T. C. DUMAS[1];

Abstracts: Implantable microelectrode arrays (MEAs) detect neuronal signals, which can be utilized in neural prosthetics or other brain-machine interface applications. Failure in chronic neuronal recordings is considered the most challenging issue with implantable MEAs. Such failures are either biotic (neuroinflammation), abiotic (delamination or corrosion of device), or a combination of both. Recent efforts seek to extend the longevity of these implants by utilizing novel materials. In this work, we have studied the performance of two candidate materials for chronic brain implants. Prior work has shown that coating *in vivo* probes with the conducting polymer (CP) poly(3,4-ethylenedioxythiophene) (PEDOT) lowers impedance and might improve the recording quality compared to gold electrodes, likely due to the increased effective surface area and reduced noise levels provided by PEDOT. The performance and stability of the PEDOT coatings can be further enhanced by replacing the common counter ion e.g. poly(styrene sulfonate) (PSS) with a smaller counter ion such as tetrafluoroborate (TFB). Alternatively, non-metallic probes might offer benefits over metallic probes by eliciting lower inflammatory response. Shape memory polymer (SMP) softens at body temperature to accommodate the brain's natural mechanical stiffness. In addition to the probes with PEDOT:TFB coated electrodes, functional SMP probes were implanted into the primary motor cortex of rats. Single unit activity and electrochemical impedance were monitored on probes with PEDOT:TFB coated electrodes for four to twelve weeks post-implant to assess recording quality and device integrity respectively. Single unit activity and electrochemical impedance were also monitored weekly for implanted SMP MEAs. Consistent with our previous *in vitro* findings, PEDOT:TFB coated electrodes exhibited decreased impedance and consistent single unit activity compared to gold coated controls over a 12 week period. In ongoing experiments, SMP probes have sustained unit activity for up to two weeks following implant, which demonstrates proof-of-concept for SMP probes in chronic neural recordings *in vivo*. Our findings suggest that the quality and durability

of brain-machine interfaces can be further improved by employing novel materials such as PEDOT:TFB and SMP for brain implants.

Title: Multi-unit recording and labeling with iridium oxide modified stereotrodes in *Drosophila* melanogaster

Authors: ***C. ZHONG**, Q. MONTARDY, X. LIU, L. WANG;
Shenzhen Inst. of Advanced Technol., Guangdong, China

Abstracts: Background: *Drosophila* is a very favorable animal model for the studies of neuroscience. However, it remains a great challenge to employ electrophysiological approaches in *Drosophila* melanogaster to study the neuronal assembly dynamics *in vivo*, partially due to the small size of the *Drosophila* brain. Small and sensitive microelectrodes for multi-unit recordings are greatly desired. New Method: We fabricated micro-scale stereotrodes for electrical recordings in *Drosophila* melanogaster. The stereotrodes were modified with iridium oxide (IrO2) under a highly controllable anodically deposition procedure to improve their electrochemical properties. Electrical recordings were carried out using the IrO2 stereotrodes to detect spontaneous action potentials and LFPs *in vivo*. The recording site was labeled by the red Nissl fluorescent in a transgenic *drosophila*, which mushroom body is marked by green

fluorescence. Results: After deposition, the IrO2 electrodes exhibited significantly higher capacitance and lower electrochemical impedance at 1 kHz. Electrical recording with the IrO2 stereotrodes in the brains of *Drosophila* demonstrated an average signal-to-noise ratio (SNR) of 7.3 and a significantly improved LFP sensitivities. 5 types of different neurons recorded were clearly separated. Electrophysiological responses to visual and odor stimulation were detected, respectively. The Nissl fluorescent labeled recording site should be mushroom body. Conclusions: The IrO2 stereotrodes are capable to meet the requirements of multi-unit recording and spike sorting, which will be a useful tool for the electrophysiology-based researches especially in *Drosophila* and other small animals. Figure 1 Spike sortings of multi-unit recordings in *Drosophila* melanogaster using iridium oxide (IrO2) stereotrodes. (A), Representative examples of raw spike data. (B), Three-dimensional views of unit clusters. (C), Averaged spike waveforms. (D), The brain of *Drosophila* melanogaster (labeled by green) and recording site (labeled by red). Title: Automated “spectral fingerprinting” of electrophysiological oscillations

Authors: M. HALLER[1], P. VARMA[1,2], T. NOTO[4], R. T. KNIGHT[1,3], A. SHESTYUK[1,3], *B. VOYTEK[4,5,6];
[1]Helen Wills Neurosci. Inst., [2]Electrical Engin. and Computer Sci., [3]Psychology, Univ. of California, Berkeley, Berkeley, CA; [4]Cognitive Sci., [5]Neurosciences Grad. Program, [6]Inst. for Neural Computation, UCSD, La Jolla, CA

Abstracts: Neuronal oscillations play an important role in neural communication and network coordination. Low frequency oscillations are comodulated with local neuronal firing rates and correlate with a physiological, perceptual, and cognitive processes. Changes in the population firing rate are reflected by a broadband shift in the power spectral density of the local field potential. On top of this broadband, 1/f^α field, there may exist concurrent, low frequency oscillations. The spectral peak and bandwidth of low frequency oscillations differ among people, brain regions, and cognitive states. Despite this widely-acknowledged variability, the vast majority of research uses a priori bands of interest (e.g., 1-4 Hz delta, 4-8 Hz theta, 8-12 Hz alpha, 12-30 Hz beta). Here we present a novel method for identifying the oscillatory components of the physiological power spectrum on an individual basis, which captures 95-99% of the variance in the power spectral density of the signal with a minimal number of parameters. This algorithm isolates the center frequency and bandwidth of each oscillation, providing a blind method for identifying individual spectral differences. We demonstrate how automated identification of individual oscillatory components can improve neurobehavioral correlations and identify population differences in spectral and oscillatory parameters.

Title: Quantum wells embedded in semiconductor microtubes as optical sensors for action potentials

Authors: ***A. KOITMÄE**[1], J. HARBERTS[1], G. LOERS[2], C. BAUSCH[1], D. DIEDRICH[1], D. SONNENBERG[1], C. HEYN[1], W. HANSEN[1], R. BLICK[1];

Abstracts: We suggest an advanced method of optical readout of action-potentials using semiconductor microtubes as resonators. The fabrication process of GaAs/InGaAs microtubes is based on the principle of self-organized rolling-up of strained semiconductor layers. The multilayer starts rolling-up during selective etching of the sacrificial layer (AlAs). The reason for this phenomenon is the slight difference of the lattice constants of InGaAs and GaAs [1,2]. The diameters of the tubes are kept in the magnitudes of the diameters of the axons (Fig. 1) and can be tuned to support a certain optical resonance mode. The toxicity issue of As is overcome using CVD deposition of Parylene-C. The optical activity of the microtubes is ensured by quantum wells (QW) embedded in the microtube multilayers. By illuminating the tubes with a green (532 nm) laser the tubes emit light at a certain wavelength (photoluminescence). Applying an external electrical field (action potential) to the QW, a shift in the emission spectrum can be observed (Stark effect). To guide the axons selectively only through the tubes, the areas of tube entrances are patterned with poly-l-lysine (PLL) using a material printer. [1] Koitmäe et al. Title: Two-dimensional, high-resolution current source density analysis of neuronal action potentials

Authors: *R. FIÁTH[1], P. BEREGSZÁSZI[3], K. KOCSIS[4], S. MUSA[5], P. RUTHER[6], I. ULBERT[2,3];

(IMEC), Leuven, Belgium; [6]Dept. of Microsystems Engin. (IMTEK), Univ. of Freiburg, Freiburg, Germany

Abstracts: Action potentials (APs) are the basic computational elements of neuronal networks. The mechanisms of generation and propagation of APs in neurons are well described. However, *in vivo* two-dimensional extracellular recordings with high-resolution could reveal valuable new findings. One of the objectives of the Neuroseeker EU FP7 project is to develop ultra-high density, programmable silicon probes with thousands of small (~5 μm diameter), closely spaced (~1 μm) contacts. We used the first design of the probes in acute and chronic *in vivo* experiments to record the activity of cortical, hippocampal and thalamic neurons and to investigate the spatiotemporal distribution of transmembrane currents flowing during their APs. The silicon probe used contains sixteen recording sites with 10 μm in diameter arranged in four rows and another ten smaller contacts with 5 μm in diameter placed in two rows. The effective recording area is approximately 70x40 μm. Rats were anesthetized with ketamine/xylazine, and wideband (0.1-7000 Hz) neuronal activity was recorded from multiple regions of the brain. Spike sorting

was performed on the recorded data to isolate single neurons. Based on the sorted data, average AP waveforms were constructed from the raw recordings and the two-dimensional current source density (CSD) was estimated and visualized with Matlab-based softwares implementing the inverse CSD (iCSD) and kernel CSD (kCSD) methods. The CSD distributions calculated by the two methods were compared with each other. After that, we analyzed the two-dimensional propagation of the APs and the distribution of their transmembrane currents in different cell types, in consecutive spikes of spike bursts and in different brain states. With this method we could detect the initiation sites of APs near the soma of the neurons and backpropagation of the action potentials into the dendrites. We found significant differences in the current distribution between consecutive spikes of bursts during the afterhyperpolarization phase of APs. Both the iCSD and the kCSD method resulted in similar CSD distributions. However, the non-regular recording contact arrangement of this 26-contact probe makes the kCSD method more suited for the estimation of CSD, because it can manage data recorded from arbitrarily distributed electrode contacts, while the iCSD method can handle only regular grids and needs the interpolation of the local field potential. Based on our results we can conclude, that the two-dimensional, high-resolution CSD may be a useful tool in the future.

Title: Flexible multi-electrode arrays for acute and chronic recordings

Authors: *C. M. LEWIS[1], E. FIEDLER[2], T. STIEGLITZ[2], P. FRIES[3];
[1]Ernst Strüngmann Inst. (ESI) For Neurosci. In Cooperation With Max Planck, Frankfurt Am Main, Germany; [2]Inst. for Microsystem Technol. (IMTEK), Freiburg, Germany; [3]Ernst Strüngmann Inst. (ESI) for Neurosci. in Cooperation with Max Planck Society, Frankfurt, Germany

Abstracts: Understanding of brain function is currently limited by our ability to record both densely within regions of interest and simultaneously sample across many areas. Techniques that allow variable sampling of space, especially over extended periods of time, promise to expand

our understanding of brain function. We have developed flexible, polyimide-based multi-electrode arrays for acute and chronic preparations. These arrays allow the placement of many recording sites in arbitrary configurations and enable precise targeting of superficial and deep stereotaxic targets. Further, their size and flexibility allows minimally invasive implantation and an enhanced lifetime. We have implanted these arrays through the dura mater of monkeys, cats and rats, avoiding the necessity to make large craniotomies, or open the dura during implantation. Recordings have yielded isolated single units, as well as multi-unit activity and local field potentials, both in acute preparations, as well as in chronically implanted animals. In chronically implanted rats, we have successfully recorded unit and LFP activity from S1 and M1 for over 6 months. Arrays can be custom tailored in order to sample areas of interest with variable resolution: dense recordings of local populations, targeted sampling of laminae, or widespread coverage of multiple areas simultaneously. It is additionally possible to electrically stimulate through the arrays, or couple them with light guides for optogenetic manipulation. The flexible, polyimide substrate is also compatible with miniature FPC connectors, overcoming a major constraint on chronic implants: the necessary size of amplifier interfaces. Ours, and similar technologies promise increasing access and appreciation of brain dynamics across spatial and temporal scales.

Title: Development and initial characterizations of a novel 3D ultra-flexible neural interface that is implantable in brain tissue with preserved structure

Authors: *J. AGORELIUS, F. TSANAKALIS, A. FRIBERG, P. PETTERSSON, L. M. E. PETTERSSON, J. SCHOUENBORG;

Abstracts: A major challenge in the field of Brain-Machine-Interface is to obtain stable and high quality neural recordings from minimally affected nervous tissue in the awake animal. Recent studies indicate that micromotions, caused by mechanical differences between tissue and implanted electrodes, play a key role for the glial reactions to the implant and thereby for the stability of recordings and survival of nearby neurons. To reduce these micromotions, we have here developed a new, ultra-flexible electrode array and methods to implant such delicate electrodes with preserved structure. In short, we have designed an ultra-thin electrode array consisting of eight gold leads (4 μm thick) insulated with parylene-C (4 μm), which are individually flexible in three dimensions and equipped with a distal uninsulated protrusion serving a dual role of anchorage and recording site. The electrodes had a mean impedance of 832 kΩ (SD=230 kΩ) at 1 kHz. To enable implantation into soft tissue of such delicate structures, the electrodes were embedded in a stiff, but dissolvable gelatin based material. The mechanical buckling force of the embedded electrodes was measured in a compression test to 0.373 N (SD=0.177 N), i.e. more than 20 000 times higher than for the non-embedded electrodes. Clarification of brain tissue was made post mortem using Methyl salicylate to visualize the structure of the implanted electrodes *in situ*. This analysis revealed that the structure of the electrode array was indeed preserved in the brain after up to 3 weeks of implantation. To verify electrode functionality, in-vivo recordings were made up to three weeks after implantation, and showed sufficient signal-to-noise ratios for high quality single unit recordings. In conclusion, we have developed a new type of ultra-flexible electrode designed to meet the needs for a stable, chronically implanted brain machine interface, confirmed that it can be implanted into the brain with retained conformation, as well as provide high quality recordings of single unit activity.

Title: Integrative physiobehavioral monitoring for health patterns feedback and research: Chronic wireless and computer vision analysis in an open-source platform

Authors: *T. A. NICK, E. D. LUNDQUIST, L. M. BERMAN, A. Z. BARNEHAMA; Neurosci., Melon, Santa Monica, CA

Abstracts: Clinical snapshots of physiological measurements, such as heart rate and electroencephalogram (EEG), have revealed early biomarkers for various disorders of the nervous system, as well as other body systems. Increasing evidence indicates that time-evolving patterns of physiological measurements may provide even earlier signs of disease and/or behavioral patterns that may lead to disease. For example, clock genes may have a role in autism (Nicholas et al., 2007, Mol Psychiatry, 12:581-92) and circadian rhythm disruption may increase cardiovascular risk factors (Arble et al., 2010; Best Pract Res Clin Edocrinol Metab, 24(5):785-800). Personal measurements of physiological cycles or trajectories over days and longer periods may assist clinicians in diagnoses and lifestyle/treatment recommendations. A user-friendly, non-invasive, self-monitoring platform is therefore required to provide long-term, even chronic, measurements of basic physiological metrics. If the software were also open-source, the platform could be specialized and extended for each person and/or researcher to enable focused and lightweight analysis of particular metrics of interest. We have built such a platform with these basic and modifiable metrics: resting pulse, heart rate variability, and pulse wave velocity using computer vision; brain frontal lobe oscillatory activity (EEG) and eye blinks with forehead electrodes; and muscle contraction with a resizable band that can be strapped to limbs. Temporal integration of these various metrics may provide additional information that is not available through isolated measures. Moreover, daily (and longer) patterns of these and other measures can be saved and viewed later by the user, physician, or researcher. The current system is built on the Apple OS X desktop and iOS mobile platforms. Raw signals from the hardware and/or processed waveforms and metrics can be displayed in a configurable display panel. The software also contains user-configurable filter settings, as well as real-time export capability for on-line analysis and feedback. The EEG hardware employs a low-power, 24-big analog front-end (Texas Instruments, ADS1294), coupled with a low-power Bluetooth SoC (Nordic nRF51822). Low-noise, differential recordings employ four forehead electrodes. We will present (1) proof-of-concept data that indicate the feasibility of this system and (2) preliminary findings on circadian variability and correlations of measured physiological parameters in healthy adults.

Title: Whole-brain electrophysiological recording in the isolated naked mole-rat brain

Authors: *D. P. MCCLOSKEY[1,3,2], T. BUDYLIN[3,2], M. ZIONS[3,2];
[1]Dept of Psychology and Program in Developmental Neurosci., City Univ. of New York, STATEN ISLAND, NY; [2]Ctr. for Developmental Neurosci., City Univ. of New York, Staten Island, NY; [3]Program in Neurosci. (Biology), Grad. Ctr. of CUNY, New York, NY

Abstracts: Electrophysiological recording of the whole brain *ex vivo* has been performed in a number of mammalian species, with the guinea pig preparation developed by Mühlethaler, de Curtis, Walton and Llinás (1993) among the most successful. In this technique, the basilar artery is catheterized and perfused with oxygenated artificial cerebrospinal fluid. Arterial pressure is maintained with the use of a peristaltic pump and the ligation of severed arteries. This approach can provide neuronal viability for a number of hours, and allows access to many different areas of the brain simultaneously. The guinea pig is particularly well-suited for this preparation because of the large diameter of the posterior communicating arteries relative to the basilar artery. Here, we have discovered that the fossorial rodent species known as the naked mole-rat (Heterocephalus Glaber)has similar cerebral vascular to the guinea pig, and is therefore well-suited for the isolated whole brain preparation. Naked mole-rats are hypoxia resistant and seizure-prone, so they provide a great opportunity to understand circuitry involved in seizure generation and hypoxia-response. Transcardial perfusion of the naked mole-rat with india ink demonstrates relatively large diameter posterior communicating arteries. Catheterizing the basilar artery in this species allows for stable electrophysiological recordings for at least 6 hours *ex vivo*. We have recorded field potentials in the piriform cortex following bipolar electrode stimulation of the olfactory bulb or lateral olfactory tract. We have also recorded field potentials in the hippocampus following stimulation of the entorhinal cortex. In the absence of stimulation, we have observed spontaneous epileptiform events in the hippocampus similar to what we have recorded in hippocampal slices of naked mole-rats. These events were enhanced with the perfusion of 10μM bicuculline. We are combining this approach with multi-electrode array recording and graph theory-based network analysis to map circuitry between areas of the brain.

Title: High spatial and temporal resolution chemical measurements with functionalized neural probe

Authors: ***E. BIGELOW**[1], C. WHITE[1], J. FEINBERG-SOMERSON[2], K. PLAXCO[2], B. G. JAMIESON[1];
[1]Diagnos. Biochips, Columbia, MD; [2]Chem. and Biochem., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstracts: This study demonstrates proof-of-concept for aptamer-based biosensing on microfabricated neural probes (array of 400 μm^2 sites). The techniques described will be applied to the *in vivo* detection of multiple chemicals at high temporal and spatial resolution. Current *in vivo* chemical detection techniques are limited to microdialysis, with low temporal resolution (measurements every 2-20 minutes), or enzyme-based sensors and fast scan cyclic voltammetry, which are limited to single analyte detection and small range of detectable target molecules. Aptamer functionalized microfabricated neural probes are predicted to collect chemical concentration data every 5 seconds *in vivo* with detection sites every 50 μm. Aptamers are particularly well suited as a bio-recognition element for sensing *in vivo*, as they are non-immunogenic, do not consume the analyte, can be tuned for a variety of binding kinetics, and can be used for detection in hypoxic conditions. In this study, neural probe sites (array of 16 400 μm^2 sites) were functionalized with aptamers by forming a self-assembled monolayer (SAM) through a 5' alkanethiol modification. Additionally, these aptamers have a 3' methylene blue modification for current-based readout and *in vivo* stability. Aptamers designed to detect kanamycin were used in this proof of concept study. Square wave voltammetry (SWV) was used to detect changes in current modulated by the 3' methylene blue groups moving closer or further away from the gold site when unbound and bound, respectively, to the analyte. Signals of up to

1.0 nA, or an 80% signal gain, were detected. The sensor was evaluated for sensitivity at various physiologically relevant kanamycin concentrations, and exhibits a linear response range of 100 nM – 10 uM. This study demonstrates a proof-of-concept for aptamer-based biosensor fabrication and readout techniques on a microfabricated electrode. Applying these methods with neurotransmitter aptamers, such as those for dopamine, GABA, and substance P, will produce a powerful new chemical detection system with high temporal and spatial resolution.

Abstracts: We have proposed a fine (<10 μm in diameter) and high-density multi-electrode array fabricated by the selective vapor−liquid−solid (VLS) growth of silicon 'whisker' wires (Fujishiro et al., 2014). Such fine electrodes potentially offer both low invasive and high spatial resolution of neuronal recordings *in vivo*. However, the fabrication of the electrode arrays with 100% yield is problematic. In addition, varied characteristics of each electrode in the array might degrade the performance of the device. To overcome the device issues, here we devised a manufacturing technique by using single whisker electrode modules. To fabricate the electrode block as a module, the silicon whisker needle electrode (3 μm in diameter, 160 μm in length) was fabricated on a low resistance one-millimeter square silicon block by the VLS growth technology. As the metallization, platinum was deposited over the needle shaft, which was then insulated with an insulating layer of parylene-C except for the electrode tip (1.5 μm in height). Such small diameter platinum-electrode exhibits a high electrolyte/electrode interfacial electrical impedance, which was decreased to a lower impedance of ~100 kΩ at 1 kHz in saline by platinum-black plating. An amplifier was connected to the backside of the electrode block via an IC-socket pin connector. To evaluate the *in vivo* recording capability of the device, fabricated electrode block modules were tested in the acute animal experiments. To access to the occipital lobe of a mouse brain, where visual areas exist, the skull and dura mater were opened under anesthesia. The electrode was stereotaxically defined and inserted into the primary visual area. Signals from the needle electrode were amplified using an amplifier with 300 Hz and 5 kHz cut-off frequencies. As a result, spike activities were detected in response to the visual stimulation (white LED flash, 500 ms in duration) for the contralateral eye. The signal/noise ratio was sufficiently large for detection of unit activity. In conclusion, we demonstrated *in vivo* recordings via microscale diameter neuroprobe block devices. The proposed electrode devices can be assembled as high yield electrode arrays in future multi-site recordings. In addition, we are currently working on the assembly of an array of heterogeneous electrodes including various lengths, shapes and materials of whisker needle electrodes for recording from various types of cortical neurons.

Abstracts: We have proposed a microfabricated needle-like penetrating 'whisker' electrode (needle diameter = < 5 μm) array, and the *in vivo* recording capability has been demonstrated [A. Fujishiro et al, Sci. Rep., 4, 4868, 2014]. However, the low-yield fabrication process of the electrode arrays is still problematic for multi-site recordings via a large number of electrodes. Here we propose the simplified fabrication process and assembly of a single whisker electrode device for the electrode arrays with 100% yield. As a piece of electrode, we design the single whisker electrode on a one-millimeter square block of silicon. Such pieces of electrode block can be assembled into numerous designs of electrode arrays with 100% yield; herein we report the fabrication process of the single whisker electrode. First of the fabrication process, a vertical microneedle of silicon (~3 μm in diameter) was fabricated on a silicon substrate by vapor-liquid-solid (VLS) crystal growth technology. After the microneedle fabrication, platinum was deposited on the top- and bottom-sides of the substrate. After the metal patterning, an insulating layer of parylene-C was deposited on the substrate and the tip section of the needle was exposed by oxygen plasma. Finally, each section of the needle electrode was separated by silicon wafer

dicing. For *in vivo* recordings, each electrode block was packaged with an IC socket pin, which can be connected to a head-amplifier of a recording system. The sidewall of the electrode block and the IC socket pin were insulated by silicone. The block size of the electrode will be minimized (< one-millimeter square) in future design. In our previous study, nanoscale-tipped probes [Y. Kubota et. al., IEEE MEMS 2014 conf., 2014] and multi-functional (e.g., drug delivery) tube probes [K. Takei et. al., Biomed. Microdevices, 11, 3, 2009] have been proposed and demonstrated in animal experiments. As a future work, these probes will be integrated in one chip, enhancing the performance of the electrode device.

Title: An array of vertically aligned nanoscale tipped microprobe electrodes

Authors: ***Y. KUBOTA**[1], H. OI[2], H. SAWAHATA[1], A. GORYU[1], Y. ANDO[2], R. NUMANO[2,3], M. ISHIDA[1,2], T. KAWANO[1];

Abstracts: Electrophysiological methodology is a way to understand the communication between neurons in a tissue. Especially, multi-channel intracellular recording within a tissue becomes a powerful methodology, in terms of the large amplitude (~100 mV) and the signal quality (synaptic potential measured) compared to extracellular recording (< 100 μV). Nanoscale bioprobe devices have been proposed for intracellular recordings. However these nanodevices cannot be used for thick tissues due to the short probe length of 100-μm-long microprobe electrodes (NTEs) array and the electrical characteristics for intracellular applications. We have

proposed nanoscale tipped high-aspect-ratio silicon-microwire array fabricated by vapor-liquid-solid (VLS) growth of silicon-microwire and the nanotip formation. After the silicon-nanowire formation, the metallization for both the nanowire and the device interconnection was conducted by metal sputtering (e.g., iridium and platinum). The sidewall of the nanowire and the interconnection were insulated with parylene, while the nanotip-section was exposed by plasma etching. The fabricated NTE exhibited the tip diameter of < 500 nm. The height/area of the nanotip exposed from the parylene-shell can be controlled by changing the time of the plasma etching, resulting in the exposed tip-height of < 5 μm. The electrolyte/metal interfacial impedance of the electrode is an important characteristic of the intracellular electrode. The impedance of the fabricated NTE measured in saline exhibited < 5 MΩ at 1 kHz, with the output/input signal amplitude ratio of > 50%. Since the measured noise of the recording system was tens of microvolts, ~ 50% attenuated intracellular potentials (>> noise level) can be obtained by the NTE. The attenuation of the O/I ratio was due to the set of the impedance of the NTE and parasitic impedances embedded in the recording system. The improving the ratio will be important for investigating intracellular signals. However, we believe that the fabricated NTE array device can be used for numerous biological samples including brain slice and perform multi-channel intracellular potential recordings deep within the tissue.

Title: Neural correlates of tourette syndrome within the centromedian thalamus, premotor and primary motor cortices

Authors: *J. B. SHUTE[1,2], N. MALING[5], J. ROSSI[3], C. DE HEMPTINNE[6], K. FOOTE[4], M. OKUN[3], A. GUNDUZ[2];
[1]BioMedical Engin., [2]J. Crayton Pruitt Family Dept. of BioMedical Engin., [3]Dept. of Neurol., [4]Dept. of Neurolog. Surgery, UF, Gainesville, FL; [5]Case Western, Cleveland, OH; [6]UCSF Sch. of Med., Neurological Surgery, CA

Abstracts: Tourette Syndrome (TS) is a neurological disorder characterized by undesired motor and vocal tics. Treatment of TS varies depending on symptom severity and individual therapy effectiveness. Deep brain stimulation (DBS) is an emerging therapy for the treatment of many neurological disorders, including severe TS through the electrical stimulation of deep brain nuclei. A patient with Tourette's Syndrome was implanted at University of Florida (UF) Shands Hospital with two bilateral subdural 4-contact cortical strip electrodes and two bilateral 4-contact subcortical depth electrodes with the aim of capturing tic-related physiology. All procedures were approved by the FDA and UF IRB. The depth electrodes were placed bilaterally within the centromedian nucleus of the thalamus (Cm) and the cortical subdural strips were placed bilaterally over the premotor (PM) and primary motor (M1) cortices. Local field potentials (LFP) from the depth electrodes, electrocorticograms (ECoG) from the cortical electrodes, and electromyograms (EMG) from electrodes placed over the forearm and cheeks were recorded intra-operatively while the patient was awake. The patient was asked in interleaved trials to suppress tics (baseline), make right and left hand movements, imitate tics, and tic freely. The patient's tics presented as right hand and right facial twitches, along with right arm flexion-extension. In our preliminary analysis, we sought to discover the neural correlates of tics as related to TS and to differentiate them from voluntary movements and from imitated tics. The initial results suggest that when compared to baseline, broadband gamma activity in PM, M1 and Cm were correlated with contralateral tic behavior compared to baseline. This observation was different than what was observed in voluntary movements, which were associated with contralateral cortical activity but not thalamic activity. Local and subcortical-to-cortical phase amplitude coupling (PAC) suggested regionally specific activation patterns across PM, M1 and Cm. Future analysis of PAC between the thalamus and motor cortex during baseline, tic, and motor activity will likely provide additional spatial and temporal features important to understanding the physiology underpinning TS. Further refinement of these findings may lead to the identification of neural signatures for TS, and pave the way for the development of responsive stimulation paradigms.

Title: Intraoperative functional mapping of hand premotor cortex for chronic implantation of subdural strip electrodes

Authors: *N. MALING[1], J. B. SHUTE[1], P. J. ROSSI[1], C. DE HEMPTINNE[2], J. C. SANCHEZ[3], B. KRETZMAN[1], A. W. SHUKLA[1], K. D. FOOTE[1], M. S. OKUN[1], A. GUNDUZ[1];
[1]Univ. of Florida, Gainesville, FL; [2]Neurolog. Surgery, UCSF, San Francisco, CA; [3]Univ. of Miami, Miami, FL

Abstracts: A patient with Tourette's Syndrome was implanted at University of Florida Health Hospital with bilateral subdural 4-contact cortical strip electrodes and bilateral 4-contact subcortical depth electrodes with the aim of capturing tic related physiology. These electrodes were connected to a chronic sensing and stimulation device Activa PC+S (Medtronic Inc, Minneapolis, MN). All procedures were approved. The patient exhibited strong hand motor tics and thus the premotor and primary hand motor cortices (PM, M1) were target locations for the cortical strips. While implantation of bilateral cortical and subcortical electrodes is a great step forward in deep brain stimulation (DBS) and in recording technology, surgical placement of chronic, small subdural strips (44mm x 8mm x 1.8mm paddle, 10.2mm center to center contact distance, 4mm contact diameter) requires precise localization to obtain relevant signals, given the uncertainty in the representation of tic phenomena in the cortex. Herein we describe a confluence of techniques, the combination of which were effective in targeting the motor and pre-motor cortex. Preoperatively, the patient underwent transcranial magnetic stimulation (TMS) for hand motor cortex mapping. Areas that induced maximal thenar group activation were labeled with fiducial markers on the scalp. 3T MRI scans were acquired with these markers to aid in identifying the structural 'hand knobs' approximately 4mm lateral to the longitudinal fissure, and anterior to the central sulcus. Subdural strips were placed through a bur-hole such that the anterior contacts were approximately over M1, and the posterior contacts were over primary somatosensory cortex (S1). Somatosensory evoked potentials (SSEPs) were elicited and recorded from the implanted ECoG strip. Phase reversal was delineated the boundary between M1 and S1. We then partially retracted the ECoG strips based on the boundary location, such that the posterior contact was placed at the posterior border of M1, and the anterior contact presumably lay over PM. To verify final placement, real-time functional mapping was carried out to verify the location of the hand representation in the underlying cortices. This mapping utilized changes in high gamma range oscillatory activity coupled to behavior to calculate the probability that the activity in the underlying cortex was specifically related to the respective motor behavior. This combination of methods ensured that the strip electrodes were optimally placed, with posterior contacts over M1, and the anterior contacts over premotor cortex. Finally, post-operative CTs were co-registered with pre-operative MRIs to confirm placement.

Title: End of anonymity for single units in extracellular recordings

Authors: *P. LEDOCHOWITSCH, D. DENMAN, A. CHENG, G. SOLER-LLAVINA, H. ZHENG, T. J. BLANCHE;
Neural Coding, Allen Inst. For Brain Sci., Seattle, WA

Abstracts: Single-unit electrodes remain the principal technology for *in vivo* electrophysiological studies. Compared to conventional single- or multi-wire electrodes, silicon multielectrode arrays ('polytrodes') provide better single-unit isolation and enable simultaneous recording from dozens of neurons. However, in practice, large-scale recordings are typically analyzed without regard for spatial interrelationships, or sufficient appreciation of sampling bias towards larger or more active neurons – due to the lack of robust techniques to extract cell type, anatomical location, morphology, or functional connectivity from extracellular electrophysiology data. Accurate, automated spike sorting remains a tremendous challenge, especially for high channel-count arrays. We are creating tools to exploit the unique electrical 'signature' of neurons recorded on polytrodes of unprecedented density to estimate cell type and soma location. To achieve this, we are combining electrophysiology with optical physiology: polytrodes with up to 900 recording sites spaced 20 μm apart, genetically targeted *in vivo* 2-photon resonant Ca^{2+} imaging in triple-transgenic mice of the type PRM-Cre x Camk2a-tTA x Ai93-GCamP6f (where PRM indicates a cell type or layer-specific promoter such as e.g. Scnn1a for layer 4), and the targeted simultaneous excitation of neurons transfected with ReaChR (a red-shifted channelrhodopsin derivative) in a 3D volume via digital holography with a spatial light modulator (SLM). From these cell type- and location-specific signatures, we extract the parameters for a hybrid monopole-dipole field model of extracellular spike potentials to test how well such a neuron localization model can be generalized to arbitrary neuron orientation, tissue

anisotropy, and cell morphology. We can also determine, for the first time, the cell type specific biases of extracellular electrodes. Compared to the currently available optical techniques for imaging population activity, polytrodes provide higher temporal resolution, allow access to all cortical layers, do not require genetic intervention, and are more readily applicable to awake behaving animals. We aim to provide complementary information about the functional and anatomical properties of a large number of neurons *in vivo*, bridging the divide between structure and function. In addition, our approach will provide ground truth data for validating spike sorting algorithms, for optimizing the design of next generation polytrodes to achieve more complete neural sampling, and allow tracking of neural ensembles over time in the event of electrode drift in chronic large scale neuronal recordings.

München, München, Germany; [4]Blackrock Microsystems, Inc., Salt Lake City, UT; [5]Systems Neurobio. Laboratories, Salk Inst., San Diego, CA

Abstracts: Research over the last few years has opened up the possibility to study brain dynamics in animals freely moving in their natural environment. However, experimentation with unconstrained large animals, such as non-human primates, requires compact and robust devices in order to acquire neural data during free movement. To address this issue we developed a high fidelity wireless transmission set up to record extracellular spikes and local field potentials from

a range of cortical areas. A compact wireless transmitter (a 96-channel wireless broadband, 0.03 Hz-7.5k Hz; Blackrock CerePlex Radio) attaches onto a skull-mounted pedestal that connects to a microelectrode Utah array (Blackrock Microsystem Inc.). The wireless transmitter (IEEE 802.11n) integrates several low power, custom integrated circuits that requires two 3V CR123A batteries, and +5V on the receiver. For flexible management of the mobile subject's electromagnetic environment, the RF receiver transmission range (radio power 15dBn) can be extended from 32ft by in-line positioning of additional antennae in 6.5ft increments. The electronic operating environment ranges from 10°C to 40 °C, 5 to 95% R.H. (non-condensing) with a sampling frequency of 20ksps. The wireless device interfaces with the Blackrock Cerebus Neural signal processor. We tested our system by acquiring and decoding neuronal responses in real time from cells populations in area V4 and in dorsolateral prefrontal cortex (dlPFC) in freely behaving monkeys (Macaca mulatta). Animals performed different foraging tasks in the presence of randomly placed objects with and without food reward. In addition, we tested the wireless system by recording in dlPFC in an 'unfairness payment experiment'. We tracked the recorded neural population over days by analyzing single unit waveforms, principal component clusters, and response properties of single units and multi-unit clusters. The wireless neural recording system that we have developed represents a step forward in our attempt to study adaptive behavior in naturalistic tasks while recording wirelessly from many neurons across multiple brain areas simultaneously.

Title: Spike sorting for large, dense electrode arrays

Authors: *S. N. KADIR[1], C. ROSSANT[1], D. F. GOODMAN[2], K. D. HARRIS[1];
[1]Inst. of Neurology, Dept. of Neuroscience, Physiology, and Pharmacol., Univ. Col. London, London, United Kingdom; [2]Eaton-Peabody Laboratories, Dept. of Otology and Laryngology, Harvard Med. Sch., Boston Massachusetts, MA

Abstracts: Understanding how the brain processes information will require simultaneous recordings of large number of neurons, both locally within structures, and distributed over wide areas of brain tissue. The only technology currently capable of such recordings is extracellular electrophysiology. Recent developments in microfabrication have enabled the production of electrodes with hundreds of low-impedance recording sites, and electrodes with thousands of sites are currently under development. The problem of using the raw data recorded by these probes to decipher the firing times of the recorded neurons - known as "spike sorting" - represents a fundamental technical challenge for systems neuroscience. Techniques for the spike sorting of data from small-scale electrode arrays such as "tetrodes" are now mature, but do not scale to next-generation, large, dense electrode arrays. Current techniques typically operate in three stages: 1) detection of spikes and extraction of a feature vector summarizing each spike's waveform across channels; 2) automatic clustering of feature vectors into groups putatively corresponding to single neurons; 3) manual inspection and correction of these groups using graphical software. Although these techniques perform close to optimally for small electrode arrays, none of these three stages scale to the large, dense geometry of next-generation electrode arrays. We present an integrated system for spike sorting next-generation electrode arrays, based on algorithms enhanced to work with large dense arrays. Our system has four components: Ï SpikeDetekt, a program for detection and analysis of action potential waveforms from large-scale arrays, based on a flood-fill algorithm that detects each spike only from spatially localized channels; Ï KlustaKwik 3.0, a program designed for automatic clustering of high-dimensional data using a novel "Masked EM" algorithm; Ï KlustaViewa, a graphical program for manual verification of machine performance, in which fast machine performance is made possible by GPU optimization, and human time is minimized by a "Wizard" that guides the operator through the manual verification process. Ï KwikFormat, an HDF5-based file format for efficient processing, storage, and sharing of large-scale electrophysiology data. All software is freely available at http://klusta-team.github.io/. Testing on data from large-scale cortical recordings suggests that performance is close to an estimate of the upper bound achievable.

Title: Model-based measurement of eeg data from linear high-density array

Authors: *R. KOZMA[1], W. J. FREEMAN, III[2], J. J. DAVIS[3], C.-T. LIN[4];
[1]Dept Mathematical Sci., Univ. of Memphis, Memphis, TN; [2]Mol. and Cell Biol., UC Berkeley, Berkeley, CA; [3]Embassy of Peace, Whitianga, New Zealand; [4]Brain Res. Ctr., Natl. Chiao Tung Univ., Hsinchu, Taiwan

Abstracts: Aim: Our goal is to validate hypotheses about the existence of metastable amplitude patterns and propagating phase gradients using a linear array of high-density noninvasive scalp electroencephalogram (EEG) array. Introduction: Intermittent transitions between brain states with and without large-scale synchronous oscillations carrying spatial patterns are hallmarks of higher cognition, which were first identified using invasive intracranial ECoG measurements. Recent results by noninvasive scalp EEG measurements indicate that it is feasible to measure these amplitude and phase patterns using scalp EEG as well [1]. Methods: Based on theoretical considerations and experimental studies, we optimize the array design, to extract cognitively relevant attributes from the measured neural fields [2]. We employ a network theory-based model called neuropercolation, which approximates neural processes in brains as a generalized percolation process through the layered sheet of the cerebral cortex [3]. Heterogeneous neuropercolation models are developed incorporating structural connectivity patterns identified by brain EEG imaging techniques [1]. Results: High temporal and spatial resolution allows studying canonical power spectral densities (PSDs) in time (PSDt) and space (PSDx) [1, 4, 5]. The canonical PSDs at rest are generally self-similar with slope indicative of the cognitive state. The self-similar range is bounded with a plateau at low frequencies up to a break frequency determined by the time of the impulse response, linear decrease in log power with log frequency determined by the decay rate of the impulse response, and a plateau at high frequencies due to the background noise level [6]. Neuropercolation models reproduce the experimental behavior near critical states and used for the extraction of cognitively relevant information from the data. Conclusions: We develop a novel experimental technology with wireless array that allows monitoring cognitive activity without significant interference with the daily activity of the participants. The experiments are interpreted using our graph-theoretical model and lead to the conclusion that the data by the high-density array manifest neural correlates of cognition.

Title: Quantitative methods for determining spike sorting quality in neonatal rodent cortex

Authors: C. LAI[1], J. BERZHANSKAYA[2], *M. T. COLONNESE[2];
[1]Electrical Engin., The George Washington Univ. SEAS, Washington, DC; [2]Pharmacol. and Physiol., The George Washington Univ. Sch. of Med., Washington, DC

Abstracts: During development neuronal circuits produce unique patterns of activity that contribute their formation. An understanding of this early activity requires examination at the level of single units embedded in the ongoing network activity, a task requiring spike sorting from high-density multi-electrode arrays. Spike sorting in young brains has a unique set of difficulties that include low spike amplitudes, a high prevalence of bursts, low firing frequencies, and less variation of action potential shapes between neuron classes. Rigorous comparison of nascent and adult networks based on spike-sorted data will require quantitative metrics of sorting quality that can be compared between groups. Here we quantify the quality of individual clusters using established measures of inter-cluster separation (L-ratio & ISO distance) complemented by a new measure of intra-cluster spike similarity ('Similarity Index') based on the mean distance between all spike waveforms. Addition of the Similarity Index allows for automatic and objective splitting of clusters tentatively identified using the masked EM algorithm (Klustakwick), as well as merging of clusters with similar waveforms. By setting a threshold for the separation and similarity metrics to define good clusters, we establish a metric of overall quality for each tet/poly-trode, the percentage of spikes assigned to usable clusters, called 'Coverage'. Quantification of the average L-ratio/ISO distance, Similarity Index, and Coverage in a population for a given set of experimental parameters can be used to quantify differences between ages. We are testing these methods using single shank parallel electrode arrays in visual cortex of unanaesthetized rats, where preliminary results show we can achieve close to 90% coverage in animals from P9 and older. These validation metrics may be useful when comparing

any potentially variant neural networks, for example seizing vs non-seizing tissue, or in models of neurological disorders that could affect activity patterns.

Title: MEMS neural probe for local drug delivery to mouse brain with simultaneous recording of neural signals

Authors: ***I.-J. CHO**[1], H. LEE[2], Y. SON[2], E.-S. YOON[2], J. KIM[3], C. J. LEE[3], D. KIM[4], Y. KIM[4];
[1]KIST, [2]Ctr. for BioMicrosystems, [3]Ctr. for Neurosci., [4]Ctr. for Neuromedicine, Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstracts: We present a multi-functional silicon neural probe that consists of a microfluidic channel for local delivery of a precise quantity of a drug and multiple recording electrodes to simultaneously monitor the effects of drug delivery. The new fabrication method developed for this integrated drug delivery probe allows the channel to be embedded in the probe substrate. Thus, no additional thickness is required due to the presence of the channel. The successfully fabricated 40-m-thick and 100-m-wide neural probe consists of a single shank with 16 multiple recording sites (10 m 10 m), a silicon channel enclosed by glass and two reservoirs (inlet and outlet with radius of 500 m and 30 m, respectively). The recording sites are located near outlet port to record neural spike signals stimulated by delivered drug. The probe was characterized for its flow rate and electric impedance. The flow rate of 0.2 l/min was obtained at the air pressure of 200 kPa and linearity confirms precise quantity control. The impedance of 16 microelectrodes was measured using electrochemical impedance spectroscopy, where an average impedance value of 1.0 M at 1 kHz was measured, which is low enough to measure neural spikes. In this work, we also demonstrate a successful *in vivo* recording of neural action potentials from the thalamus of an anesthetized mouse. The fabricated MEMS neural probe was robust enough to penetrate the mouse's pia without bending or fracturing. We moved the implanted neural probe

to the target position (AP: 3.2, ML: 1.2, DV: -4.56) and delivered 0.6 l of Baclofen (100 mM) to induce absence seizure in a wild type mouse through the integrated microfluidic channel. And, we were able to monitor synchronous spike-and-wave discharges (SWDs) using integrated microelectrodes. Also, the SWDs were disappeared and basal neural spikes were appeared again in 1 hour after drug injection. These results are similar to the results of intraperitoneal injection and it confirms that Baclofen was successfully delivered to the mouse brain. In this abstract, we present an improved multi-functional silicon neural probe that is capable of selectively delivering a chemical to a highly localized region of interest and recording neuron responses *in vivo* simultaneously. By embedding the channel in the substrate, the thickness of the probe is no longer limited by the presence of the channel and thus the cell damage induced by such probe can be further minimized. In addition, the presented probe has a wide range of uses in the neuroscience including monitoring the effects of drugs for treatment of physiological disorders and tracing neural pathways.

Title: A comparison of metrics for phase-amplitude coupling

Authors: *C. RENNÓ-COSTA, A. B. L. TORT;
Brain Inst., Federal Univ. of Rio Grande do Norte, Natal, Brazil

Abstracts: Phase-amplitude cross-frequency coupling (PAC) occurs when the amplitude of a higher frequency oscillation is modulated by the phase of a lower frequency oscillation. Recent studies in neurobiology have linked PAC to aspects ranging from anatomical structure to

cognitive function. For example, theta-gamma coupling in the hippocampus has been suggested to constitute a neuronal correlate of learning. Also, altered PAC has been linked to brain disorders such as Parkinson's disease and schizophrenia. As a consequence, the assessment of PAC has become standard in the analysis of electrophysiological signals such as EEG, ECoG and LFP. However, different groups have developed different metrics to measure PAC that differ in the way PAC is defined and thus may not necessarily produce similar outcomes. For instance, while some groups define PAC intensity as the phase consistency between the amplitude and phase time series, others consider PAC as the magnitude of the amplitude variation within a phase cycle. These methodological aspects should be taken into account when interpreting PAC measurements, especially when comparing results from different labs. To provide a guide for interpreting PAC measures, we performed a systematic analysis using synthetic signals, which were parameterized by: the frequency of the modulatory and modulated signals; the amplitude of the modulatory and modulated signals; the magnitude of the amplitude variation of the modulated signal; the modulatory phase; the modulation width; the signal-to-noise ratio; and the consistency of the modulation across phase cycles. We have studied 12 published PAC metrics including: modulation index (MI); height ratios; power spectral density (PSD) of the amplitude envelope; mean vector length (MVL); phase-locking value (PLV); correlation coefficients; the general linear model (GLM); coherence between the amplitude envelope and the modulatory signal; and amplitude weighted phase locking factor (wPLF). Our analysis reveals that PAC metrics are differently affected by variations in signal parameters. Nevertheless, we could still classify the metrics into clusters according to their robustness to specific parametric changes. Based on these results, we propose the use of complementary metrics from different clusters for a more accurate assessment of PAC. As a by-product of this research, we organized the source code into a single MATLAB/Octave toolbox, named COMODO, which is freely available at http://neuro.ufrn.br/comodo. COMODO allows PAC analysis with a single-line command and the quick switching between metrics. Finally, new metrics can be added into COMODO using available templates.

Abstracts: This paper describes a method for assembling *in vitro* neural cells with control over morphology to engineer geometrically controlled neuronal networks. Engineering of *in vitro* neuronal netoworks has long been pursued in the microengineering field by controlling chemical/physical microenvironments around neural cells using microfabrication techniques. The advantages of the microengineering-based *in vitro* neuronal network construction are that we can define network structures by micropatterns of cell-adhesive regions and record electrical signal by embedded microelectrodes, which facilitate analyses of neural information processing. However, it is still challenging to engineer neuronal networks with full control over morphology and connectivity of individual neural cells that is essential for individual cell-based analyses. Here, we propose a method for engineering individual cell-based neuronal networks by controlling morphology and connections of single neural cells using a microfabricated reconfigurable plate array. We fabricated the cell-adhesive micro-plates in the shape of a soma-sized circle and neurite-sized lines radiated from the circle, arrayed on a cell non-adhesive background. When we seeded neural cells on the micro-plate array, some single cells were isolated on single micro-plates with their somas localized on the circle parts and their neurites grown along the line parts. Consequently, some single neural cells which were morphologically defined by the shape of the microplates could be found in the microarray. Morphologically defined single neural cells were able to be selectively assembled into desired geometries by micromanipulation. We observed that assembled neural cells continued growth to form cell-cell contacts that are necessary for synaptogenesis and neural circuit formation. The advantages of this method over previous microengineering methods are controllability of individual soma position and neurite number. We envision that our technique would be a useful tool in individual cell-based analyses of synaptogenesis and neural information processing.

Title: Stretchable array for epidural and subdural electrocorticogram recordings in freely moving rodents

Authors: *A. HIRSCH[1], N. PAVLOVA[2], I. MINEV[3], Q. BARRAUD[2], J. GANDAR[2], G. COURTINE[2], S. P. LACOUR[3];

Abstracts: Electrocorticography (ECoG) uses electrode array placed over the cerebral cortex to record electrophysiological signals. Short-term implantation of ECoG arrays is commonly used at the clinic for brain mapping and pre-surgical localization of epileptic seizure. Recent studies have demonstrated that ECoG arrays may support the design of brain machine interfaces with stable performances for extended durations. These new developments have created a need for chronic, biostable arrays with high electrode density. Micron scale ECoGs, termed μ-ECoG, are miniaturized array prepared with microfabrication techniques and implemented on thin plastic films. Implants prepared on <15 μm thick plastic substrate conform the complex surface of the brain. However, their local mechanical mismatch with delicate brain tissue may impede long-term, chronic use. Here, we introduce an alternative design where the electrode array is made of ultra-thin and elastic metal film embedded in a soft, elastic silicone. The soft μ-ECoG array hosts 3x3 electrodes distributed over 2.25mm^2. The microfabrication approach also allows the implant design to be customized and scaled up to larger surface areas. Combined with optimized surgical techniques for chronic epidural and subdural implantation in rats and mice, we obtained robust recording of neuronal activity in awake, freely behaving animals for extended periods of time. Post-mortem histological evaluations showed improved biotolerance of the soft implant with brain tissue compared to standard μ-ECoG technologies. Moreover, the transparency of the silicone elastomer allows to combine soft μ-ECoG recordings with local photostimulation. The resulting chronic, bi-directional optoelectronic neural interface opens new avenues for the design of closed-loop neuromodulation therapies. Funding: Fondation Bertarelli and FNS nano-tera.ch

Title: Bio-coating to improve long-term performance of chronic intracortical implants

Authors: ***S. DE FAVERI**[1], E. MAGGIOLINI[1], E. CASTAGNOLA[1], A. ANSALDO[1], D. RICCI[1], L. FADIGA[1,2], F. BENFENATI[1,3];

Abstracts: Intracortical microelectrodes have been widely used in animal neurophysiology to chronically record neural activity, providing high precision in detecting particular groups of neurons and allowing single unit activity (SUA) recording. Unfortunately, it is widely known that intracortical implants lose their recording ability over time because of the inflammatory reaction that occurs around the implanted device and therefore the quest to solve or, at least reduce, their invasiveness is very strong. In a previous work, we were able to assemble a biocompatible device by seeding living cells on the microelectrode shaft and embedding it in a soft fibrin layer. Moreover, we demonstrated that fibrin 'per se' is highly biocompatible, forms a uniform coating of controllable thickness, does not swell, does not alter the electrochemical properties of the microelectrode and allows good quality recordings. Finally, we demonstrated that fibrin reduces the number of reactive astrocytes and is fully reabsorbed by the surrounding tissue within seven days after the implant. In the present work, we evaluate the chronic performance of our bio-inspired hybrid microelectrode after the implant in rat cerebral cortex. The device is coated with autologous fibroblasts embedded in a fibrin layer. Autologous fibroblasts are used to mimic the host tissue and immunologically hide the microelectrode to further increase the lifetime of the implant. We investigate the tissue reaction due to the presence of bio-coating by immunofluorescence at increasing time intervals from the implant and the quality of neural recordings over time. The results show that the electrochemical properties of the microelectrode are not affected by the bio-coating, the bio-inspired hybrid microelectrode markedly reduces the extent of the tissue reaction and its chronic performances are improved. In

conclusion, the present method shows a good potential to improve the biological integration of neural devices for achieving successful long-term neural implants.

Title: *In vitro* recording of hippocampal gamma oscillations with multi-electrode arrays for CNS drugs characterization

Authors: *E. STEIDL, R. TEYSSIE, M. GLEYZES, F. MADDALENA, H. SAVINEL, B. BUISSON;

Abstracts: The need of translational biomarkers is an urgent need for many CNS Drug Discovery programs. Neuronal network oscillations in the gamma range contribute to cognitive function, whereas it has been shown that they are disturbed in some psychiatric disorders, such as Schizophrenia. Gamma Oscillations are recorded both in the Electro-encephalogram (EEG) of human subjects and rodents. A few publications have illustrated that Gamma Oscillations could be triggered in acute brain slices recorded *in vitro* with glass electrodes. Using Multi-Electrode Arrays (MEA) recordings we demonstrate that Kainate elicits Gamma Oscillations in acute rat brain hippocampal slices in a dose-dependent manner, for concentrations ranging from 10 to 300 nM. Maximal Kainate-induced oscillatory activity is observed at 100 nM, and strongly decreases at 300 nM. Oscillations in the gamma range are characterized by calculating their power spectrum (using a fast Fourier's transform algorithm, and considering the 20-80 Hz range) and their amplitude. Thanks to MEA recordings, with electrodes covering the whole hippocampal slice area, we illustrate that Gamma Oscillations are of larger amplitude specifically in the CA3 region. Under 100 nM Kainate exposure, the oscillations develop over a 20 minute time-window and become steady for at least a 1-hour additional period. Network oscillations depend on synchronous and rhythmic fluctuations of membrane potentials of populations of neurons, defining temporal windows of increased and reduced excitability. GABAergic interneurons play a key role in the generation of Gamma Oscillations, by synchronizing the activity of the

ensemble of neurons of the hippocampal network. In accordance with these findings, 1 μM Picrotoxin (a selective GABA-A receptor antagonist) strongly inhibits Gamma Oscillations elicited by 50 nM Kainate. In addition, compounds that modulate the excitation-inhibition balance also modulate Kainate-induced Gamma Oscillations: NMDA receptors antagonists, such as Ketamine (100 μM) and MK-801 (20 μM) potentiate Gamma Oscillations. Finally, we demonstrate that Clozapine (30 μM; a Serotonin and Dopamine receptors antagonist used as antipsychotic) decreases the oscillations amplitude and also strongly decreases the strength of Kainate-induced Gamma-Oscillations. In conclusion we have established a robust and rapid *in vitro* assay based on MEA recording of acute hippocampal slices that allows documenting the activity of well-known CNS drugs and to profile new chemical entities for CNS-related disorders.

Title: High fidelity biopotential recordings in mice using a novel telemetry implant

Authors: *S. MALPAS, S. LAU, D. RUSSELL, D. MCCORMICK, S.-J. GUILD, D. BUDGETT, M. KONDO;
Millar Inc, Auckland, New Zealand

Abstracts: We have developed a fully implantable telemetry device for use in mice. The device is capable of sampling biopotential signals (EEG,EMG,ECG) at 2000 Hz. The device has a volume of 1.45 cc meaning it is suitable for mice over 20 gm in weight. An novel aspect to the device is that it contains no battery. Power to run the implant is provided by a wireless power pad placed under the cage of the animal. This provides continual operation of the telemeter during a range of normal animal behaviors. We have assessed the ability of this device to record biopotential signals over many weeks. We believe this technology offers new experimental paradigms to be explored.
