Title: Rhox8 expression in rodent brains

Authors: H. G. HUFFMAN[1,2], E. D. GRISLEY[1,2], J. A. MACLEAN, II[2], *J. L. CHEATWOOD[1];
[1]Anat., SIU Sch. Med., CARBONDALE, IL; [2]Physiol., SIU Sch. Med., Carbondale, IL

Abstract: Homeobox genes encode transcription factors that govern many processes during development. This 60-amino acid DNA-binding motif associates with promoters by either activating or suppressing the transcription of downstream target genes. Recently, the Rhox, -(X-linked reproductive Homeobox)-, genes were discovered. The Rhox gene set is expressed during embryonic development in the testis, but a select few of these genes continue to show high expression after birth which makes them candidates for controlling postnatal and adult developmental events. At their peak expression in the testis (postnatal day 12), all Sertoli cells express Rhox5, Rhox8, and Sox9, but Rhox5 expression become more restrictive after postnatal day 30. RHOX8 protein is abundant in the testis, epididymis, ovary, and it is weakly detected in the placenta. Of all 33 mouse Rhox genes, Rhox8 is the only one to show expression in somatic cells in the embryonic testis. All others are expressed solely in germ cells. It is a common phenomenon that testis expressed genes exhibit brain-specific splicing or transcripts from alternative promoters. Given Rhox8's potentially unique transcriptional control in the testes, we wanted to determine if Rhox8 was similarly uniquely expressed in the brain. Thus, we examined whether the mRNA of the somatic transcription factors Rhox8, Sox9, and Rhox5 could be detected in adult rat and mouse brain tissue. Rats were euthanized, and brains were removed and flash-frozen. To study the basic expression of the Rhox8, Sox9, and Rhox5 gene in brain tissue, we extracted RNA rat and mouse brains, and then converted the RNA to cDNA in order to perform qPCR (quantitative real-time polymerase chain reaction). Rhox8, Rhox5, and Sox9 were all found to be highly expressed in positive control adult mouse testis tissue. However, only Rhox8 had moderate expression in mouse cortex and hippocampus. As expected we found Rhox8 to have moderate expression in adult rat cerebellum, Sox9 had minimal expression, but

Rhox5 had no detectable expression. These low levels may be due to the use of whole cerebellum in the rat, which contains many cell types which do not appear to express Rhox8 in addition to neurons, some of which were immunopositive for RHOX8 in the mouse brain. Further characterization of RHOX8 expression in adult rats and adult and developing mice was ongoing at the time of abstract submission.

Title: Spatiotemporal dimorphic expression of Xlr3 genes in the developing male and female cortex

Authors: *A. MCDONOUGH[1], J. BERLETCH[2], C. DISTECHE[2], R. HEVNER[3,1];
[1]Ctr. for Integrative Brain Res., Seattle Childrens Res. Inst., Seattle, WA; [2]Dept. of Pathology, [3]Neurolog. Surgery and Pathology, Univ. of Washington, Seattle, WA

Abstract: The high occurrence of neurodevelopmental disorders in males may in part be explained by the inheritance of their X-chromosome from their mothers, particularly if certain genes are maternally imprinted and those genes influence cognitive function. This hypothesis is supported by comparative studies on women with Turner syndrome who have inherited solely a maternal or paternal X-chromosome, who exhibit parent-of-origin effects correlating with differing types of cognitive impairment. Further studies on mouse models of Turner syndrome suggest some X-linked genes may be imprinted and expressed solely from one X-chromosome. The observed sex biases in susceptibility for many neurodevelopmental and neuropsychiatric disorders, and studies on transgenic mice that separate the sex chromosome complement from gonadal sex, suggest differences in brain structure, and thus development and plasticity, may be due to the sex chromosomes rather than gonadal hormones. In preliminary studies we saw high expression of Xlr3 genes in the developing mouse cortex. Based on these findings and previously published research, we hypothesize that these genes function as transcriptional regulators and

they are expressed from the maternal X-chromosome in both males and females, and repressed on the paternal X-chromosome in females. Using *in situ* hybridization and q-PCR we have characterized the expression patterns and levels in the developing male and female cortex during multiple stages of neurogenesis. This knowledge may help explain observed clinical differences in susceptibility to autism and other neurodevelopmental and neuropsychiatric disorders.

Title: Stroke injury enhances neurogenesis in multiple new stem cell niches along the ventricular system at sites of high blood-brain-barrier permeability

Authors: *R. LIN[1], J. CAI[1], C. NATHAN[1], X. WEI[1], S. SCHLEIDT[1], R. ROSENWASSER[2], L. IACOVITTI[1];
[1]Farber Inst. of Neuroscience, Dept. of Neurosci., [2]Dept. of Neurolog. Surgery, Thomas Jefferson Univ., Philadelphia, PA

Abstract: Previous studies have established the subventricular (SVZ) and subgranular (SGZ) zones as sites of neurogenesis in the adult forebrain (Doetsch et al., 1999a). Recently, our group also suggested that circumventricular organs (CVOs) serve as adult neural stem cell niches (Bennett et al., 2009, 2010). Since NSC proliferation and differentiation is relatively low in all of these sites in the quiescent brain, in this study, we sought to determine whether these processes might be amplified following perturbation. To do so, rats were subjected either to focal ischemic injury (MCAO) or sustained intraventricular infusion of the cell mitogen bFGF (via Alzet pump). Our data show that both stroke and bFGF induce a long-lasting (14 days) rise in the proliferation ($BrdU^+$) of $nestin^+$, $Sox2^+$, $GFAP^+$ NSCs and increase their differentiation into $Olig2^+$ glial progenitors and Dcx^+ neuroblasts in the SVZ and CVOs but also in several other novel sites along the third (3V) and fourth (4V) ventricles. Importantly, all these sites were supplied by a

rich vasculature of fenestrated capillaries and a blood-brain-barrier (BBB) that was highly permeable to systemically injected sodium fluorescein. These data indicate that stem cell niches exist not only near the lateral ventricle but at multiple sites along the entire ventricular system, consistent with the potential for widespread neurogenesis and gliogenesis in the adult brain. We further suggest that because of their leaky BBB, all of these niches are well positioned to respond to systemic cues following injury which could be important for brain repair.

Title: Differences in proliferation behaviour and expression of phenotypic markers in embryonic mouse adrenal chromaffin cells and sympathetic neuroblasts

Authors: ***W. CHAN**[1], D. G. GONSALVEZ[1], H. M. YOUNG[1], E. M. SOUTHARD-SMITH[2], K. N. CANE[1], C. R. ANDERSON[1];
[1]Dept. of Anat. and Neurosci., Univ. of Melbourne, Melbourne, Australia; [2]Div. of Genet. Medicine, Dept. of Med., Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract: Adrenal medullary chromaffin cells and peripheral sympathetic neurons originate from a common sympathoadrenal (SA) progenitor cell. The time course and signalling mechanisms underlying this lineage separation during embryonic development are not fully understood. The present study investigates the expression patterns of phenotypic markers as well as cell cycle dynamics in the embryonic murine adrenal medulla and the neighbouring suprarenal ganglion by immunohistochemical analysis. Transverse sections of the adrenal region in E10.5-16.5 C57BL/6 mice were processed with antibodies against Sox10, tyrosine hydroxylase (TH), phenylethanolamine N-methyltransferase (PNMT) and cocaine and amphetamine regulated transcript (CART). Ki67 immunohistochemistry, coupled with dual-labelling with S-phase markers, bromodeoxyuridine (BrdU) and 5-ethynyl-2'-deoxyuridine (EdU), allowed cell cycle analyses. The noradrenergic marker, TH was detected in cells in both the adrenal and sympathetic region, but with much stronger immunoreactivity (IR) for TH in the adrenal. There was strong CART immunostaining in most neuroblasts, whereas it was detected in only a

handful of adrenal chromaffin cells. Comparison of CART-IR versus TH-IR showed that neuroblasts have low intensity of TH-IR but high intensity of CART-IR, while chromaffin cells in the adrenal medulla had high intensity TH-IR without detectable CART-IR. This phenotypic segregation appeared as early as E12.5 when anatomical segregation of the two cell types is difficult. The adrenergic marker, PNMT, was first detected in a subpopulation of chromaffin cells from E14.5. Chromaffin cell and neuroblasts lineages showed differences in proliferative behaviour from their earliest appearance at E12.5. Initially, 70% of Sox10+ neural crest progenitors were proliferating at E10.5 but dramatically withdrew from the cell cycle at E11.5 as they started to express TH and differentiate into neuroblasts and chromaffin cells. Whereas 88% of TH+ neuroblasts were back in the cell cycle at E12.5, only around 20% of TH+ chromaffin cells were in the cell cycle at E12.5 and subsequent days. Cell cycle length increased modestly for TH+ cells in the ganglion and the adrenal medulla from E12.5. This study identifies the intensity of TH-IR and the expression of CART as phenotypic markers for early discrimination of the chromaffin cells and sympathetic neuroblasts. Developing chromaffin cells also show strikingly less proliferative activity relative to sympathetic neuroblasts.

Title: The developmental genetic basis of cortical interneuron identity - the case of chandelier cells

Authors: *S. M. KELLY[1,2], M. HE[1], Z. HUANG[1];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Stony Brook Univ., Stony Brook, NY

Abstract: Neuronal firing activity within the cerebral cortex is regulated by a diverse assortment of inhibitory GABAergic interneurons, which are able to finely tune circuit activity through a vast array of morphological, molecular, synaptic, and electrophysiological properties. Most cortical interneurons in rodents arise predominantly from three neurogenic zones: the medial and

caudal ganglionic eminences (MGE, CGE), and the pre-optic area (POA). There is evidence that interneuron class identity is determined in part in part by spatial and temporal origin within the subpallium. Furthermore, intrinsic genetic programs and extrinsic cortical signals are both likely to play a role in defining different neuronal subtypes within each class and distributing these cells to cortical layers and regions in the proper density to allow the formation of meaningful circuit motifs. To approach a complete understanding of interneuron development, our studies have focused on characterizing the entire life history of the chandelier cell, arguably the most distinct and uniform GABAergic interneuron yet to be described. Chandelier cells have an unmistakable axon arbor of hundreds of vertically arranged cartridge synapses, each of which specifically innervates the axon initial segment of a pyramidal cell, the site where action potentials are generated. Neocortical chandelier cells (ChCs) are generated between mid-gestation and birth from progenitors in the MGE expressing the homeodomain transcription factor Nkx2.1. Here, using intersectional genetic fate mapping and novel birth dating techniques, we provide an experimental system to examine for the first time the cellular and molecular nature of progenitors that produce several well-defined MGE cell subtypes in cerebral cortex. Further, we have compared the birth timing and progenitor origin of ChCs found in various regions of the cerebrum, such as the hippocampus, piriform cortex, and neocortex. Through these studies, we hope to discover and characterize the mechanism by which Nkx2.1+ progenitors produce and distribute a diverse family of interneurons to be integrated into specific types of cognitive circuits throughout the cerebral cortex.

Title: Molecular characterization of human cortical interneurons

Authors: ***J. L. CLOSE**[1], B. LEVI[1], V. MENON[1], S. ANDERSON[2], S. RAMANATHAN[3]; [1]Allen Inst. For Brain Sci., Seattle, WA; [2]Univ. of Pennsylvania, Philadelphia, PA; [3]Harvard Univ., Cambridge, MA

Abstract: We have established a robust protocol for generating cortical interneuron progenitors from human embryonic stem cells. The gene expression profile of these cells has been assayed at

the population, subpopulation and single-cell level to determine progenitor diversity and lineage relationships within heterogeneous pools of interneuron precursors and differentiating neurons. Using reporter lines developed to visualize specific populations and developmental stages, we have determined the gene regulatory networks that underlie the production and maturation of human interneuron subclasses that are crucial to cortical processing.

Title: Serotonin receptor 5-HT3A in the development of autonomic and sensory innervation of the lower urinary tract

Authors: *E. RITTER[1,3], D. P. BUEHLER[2], H.-H. WU[4], E. SOUTHARD-SMITH[2]; [2]Genet. Med., [1]Vanderbilt Univ., Nashville, TN; [3]Neurosci. Grad. Program, Vanderbilt Brain Inst., Nashville, TN; [4]Dept. of Pediatrics, Keck Sch. of Med. of Univ. of Southern California, Los Angeles, CA

Abstract: Decades of research demonstrate the importance of serotonin (5-HT) signaling in the fetal development and postnatal maturation of various neuronal populations. While most of these studies focused on the brain and enteric nervous system of the gut, very few have inspected the role of 5-HT in development of other peripheral nervous system components. In a gene expression analysis conducted in our lab, we noted increased expression of the type 3A serotonin receptor (5-HT3A) in fetal pelvic ganglia that provide autonomic innervation to the bladder and urethra. This finding, along with reports of 5-HT3A in adult urinary function and visceral pain, led us to pursue the role of this receptor in the development of bladder autonomic and sensory innervation. We aim to define the temporal, spatial, and cell-type specific expression patterns of

the 5-HT3A receptor throughout lower urinary tract development as a basis for interrogating gene function in this system. By employing the Htr3a-EGFP transgenic reporter mouse line and immunohistochemistry, we have characterized expression of the 5-HT3A receptor in a variety of both autonomic and sensory neuronal subtypes within the pelvic and dorsal root ganglia. Expression of 5-HT3A begins early in the development of bladder innervation at 12 days post coitus, which is the earliest time point 5-HT3A has been identified in mouse embryos. 5-HT3A co-localizes with both sympathetic and parasympathetic markers in the pelvic ganglia throughout fetal development, as well as several markers of nociceptive neurons in the dorsal root ganglia and bladder urothelium. Ongoing experiments are focused on determining roles for 5-HT3A signaling in urinary tract function and acute neurogenic inflammation in knockout mice. Given that very few treatment options are available for urinary incontinence and pelvic pain syndromes, elucidating the mechanisms of neurogenesis and maturation in the lower urinary tract lends itself to the identification of novel and specific therapeutic targets for treating these prevalent disorders.

Title: Modeling neurodevelopmental disrutpion and glioblastoma with crispr/cas9 system

Authors: ***F. CHEN**[1], A. CHE[2], A. BECKER[4], J. LOTURCO[3];
[1]Dept. of Physiol. and Neurobio., Univ. of Connecticut, STORRS MANFLD, CT; [2]PNB, [3]Physiol. and Neurobio., Univ. of Connecticut, Storrs, CT; [4]Dept. of neuropathology, Univ. of Bonn Med. Sch., Bonn, Germany

Abstract: The newly developed CRISPR/Cas9 system offers fast, convenient, specific yet efficient way for genome editing. Here we report successful modeling of neurodevelopmental disorder as well as gliaoblastoma multiforme in rat using CRISPR/Cas9 system. *In vivo*

transfection of radial glia with sgRANs targeting PTEN successfully abolished PTEN expression in cells in radial glia lineage i.e. neurons, astrocytes and oligodendrocytes. PTEN-null neurons showed increased soma size, hypertrophic dendrites and axons. PTEN null neurons also showed altered electrophysiological properties such as decreased input resistance, increased sEPSC and mEPSC. These results indicate CRISPR/Cas9 can be used *in vivo* to manipulate gene expression. Moreover, electroporation of three sgRNAs targeting PTEN, NF1 and P53, respectively, into rat radial glia and successfully induced glioblastoma multiforme formation. To our knowledge, this is the first successful demonstration of modeling neurodevelopmental disorder and glioblastoma using CRISPR/Cas9 system.

Title: Primitive neural stem cells at the top of the neural stem cell hierarchy

Authors: *S. YAMMINE[1], R. LEEDER[2], D. VAN DER KOOY[1];
[1]Mol. Genet., [2]Inst. of Med. Sci., Univ. of Toronto, Toronto, ON, Canada

Abstract: Primitive neural stem cells (pNSCs) are Oct4+GFAP- cells that can be isolated from the mouse embryo as early as E5.5, and persist throughout development into adulthood where they are a rare population residing in the subependymal zone of the lateral ventricles. pNSCs are LIF-dependent and can be clonally passaged *in vitro* to self-renew or give rise to definitive (d)NSCs, which are GFAP+ and dependent on EGF and FGF. Given that pNSCs arise earlier in development than dNSCs and are upstream dNSCs *in vitro*, we asked whether this hierarchy is true *in vivo*, and what the role of an upstream pNSC population is in the embryo and adult mouse brain. We have previously shown that expression of the pluripotency gene Oct4 is an exclusive marker for pNSCs, so we used Oct4fl/fl;Sox1Cre mice to assess the requirement of Oct4 in pNSCs. The forebrain of adult mice homozygous for the Oct4 conditional knockout did not give rise to any pNSC-derived neurospheres *in vitro*, while dNSC-derived neurospheres were not affected by Oct4 loss. This indicates a requirement for Oct4 expression in either the survival or

proliferation of pNSCs, and offers a mouse model for loss of pNSC function. We hypothesized that rare pNSCs serve as a reserve pool of NSCs in the adult brain. To test this, we ablated dNSCs and downstream progenitors by administering 7 days of AraC followed by 3 days of ganciclovir (GCV) to Oct4fl/fl;Sox1Cre;GFAP-tk mice by intraventricular infusion. While no dNSC-derived neurospheres form immediately after this ablation paradigm, the level of dNSC-derived neurospheres from control mice without the loss of Oct4 recover to 50% naive abundance 4 weeks post-treatment. In mice homozygous for the loss of Oct4, however, we observed a significantly reduced recovery of dNSCs following AraC/GCV infusion to only 6% 4 weeks post-treatment. Using Oct4fl/fl;Sox1Cre mice, we have observed that pNSCs in the perinatal brain also are sensitive to the loss of Oct4. Next we asked whether pNSCs are required for the initial establishment of the NSC lineage in the early embryo, as they are for repopulating a depleted NSC lineage in the adult. Preliminary results using mice with tamoxifen-inducible Oct4 excision suggest that pNSCs in the early embryo also are Oct4-dependent, providing a novel loss of function model to study the role of pNSCs at the onset of brain development. In conclusion, pNSCs in the early embryo, perinatal and adult brain are dependent on Oct4. Further, pNSCs are responsible for the repopulation of the depleted dNSC pool in the adult brain, strongly suggesting pNSCs are at the top of the neural stem cell lineage *in vivo* and may be responsible for the initial establishment of the NSC lineage in the early embryo.

Title: Dispersion of clonally related interneurons

Authors: *C. MAYER[1], X. H. JAGLIN[1], C. STREICHER[2], J. DIMIDSCHSTEIN[1], S. HIPPENMEYER[2], L. CEPKO[3], G. J. FISHELL[1];
[1]Physiol. & Neurosci., NYU Neurosci. Inst., New York, NY; [2]Inst. of Sci. and Technol. Austria, Klosterneuburg, Austria; [3]Departments of Genet. and Ophthalmology and HHMI, Harvard Med. Sch., Boston, MA

Abstract: Unlike pyramidal cells, GABAergic interneurons originate in subpallial germinal zones and migrate tangentially to reach the cortex. The majority of GABAergic interneurons originate from the medial ganglionic eminence (MGE), which in addition to cortical interneurons also generates interneurons destined for the striatum and hippocampus, as well as projection neurons for the globus pallidus, amygdala, and septum. It is poorly understood whether these cell types are generated from distinct intermixed progenitors, or from the same progenitors through a stochastic or temporally regulated program. To determine the relationship of MGE-derived interneurons, we specifically marked precursor cells in the MGE by *in utero* intraventricular injections of a retroviral library encoding GFP, and we identified sibling cells by DNA sequencing of a diverse set of viral DNA tags. Specificity of viral infection was achieved through the selective expression of the receptor for this retrovirus being confined to the MGE in a Cre-dependent manner. After cell migration, virally labeled neurons originating from the MGE were widely spread throughout the telencephalon. Clonally-related interneurons rarely exhibited spatially isolated clusters, as had been previously observed for cortical pyramidal clones. Instead, sibling neurons where spread across functional cortical areas and brain structures, including the hippocampus, striatum and cortex. Our results support the hypothesis that environmental cues rather than intrinsic programs determine the spatial distribution of interneurons. We will present our findings on the spatial spread and cell type differentiation of clonally-related interneurons.

Title: The role of Gsx2 in the generation of the septum-derived olfactory bulb interneurons

Authors: *S. QIN[1], H. CHAPMAN[3], S. M. WARE[4], R. R. WACLAW[2], K. CAMPBELL[1]; [1]Developmental Biol., [2]Exptl. Hematology and Cancer Biol., Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [3]Cell Biol. and Human Anat., Univ. of California, Davis, Davis, CA; [4]Pediatrics and Med. and Mol. Genet., Indiana Univ., Indianapolis, IN

Abstract: The homeobox gene Gsx2 is expressed in the ventricular zone (VZ) of the developing ventral telencephalon. Previous studies have suggested that Gsx2 is crucial for the specification of distinct neural cell types, including olfactory bulb (OB) interneurons, which originate from the dorsal lateral ganglionic eminence (dLGE) and septum and migrate rostrally toward the OB, where they radially migrate to populate different layers and terminally differentiate. Gsx2 was shown to be important for the specification of dLGE-derived OB interneurons; however, whether it is involved in the generation of septum-derived OB interneurons is unclear. In this study, we conditionally inactivated Gsx2 in the septum without drastically affecting it in the dLGE using Olig2Cre mice and examined whether septum-derived OB interneurons were impaired. Our results using a Zic3-LacZ reporter, which is expressed by many septal cells and their OB derivatives, suggest that septal progenitors give rise to a subpopulation of Sp8+ and calretinin (CR)+ OB interneurons in the glomerular layer (GL). Moreover, conditional inactivation of Gsx2 using Olig2Cre impaired the generation of septum-derived Sp8+ and CR+ OB interneurons in the GL. To investigate the cause(s) of the phenotype, we analyzed control and Gsx2 conditional knockout (Gsx2 cKO) embryos and found reduced specification of Sp8+ neuroblasts in the mutant septum. By analyzing proliferation markers Ki67 and BrdU, we observed reduced number of intermediate progenitors (INPs) as well as increased cell cycle exit in the subventricular zone (SVZ) of the mutant septum, suggesting Gsx2 is crucial for the generation and/or expansion of INPs in the SVZ of the septum. In summary, our results support the notion that Gsx2 is required for the normal specification and expansion of septum progenitors that give rise to a subpopulation of OB interneurons.

Title: Netrin-1 promotes neuroblast lineage plasticity in the subventricular zone after neonatal brain injury

Authors: *M. RAYMOND, S. FOX, P. LI, V. GALLO;
Children's Natl. Med. Ctr., Washington, DC

Abstract: Infants born preterm and with very-low-birth-weight are susceptible to hypoxia-induced diffuse white matter injury (DWMI) leading to loss of oligodendrocytes, myelin abnormalities, and long term behavioral disorders. Progenitor cells residing in the developing brain hold great potential as a means to prevent or reverse DWMI caused by hypoxic events. Using a model of chronic hypoxia in the perinatal rodent, resulting in DWMI similar to what is observed in preterm infants, we use genetic lineage tracing to demonstrate that distinct progenitor/stem cell populations are capable of regenerating oligodendrocytes in WM after injury, including Glial Fibrillary Acidic Protein (GFAP)-, Platelet Derived Growth Factor Receptor-α (PDGFRα)-, Ascl1 (Mash1)-, and Glutamate Decarboxylase-65 (GAD65)-expressing cells. We also demonstrate hypoxia-induced increase in the expression of the chemotropic factor netrin-1 (NTN1) in both the subventricular zone (SVZ) and choroid plexus (CP). GAD65-expressing progenitors express the NTN1 receptors deleted in colorectal cancer (DCC), uncoordinated homolog 2 (Unc5H2), and Unc5H4. Using both *in vivo* and *in vitro* methods, we demonstrate a NTN1- mediated migratory effect on GAD65-expressing progenitors of the SVZ resulting in an increase in GAD65-derived glia in the overlying WM. We also show that NTN1 plays a role in lineage determination, as treatment of SVZ progenitors with NTN1 lead to the generation of oligodendrocytes and astrocytes derived from GAD65-expressing cells. Our study demonstrates novel sources of glia in the developing brain following DWMI, and reveals NTN1 as a molecular signal associated with GAD65-progenitor migration and lineage plasticity in the postnatal brain. Abstract: The adult mouse subependymal zone (SEZ) harbors a population of adult neural stem cells (aNSCs) known as type B cells that give rise to neuronal and oligodendroglial progeny. However it is not known how the aNSCs behave during their lineage progression towards the neurogenic or oligodendrogliogenic fate. Likewise is not known whether the same aNSC can give rise to neuronal and oligodendroglial progeny or whether these distinct progenies constitute entirely separate lineages. Continuous live imaging and single cell tracking of aNSCs and their progeny isolated from the mouse SEZ revealed the lineage progression of the aNSCs. Moreover we confirmed that aNSCs exclusively generate oligodendroglia or neurons, but never both within a single lineage. Furthermore, activation of canonical Wnt signaling selectively stimulated proliferation within the oligodendrogliogenic lineage, resulting in a massive increase in oligodendrogliogenesis without changing lineage choice or proliferation within neurogenic clones. *In vivo* activation or inhibition of canonical Wnt signaling respectively increased or decreased the number of Olig2 and PDGFR-a positive cells, suggesting that this pathway contributes to the fine tuning of oligodendrogenesis in the adult SEZ.

Title: Characterization of neural crest stem cells isolated from human adult bone marrow

Authors: *S. WISLET, C. COSTE, V. NEIRINCKX, B. ROGISTER, A. GOTHOT;
Univ. of Liège, Liège, Belgium

Abstract: Adult neural crest stem cells (NCSC) are of extraordinary high plasticity and promising candidates for a use in regenerative medicine. Several locations like skin, dental pulp or bone marrow have been described in rodent. However, very few information is available concerning their correspondence in human tissues. The main objective of this project was then to isolate and characterize NCSC from adult human bone marrow. In order to reach that goal, we decided to compare three different sources of adult human stem cells: 1) MSC isolated from adipose tissue, considered as negative control for NCSC; 2) NCSC from dermis, considered as positive control; 3) MSC isolated from iliac bone marrow. Those three cell types were compared using several methods: 1) cell culture: we evaluated all cell types to be cultivated in clonal, adherent or sphere conditions. 2) cell differentiating abilities: we compared all cell types to differentiate into adipocytes, osteocytes, chondrocytes, melanocytes, and Schwann cells. 3) Expression profile: we evaluated the expression of stem cell and NCSC markers like Sox2, Notch1, Oct3/4, AP2, Ascl1, Brn3a, FoxD3, Msi1, Ngn1, P75NTR, Pax3, Pax6, Snail1, Sox1, Sox9, and Sox10. 4) Injection into chick embryos: in this last experiment we analyzed the ability of all cell types to migrate and follow migration pathway of chick NCSC. Altogether, it appeared that the ability of cells to growth as spheres seemed to be linked to their embryonic origin (neural crest). NCSC were confirmed to be present in human dermis, in human adult bone marrow, but also and surprisingly, in human adipose tissue. NCSC from all tested tissues were FoxD3, Msi1, Ngn1, P75NTR, Slug and Twist-positive, but negative for all other tested makers. Finally, all NCSC injected into chick embryos, were able to migrate and differentiate into mature cell types classically observed for NCSC, while MSC were quiescent on the site of injection.

Title: Effects of zinc on adipose-derived mesenchymal stem cell (AD-MSCs) proliferation and differentiation

Authors: *H. KIM[1], B. LEE[1], J. KIM[1], B. CHOI[1], I. KIM[1], S. LEE[2], M. SOHN[3], S. SUH[1]; [1]Dept. of Physiol., Hallym Univ., CHUNCHEON, Korea, Republic of; [2]Dept. of Med. biology, Hallym Univ., Chuncheon, Korea, Republic of; [3]Dept. of Nursing, Inha Univ., Incheon, Korea, Republic of

Abstract: Zinc is an essential element required for cell division, migration and proliferation. Zinc is highly localized in the synaptic vesicle of mossy fiber terminals of the dentate granule cells where neural cell proliferation is most active in the adult brain Especially, in zinc deficient conditions, cell proliferation and differentiation of neural progenitors are impaired significantly. Our previous study demonstrated that zinc chelation reduced hypoglycemia- or seizure-induced neurogenesis in adult animals. Mesenchymal stem cells (MSCs) are multi-potent stem cells that have the capacity to differentiate into osteoblasts, chondrocytes, adipocytes, and neuron-like cells. Since MSCs are derived from various sources including adipose tissue which is abundant and easily obtained, it could be an ideal candidate for cell replacement therapy. Several studies have revealed that MSCs can differentiate into neurons when exposed to the appropriate soluble external factors, which can be supplied in cell culture medium. Thus, the objective of this study was to evaluate the effect of zinc on adipose-derived mesenchymal stem cell proliferation and differentiation. To evaluate the role of zinc on cellular proliferation, adipose-derived MSCs (AD-MSCs) were cultured in 96-well plate at 5×10*2 cells per well. After the cells had attached they were treated with culture media containing zinc at the following concentrations: 0, 10, 30, 50, 100 and 300μM. Zinc treated medium was changed every 3 days for 14 days. AD-MSCs proliferation was analyzed at day 3, 6, 9 and 14 with cell counting kit (CCK-8) assay. AD-MSCs proliferation was significantly increased by zinc supplement in a dose-dependent manner except 300μM. In 300μM zinc survival rate was only 35% and 8% at day 3 and day 6, respectively, compared with control. To investigate whether extracellular zinc chelation affects mesenchymal stem cell proliferation, cultured AD-MSCs were treated with CaEDTA(1mM) or clioquinol(CQ)(50μM) in medium. CaEDTA had no effect on AD-MSCs proliferation compared with control. However, in CQ treated AD-MSCs were dead within 24 hours. Taken together, the present study found that zinc is a vital element for AD-MSCs proliferation and differentiation but high concentration of zinc is harmful.

Abstract: We created an Nse-CreERT2 mouse line expressing the tamoxifen-inducible CreERT2 recombinase under the control of the neuron-specific enolase (Nse) promoter. By using two different Cre reporter lines we could show that this Nse-CreERT2 line has recombination activity in the granule cells of all cerebellar lobules (Fig.1 A-C) as well as in postmitotic granule cell precursors (GCP) in the external granular layer of the developing cerebellum (Fig.1 D-G). A few hippocampal dentate gyrus granule cells showed Cre-mediated recombination as well. Cre

activity could be induced in both the developing and adult mouse brain. The established mouse line constitutes a valuable tool to study the function of genes expressed by cerebellar granule cells in the developing and adult brain. In combination with reporter lines it is a useful model to analyze the development and maintenance of the cerebellar architecture including granule cell distribution, migration, and the extension of granule cell fibers *in vivo*. Figure 1: CreERT2 activity in the cerebellum is restricted to granule cells. A-C: NSE-CreERT2 mice were bred to a R26-LoxP-stop-LoxP-LacZ reporter line and tamoxifen was injected at adult age. A: Schematic overview, B: LacZ staining (blue) is restricted to the GCL, one lobule is shown enlarged in (C). D-G: NSE-CreERT2 mice were bred with a R26-CAG-LoxP-mTomato-LoxP-mGFP reporter mouse, injected at P3 and sacrificed at P8. D: overview of the cerebellum, GFP immunoreactivity illustrates cells in that recombination has occured, mTomato is expressed in non-recombined cells. Frames E-G are shown enlarged, E'-G' = further enlargement to show mGFP-immunoreactive granule cell precursors in the inner EGL. Arrowheads in E-G point to the fissure between two lobules. Arrows point to precursors in the EGL, presumable migrating radially (E') or tangentially (F',G'). WM = white matter, GCL = granule cell layer, mGFP = membrane tagged GFP. mTomato = membrane tagged Tomato. IGL = internal granule cell layer, EGL = external granule cell layer.

Abstract: The current landscape of interactome is either a static network of proteins reconstructed from observations made outside endogenous context or a dynamic network of proteins implicated through genetic interactions occurring inside intact animals without evidence of physical association between proteins. Here, we describe strategies to visualize dynamic protein interactions within living animals. Using optically transparent organisms and Förster resonance energy transfer as a proxy for physical association between proteins (FRET App), we quantitate when and where a ubiquitously expressed molecular switch signals through broadly connected partners. Freely dispersing, the proteins physically associate in a fraction of the time and place where they co-localize. Their restrictive signaling captured at the level of whole brain and single neurons is consistent with the knockout phenotype that emerges during neuronal network formation. Imaging the dynamic protein network within intact animals supplements analyses of protein function and provides insights to how molecular integration underscores complex cellular networks.

Title: Effects of cytomegalovirus infection in human neural precursor cells depend on differentiation state

Authors: *H. M. GONZÁLEZ[1], C. SALAZAR-ALDRETE[1], A. HERNÁNDEZ-SALINAS[2], M. JIMÉNEZ-CAPDEVILLE[1], D. NOYOLA[2], C. CASTILLO[1];

Abstract: Cytomegalovirus (CMV) is the most common cause of congenital infection in developed countries and a major cause of developmental brain disorders in children, including mental retardation and hearing loss. However, the mechanisms that produce central nervous system damage during congenital CMV infection have not been clearly elucidated. Some *in vitro* models have demonstrated that neural precursor cells (NPCs) show the greatest susceptibility to CMV infection in developing brains. We sought to establish an *in vitro* model of CMV infection of the developing brain in order to analyze the cellular events associated to invasion by this virus. Two different NPCs were used, the human SK-N-MC neuroblastoma cell line and an immortalized neural cell line, hNS-1. The aim was to investigate the effect of the differentiation stage in relation to the susceptibility by comparing the neuroblastoma cell line with the multipotent cell line hNS-1. We infected both cell lines with the human CMV laboratory strain AD169 at multiplicity of infection of 0.1 and 0.01. Viral infection was corroborated by detection of the CMV glycoprotein B using an indirect immunofluorescence assay. We found that the effects of the virus were more severe in the neuroblastoma cell line where a notorious loss of cultured cells was noticed and low viral concentrations induced cellular proliferation in a transitory way, in addition to possible differentiation stimulation. Furthermore, we induced hNS-1 to differentiate and evaluated the effect of CMV in these differentiated cells. Like SK-N-MC cells, hNS-1 differentiated cells were also susceptible. Viability of differentiated hNS-1 cells decreased after CMV infection in contrast with undifferentiated cells. In addition, differentiated

hNS-1 cells showed an extensive cytopathic effect whereas the effect was scarce in undifferentiated cells. Our results show that NPCs are permissive to CMV infection and the differentiation degree is an important factor for virus susceptibility, those characteristics make CMV able to produce changes in the developing brain and also it may contribute to establish a critical period time where the infection may be more severe.

Title: Effects of gdnf and et3 on proliferation and differentiation of postnatal neural progenitors in murine model

Authors: *A. CARREON-RODRIGUEZ[1,2], R. HARTMANN[4], H. HORDER[4], J. BELKIND-GERSON[3], A. M. GOLDSTEIN[2];
[1]Inst. Nacional De Salud Publica, Cuernavaca Morelos, Mexico; [2]Pediatric Surgical Res. Lab., [3]Dept. of Pediatric Gastroenterology, Massachusetts Gen. Hospital/Harvard Med. Sch., Boston, MA; [4]Univ. of Applied Sci., Kaiserslautern, Germany

Abstract: **Purpose:** The aim of this study was to characterize enteric neural stem cells (ENSC) of the postnatal murine intestine using the neurosphere culture system. We demonstrated the effects of GDNF, Et3 and their combination on the development and maturation of ENSCs isolated from postnatal murine muscularis and mucosa-submucosa-layer *in vitro* **Materials & Methods:** Large intestine of postnatal mice (P19 – P35) was separated into mucosa-submucosa and muscularis layer. The tissue was minced and digested with dispase and collagenase and mechanically dispersed and filtered. The cells were grown in Proliferation NeuroCult Medium supplemented with EGF, bFGF and heparin in low adherence plates and divided into control or groups treated with GDNF, Et3 or their combination. Cells were incubated at 37^{o}C and neurosphere-like bodies (NLB) developed in suspension. At day 5, the number and diameter of NLB's (Feret's diameter) were determined by phase-contrast microscopy taking 50 um as lower

limit, and then NLBs were dispersed, and plated in a suspension with Differentiation Neurocult Medium. Each control or treated group was split again in four groups control or treated with GDNF, Et3 or their combination (GE) during differentiation phase for 1 week, at the end of which expression of TuJ1 (neural cell body and neurites) and GFAP (glial) was determined by immunocytochemistry (ICC). Statistical analysis were performed by Anova followed by Fisher LSD. **Results:** The muscularis-derived cells treated with combination of GE gave the highest number of NLB's compared to other groups. In contrast treatment with GE on muscularis-derived cells produced smaller NLB's compared to other groups but not affecting the number of them. Regarding differentiation capacity, a difference was found in muscularis-derived vs. mucosa-submucosa-derived neurospheres. A higher cell density, sprouting and networks were more pronounced in the muscularis-derived populations within the muscularis culture, pretreatment with Et3 gave rise to TuJ1+ neuronal cells migrating out of the neurosphere and forming dense networks of cells. **Conclusions:** Et3 on its own seems to have a stronger impact on number of postnatal mucosa-submucosa spheres vs embryonic cultures. Our results of ICC against GFAP and TuJ1 also demonstrate an important supporting role of Et3 pretreatment during proliferation with the effect to stimulate migratory processes and neuronal phenotype during differentiation in postnatal muscularis-derived enteric neurospheres. In contrast,mucosa-submucosa-derived spheres seem to benefit of GDNF pretreatment during proliferation which later enhances neuronal growth during differentiation.

Title: Expression of cortical neuron markers in cells derived from human amniotic epithelial cells

Authors: D. AVILA-GONZALEZ[1,2], I. L. GARCIA-CASTRO[1], A. MOLINA-HERNANDEZ[1], G. GARCIA-LOPEZ[1], *N. F. DIAZ[1];

Abstract: The human pluripotent stem cells (PSC), i.e. embryonic stem cells and induced PSC, have the capacity to differentiate into all cell types that conform the embryo. These cells express the transcription factors OCT4, SOX2 and NANOG as well as TRA 1-60, SSEA-3 and -4, surface PSC-specific antigens. Furthermore, in recent years significant advances have been made in differentiation of PSC into a specific neural type. However, there are several issues to be solved before its clinical therapeutic applicability, i.e: immune rejection, chromosomal and epigenetic aberration, possible formation of tumors, etc. On the other hand, the human amniotic epithelial cells (hAEC) have been postulated as a reservoir source of PSC. Several laboratories have described that hAEC share characteristics with PSC and can differentiate into specialized cells. Also, these cells synthetize and release brain-derived neurotrophic factor and neurotrophin 3, which are involved in neuron differentiation. Finally, hAECs have several properties that can be useful in the clinic, such as low immunogenicity, anti-viral and anti-bacterial effects, etc. The main objective of this study was to analyze if hAEC have the ability to differentiate into cortical neurons. To this end, we used a reproducible protocol to obtain hAEC from normal pregnancy at term. The tissue was collected in accordance to institutional ethics committee guidelines. After mechanic separation and enzymatic treatment, hAEC were cultured in standard medium adding epidermal growth factor until they reached confluence. As a first approach, we analyzed the presence of the pluripotent stem cell markers in our cultures. Our results showed that the cells were positive to pluripotency transcription factors and surface antigens, as well as, E-cadherin (cell adhesion molecule). Then, we determined if these cells were able to differentiate into neural types of the cerebral cortex. In a first stage, we utilized the fibroblastic growth factor type 2 and an inhibitor of Activin/Nodal signaling (SB431542) in a chemically defined medium to generate neural progenitor cells from hAEC. Then, we withdrew all factors from the medium to induce cortical fate differentiation. Until now, our results have shown the presence of neural progenitor (PAX6) and intermediate progenitor (Tbr2) markers in our cultures. According to these results, hAEC would be a good model to study the differentiation of human neuronal lineages.

Title: Investigation of the relationship between iPS and C2C12 cells regarding both diffusible factors and cell-cell contacts

Authors: *T. SHINGEN, T. NEDACHI, H. KAWAGUCHI;
Toyo Univ., Itakura, Japan

Abstract: Induced pluripotent stem (iPS) cells have the capability to differentiate into various types of cells induced by diffusible factors *in vitro*. However, we expect a new method by which iPS cells directly differentiate into various organs *in vivo*. The development of this method requires the elucidation of the relationship between iPS cells and other types of surrounding cells regarding both diffusible factors and cell-cell contacts. After C2C12 cells, a cell line derived from mouse myoblastoma, were cultured on 35-mm dishes, the supernatant was collected and filtered to prepare C2C12 cell conditioned medium (C2C12-CM). We found that iPS cells originated from the mouse skin efficiently differentiated into neuronal cells by the addition of C2C12-CM (level of significance, $p < 0.05$), analyzing the intensity of fluorescence by immunofluorescent staining using an anti-βIII-tubulin antibody. Subsequently, iPS and C2C12 cells were co-cultured separately on 35-mm dishes using a cloning ring, which was removed after 1 day of cultivation. We also found that the direction of the outgrowth of neuritis derived from the induced neuronal cells tended to be opposite to that of C2C12 cells after cultivation for 12 days. Therefore, the detailed time course of the differentiation of induced neural cells was observed via time-lapse videomicroscopy using an incubator microscope during the co-culturing of iPS and C2C12 cells. The time course of the expression of various mRNA, such as βIII-tubulin, Lim-3, and NeuN, in differentiated iPS cells by the addition of C2C12-CM was also investigated using RT-PCR. This study was partially supported by the Institute of Industrial Technology Grant, Toyo University.

Title: Definitive multiplex biomarker identification of embryonic rat cortical neural stem cell phenotype reveals that these cells are ontogenetically restricted only to early embryonic development but can recapitulate their embryonic seminal properties both *in vitro* and *in vivo* after implantation into adult rat brain

Authors: *D. MARIC, N. POTHAYEE, Y. H. CHANG, A. SEDLOCK, K. SHARER, N. BOURAOUD, J. L. BARKER, A. KORETSKY;
NINDS/NIH, Bethesda, MD

Abstract: Embryonic cortical neural stem cells (ecNSCs) in the rat emerge from telencephalic neuroepithelium (NE) at the onset of neural tube closure at 11 days of gestation (E11), where they undergo both symmetrical divisions to maintain their self-renewal and asymmetrical divisions to begin initial differentiation along the neuronal and glial cell lineages. Mediating this critical transition is the interplay of at least two transcription factors, Sox2 and Pax6, with increased expression of the latter being crucial in driving ecNSCs toward lineage commitment and promoting expression of LeX antigen (aka SSEA-1 or CD15), one of the earliest phenotypic markers identifying embryonic cortical neuroglial progenitors (ecNGPs). Using these established neural cell lineage delimited properties, we developed a comprehensive multiplex fluorescence immunostaining method combining up to 30 relevant biomarkers to phenotypically identify bona fide ecNSCs, their intermediates and differentiated endpoints both *in situ* and *in vitro*. Applying this phenotyping method to sagittal rat brain sections staged over E11-22 and over perinatal-adult period of rat cortical development, it was evident that ecNSCs uniquely express a $Nestin^{+}CD29^{+}PCNA^{+}$ $Sox2^{+}Pax6^{-}Tbr2^{-}Tbr1^{-}Olig2^{-}LeX^{-}GLAST^{-}S100^{-}GFAP^{-}Doublecortin^{-}$ $CD57^{-}PSA\text{-}NCAM^{-}$ phenotype, thus identifying them as authentic self-renewing NSCs. Over E12-15, Pax6 is progressively up-regulated in ecNSCs initially promoting their asymmetrical divisions into $Nestin^{+}CD29^{+}Sox2^{+}Pax6^{+}LeX^{+}$ ecNGPs, which give rise both to $Tbr2^{+}LeX^{+/-}$ $Doublecortin^{+}$ neuronal progenitors and $Tbr2^{-}LeX^{+/-}GLAST^{+}$ radial glia. After E17, the above ecNSC phenotype is no longer detectable in the cortical NE or other purported NSC niches implying a very limited ontogenetic existence of these cells during embryonic cortical development. Similarly, in adult rat brain, neither ependymal nor subependymal cells lining the SVZ, a purported source of adult cortical NSCs (acNSCs), nor their putative NSCs counterparts in the dentate gyrus of hippocampus exhibited the unique phenotype of ecNSCs, implying that neurogenic and gliogenic potentials in adult rat brain are derived from a separate seminal pool of neural stem/progenitor cells rather than embryonic-like NSCs. However, using optimized multiplex biomarker cell identification methods to phenotype live ecNSCs and preparative FACS

cell sorting to isolate a pure population of these cells, it was possible to recapitulate their embryonic seminal properties both in short-term cultures under permissive growth conditions and after implantation of these cells into lateral ventricles of 3-week-old rat brains.

Abstract: Cell therapy is one of the approaches for treatment of locomotive deficits in spinal cord trauma and neurodegenerative disorders. Neural stem cells (NSCs) derived from bone marrow stromal cell (BMSCs) are considered as a feasible option for cell therapy. NSCs can be used as autologous without mutagenic and ethical problems. *In vitro* study showed that several chemicals could induce BMSCs into neural phenotypes, while some of these chemicals were reported to have mutagenic, teratogenic or carcinogenic properties. In this study, we have investigated the feasibility of using of Selegiline as an efficient inducer for neuronal differentiation of rat BMSCs and its effect on gene expression of neurotrophins and their receptors during neural differentiation of rat BMSCs. Selegiline has multiple effects which makes it a good candidate for neuroprotection as well as induction of neurotrophic factors. The optimal concentration of Selegiline was selected by dose response and time course studies using the percentage of viable cells and percentages of immunoreactive cells to Nestin and Neurofilament 68 (marker for neural progenitor), while the markers of neuron such as Tyrosine Hydroxylase, Neu-N and Neurofilament 200 were also evaluated. The expression profile of neurotrophins including NGF, BDNF and NT-3 and their receptors (TrkA, TrkB, TrkC and

p75NTR) receptors was evaluated. The results indicated that the NSCs are immunoreactive for Neurofilaments 68, Nestin, Tyrosine Hydroxylase but they are not immunoreactive to Neurofilaments -200 and Neu-N. According to results of RT-PCR, NGF and BDNF but not NT-3 are expressed in both un-differentiated as well as the induced BMSCs. In contrast, TrkA and TrkB is expressed just in neurally differentiated cells, while TrkC is not expressed in these cells either before or after differentiation. Interestingly, p75NTR expression is absent in un-differentiated cells but is initiated upon the induction of neural differentiation. Based on these results, Selegiline is an inducer for BMSCs. Moreover, the expression of neurotrophin genes and their receptors suggested the autocrine mode of action of induced BMSCs.

Title: Neuronal and vascular anatomy in the zebrafish brain

Authors: *S. RAHMAT, E. GILLAND, T. HEINBOCKEL;
Howard Univ., Washington, DC

Abstract: Although embryonic and larval vasculature in zebrafish has been described, few studies have documented brain vessels and related neuroanatomy beyond two weeks of development. Transgenic zebrafish, between one and twelve weeks old, expressing GFP in cranial motor neurons were injected with fluorescent vascular dye and examined with confocal angiography to demonstrate maturation of cerebral vasculature. A segmental series of midline hindbrain central arteries (CAs) in early larvae connect the basilar artery to bilateral venous channels by extending intra-rhombomerically through the mid portion of rhombomeres (r) r3-8, medial to the reticulospinal neuronal clusters in each segment. Each midline CA divides into paired trunks near the ventricular surface at the level of the medial longitudinal fasciculus

(MLF), continues branching within the hindbrain neuroepithelium and ends as numerous small, unbranched channels that traverse nuclei and fiber tracts before draining into a laterally-located pial venous plexus. While hindbrain CAs in younger stages (week one) were roughly similar along the series, the r3 and r8 stems became progressively larger than the others during weeks two and three, with more elaborate branching and increased neurovascular territorial supply. By 75 days, the r3 CA was effectively the arterial supply of the entire rostral hindbrain, including branches that supply the cerebellum, the trigeminal motor nucleus in r2 and the migrated facial motor nucleus in r7. Since small r4-7 CAs are present in mature brains, it is likely that the increased territory of the r3 CA resulted from angiogenic sprouting of existing branches rather than capture of neighboring arterial trees by vessel fusion. In contrast, other major cerebellar, midbrain and forebrain arterial vessels supplied roughly the same neuronal territories in mature animals as in early larvae, but with greatly increased branching. Zebrafish hindbrain vascular and CNS elements are patterned in relation to the early rhombomeric segmental framework, with some aspects of the segmental plan being maintained in adult brains, while other, clearly non-segmental features arise during post-larval brain maturation.

Title: Development of serotonergic neurons in the larval zebrafish spinal cord

Authors: *J. E. MONTGOMERY[1], T. D. WIGGIN[1], B. CORWIN[1], C. LILLESAAR[2], L. BALLY-CUIF[3], M. A. MASINO[1];
[1]Dept. of Neurosci., Univ. of Minnesota, Minneapolis, MN; [2]Dept. of Physiological Chem., Würzburg Univ., Würzburg, Germany; [3]Zebrafish Neurogenetics, Inst. of Neurobio. Alfred Fessard, Gif-sur-Yvette, France

Abstract: In vertebrates, much of the neural circuitry that is required for coordinated locomotion is contained within the spinal cord. The output of this circuitry is modulated by serotonin, which is derived from two distinct sources in vertebrates; 1) descending projections originating in the raphe and 2) a population of intraspinal neurons. The number and distribution of the intraspinal serotonergic neurons (ISNs) vary between species, as mammals possess a relatively small number of ISNs when compared to fish and amphibians. Although the functional properties of the ISNs have not been established in zebrafish, morphological evidence suggests that they innervate motor neurons and thus modulate their activity. Study of ISN development and morphological properties will likely provide insight into the role of 5-HT in establishing mature locomotor behavior in zebrafish larvae. A 3.2kb fragment of the zebrafish *pet1* promoter was used to drive expression of fluorescent reporters in the ISNs of developing zebrafish larvae. Confocal imaging of EGFP expression *in vivo* was used to quantify ISN cell number and location along the rostro-caudal and dorso-ventral axes of the spinal cord. We selectively photoconverted single Kaede-expressing ISNs with a UV laser to visually isolate and characterize individual neurons. Projection distance, neurite length, and arborization were measured in photoconverted ISNs and tracked from 3-10 days post fertilization (dpf). ISN cell number and morphological characteristics exhibited the greatest changes between 3 and 4 dpf. The timing of these morphological changes corresponds with the switch in zebrafish swimming behavior from long, infrequent swimming episodes at 3 dpf to shorter, more frequent swimming episodes at 4 dpf. Future work will test the functional maturation of the ISNs as well as their involvement in modulating locomotor activity.

Title: Hairy and enhancer of split 6 (Hes6) gene modulates the neuroblast and astrocytes differentiation in the dentate gyrus without any influences on cell proliferation and integration into mature neurons

Authors: *S. NAM[1], J. KIM[1], J. KIM[2], I. HWANG[1], J. SEONG[1], Y. YOON[1];
[1]Deptment of Anat. and Cell Biol., Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Dept. of Life Sci. and Ewha Res. Ctr. for Systems Biol., Ewha Womans Univ., Seoul, Korea, Republic of

Abstract: Hes6 is a member of hairy-enhancer of split homologs (Hes) and it functions in interaction with other Hes family genes. During development, Hes genes are expressed in neural stem cells and proliferating cells. However, role of Hes6 is demonstrated as opposite to role of other Hes family in cell culture studies and developing embryo or postnatal studies. Hes6 promotes neuronal differentiation and suppresses glial differentiation. Also, overexpressed Hes6 induced neuronal apoptosis. Like neurogenesis in developing brain, neural stem cells in a dentate gyrus of the adult hippocampus have the ability to proliferate and differentiate to neuronal cells or glial cells. Hes6's participation in the process of neurogenesis during the developing stage has been demonstrated. Until now, unlike its unveiled role in the development stage, Hes6 participation and its effect on adult hippocampal neurogenesis in not demonstrated. Therefore, in present study, we investigated the effects of the Hes6 on the process of the adult hippocampal neurogenesis by comparing the Hes6 knockout and its wild mice. To do this, we immunstained the relevant marker protein of proliferating cell(Ki67 and BrdU), post-mitotic neuroblast (DCX), mature neuronal cell (NeuN) and astrocyte (GFAP). Additionally, we injected 5-bromo-20-deoxyuridine to trace the fate of the mitotic cell at that time. Condition of the Hes6 knockout negatively affects adult hippocampal neurogenesis, in the aspect of neuronal differentiation. On the contrary, the astrocyte differentiation was increased in the knockout group compared to the wild group. Proliferating cell was slightly reduced in the knockout group, but the difference was not statically significant between two groups. Unlike the slight reduction pattern of Ki67 or BrdU cell, the ration of the BrdU and NeuN double positive cell was slightly higher in the knockout group. These results suggest that Hes6 is related with the regulation of the neuronal and glial differentiation even in the process of adult hippocampal neurogenesis.

Title: New insights in striatal development: Characterization of Znf521 in mouse and human brain

Authors: M. PARDO[1], N.-N. VINH[2], L. MARION-POLL[3], J.-A. GIRAULT[3], R. MARTÍN-IBÁÑEZ[1], A. ROSSER[2], *J. M. CANALS[4];
[1]Dept. of Cell Biology, Immunol. and Neurosci., Fac. of Medicine, IDIBAPS, Univ. of Barcelona; Ctr. de Investigación Biomédica en Red sobre Enfermedades Neurodegenerativas (CIBERNED), Barcelona, Spain; [2]Cardiff Sch. of Biosciences, Univ. of Cardiff, Cardiff, United Kingdom; [3]Inserm UMR-S 839; Univ. Pierre & Marie Curie, Sorbonne Universités; Inst. du Fer à Moulin, Paris, France; [4]Univ. of Barcelona, Barcelona, Spain

Abstract: Many factors involved in striatal development remain uncharacterized. Here we describe Znf521 expression during mouse and human brain development, a transcription factor (TF) first identified in B cell development. During mouse development, Znf521 is expressed in brain structures such as the Lateral and Medial Ganglionic Eminences (LGE and MGE, respectively), olfactory bulb, septum, thalamus, cortex and cerebellum. In the LGE, Znf521 protein is detected in the mantle zone (MZ) at E12.5 and is expressed until adulthood. Znf521 expression changes during development, being homogeneous at embryonic LGE stages but becoming more lateral at postnatal ages. Furthermore, most Znf521 expressing cells do not colocalize with the proliferative marker Ki67. This suggests that Znf521 is expressed by postmitotic neurons, which was verified by NeuN colocalization. Interestingly, Znf521 also colocalizes with MSN markers such as Ctip2 and FoxP1 whereas its expression does not coincide with interneuron markers such as parvalbumin and choline acetyltransferase (ChAT). Since MSNs can be subdivided into two subpopulations, positive for either enkephalin or Substance P, we next performed double *In situ* hybridization-immunohistochemistry for enkephalin or Substance P and Znf521. Our results show preferential colocalization with Substance P suggesting that Znf521 is involved in direct pathway neuron generation. We also analyzed Znf521 in the direct pathway by localizing Znf521 in D1- or D2-GFP mouse models. We and others have defined a set of LGE specific TFs that participate in MSN development. For this reason we studied the relationship between Znf521 and striatal TFs including Ebf1, Helios, and Ikaros. Our results indicate that Znf521 and Helios are expressed by different MSN populations, while Ikaros and Znf521 only colocalize in the lateral LGE. We next analyzed Znf521 expression and localization during human fetal LGE development in fetuses aged 7 to 13.5 weeks post conception (wpc). As in mouse development, Znf521 expression was observed in the LGE/striatum, internal capsule, choroid plexus, and septum. In the basal ganglia Znf521 is expressed in the MZ with a lateral pattern of expression from 8 wpc onwards. Most Znf521

positive cells were found in the MZ and do not colocalize with Ki67, although a few Znf521 positive proliferating cells are detected in the SVZ. Our results also demonstrate that Znf521 is expressed by human MSNs during development since it colocalizes with Ctip2 and some FoxP1 positive cells. These results demonstrate that Znf521 is expressed by a subset of MSNs during mouse and human development, suggesting that it may be involved in striatal neurogenesis.

Title: Sox8 is required for the formation of the striatonigral pathway

Authors: ***P. MERCHAN SALA**[1], T. L. SCHAEFER[3], A. A. ASHWORTH[3], M. WEGNER[4], K. CAMPBELL[2];
[1]Developmental Biol., [2]Developmental Biol. and Neurosurg., Cincinnati Children's Med. Ctr., Cincinnati, OH; [3]Div. of Psychiatry, Cincinnati Children's Hosp. Med. Ctr., cincinnati, OH; [4]Inst. of Biochem., Univ. of Erlangen, Nuremberg, Germany

Abstract: The striatum is the major component of the basal ganglia. It receives information from different areas of the cortex and once integrated it sends its outputs to either the globus pallidus or the substantia nigra pars reticulata (SNr) which ultimately feedback to the premotor cortex via the thalamus. Thus the striatum plays key roles in the control of motor behavior as well as in learning and other cognitive functions. The striatal output pathways are classified into indirect (striatopallidal) and direct (striatonigral) pathways. Imbalances in the activity of these pathways are thought to underlie the behavioral abnormalities observed in a number of neurological disorders including attention deficit hyperactivity disorder (ADHD) and Parkinson's disease. Little is known about the molecular genetic mechanisms that control the formation and function of the direct and indirect pathways. In this respect, the SoxE family member, Sox8, is expressed in the developing and adult striatum. Moreover, using GENSAT Sox8-EGFP mice we have found that the direct pathway is specifically labeled from embryonic to adult stages. Using

Sox8lacZ mice, we found that there is a dramatic reduction in the formation of striatonigral pathway in both homozygous and heterozygous animals. This is despite the fact that the striatum appears normal in size. Our preliminary findings suggest that substance P-positive fibers abnormally terminate in the globus pallidus of Sox8 mutants suggesting that Sox8 is required for long axon growth of direct pathway fibers. We are currently attempting to identify downstream effectors of Sox8 using RNA-seq and are particularly interested in identifying dosage-sensitive genes that may explain the haploinsuffient phenotype. Moreover, we have developed a gain-of-function approach using Dlx5/6-tTA mice to drive a tetO-Sox8-IRES-EGFP transgene, in order to examine whether Sox8 is sufficient to instruct a direct pathway phenotype. Finally, we have conducted several behavioral tests on the Sox8 mutants and our preliminary results indicate that both the homozygous and the heterozygous mice display increases in basal locomotor activity as well as impaired cognition and social behavior.

Title: Hox genes govern the development of respiratory circuits

Authors: ***P. PHILIPPIDOU**[1], L. JEANNOTTE[2], J. S. DASEN[1,2];
[1]NYU Med. Ctr., New York, NY; [2]Univ. Laval, Québec, QC, Canada

Abstract: Breathing is a basic motor behavior that is essential in all terrestrial vertebrates. The frequency and amplitude of respiratory contractions are driven by neural networks residing in the brainstem that coordinate the activation of dedicated sets of spinal motor neurons (MNs). Motor neurons within the spinal cord directly drive the activity of inspiratory and expiratory muscles, including the diaphragm and intercostals. Despite the complexity of the neural networks that

regulate respiratory rhythms, diaphragm contraction is controlled by a single motor input supplied by MNs within the Phrenic Motor Column (PMC). We identified a transcriptional network orchestrated by two Hox transcription factors (Hoxa5 and Hoxc5) that controls critical aspects of respiratory circuit assembly. Selective deletion of Hox5 genes from MNs in mice leads to perinatal lethality due to respiratory failure. In Hox5 mutant mice, there is an extinction of PMC identity, characterized by a loss of PMC molecular determinants, progressive loss and disorganization of phrenic MNs, axonal misrouting, and, most strikingly, a dramatic loss of synaptic contacts at the diaphragm muscle. Several PMC-specific genes, including cell adhesion molecules and trophic factors, are downregulated in Hox5 mutants, differentially contributing to the multiple aspects of this phenotype. Erosion of PMC identity from cervical MNs also results in aberrant breathing cycles, indicating that establishing phrenic MN identity through Hox5 gene activity is an obligate step in the wiring of mammalian respiratory networks.

Title: The role of Pitx2 in the development of spinal ventral interneurons

Authors: I. ROZANI, *D. A. MANGOURA, L. ZAGORAIOU;
Neurosci. Ctr., Biomed Res. Found Athens Acad., Athens, Greece

Abstract: In the ventral spinal cord, interneuron specification is controlled by the combinatorial expression of certain transcription factors. We have identified a small interneuron population that expresses the paired-like homeodomain transcription factor Pitx2. We undertook an analysis of Pitx2 deficient embryos to determine how loss of Pitx2 affects interneurons that express it. Pitx2 is involved in the development of many organs. In the CNS, Pitx2 is expressed in the hypothalamus where it contributes to the formation of the mammilothoracic tract, in the midbrain where it promotes neuronal migration and GABAergic differentiation, in rhombomere 1 and in

the spinal cord. Our analysis was performed in Pitx2 cre homozygous animals. The cre recombinase cassette has been knocked-in in the homeodomain resulting in a Pitx2 allele that produces a truncated form of the Pitx2 protein and in homozygosis, a Pitx2-deficient animal. We have previously generated an antibody that targets an epitope preceding the homeodomain. This enables us to visualize the Pitx2 deficient cells, since they produce the truncated Pitx2. Pitx2 deficiency causes lethality around embryonic day e15.5 due to cardiac arrest, so we performed the analysis at e13.5 and e15.5. We have demonstrated that, during spinal cord development, Pitx2 expressing interneurons, which originate from the p0 domain, migrate from a dispersed ventrolateral position at e11.5 to a cluster around the central canal at e15.5. In Pitx2 deficient spinal interneurons the truncated protein displays diffuse cytoplasmic localization in contrast to the normal protein which is confined in the nucleus. These neurons are mislocalized in spinal cord sections of e13.5 and e15.5 embryos; a pattern that resembles an earlier developmental time point. We set out to analyze the phenotype of Pitx2 deficient neurons. We have shown before that half of the Pitx2 spinal interneurons are cholinergic. Here, we note that at e15.5 Pitx2 deficient neurons do not express the cholinergic markers vAChT and ChAT. Pitx2 deficient neurons seem to be lacking other subpopulation markers too. Moreover, we observed mislocalization of another migratory population of V0 origin, namely Evx1/2, in Pitx2 cre homozygotes when compared to heterozygotes. The aforementioned observations may be indicative of the involvement of the Pitx2 transcription factors in key developmental processes of spinal interneurons, like migration, specification and potentially, non-cell autonomous functions. However, more experiments are required to exclude general developmental arrest due to the overall lack of the Pitx2 transcription factor.

Title: Birthdate and SHH signaling differentially specify PV versus SST expressing cortical interneuron fates from mESCs

Authors: J. A. TYSON[1], A. M. MAROOF[2], *S. A. ANDERSON[3];
[1]Psychiatry, UPenn Sch. of Med., Philadelphia, PA; [2]Harvard Stem Cell Inst., Boston, MA;
[3]Psychiatry, Children's Hosp. of Philadelphia/Upenn Sch. Med., Philadelphia, PA

Abstract: Abstract: Medial ganglionic eminence (MGE)-derived GABAergic cortical interneurons consist of multiple subtypes that are involved in many cortical functions. In addition, they have a remarkable capacity to migrate, survive, and integrate into cortical circuitry after transplantation into postnatal cortex. These features have engendered considerable interest in generating distinct subgroups of interneurons from pluripotent stem cells for the study interneuron fate, function, and for the development of cell-based therapies. While advances in this effort have occurred, the capacity to generate highly enriched pools of subgroup fate-committed interneuron progenitors from PSCs has remained elusive. Previous studies have suggested that the two main MGE-derived interneuron subgroups, those that express somatostatin and those that express parvalbumin, are specified in the MGE from Nkx2.1-expressing progenitors at higher or lower levels of sonic hedgehog (Shh) signaling, respectively. To further explore the role of Shh and other factors in cortical interneuron fate determination, we generated a dual-reporter line such that Nkx2.1-expressing progenitors express mCherry and postmitotic Lhx6-expressing MGE-derived interneurons express GFP. We find that exposure to higher Shh levels and collecting GFP-expressing precursors after 12 days in culture results in a strong enrichment for SST interneurons over those expressing PV, while the reciprocal enrichment for PV interneurons is produced by lower Shh and collecting mCherry-expressing after 17 days in culture. These findings confirm that fate determination of cortical interneuron subgroups is critically influenced by Shh signaling, and provide a system for the further study of interneuron fate and function. This work is funded by R01 MH066912-01 and T32 1T32HD060600.

Title: Non-canonical Wnt signaling regulates cortical interneuron subtype specification

Authors: *E. AU[1], M. MCKENZIE CHANG[2], G. J. FISHELL[2];
[1]NYU Med. Ctr., NEW YORK, NY; [2]Neurosci., NYU Langone Med. Ctr., New York, NY

Abstract: Cortical GABAergic interneurons exhibit remarkable diversity as a cell population with respect to intrinsic firing properties, subtype marker expression, layer organization, synaptic connectivity and morphology. The means by which this diversity is achieved is still largely unknown. We have identified a novel rostral-caudal Wnt gradient within the medial ganglionic eminence (MGE) that delineates the specification of the two main classes of cortical interneuron subtypes. Caudally- situated MGE progenitors receive high levels of Wnt signaling and give rise to somatostatin (SST)-expressing cortical interneurons Parvalbumin-expressing basket cells, by contrast, originate mostly from the rostral MGE where Wnt signaling is attenuated. Interestingly, canonical Wnt signaling through β-catenin is not required for this process. Wnt signals transmitted via cleavage of the intracellular domain of the non-canonical receptor Ryk, however, are sufficient to drive interneuron progenitors to a SST fate. Graded Ryk gain-of-function experiments performed in mouse ES-derived cortical interneurons reveal a dose-dependent effect, suggesting Ryk signaling acts in a gradient.

Title: Necdin regulates RanGAP1 sumoylation during neuronal differentiation

Authors: *K. FUJIWARA, K. HASEGAWA, K. YOSHIKAWA;
Lab. of Regulation of Neuronal Develop., Inst. For Protein Research, Osaka Univ., 3-2 Yamadaoka, Suita-Shi, Japan

Abstract: Sumoylation is a ubiquitin-like post-translational modification of proteins and modulates their biological function, subcellular localization and stability. Many sumoylated proteins have recently been identified in neurons. However, the physiological role of sumoylation in neuronal differentiation remains unclear. We analyzed the sumoylation profile of proteins during neurogenesis *in vivo* and *in vitro*. Expression levels of the Ran GTPase activating protein RanGAP1, the most abundant sumoylated protein involved in the nuclear transport, were

markedly reduced during embryonic development of the mouse brain. Furthermore, RanGAP1 was rapidly desumoylated and degraded during differentiation of primary neural progenitor cells (NPCs). Necdin, a pleiotropic protein expressed abundantly in postmitotic neurons, promotes neuronal differentiation and survival. We found that necdin interacted with sumoylated RanGAP1, and these proteins were co-localized at the nuclear envelop of NPCs. Although sumoylated RanGAP1 associated with RanBP2, a nuclear pore component, is intensively protected from SUMO protease (Senp), coexpression of necdin and Senp reduced the sumoylated RanGAP1 level even in the presence of RanBP2. Furthermore, the sumoylated RanGAP1 level was increased in necdin-deficient NPCs. To analyze the relation between neuronal differentiation and the nuclear transport, we stably expressed GFP-fused SV40 NLS (nuclear localization signal)-HIV Rev NES (nuclear export signal) shuttling reporter protein in primary NPCs by lentivirus-mediated gene transfer. The GFP-fused shuttling reporter localized to the nucleus of undifferentiated NPCs but was translocated to the cytoplasm when neuronal differentiation progressed. These results suggest that necdin promotes desumoylation and subsequent degradation of RanGAP1 to downregulate the nuclear transport during neuronal differentiation.

Title: Neurog1 genetic inducible fate mapping (GIFM) reveals the existence of complex spatiotemporal cyto-architectures in the developing cerebellum

Authors: ***E. A. OBANA**[1], T. G. LUNDELL[1], K. J. YI[2], K. L. RADOMSKI[2], Q. ZHOU[2], M. L. DOUGHTY[2];
[1]USUHS Program in Neurosci., Bethesda, MD; [2]USUHS Dept. of Anatomy, Physiol. and Genet., Bethesda, MD

Abstract: Neurog1 is a pro-neural basic helix-loop-helix transcription factor (bHLH) expressed in progenitor cells located in the ventricular zone and subsequently the presumptive white matter tracts of the developing mouse cerebellum. We used genetic inducible fate mapping (GIFM) with

a transgenic Neurog1-CreER allele to characterize the contributions of Neurog1 lineages to cerebellar circuit formation in mice. Neurog1-CreER GIFM labeled Purkinje cells and all GABAergic interneuron cell types of the cerebellar cortex but no non-neuronal cells in the cerebellum. The spatio-temporal sequence of GIFM was unique to each neuronal cell type. GIFM on embryonic days (E) 10.5 to E12.5 labeled Purkinje cells with medial-lateral settling patterns dependent on the day of tamoxifen delivery. GIFM on E11.5 to P7 labeled interneurons and the temporal sequence of tamoxifen delivery correlated with the final inside-to-outside resting position of GABAergic interneurons in the cerebellar cortex. Proliferative status and long-term BrdU retention of GIFM lineages revealed Purkinje cells express Neurog1 around the time they become post-mitotic. In contrast, GIFM labeled mitotic and post-mitotic interneurons. Neurog1-CreER GIFM reveals a correlation between the timing of Neurog1 expression and the spatial organization of GABAergic neurons in the cerebellar cortex with possible implications for cerebellar circuit assembly.

Title: Prdm8 regulates the guidance molecules during neocortical development

Authors: ***K.-I. MIZUTANI**[1], M. INOUE[1], M. KATO[2], A. HONDA[1], R. IWAI[1], Y. SHINKAI[2];
[1]Doshisha Univ., Kizugawa-Shi, Japan; [2]Riken, Saitama, Japan

Abstract: During neocortical development, a multitude of cellular events must all occur with exquisite spatiotemporal control, resulting in quite synchronized progress of neurogenesis and angiogenesis. Recent studies have led to the notion that neuronal and vascular networks appear to be guided by similar guidance molecules, which are mediated by ligand-receptor system. Extracellular guidance cues, including netrins, semaphorins and ephrins, act as a molecular signaling that are involved in establishment of these networks, although the importance of this

guidance molecules for the establishment of mature cortical cytoarchitecture and the precise genetic control of these molecules remain largely unknown. Members of the Prdm proto-oncogene transcription factor family are new candidates implicated in the control of the developing neocortex. This is because multiple genes in the Prdm family are expressed in the developing mouse neocortex in a spatially and temporally restricted manner. We established the Prdm8 reporter mouse line, Prdm8-mVenus, and observed that the expression of mVenus was mainly restricted to the intermediate zone in the developing neocortex. And, we confirmed that the mVenus expression was found to be gradually upregulated to the point at which the netrin receptor Unc5D expression was gradually downregulated. Also, the Prdm8 overexpression in neocortical cells significantly suppressed the expression of Unc5D. The microarray identified over 90 transcripts with two-fold higher expression in the mVenus-positive cells compared with that in the mVenes-negative cells at E15.5. Interestingly, these genes included those involved in the signaling of guidance molecules, such as semaphoring signaling (Plxnd, Ebf3, Nrp2, and Sema3c), ephrin signaling (Epha6), and slit signaling (Slit3). In addition, the genomic binding sites of Prdm8 in the dorsal telencephalon were mapped by chromatin immunoprecipitation followed by high-throughput sequencing (ChIP-seq), and we identified 6,622 specific Prdm8 binding sites, and found that some peaks contain upstream region of guidance molecules, such as Unc5D, Ebf3, and Slit3, suggesting the possible involvement of Prdm8 in the regulation of some guidance molecules during neocortical development. Furthermore, we established Prdm8 KO mice and observed that both neuronal migration and the vascular density were significantly affected adjacent to the intermediate zone. These results suggest that the Prdm8 is one of the important factors to control the precise neuronal and vascular development by the regulation of guidance molecules during neocortical development.

Title: The influence of chronic alpha1A-adrenergic receptor activation on cell survival and fate in the adult mouse dentate gyrus

Authors: *K. COLLETTE[1], S. SCHUCK[2], D. PETERSON[2], V. A. DOZE[1];

[2]Dept. of Neurosci., The Chicago Med. Sch. at Rosalind Franklin Univ., North Chicago, IL

Abstract: Norepinephrine (NE) is a catecholamine neurotransmitter implicated in a range of diverse functions from regulation of mood to epilepsy. Norepinephrine binds to adrenergic receptors (ARs) of which there are three families: α_1, α_2, and βARs, which were categorized pharmacologically and genetically. The α_1AR family is further divided into α_{1A}, α_{1B}, and α_{1D}ARs. The α_{1A} and α_{1B}AR subtypes are highly expressed in the brain, particularly the hippocampus, a region crucial for learning and memory. Chronic activation of the α_{1A}AR subtype increases proliferation in the subgranular zone of the adult mouse hippocampus. Previous work in our lab showed that stimulation of the α_{1A}AR also induces differentiation of neural progenitor cells in neurospheres cultured from the subventricular zone (SVZ) of the lateral ventricles. In corroboration with this, neurospheres cultured from α_{1A}AR knockout (α_{1A}AR-KO) mice reverted back to or maintained an undifferentiated state. However, the survival and differentiation of adult-born cells has not been evaluated *in vivo*. In the subgranular zone of normal mice, 60 percent of new cells do not survive longer than one week but of those that do most differentiate into excitatory granule cells. We treated mice with an α_{1A}AR-selective agonist, cirazoline, in drinking water for 8 wks to determine the effect of α_{1A}AR activation on survival and cell fate of the adult-generated cells. Control mice received untreated water. Animals were injected with BrdU after 4 wks of treatment to label dividing cells and perfused 4 wks later to allow time for the new cells to differentiate. Immunohistochemical markers combined with BrdU labeling were used to identify the surviving cells, including NeuN for mature neurons, Prox1 for granule cells, DCX for immature neurons, and GFAP for astrocytes. Fluorescence microscopy and stereological cell counting are being used to quantify the number and ratio of each type of cell that survived. We expect that cirazoline treatment will have increased the number of new cells differentiating into mature cell types. We also expect that the majority of these cells will be excitatory granule cells but preliminary work suggests the possibility that a very small number of adult-born cells may differentiate into interneurons. Future work may assess the integration and functionality of the newly integrated cells.

Abstract: Medium Spiny Neurons (MSN) control the initiation of voluntary movements, promoting the execution of certain motor actions while preventing unnecessary ones. This role is achieved by the parallel action of two MSN subtypes: D1 MSN promote movement initiation while D2 MSN inhibit motor activation. Achieving the correct specification of MSN subtypes is essential for brain functioning; however, it is still largely unknown how this process is regulated during development. FACS-sorting experiments and full-knockout analysis established that the transcription factor *Ebf1* (Early B-cell factor 1) is required for generating subsets of D1 MSN. However the cell-autonomous roles of Ebf1 remain largely to be deciphered. Here we have taken advantage of genetic targeting of MSN subtypes and Cre-Lox recombination to conditionally delete Ebf1 in all MSN or only D1 MSN and analyze how this deletion affects MSN developmental dynamics at both cellular and population scale. Our results provide novel insights on the way transcription factors act at different levels to determine the binary choice between neuronal subtypes and their integration in the brain circuitry.

Title: Brain maturation and neuron activity dynamically regulate histone variant expression

Authors: *A. A. THAMBIRAJAH[1,2], J. C. DIORIO[1,2], M. J. MEANEY[1,2];
[1]Neurol. and Neurosurg., Douglas Mental Hlth. Univ. Institute/ McGill, Montreal, QC, Canada;
[2]Ludmer Ctr. for Neuroinformatics and Mental Hlth., Montreal, QC, Canada

Abstract: The formation of brain circuitry during early development relies upon the precise input of excitatory and inhibitory stimuli. While brain maturation is dependent upon coordinated cascades of gene expression, it will also alter the utilization of genetic information. Associated events, such as neuron activation, influence this modulation of gene expression. The molecular cues that govern these changes in gene expression are becoming better understood, but less is known of the epigenetic-mediated control. DNA, which encodes genetic information, is repeatedly wrapped around sets of histone proteins. This combination of DNA and histones produces the macromolecular structure of chromatin, which not only permits the spatial compaction of DNA, but controls gene expression. Specialized forms of histones, histone variants, have unique roles in regulating chromatin metabolism. Such roles are involved in transcription, replication, DNA damage repair and more. Histone variants of the H2A family (H2A.Z, H2A.X, and macroH2A) are significantly decreased during early postnatal development in the male rat hippocampus, particularly between postnatal day 4 (P4) and P15. Post-translationally modified forms of these H2A variants are similarly decreased during this time period. As P4 - P15 coincides with a period of enhanced postnatal synaptogenesis and neurogenesis, it was of interest to ascertain if these changes in the H2A histone variants are associated with neuron activation. Primary hippocampal neuron cultures were treated with KCl and the H2A variants showed differential changes in protein expression in response to calcium-dependent stimulation. Treatment of hippocampal primary cultures with the excitatory neurotransmitter glutamate recapitulated these results. The receptor-dependent activation of specific histone variants and their associated genomic locations is currently being interrogated. This work provides a deeper understanding of how neuron maturation and activity and the underlying epigenetic changes in histone variants reciprocally exert their effects on brain physiology and gene expression.

Title: TxnRd2-mediated metabolic redox dysregulation during neuronal differentiation results in changes in mitochondrial distribution and abnormal neurite arborization

Authors: *A. FERNANDEZ[1,2,3,4], T. MAYNARD[1,3,4], D. MEECHAN[1,3,4], B. KARPINSKI-OAKLEY[1,3,4], M. BRIELMEIER[5], A. S. LAMANTIA[1,3,4];

Abstract: Oxidative stress and metabolic redox imbalance may accompany altered cortical circuit organization and function in patients with neuropsychiatric disorders. However, the effects of abnormal redox regulation during development of cortical circuits are still unknown. 22q11 deletion syndrome (22q11DS) has been suggested as a model for studying the neurodevelopmental origins of neuropsychiatric disorders. Individuals with 22q11DS are more susceptible to these disorders than the rest of the population. About one quarter of the genes located in the commonly deleted region in the 22q11DS encode proteins that localize to mitochondria. Among those, mitochondrial thioredoxin reductase (TxnRd2) encodes a primary mitochondrial H2O2 scavenger that is maximally expressed during cortical circuit differentiation. Thus, we asked whether redox dysregulation due to changes in dosage of TxnRd2 alters cortical neuronal differentiation. Primary cortical neuronal cultures from E16.5 mouse embryos were electroporated with farnesylated-GPF and mitochondrial-flagged TxnRd2 siRNA or overexpression plasmids. TxnRd2 depleted neurons were also treated with ROS scavengers to reestablish intracellular redox balance and link TxnRd2 scavenging activity to cortical neuron differentiation. We also determined the role of TxnRd2-mediated redox regulation in arborization using a conditional knockout mouse line. We evaluated changes in arborization and mitochondrial distribution by Sholl analysis. Depletion of TxnRd2 results in decreased neurite outgrowth and complexity, which is reestablished upon treatment with ROS scavengers. TxnRd2 overexpression leads to no significant changes in arborization. Changes in neurite outgrowth and

mitochondrial distribution upon TxnRd2 imbalance suggest a key role of TxnRd2 in neuronal differentiation. Antioxidant rescue of neurite outgrowth in TxnRd2 depleted neurons implies an inverse correlation between ROS accumulation and TxnRd2 activity. These data suggest antioxidant defense as key for cortical neuron developmental capacity and provide insight into the role of redox imbalance in abnormal circuit formation in a wide range of behavioral disorders.

Title: The tumor suppressor lkb1 regulates myelination through mitochondrial metabolism

Authors: *B. DASGUPTA;
Div. of Hematology/Oncology, Washington Univ., Cincinnati, OH

Abstract: Myelination of peripheral axons by Schwann cells (SC) is essential for proper transmission of action potentials. A prerequisite to myelination is SC differentiation, and compelling recent evidence indicates that metabolic reprograming from a glycolytic to oxidative metabolism occurs during cellular differentiation. It is unknown if this reprograming is required for SC differentiation. Little is also known about genes that regulate this metabolic transition. We have discovered that metabolic reprograming is required during SC differentiation and the tumor suppressor *Lkb1* regulates this critical step. *Lkb1* deletion in SCs causes hypomyelination, muscle atrophy, hindlimb dysfunction and peripheral neuropathy. *Lkb1* null SCs failed to optimally activate mitochondrial oxidative metabolism during differentiation. Mitochondrial deficits were reflected by diminished oxygen consumption and production of the TCA cycle substrate citrate, which is a precursor to cellular lipids. Consequently, myelin lipids were reduced in *Lkb1* mutant sciatic nerves. Citrate synthase (CS) activity was reduced in *Lkb1* mutant SCs and overexpression of CS or exogenous citrate rescued differentiation/myelination defects of *Lkb1* mutant SCs. We propose that *Lkb1*-mediated metabolic shift through regulation of CS activity during SC differentiation increases mitochondrial metabolism and lipogenesis, necessary for normal myelination.

Neuroscience, Dept. of Neurosurg. and Neurology, Karolinska Institutet, Karolinska Univ. Hosp., Stockholm, Sweden; [5]Dept. of Forensic Medicine,Karolinska Insitutet, Stockholm, Sweden

Abstract: Oligodendrocytes are the cells wrapping layers of specialized cell membrane around nerve fibers forming myelin, which provides electrical insulation to facilitate fast propagation of nerve impulses. This insulation increases also axonal conduction velocities and hence the speed of neural processing. Myelination is largely a postnatal process and it continues well into adulthood in humans. The myelination of axons is dynamically altered by experience throughout life and thought to mediate neural plasticity by optimizing the performance of the circuitry. Practicing a skill can increase the volume of white matter regions engaged in carrying out the task and, conversely, reducing external stimuli by social isolation, leads to hypomyelination and impaired cognitive functions. How myelin is reshaped during brain maturation and in response to experience is not fully understood. Myelination can in theory be modified by mature oligodendrocytes and/or by exchanging oligodendrocytes and their myelin sheaths. Recent observations support that oligodendrocyte generation contributes to myelin remodeling. It is less clear to what degree mature oligodendrocytes can modulate their myelination. However, how this appear in the human brain remains elusive as methods employed in experimental animals, such as paradigms with labeled nucleotide analogs are not possible to apply in humans. We have

assessed the dynamics of oligodendrocyte generation and myelination in the human brain. The final number of oligodendrocytes in the corpus callosum is established around five years of age, whereas the myelin volume increases well into adulthood. By analyzing the concentration of the integration of ^{14}C, derived from nuclear bomb testing during the Cold War, in genomic DNA of oligodendrocytes, we demonstrate that there is limited exchange of oligodendrocytes and in contrast a high turnover rate of myelin. We provide data that myelin remodeling is mainly carried out by mature oligodendrocytes in humans.

Title: Orphan GPR110 is a target receptor for synaptamide, a potent endogenous inducer of neuronal differentiation derived from omega-3 fatty acids

Authors: *J. LEE, G. KHAREBAVA, B. HUANG, M. RASHID, S. PATNAIK, J. MARUGAN, H.-Y. KIM;
NIH, Bethesda, MD

Abstract: Docosahexaenoic acid (DHA), a polyunsaturated fatty acid highly enriched in the brain, is known to be essential for proper brain development; however, underlying mechanisms are not clearly understood. N-Docsahexanoylethanolamine (synaptamide), an endogenous metabolite of DHA, potently induces neurogenic differentiation of neural stem cells (NSCs) and promotes neurite growth and synaptogenesis in developing neurons. Nevertheless, its target receptor has not been identified. In this study, we demonstrate that orphan G-protein coupled receptor 110 (GPR110) is the synaptamide receptor that mediates neurogenic differentiation and neurite outgrowth. Mass spectrometry-based proteomics approach using biotinylated synaptamide analogues followed by affinity purification revealed binding of synaptamide to GPR110 in brain cells. Among long chain N-acylethanolamines, synaptamide specifically

exhibited such binding, and induced cAMP-dependent neurogenic differentiation and neurite outgrowth which were effectively blocked by GPR110 knockdown or pretreatment with N-terminal targeting GPR110 antibody, indicating that GPR110 is a functional receptor for synaptamide. The GPR110 expression is high in NSCs and fetal brains but significantly decreases in the brain after birth. In adult brains, high localization of GPR110 was observed in the hippocampal dentate gyrus region, which is known to retain neurogenic capacity throughout life, suggesting a role of GPR110 in neurogenesis even after development. Identification of GPR110 as a functional synaptamide receptor provides new insight into the mechanism of DHA function in the brain and offers a potential novel target for controlling neurodevelopment and function.

Title: Altered expression on the level of miR-125b in serum from gestational diabetic women a possible biomarker for fetal central nervous system development

Authors: M. LAMADRID[1,4], M. S. CRUZ-RESÉNDIZ[1], N. F. DÍAZ[1], H. FLORES-HERRERA[2], G. GARCÍA-LÓPEZ[1], *A. MOLINA[3];
[1]Biología Celular, [2]Inmunobioquímica, [3]Neurosci, Inst. Nacional De Perinatología., México, DF, Mexico; [4]Posgrado en Ciencias Biológicas, UNAM, México, DF, Mexico

Abstract: MicroRNAs are a class of non-coding small RNAs of 18-25 nucleotides in length that regulated post-transcriptionally mRNAs targets by binding the 3' untranslated region. These molecules are involved in several cellular processes such as proliferation, differentiation, maturation, maintenance and death. Several microRNAs have been proposed as biomarkers since they have been detected in body fluids such as urine, serum or plasma. During central nervous

system development microRNAs are known to participate in neuron differentiation and several microRNAs are enriched during neurogenesis in embryo brain development, showing a particular profile and domains on its expression. MiR-125b is a homolog of the heterocronic microRNA lin-4. In murine its expression increases gradually from embryonic day twelve until birth, while its overexpression in human pluripotent stem cells impairs its self-renewal and induce differentiation into neurons. In zebra fish its loss lead to the accumulation of mitotic cells, an increase in cell death and a reduction in neural differentiation. Neuron differentiation by miR-125b is due to a repression of multiple targets involved in both proliferative and apoptotic processes. It has been reported that gestational diabetes impair offspring's cognitive, social and/or motor skills. By qRT-PCR we analyzed the expression of miR-125b in healthy and gestational diabetic women serum samples. To explore common targets between human and murine we use MicroCosm Targets Version 5 from The European Bioinformatics Institute, UK. Our results showed that miR-125b has a temporal regulation in healthy women that was not observed in gestational diabetic women. Relative expression levels in healthy samples were 1 ± 0.8, 903 ± 0.5 and 115.4 ± 0.8 at first, second and third trimester respectively. Significant increases were obtained in gestational diabetic samples per trimester when compared to healthy women, with 95 fold and 70 times at the second and third respectively. From our results we conclude that: 1.- miR-125b has a temporal regulation in healthy pregnant women serum samples, with its highest levels at the neurogenic period, similar of that observed in animal models, 2.- there is an up regulation in miR-125b level in gestational diabetic women and 3.- that miR-125b serum levels may be a reflect of a deregulation in embryo tissue during central nervous system development that could affect neurogenesis.

Title: Reversal of ketamine-induced neurotoxicity and cardiotoxicity in zebrafish embryos: Direct involvement of the energy metabolism pathway

Authors: *J. KANUNGO[1], X. GUO[2], E. CUEVAS[2], M. DUMAS[2], S. ALI[2], M. PAULE[2], S. LANTZ-MCPEAK[2];
[1]Neurotoxicology, Natl. Ctr. For Toxicological Research/Food and Drug Admin., Jefferson, AR;
[2]Neurotoxicology, Natl. Ctr. for Toxicological Research/Food and Drug Admin., Jefferson, AR

Abstract: Ketamine, an antagonist of the N-methyl-d-aspartate (NMDA) receptors, is a pediatric anesthetic. We demonstrate that ketamine is cardiotoxic and neurotoxic in zebrafish embryos. The exact mechanism(s) of how ketamine causes similar effects in mammals remains unclear. Using image-based high content analysis, we also show that ketamine induces developmental toxicity in zebrafish embryos. We have characterized the pathways modulated by ketamine in causing these effects. First, we show that the amino acid, acetyl l-carnitine (ALCAR) rescues ketamine-induced attenuation of heart rate, neurotoxicity and developmental toxicity in the 28 hours post-fertilization embryos exposed to these drugs for 20h. In these embryos, ketamine reduced heart rate and caused both motor and sensory neuron toxicity. Our follow-up studies focused on the mode of action of ALCAR's counteractive effects on ketamine-induced toxicities. Since NMDA receptors are calcium permeable and ketamine as its antagonist could alter cardiac function and induce neurotoxicity in the zebrafish embryos, the effect was likely due to blockade of calcium entry in to the cardiomyocytes and neurons. ALCAR can open the L-type calcium channels and also generate ATP through fatty acid transport and metabolism. First, we tested whether in presence of calcium chelators and L-type calcium channel blockers (e.g., verapamil), ALCAR was ineffective in reversing ketamine's effect. Microarray studies also revealed that gene expression involved in ATP synthesis was altered in the embryos exposed to ketamine. Based on this genomic data, we interfered with the ATP synthesis pathway using specific inhibitors in order to monitor the effects of these drugs on the cardiac rate and the nervous system. These studies revealed that mitochondrial function is a target of ketamine. Verapamil and ketamine together were more toxic than each drug alone indicating that their effects were additive. ALCAR was effective in counteracting the effects of verapamil or verapamil and ketamine, but not in presence of an inhibitor of ATP synthesis. Our combined *in vivo* and *in vitro* studies suggest that the energy metabolic pathway plays a direct role in ketamine-induced effects on the zebrafish embryos.

Abstract: Cell therapy has been studied a lot to apply to neurodegenerative diseases. Cell transplantation is one of the ways to recover the functionality of damaged neural tissue in these diseases. But overcoming limitation of low survival rate of transplanted cells is the most important thing for cell therapy. The purpose of this study is to develop a neurodegenerative disease treatment technology using Neurospheroid. Transplanted Neurospheroid could regenerate neuronal network and protect nerve by neurotropic factor and anti-inflammatory function. Through this study we aim to secure core medical technology and verify the utility of technology. We fabricated uniform sized Neurospheroids on the PEG microwell. Si master was fabricated using MEMS technology and PDMS mold was made of curing of PDMS solution on the Si master. PEG microwell with desired size was fabricated using PDMS mold. To observe advantage of culture method maintaining spheroid shape, we compared single cell (2D) culture and spheroid (3D) culture using primary neurons obtained from Sprague-Dawley rat embryo. Through Live and Dead assay, we identified viability of Neurospheroid in microwell and retrieved from microwell stage. We observed the neuronal properties of Neurospheroid with immunocytochemistry. The neuronal activity test was performed through multi-electrode arrays (MEAs). 2D cultured single cells showed signals 2 weeks after seeding on the MEAs. When reseeding spheroid, we observed electrical signal 1week after reseeding and identified strong and frequent electrical signals. This indicates spheroid shape cells may be helpful for recovery and regeneration. We proceeded with differentiation test which differentiates human neural stem cells into dopaminergic neurons using fabricated PEG microwell to maintain spheroid shape of stem cells. We observed differentiation states through immunocytochemistry and RT PCR.

Expression of stem cell markers, Nestin and Sox2, were decreased depending on the stage of differentiation. Expressions of MAP2, TuJ1, Kv1.1, Nfm and SCN5a, the neuronal markers, were increased. Especially, expression of TH, dopaminergic neuron marker, was increased and this indicates that neural stem cells differentiate into dopaminergic neuron. The result of MEA analysis demonstrates electrical function of differentiated Neurospheroid. Our findings suggest that this method could be basis for treating severe degenerative brain disease. This study provides possibility that 3D cultured Neurospheroids can be effective way in the future study of neurodegenerative diseases therapy.

Abstract: *In vitro* reconstruction of 3D neural network is important for the investigation of the mechanism of network formation and neuronal activity change in complex neural tissues *in vivo*. Many groups have reported 3D neuronal culture formed by hydrogel scaffolds, beads, and spheroids, but it is complicated to fabricate macroscopic neural networks using these methods without any scaffold materials. Here, we describe a method to fabricate 3D neural networks by neural microfiber assembly without using any scaffold material. We already developed a cell-encapsulating core shell hydrogel fiber, named the cell microfiber. Using this system, we fabricated mouse neural stem cell (NSC) microfibers by a coaxial laminar flow device. The formed microfiber provides a fiber-shaped 3D microenvironment (inner diameter: ~80 um, length: >several meters) constructed with sodium alginate shell. At 14 days after differentiation induction, we could observe that many neurons extend their dendrites and axons into the fiber-

shaped 3D microenvironment. We also observed many astrocytes. To fabricate complex 3D neural tissue, NSC microfibers were cut to the same lengths by a neural microfiber cutting system and cultured into a PDMS mold under differentiation-induction medium. After 24 hours, the edges of neural microfibers bounded to each other with cell-connection units. Using this process, we successfully made different angle connections of neural microfibers, and these architectures kept the angles for long term culture (> 1 month). Since alginate shell could be dissolved by alginate lyase treatment with the connection shape maintained, we can obtain 3D neural networks easily without any scaffold material. We believe that our neural microfiber assembly is a useful tool for fabrication of large complex 3D neural networks. Our 3D neural tissue is also a powerful approach for various fields including neural tissue engineering, analysis of 3D neural network, and pharmacological assay for drug screening.

Title: Activity-dependent regulation of dendritic complexity by Semaphorin3A through Farp1

Authors: *L. CHEADLE[1,2], T. BIEDERER[3];
[1]Harvard Med. Sch., Boston, MA; [2]Interdepartmental Neurosci. Program, Yale Univ., New Haven, CT; [3]Dept. of Neurosci., Tufts Univ. Sch. of Med., Boston, MA

Abstract: Dendritic arbors are complex neuronal structures that receive and process synaptic inputs. Investigation of mechanisms that govern the development of dendrites and their synapses is critical as disruption of these processes can lead to disorders such as Autism. One mechanism regulating dendrite differentiation is Semaphorin/Plexin signaling, specifically through binding of soluble Sema3A to Neuropilin/PlexinA co-receptors. We here show that the protein Farp1 (FERM, RhoGEF (ARHGEF), and pleckstrin domain protein 1), a Rac1 activator previously identified as a synaptogenic signaling protein that binds the adhesion molecule SynCAM 1, is

necessary to establish dendrite tip number and total dendritic branch length in maturing rat neurons, and is sufficient to promote dendrite complexity. Aiming to define its upstream partners, our results support that Farp1 interacts with the Neuropilin-1/PlexinA1 complex and co-localizes with PlexinA1 along dendritic shafts. Functionally, Farp1 is required by Sema3A to promote dendritic arborization of hippocampal neurons, and Sema3A regulates dendritic F-actin distribution via Farp1. Unexpectedly, Sema3A also requires neuronal activity to promote dendritic complexity, presumably because silencing neurons leads to a proteasome-dependent reduction of PlexinA1 in dendrites. These results provide new insights into how activity and soluble cues cooperate to refine dendritic morphology through intracellular signaling pathways.

Title: Effect of CSMD3, a candidate gene of neuropsychiatric disorders, on neuronal morphology

Authors: ***M. TOMOHARU**, T. KOHNO, M. HATTORI;
Nagoya City Univ., Nagoya, Japan

Abstract: Schizophrenia and autism are characterized by difficulties with social interaction and communication. It is speculated that the onset of these neuropsychiatric disorders are greatly affected by hereditary factors. Recently, it was reported that CUB and sushi multiple domain 3 (CSMD3) is one of the genes that are mutated in a few schizophrenia and autism patients. CSMD3 encodes a huge putative transmembrane protein that is expressed in fatal and adult brains. However, its biochemical properties and functions remain largely uncharacterized. In this study, we tried to clarify the function of CSMD3 on neuronal morphology. We first confirmed that CSMD3 is a type I transmembrane protein that is mainly expressed on the plasma membrane. Myc-CSMD3 and Venus-CSMD were co-expressed in COS7 cells and immunoprecipitation with anti-GFP antibody that recognizes Venus was performed. Myc-CSMD3 was found in the precipitate, suggesting that CSMD3 can form a homomultimer. We

also found that co-expression of CSMD3 with constitutively active Fyn resulted in tyrosyl phosphorylation of CSMD3. When full length CSMD3 was overexpressed in cultured hippocampal neurons, the number of short branched dendrites increased. On the other hand, a mutant CSMD3 that lacked the extracellular and intracellular regions had no effect. A mutant CSMD3 without the intracellular region had a similar effect as the full length. It was thus suggested that extracellular region, but not intracellular region of CSMD3, is required for its effect on the dendritic morphology. We speculate that CSMD3 may function as an adhesion molecule or a co-receptor for unidentified membrane protein to regulate dendrite development and its malfunction may be one of the factors in the pathogenesis of neuropsychiatric disorders.

Title: Acute and chronic effects of transient mutant DISC1 expression in layer 2/3 mouse barrel cortex

Authors: ***N. R. HARDINGHAM**[1], G. SEATON[2], K. FOX[2];
[2]Sch. of Biosci., [1]Cardiff Univ., Cardiff, United Kingdom

Abstract: DISC1 has been implicated in schizophrenia and has an important role in brain development. We used a transgenic mouse with a dominant negative fragment of the DISC1 c-terminal (DISC1-cc), activated for 24-48 hours by injection of tamoxifen. Activation of the mutant protein at P7 in mice results in schizophrenic like behaviour (Li *et al*, 2007) and a loss of experience dependent plasticity in layer 2/3 of adult barrel cortex, while activation of DISC1-cc at P28 has no effect on experience dependent plasticity (Greenhill and Fox, SfN 2012). We have already shown that mutant DISC1 retards dendritic growth and short term plasticity in layer 2/3 barrel cortex neurons at the P14 time point (Hardingham et al, SfN 2012). The transgene could thus have both short term and long term effects on layer 2/3 neurons. In order to temporally examine the effect of transient expression of mutant DISC1 on the neurons we made whole cell recordings from layer 2/3 neurons at P8, P14 and P28. To study excitatory synapses we recorded

mEPSPs and measured spine density from characterised dendrites. Deficits in spine density were observed in DISC1 mice at P8 but these had recovered by P28. We also pharmacologically measured NMDA to AMPA ratios at various stages of development and found there to be a difference between WT and DISC1 mutants at P28 ($p<0.05$) but no difference between the two at P14. To study the effects of transient expression of mutant DISC1 on inhibition we recorded mIPSCs from a population of neurons. By morphologically reconstructing a population of layer 2/3 neurons injected with biocytin we showed that dendritic development was attenuated in DISC1 mutants at both P11 and P14 but it had eventually recovered in adults and that in WTs most dendritic development had already taken place by P11. Furthermore, by detailed analysis of dendritic order and intermodal distance we demonstrated that DISC1 neurons had abnormal internodal distances in basal dendrites that were not compensated in adulthood and also enhanced higher order branching of the apical dendrite. We measured levels of LTP and LTD in adult mice (P50-P64) given transient expression of mutant DISC1 and in wild type littermates. We found that, similar to observations at P28, LTP was absent in the mutant DISC1 adult mice (comparison with WT, $p<0.05$) but that LTD was still present. Thus it would seem that LTP and certain aspects of dendritic branching are not compensated for in later life and that transient expression of mutant DISC1 can have both acute and chronic effects on the neurons.

Title: Purkinje neuron developmental markers *in vivo* and *in vitro*

Authors: T. N. FAULL, L. M. ROBERTSON, A. R. DEMCHAK, *M. E. MORRISON; Biol., Lycoming Col., Williamsport, PA

Abstract: The cerebellum coordinates movement and balance. It is composed of only a few cell types including Purkinje neurons, whose dendrites receive inputs via synapses from granule cell parallel fibers and olivary climbing fibers. The Purkinje neurons integrate these inputs, calculate motor error, and send corrective signals through their axons which synapse onto the deep cerebellar nuclei. The early development of Purkinje neuron axons and dendrites is the subject of this study. The growth of Purkinje neurons in the mouse can be divided into several stereotyped

stages. In the prenatal stage, the Purkinje cells are arranged in masses within the cerebellar anlage. From postnatal day 0 to postnatal day 3 *in vivo*, the cells extend numerous, very simple processes. As the cell continues to develop during the first two postnatal weeks, these processes recede back into the cell, and apical dendrites begin to appear. By the second or third postnatal week, the Purkinje neurons have a highly branched dendrite studded with spines. This series of developmental changes is recapitulated in cell cultures made from neonatal mouse cerebella, with a slight time delay of a few days as the cells recover from the cell dissociation process. Knowing more about the nature of the early Purkinje cell processes could help in the design of treatments to support Purkinje cell regeneration after injury or in the face of cerebellar ataxias. Our goal is to characterize the primitive processes of Purkinje cells in early postnatal mice and in cerebellar cultures derived from these mice: are they axonal, dendritic, both, or neither? In this study, immunohistochemistry of cryostat sections and immunocytochemistry of cultured cerebellar cells was used to establish the locations of several proteins in developing Purkinje neurons, including calbindin D28k, MAP2 (a dendritic marker), and neurofilament H (an axonal marker).

Title: Kainic acid induces alterations in dendritic spine number and motility in hippocampal neurons

Authors: *T. LORTKIPANIDZE[1], M. ZHVANIA[1,2], T. BIKASHVILI[2], N. JAPARIDZE[2]; [1]Inst. of Mol. Biochem., Ilia State Univ., Tbilisi, Georgia; [2]I.Beritashvili Ctr. of Exptl. Biomedicine, Tbilisi, Georgia

Abstract: Dendrites and spines undergo dynamic changes in physiological conditions, such as learning and memory, and in pathological conditions, such as epilepsy. Abnormalities in dendritic spines have commonly been observed in brain specimens from epilepsy patients and

animal models of epilepsy. However, the functional implications and clinical consequences of this dendritic pathology for epilepsy are uncertain. Motility of dendritic spines and axonal filopodia has been recently discovered by the advanced imaging techniques, and remains to a large degree an exciting phenomenology in search of function. Here we demonstrate the effect of Kainic Acid (KA), which is a structural analogue of glutamate, on dendritic spine number and motility in hippocampal CA1 area at the different stages of brain development. In order to reveal the changes that take place in spine and filopodial motility in the epileptic model of brain, time-lapse imaging of acute hippocampal slices treated with various concentrations of KA after different incubation time points was performed. The effects of KA exposure were tested on the slices from young (Postnatal day (P7-P10) and adolescent (P28-P30) Thy1-YFPH transgenic mice. Slices were treated with either 50 μM or 100 μM of KA, for either 30 or 100 min. The results obtained in our experiments show diverse effects of KA in 2 different age groups. According to our results, 100 μM/100 min KA treatment increases spine motility at early stage of brain development (P10) by 41.5%, while in P30 mice spine motility is increased only by 3%. As for spine number in was significantly increased in both age groups (P10 and P30) at 50μM /30 min KA treatment, and decreased at 50μM /100 min , but this reduction was more dramatic in P10 mice. Our findings also indicate that effect of KA on hippocampal dendritic spine motility is predominantly time - rather than concentration - dependent.

Abstract: Neurite growth is regulated by many intracellular signaling pathways, among which signaling via mammalian target of rapamycin complex 1 (mTORC1) is of particular relevance because it controls the translation of a substantial subset of mRNAs that encode proteins with roles in neurite growth. Phosphatase and tensin homolog (PTEN) is a lipid phosphatase that converts phosphatidylinositol-3,4,5-trisphosphate to phosphatidylinositol-4,5-bisphosphate, and thereby antagonizes the phosphoinositide-3-kinase-mTORC1 (PI3K-mTORC1) signaling. Therefore, the regulation of PTEN expression, subcellular localization, and activity in neurons is of particular interest in the context of neurite growth regulation. Previous studies indicated that the Nedd4 family E3 ubiquitin ligases Nedd4-1 and Nedd4-2 ubiquitinate PTEN and target PTEN for proteosomal degradation, thereby negatively regulates PTEN expression and subsequently activates the PI3K-mTORC1 signaling. However, other studies argued that PTEN is the physiological substrate of Nedd4-1. In the present project, we aim to resolve the conflict and address the relationship between PTEN and Nedd4-1/Nedd4-2 in the regulation of neurite growth in mammalian central nervous system neurons. Using brain specific conditional knock-out mice as models, we found that Nedd4-1 and Nedd4-2 are required for axonal growth in murine central nervous system neurons. However, account for the underlying molecular pathways, PTEN is not a substrate of Nedd4-1 and Nedd4-2. Rather, PTEN negatively regulates Nedd4-1, but not Nedd4-2 protein expression through modulating the activity of mTORC1. Our data indicate that Nedd4 family E3 ligases promote axonal growth in the developing mammalian brain, where PTEN is not a relevant substrate. Instead, PTEN controls neurite growth by regulating Nedd4-1 expression through mTORC1.

Title: Carbamylated erythropoietin promotes neurite outgrowth and neuronal spine formation in association with CBP/p300

Authors: *M. CHOI[1], S. LEE[2], S. KO[2], S. WANG[2], H. SON[1,2];
[1]Dept. of Biochem. and Mol. Biol., [2]Dept. of Biomed. Sci., Hanyang Univ., Seoul, Korea, Republic of

Abstract: Both erythropoietin (EPO) and carbamylated EPO (cEPO) have been shown to increase the length of neurites and spine density in neurons. However, the molecular mechanism underlying the EPO- and cEPO-induced neuronal differentiation has yet to be investigated. To address this issue, we investigated epigenetic modifications that regulate gene expression in neurons. Neurons treated with EPO or cEPO display an upregulation of E1A-binding protein (p300) and p300-mediated p53 acetylation, possibly increasing the transactivation activity of p53 on growth-associated protein 43 (GAP43). Treatment of cells with cEPO markedly increases spine formation and potentiates p300-mediated transactivation of PSD95, Shank2 and 3 compared to EPO. These results demonstrate that cEPO controls neuronal differentiation via acetylation of transcription factors and subsequent transactivation of target genes. These findings have important medical implications because cEPO is of interest in the development of therapeutic agents against neuropsychiatric disorders.

Title: The role of sap97 in asd and scz

Authors: *P. GUPTA[1], L. ZHANG[2], J. MOJSILOVIC-PETROVIC[2], R. G. KALB[2,3];
[1]Neurosci. Grad. Group, Univ. of Pennsylvania Perelman Sch. of Medi, Philadelphia, PA; [2]Children's Hosp. of Philadelphia, Philadelphia, PA; [3]Dept. of Neurol., Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA

Abstract: Aberrant brain circuitry is implicated in various neuropsychiatric disorders such as autism spectrum disorders (ASD), schizophrenia (SCZ), and intellectual disability. Both ASD and SCZ are classified as “synaptopathies,” as a majority of the genes mutated in these disorders play a critical role in synaptic development, function, and neuronal connectivity. Consequently, the genes regulating dendritic growth and arborization are imperative for the formation of functional neuronal networks. Synapse-associated protein of 97kDa (SAP97) is one such gene that is implicated in regulating glutamatergic synaptic transmission within the nervous system and is involved in mediating dendritic morphogenesis. Additionally, whole exome sequencing data suggests SAP97 may play a risk-determining role in the onset of ASD and SCZ. In order to determine whether SAP97 directly contributes to the behavioral phenotypes associated with ASD and SCZ, we will study mice that lack neuronal SAP97. We will subject these mice to a battery of behavioral paradigms to screen for a ASD or SCZ phenotype. Interestingly, signaling through the Wnt/β-catenin pathway is also involved in the pathophysiology of ASD and SCZ and is critical for dendritic growth. Integration of SAP97 and Wnt/β-catenin into a single pathway would bolster the role of SAP97 in ASD and SCZ, as well as clarify the mechanism by which SAP97 regulates dendritic growth and contributes to normal neuronal development. We are currently using rodent hippocampal cultures as an *in vitro* model to study dendritic growth after manipulation of the levels of SAP97 and β-catenin. In order to determine whether SAP97 functions downstream of β-catenin, we are stimulating β-catenin signaling by expressing a stabilized form of β-catenin along with a construct that knocks down SAP97. If SAP97 function is necessary for Wnt/β-catenin-mediated dendritic growth, we expect to see blunted dendrite and synapse growth upon knockdown of SAP97. Our findings will determine whether SAP97 plays a direct, causative role in the symptomology associated with ASD and SCZ, as well as elucidate the molecular pathways involved in the development of proper neuronal connectivity. Given that

aberrant brain circuitry is associated with myriad neuropsychiatric disorders, it is essential to establish the neurobiological mechanisms regulating dendritic morphogenesis.

Title: Cellular constituents of Nogo-A contribution to structural plasticity in the mouse cerebral cortex

Authors: ***C.-C. CHEN**[1], A. ZEMMAR[2,3], F. VAJDA[2], G. CARSON[1], N. ISAAD[1], J. BOZEMAN[1], B. TEWS[2,3], M. SCHWAB[2,3], Y. ZUO[1];
[1]Mol. Cell and Dev Biol, Univ. of California, Santa Cruz, Santa Cruz, CA; [2]Brain Res. Institute, Univ. of Zurich, Zurich, Switzerland, Switzerland; [3]Biol., ETH Zurich, Zurich, Switzerland, Switzerland

Abstract: Nogo-A has been described as a myelin-associated inhibitor of neurite outgrowth and is important for functional neuroregeneration following central nervous system injury. Its physiological functions, however, remain less well defined. Aside from its main expression site in oligodendrocytes, Nogo-A is also expressed by subsets of cortical neurons. While Nogo-A is known to negatively regulate structural and functional synaptic plasticity, the specific roles played by neuronal vs. myelin Nogo-A for such structural alterations remain unclear. To address this question, we generated mouse lines in which the Nogo-A gene is specifically knocked out for (i) oligodendrocytes (glial Nogo-A KO) or (ii) neurons (neuronal Nogo-A KO). We analyzed neuronal morphology, dendritic branching pattern, and spine density in layer 2/3 pyramidal neurons from adult motor cortex under normal physiological conditions. We found that in the absence of Nogo-A, the complexity of dendritic features was increased, exemplified by an

overall elevation in dendritic length and the number of bifurcations in the animals lacking Nogo-A. In glial Nogo-A KO mice, these effects were larger than in neuronal Nogo-A KO mice. In addition, deletion of Nogo-A in neurons, but not oligodendrocytes, was associated with higher densities of perineuronal nets around cortical inhibitory neurons. Last, dendritic spine densities were elevated in apical dendrites but normal in basal dendrites, again with a more pronounced effect in glial Nogo-A KO than neuronal KOs. Our data indicate that oligodendrocytic and myelin Nogo-A influences complexity and plasticity of dendrites in the mouse motor cortex, but neuronal Nogo-A also participates in such regulation, although to a lesser extent. Understanding the different cellular constituents of Nogo-A contribution to the formation of dendrites and the limitation of adult plasticity provides a framework on how developmental critical period and maturation of cortical circuitries are related.

Title: CRMP4 contributes to formation of the olfactory bulb neural circuits

Authors: *A. TSUTIYA[1], H. WATANABE[1], M. NISHIHARA[2], Y. GOSHIMA[3], R. OHTANI-KANEKO[1];
[1]Toyo Univ., Itakura, Oura, Gunma, Japan; [2]The Univ. of Tokyo, Tokyo, Japan; [3]Yokohama City Univ., Kanagawa, Japan

Abstract: Although collapsin response mediator proteins (CRMPs, CRMP1-5) are indicated to play important roles in growth cone collapse and axon guidance induced by semaphorin 3A, the function of CRMP4 in the developing brain remains unclear. In our previous studies, we investigated the expression of *Crmp4* mRNA in brains of neonatal to adult mice and discovered prominent *Crmp4* mRNA expression in the olfactory bulb (OB) during the early postnatal period

(Tsutiya and Ohtani-Kaneko, 2012). This result promoted us to explore phenotypes of the OB in *Crmp4*-knockout (KO) pups to reveal roles of CRMP4 in the developing brain. We found altered thickness of layers in the OB and abnormal morphology of mitral cells (MCs) in *Crmp4*-KO pups. Moreover, we revealed that olfactory discrimination ability was impaired in *Crmp4*-KO pups, compared to that in wild-type (WT) pups (Tsutiya et al., Neuroscience 2013, San Diego). In this study, we aimed to elucidate mechanisms underlying the physiological alteration in *Crmp4*-KO pups. In order to examine the excitation of neural cells in the OB, we first compared c-Fos expression, an activity-dependent neuronal marker, in the OB between WT and *Crmp4*-KO pups after olfactory stimulation of ethyl acetate (EA), a commonly used non-biological odorant. Without stimulation, c-Fos-positive cells were slightly observed in both WT and *Crmp4*-KO pups. After EA-treatment, c-Fos-positive cells were significantly increased in a restricted small area of the MC layer and granule cell layer in WT pups, compared to those in WTs without stimulation. However, c-Fos-positive cells were broadly and dramatically increased in all layers of the OB in *Crmp4*-KO pups treated with EA. These results clearly showed altered neural activities in *Crmp4*-KO pups after olfactory stimulation. Next, we focused on tyrosine hydroxylase (TH) neurons, since they carry out an important task in regulating excitation of neurons in the OB. The number of TH neurons in the OB was significantly greater in *Crmp4*-KO mice than in WTs. Furthermore, we carried out primary culture of the OB cells to examine the morphological changes of developing TH neurons derived from *Crmp4*-KO mice. TH neurons derived from *Crmp4*-KO mice had more neurites than those from WT mice. In conclusion, these studies showing the altered excitation of neurons and changes in TH neurons revealed important roles of CRMP4 in the formation of the OB neural circuits.

Title: The role of ubiquitin ligase E3B in neural development

Authors: *M. C. AMBROZKIEWICZ[1], B. ALTAS[1], S. RIPAMONTI[1], A. RONNENBERG[2], H. EHRENREICH[2], J. S. RHEE[1], N. BROSE[1], H. KAWABE[1];
[1]Mol. Neurobio., [2]Clin. Neurosci., Max Planck Inst. of Exptl. Med., Göttingen, Germany

Abstract: Protein ubiquitylation plays indispensable role in various aspects of neurodevelopment. Perturbations in the ubiquitin signaling follow with dramatic consequences for neuronal function, which ultimately leads to neurological disorders and intellectual disability. Recently, whole-exome sequencing of patients with blepharophimosis-mental retardation syndrome (BMR) revealed truncating mutations in Ube3b - gene encoding for ubiquitin ligase E3B. BMR is a heterogeneous group of disorders characterized by facial dimorphisms, failure to thrive and microcephaly. Neurological features of the BMR patients show abnormal brain image with Chiari type I malformation and hypoplasia of corpus callosum. Interestingly, in a similar study, recessive point mutation in Ube3b was identified in an individual suffering from autism - a neurodevelopmental disorder characterized by abnormalities in social behavior. To elucidate the role of this ubiquitin ligase in the development of the nerve cell, we generated UBE3B knock-out mouse line. Straight UBE3B KO animals recapitulate the phenotype of the BMR patients with most prominent features being severe facial dimorphisms, kyphosis and microcephaly. The analysis of primary hippocampal neurons prepared from UBE3B KO animals reveals a dramatic reduction of dendritic tree complexity, which seems to be controlled in a cell autonomous fashion. Using the UBE3B KO mice, we will further characterize the role of the ubiquitin ligase in the nerve cell using biochemical, electrophysiological and behavioral assays. This study will contribute to the present outlook on the pathology of neurodevelopmental disorders.

Title: Activation of AhR signaling pathway regulates dendritic growth in the developing mice

Authors: *E. KIMURA[1], K.-I. KUBO[2], T. ENDO[1], W. LING[1], K. NAKAJIMA[2], M. KAKEYAMA[1,3], C. TOHYAMA[1];
[1]Lab. Environ. Hlth. Sci., CDBIM, Grad. Sch. of Med., Univ. of Tokyo., Tokyo, Japan; [2]Dept. of Anat., Keio Univ. Sch. of Med., Tokyo, Japan; [3]Grad. Sch. of Biomed. Sci., Nagasaki Univ., Nagasaki, Japan

Abstract: Normal growth of dendrites is required for the neural network formation that ensures higher brain function in humans and laboratory animals. Although abnormal activation of aryl hydrocarbon receptor (AhR) has been suggested to disrupt higher brain function, the physiological role of AhR remains elusive. In this study, we studied whether and how activation of AhR signaling affected dendritic growth in the developing brain from the fetal mice that were subjected to *in utero* electroporation (IUE) of constitutively active (CA)-AhR-expressing neurons. Pregnant C57BL/6 mice were deeply anesthetized on GD 14. Either of the following three kinds of plasmids, i.e., pCAG-tdTomato (Control), pCAG-tdTomato and pCAG-AhR (WT-AhR), or pCAG-tdTomato and pCAG-CA-AhR (CA-AhR), was injected into the lateral ventricle by IUE. On postnatal day 14, brains were collected and analyzed for dendritic morphology of tdTomato-expressing neurons using Neurolucida software. Dendritic length of apical tree of reconstructed pyramidal cells of hippocampal CA1 region was shown to be significantly decreased in CA-AhR-expressing cells compared with Control and WT-AhR-expressing cells. Dendritic complexity was estimated by Sholl analysis. CA-AhR-expressing cells were found to have a significantly smaller number of Sholl ring intersections of apical tree than Control and WT-AhR-expressing cells. No significant changes in both dendritic length and complexity were found between Control and WT-AhR-expressing cells. In conclusion, our present study demonstrates a possible role of activation of AhR signaling in dendritic growth and an involvement of AhR in dendritic growth in the developing brain. Further studies are needed to evaluate the significance of AhR signaling in the brain development such as cell migration and axonal growth.

Title: Role of ryanodine receptor type 2 expressed by cerebellar granule cells in dendritic differentiation of Purkinje cells

Authors: *M. TANAKA, R. OHASHI, M. MIURA, N. HIRASHIMA;
Dept. Cell. Biophys., Grad. Sch. Pharmaceut. Sci., Nagoya City Univ., Nagoya, Japan

Abstract: Cerebellar Purkinje cells have the most elaborate dendritic trees among neurons in the brain. Purkinje cell dendrites receive numerous glutamatergic synaptic inputs from granule cells, forming a main component of cerebellar neuronal circuitry. Ryanodine receptor (RyR), an intracellular calcium release channel, mediates calcium-induced calcium release in many types of cells including cerebellar Purkinje and granule cells. In regard to the expression pattern of RyR subtypes in the cerebellum, Purkinje cells show high expression of RyR type 1 (RyR1) in addition to lower expression of RyR type 2 (RyR2), whereas granule cells highly express RyR2. The expression level of RyR type 3 is very low in both Purkinje and granule cells. Recently, we developed single-cell electroporation technique for introducing siRNA into specific neurons in primary neuronal cultures (J. Neurosci. Meth. 178:80-86, 2009; Neurochem. Res. 36:1482-1489, 2011; Neuromethods 65:129-139, 2012). Using this technique, we previously showed that Purkinje cell-specific knockdown of RyR1 inhibited dendritic differentiation of Purkinje cells in cerebellar cell cultures. In addition, knockdown of RyR2 expressed by granule cells using a transfection reagent also inhibited dendritic differentiation of Purkinje cells. In the present study, we analyzed the role of RyR2 expressed by granule cells in dendritic differentiation of Purkinje cells in detail. Ryanodine (10 μM), a blocker of RyR, reduced the elevation of intracellular calcium concentration in both Purkinje and granule cells in response to glutamate stimulation and markedly inhibited dendritic differentiation of Purkinje cells in cerebellar cell cultures. ELISA analysis showed that ryanodine reduced the levels of brain-derived neurotrophic factor (BDNF) in the culture medium. When we added BDNF in addition to ryanodine into cultures, the ryanodine-induced inhibition of dendritic differentiation of Purkinje cells was partially rescued. In contrast, nerve growth factor did not rescue the ryanodine-induced inhibition of dendritic differentiation of Purkinje cells. In addition, ryanodine reduced glutamate release from granule cells after depolarization. These results suggest that dendritic differentiation of Purkinje cells is promoted not only by RyR1 expressed by Purkinje cells themselves, but also by RyR2 expressed by granule cells, through secretion of BDNF and glutamate from granule cells.

Title: Neonatal blockade of glutamatergic transmission alters the dendritic spines types on dorsal hippocampus and the learning and memory processes in the rat

Authors: *C. A. PINZÓN;
Inst. De Fisiología, Puebla, Mexico

Abstract: The mechanisms by which the brain processes and retains information it receives from the environment has been a focus of interest for long. However several studies have shown the critical role of dendritic spines in the information process, being that the most of the excitatory synaptic inputs in the brain occur in dendritic spines (over 90 %), dendritic spines are also highly modifiable, and this process is called dendritic plasticity. Likewise is known that the glutamate receptors play an important role in modulating of synaptic strength, the growth of neurons and neuronal plasticity. The main objective of this study was to evaluate the effect of the neonatal blockade of different types of glutamate receptors on dendritic spines in the hippocampus and the memory and learning process. Chronic administration of specific antagonists of iGluRs on rats Sprague Dawley strain was made at an early stage (PD1 at PD15), to subsequently determine the changes, produced in the adult stage (PD60), in the hippocampus and behavior of the rat. This in order to assess learning and memory in animals treated with the antagonists and determine what type of spines formed by antagonizing iGluRs for behavioral changes ultimately bind to neuronal morphological alterations. The behavioral test was evaluated by NOR (Novel Object Recognition), the results shown a diminution in the treated groups of index of discrimination with respect to the control groups, indicating an alteration in the processes of learning and memory. In addition we evaluated the spines typification by using Golgi-Cox technique in dorsal hippocampus (CA1), finding reduction in the mature spines.

Title: Inhibition of Bcl-xL arrests neurite outgrowth

Authors: *H.-A. PARK, P. LICZNERSKI, K. N. ALAVIAN, M. SHANABROUGH, E. A. JONAS;
Yale Sch. of Med., New Haven, CT

Abstract: Bcl-xL, an anti-apoptotic member of the Bcl2 family, protects cell survival in rapidly dividing cells and developing neurons, but was not previously known to regulate neuronal growth. Neuronal outgrowth and synapse formation are necessary for cell survival in development, and it is apparent that growth and synapse formation go hand-in-hand. We have shown previously that Bcl-xL is necessary for changes in synapse number, size, activity, and for enhancement in mitochondrial metabolism. In this study we set out to determine if Bcl-xL were necessary for neurite outgrowth and if neurite outgrowth were in turn required for survival in the presence or absence of stress. We found that, in the absence of stress, depletion of Bcl-xL slowly impaired neurite outgrowth in hippocampal neurons followed by delayed cell death. The rapidity of decline in neurite outgrowth markedly increased upon exposure to hypoxia in neurons depleted of Bcl-xL. Hypoxic neurons depleted of Bcl-xL demonstrated a more striking loss of neuritic processes and an increased propensity to apoptotic and necrotic death compared to hypoxic controls. Normoxic hippocampal neurons lacking Bcl-xL had increased expression of death receptor 6 (DR6), a molecule that regulates axonal pruning; increased DR6 expression was also found in neurons after *in vivo* ischemia or *in vitro* hypoxia. Depletion of DR6 partially protected from loss of neurite outgrowth, suggesting that DR6 is an important downstream effector of Bcl-xL in neuronal outgrowth. We suggest that DR6 levels are normally suppressed by Bcl-xL expression, and that depletion of endogenous Bcl-xL leads to upregulation of DR6, failure of neuronal growth in non-stressed cells and exacerbation of hypoxia-induced neuronal injury. Taken together, this study suggests that Bcl-xL regulates neurite outgrowth during development and during hypoxic insult, opposed by DR6. Therapeutically, stimulation of factors implicated in neurite formation may protect neurons against acute hypoxic injury or chronic neurodegenerative stimuli.

Title: miR92a and 301a regulate human-specific changes in cortical development

Authors: *P. GUIJARRO[1], Z. QIU[2], P. KHAITOVICH[1];
[1]PICB, Shanghai, China; [2]Inst. of Neurosci., Shanghai, China

Abstract: Human cognition is considered to have evolved from the closest living relative the chimpanzee by specific changes in human brain developmental program, leading to an extended period of dendritogenesis, synaptogenesis and synaptic remodeling. This delay in acquiring the mature neural network is especially relevant in the prefrontal cortex, and it can possibly explain the unique capacity of human infants to learn cultural knowledge and cognitive skills. In previous studies we identified a group of mRNAs in the prefrontal cortex that showed different expression patterns between humans and chimpanzees. These genes were enriched in synaptic and neural connectivity functions, and were targets of microRNAs 92a and 301a. In the present study, plasmids containing miR92a or 301a were transfected in three different neuronal cell types (human SHSY5Y, mouse N2A and mouse primary neurons) using liposomes. 3 days after transfection, cells overexpressing miR92a or 301a had significantly shorter neurites, indicating that they might inhibit genes related to neuronal differentiation. Expression analysis of the mouse prefrontal cortex by qPCR showed high levels of miR92a and 301a at embryonic and early postnatal stages. Expression abruptly decreased during the second postnatal week, a period when dendritic and synaptic remodeling take place Overall, our preliminary data favor the hypothesis that miR92a and 301a are critical in the acquisition of the specific expression profile of the human prefrontal cortex by regulating genes involved in late stages of neuronal development like dendritogenesis and synaptogenesis.

Title: Differential regulation of the Wnt signaling pathway by gamma-protocadherin family proteins

Authors: *K. MAH, J. A. WEINER;
Biol., Univ. of Iowa, Iowa City, IA

Abstract: The formation of neural circuits during brain development depends on a variety of growth factors (e.g., FGFs, Wnts, TGFβs) and their associated signaling pathways, as well as on specific cell-cell contacts mediated by a variety of adhesion molecules. How these distinct mechanisms might interact to regulate circuit formation is not clear. The protocadherin gamma (Pcdhg) gene cluster encodes a family of 22 cell adhesion molecules that we have implicated in the regulation of synaptogenesis, neuronal apoptosis, neuron-astrocyte interactions, and branching of axons and dendrites, primarily through mechanisms that remain unknown. Recently, it was reported that Pcdhg genes are epigenetically silenced in some cancer cell types, and that overexpression of Pcdhg genes in these cells could reduce tumor growth by inhibiting the canonical Wnt signaling pathway (Dallosso et al., 2009, 2012; PMIDs: 19956686, 22249255). As Wnt signaling regulates many aspects of neural development, we asked how the γ-Pcdh proteins might inhibit Wnt signaling, and whether this plays a role in the γ-Pcdhs' many neural functions. Using the TOP-FLASH assay and quantitative RT-PCR for Axin2 in HEK293 cells, we find that individual γ-Pcdhs differentially affect canonical Wnt3a signaling: γ-Pcdh-C3 and -A11 significantly attenuate Wnt signaling, while most other isoforms, surprisingly, significantly increase Wnt signaling. Focusing on the C3 isoform, we performed a structure-function analysis to determine which domains of the molecule (ectodomain with 6 extracellular cadherin repeats, variable cytoplasmic domain specific to this isoform, or constant C-terminal domain shared by all γ-Pcdhs) were important for its inhibition of Wnt signaling. We found that all constructs containing the variable cytoplasmic domain (VCD), but not one lacking it, were active; thus the differential effects of γ-Pcdh isoforms is consistent with the fact that the VCD is the domain with the most sequence diversity amongst the Pcdhg family. Though the VCD is normally juxta-membrane, the entire cytoplasmic domain (VCD+constant domain) of γ-Pcdh proteins has been reported to be cleaved by gamma-secretase and enter the nucleus. We are thus now utilizing new constructs, encoding the C3 VCD with or without palmitoylation or nuclear localization sequences to determine where in the cell the VCD acts to inhibit the Wnt pathway. We are also crossing a Wnt reporter line with a nuclear GFP read-out to both constitutive or floxed conditional Pcdhg mutant mice, and to mice harboring a Cre-inducible Pcdhg-A1 or -C3

transgene, to assess whether the γ-Pcdhs similarly regulate Wnt signaling in the nervous system *in vivo*.

Title: Comparing stochastic growth models to explore the developmental mechanisms of dendritic arbors

Authors: *S. NANDA[1], R. ARMAÑANZAS[2], R. PAREKH[2], S. POLAVARAM[2], D. N. COX[2], G. A. ASCOLI[2];
[1]Neurosci., Krasnow Inst. of Advanced Study, Fairfax, VA; [2]Krasnow Inst. for Advanced Study, George Mason Univ., Fairfax, VA

Abstract: Complex developmental processes produce mature dendritic morphologies, which in turn affect the computational properties of neurons and networks. Stochastic algorithms to generate artificial dendritic arbors provide a powerful method for exploring the mechanisms of dendrite development. Furthermore, these algorithms allow for a complete quantitative characterization of dendritic morphology. Here we focus on distinct morphological classes of dendritic arborization (da) neurons from *Drosophila* larvae. Computer simulations are both constrained and validated directly with experimental data using digital reconstructions of dendritic morphology of class I-IV da neurons from NeuroMorpho.Org. First, the statistical distributions of the (basic) model parameters controlling growth are extracted from real neurons; then the resulting synthetic morphologies are compared to the real ones using different (emergent) morphological measurements. In one model, growth rules are expressed in terms of

local morphological properties (e.g. tapering, branch elongation, and termination probability) that depend on “fundamental determinants”, such as radius, branch order, and path distance from the soma. A complementary model controls dendritic structure by the density profile of the (desired) spanning field and a balancing factor, which weighs the costs of wiring length and conduction time. In a third (intermediate) alternative, branching is constrained by the expected number of terminal tips in a specific sub-tree and the path distance from the soma. Comparing the outcomes of these models reveals the relative importance of various morphological and functional parameters in producing the observed structural variations found in real neurons. The resulting quantitative hypotheses are being tested with multi-channel time-lapse imaging of da neuron development tagging the putative molecular substrates, including microtubules and neurofilaments.

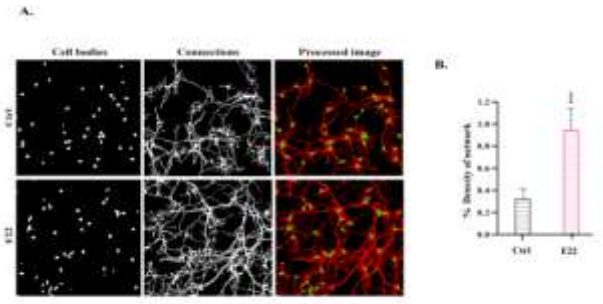
Abstract: The phospholipids in brain membranes contain different polyunsaturated fatty acids (PUFAs), which are critical to the nervous system function and structure. Particularly, brain function is critically dependent on the intake of the so-called ’essential’ fatty acids that cannot be readily synthesized by the human body. Among these are omega-3 (n-3) and omega-6 (n-6) PUFAs, which are required for brain development and maintaining optimal brain function. Here, we developed a novel phospholipid liposome formulation (F22) containing a variety of fatty acids as nanocarriers. They were derived from natural lecithins by enzymatic processing and

enhance metabolic activity and support neural network formation in 2D and 3D cultures of primary cortical neurons. Furthermore, extracellular recordings with microelectrode arrays (MEA) revealed a significant increase in spontaneous activity in cultures treated with these bio-inspired materials.



A & B. Network formation analysis in cortical neurons after treatment with F22 for 3 days and in control condition as indicated. Different channels of cell bodies, connection and processed images are represented. Values are presented as mean ± SD, (for B, n=80 images for each condition, from 4 independent experiments).

Title: High-resolution analysis of Semaphorin 3A effects on filopodia of developing dendrites using SLIM imaging and microfluidic environments

Authors: *A. JAIN[1], T. KIM[2], G. POPESCU[2], M. U. GILLETTE[1];
[1]Dept. of Cell and Develop. Biol., [2]Electrical & Computer Engin., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: The intricate wiring of the nervous system relies on filopodial navigation to form complex interconnections between neurons through their axons, dendrites, and the cell soma itself. Until recently, cellular investigations into filopodial dynamics had focused primarily on axonal growth cone filopodia. Spurred by technological advances, scientists have now begun to explore the structural and functional landscape of dendritic filopodia. These are dynamic 200-300 nm wide, 2-20 μm long protrusions that occur predominantly during early postnatal development and mediate crucial developmental processes. Even so, several structural and chemical cues guiding filopodial navigations remain obscure. Semaphorin 3A (Sema3A) is one such cue that, in particular, needs to be investigated, since, being a signaling protein that selectively promotes dendrite survival and growth, its effects on the dendritic filopodia are all the more relevant. Here we investigate the role of Sema3A in guiding dendritic morphogenesis, spinogenesis, and synaptogenesis. We show that it acts not only at the level of the dendrites, promoting neurite survival and growth, but also at the level of the filopodia. Since there has been some evidence indicating a difference in filopodia borne along dendrite tips vs. those borne along dendrite shafts, we treat the two populations as distinct and tease apart their different responses. Structural analyses of numbers, lengths, and locations are complemented by studies of dynamic functional aspects, such as motility, and extension-retraction rates. This is made possible through Spatial Light Interference Microscopy (SLIM), an innovative quantitative phase imaging method that makes possible high-resolution label-free imaging of live cells through interferometry (Wang et al, Opt Express, 2011) and allows measurements of the dry mass of live neurons at femtogram levels (Mir et al, Sci Rep, 2014). This convergence of filopodial investigations and the technology for engineering micro-environments, when coupled with high resolution imaging and analysis, enabled new insights on local signals, including Sema3A, that initiate and establish neuron-neuron interactions at the filopodial level. A greater comprehension of such processes that shape the development of neuronal networks is helping unravel the mechanistic bases of developmental disorders and diseases.

Title: Mitochondrial motility and function in developing neural dendrites

Authors: *M. FAITS, D. KERSCHENSTEINER;
Dept. of Ophthalmology and Visual Sci., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Mitochondria are essential for neuronal function; they provide energy (ATP) to maintain ionic gradients and support synaptic function, and participate in Ca^{2+} buffering. The complex morphology of neurons presents a unique challenge: mitochondria must traffic from the soma throughout long and highly branched axons and dendrites to reach sites of demand. While previous studies have focused on mitochondrial movement in axons, much less is known about the signals and transport steps that control mitochondrial movement and localization in dendrites. In particular, how mitochondrial distribution is regulated during dendritic development, when sites of energy consumption and Ca^{2+} entry in neurons are in flux, has not been explored. Here, we analyze the trafficking of mitochondria in dendrites of ganglion cells (GCs) in the intact developing mouse retina combining biolistic and viral gene delivery with confocal and multiphoton live imaging. Fast time-lapse imaging revealed that dendritic mitochondria can be grouped into two pools: motile and stationary. Whereas stationary dendritic mitochondria stay in place for long periods, motile mitochondria are highly dynamic and engage in runs of movement and pauses of various durations. Interestingly, the ratio of stationary/motile mitochondrial pools increases with developmental age. Pharmacologic manipulations that artificially increase or decrease neuronal activity in mature cultured neurons had been found to decrease and increase, respectively, mitochondrial motility in a Ca^{2+}-dependent manner, but how physiologically occurring activity patterns affect mitochondrial movement in dendrites has not been examined. To test whether physiologic neural activity affects mitochondrial movement during development, we simultaneously imaged mitochondrial movements and intracellular Ca^{2+} in the intact developing retina. We find that GCs exhibit both global increases in dendritic Ca^{2+} associated with action potential firing as well as localized increases limited to small regions of dendrite. Surprisingly, neither local nor global Ca^{2+} signals affect mitochondrial movements, suggesting that physiologic patterns of activity during development play only a minor role in regulating mitochondrial transport and localization.

Title: Interplay of non-prenylatable Rac1 and RhoA in B35 neuroblastoma cells

Authors: *J. M. REDDY[1,2], N. G. R. RAUT[2], D. L. HYNDS[2];
[1]Biol., Texas Woman's Univ., Fort Worth, TX; [2]Biol., Texas Woman's Univ., Denton, TX

Abstract: Rho family guanine nucleotide triphosphatases (GTPases) are molecular switches that play a fundamental role in axon growth and guidance by directing growth cone cytoskeletal changes through interaction with downstream effectors. Small GTPases are considered active when bound to guanosine triphosphate (GTP), a process promoted by plasma membrane-associated guanine exchange factors (GEFs), and inactive when bound to guanosine diphosphate (GDP). RhoA, a member of the Rho family GTPases, participates in the formation of focal adhesions, retraction of neuron processes in response to injury or insult and growth cone collapse. Rac1, thought to be a competitor of RhoA, is responsible for cell proliferation, cell cycle entry, and extension of neuronal processes. The interplay between Rac1 and RhoA dynamics is not well elucidated, though they are thought to be direct competitors with opposing functions. Both require prenylation for membrane localization, though active forms of both have been found in other cellular compartments (GTP bound Rac1 in the cytosol and GTP RhoA primarily in the cytosol and nucleus). We have created non-prenylatable RhoA and Rac1 constructs to inhibit membrane attachment, and after transfection, we determined overexpression of wild-type RhoA decreases Rac1 GTP loading in the cytosol, and overexpressing the mutant form of RhoA demonstrated near normal levels of Rac1 GTP loading. Overtransfection of wild-type Rac1 inhibited RhoA GTP loading in all cell fractions while overexpressing the Rac1 mutant did not affect RhoA loading. With emerging evidence of differential activation of these Rho GTPases based on their subcellular localization, determining how activation of these GTPases are regulated is next step in understanding Rho GTPase dynamics. Understanding how

prenylation of RhoA and Rac1, and how their competition impacts function in neurite outgrowth, may identify novel targets to facilitate axon regeneration in traumatic or degenerative neurological conditions.

Title: Dscams promote self-avoidance by masking adhesion through both MAGI-dependent and -independent mechanisms

Authors: ***R. W. BURGESS**[1], A. M. GARRETT[1], A. L. D. TADENEV[1], A. KHALIL[2], P. G. FUERST[3];
[1]The Jackson Lab., BAR HARBOR, ME; [2]The Univ. of Maine, Orono, ME; [3]Univ. of Idaho, Moscow, ID

Abstract: During development, neurons balance attractive and repulsive signals to properly position cell bodies and processes and to form synapses with appropriate partners. The Dscams (from Down syndrome cell adhesion molecule) are Ig-superfamily members important for self-avoidance in developing neurons. *Drosophila* Dscam1 promotes self-avoidance by generating up to 19,008 strongly homophilic isoforms, of which a given neuron expresses 10-50 chosen stochastically. This allows neurites to recognize and actively repel those from the same cell, while still interacting with neighboring cells. Dendritic arbors from Dscam1 mutant neurons exhibit increased self-crossings and self-fasciculation. Similar phenotypes are observed in mice mutant for the orthologous Dscam or Dscaml1 genes, despite the absence of extensive alternative splicing. In the retina, mutant neurons of a given subtype form tight dendritic fascicles and lose

their non-random mosaic spacing as their cell bodies pull into clumps. These clumps are homotypic, indicating that a shared cell-type identity promotes this interaction. In the wild type retina, processes from neurons expressing a single Dscam (either Dscam or Dscaml1) overlap extensively with other cells expressing the same gene, suggesting that normal homotypic avoidance does not involve a strong repulsive mechanism. The C-termini of both DSCAM and DSCAML1 comprise canonical PDZ-interacting domains that interact with members of the MAGI family (membrane associated guanylate kinase inverted). To investigate the functional significance of this interaction, we generated knock-in mice in which the sequences encoding the final ten amino acids were replaced with epitope tags. We found that the C-termini are required for homotypic avoidance in some cell types, but not others. Furthermore, in one cell type DSCAM's C-terminus was required to promote cell body self-avoidance, but not dendrite self-avoidance. We hypothesize that Dscams do not mediate active repulsion of homotypic neurons, but instead mask a cell-type-specific repertoire of cell adhesion molecules (CAMs) that cause fasciculation and cell body clumping when unopposed. In this hypothesis, some CAMs are masked by a DSCAM/MAGI dependent mechanism, and other CAMs can be masked by DSCAM independent of MAGIs. This hypothesis predicts that loss of function of key CAMs along with Dscams will partially rescue the fasciculation. We are testing this masking hypothesis by generating double-mutant mice with Dscam and known CAMs. We are also examining protein-protein interactions and cell-type-specific transcriptomes to identify other candidate members of the proposed adhesion code.

Title: The role of Sox11 in neuronal maturation in the mouse cerebral cortex

Authors: *Y. HOSHIBA[1], T. TODA[1], M. WEGNER[2], S. YANAGI[3], H. TANAKA[3], H. KAWASAKI[1];
[1]Dept. of Med. Neurosci., Kanazawa Univ., Ishikawa, Japan; [2]Inst. for Biochemistry, Univ. of Erlangen, Erlangen, Germany; [3]Sch. of Life Sciences, Tokyo Univ. of Pharm. and Life Sci., Tokyo, Japan

Abstract: Although the maturation of neurons during development is important for neuronal functions, the molecular mechanisms underlying the maturation of neurons are not fully understood. In this study, we examined the role of the transcription factor Sox11 in the maturation of excitatory neurons in the cerebral cortex during development. We found that Sox11 expression was decreased in maturating neurons. Overexpression of Sox11 using *in utero* electroporation suppressed the expression of mature neuron markers and increased the expression of the immature neuron markers. *Sox11*-knockout mice showed enhanced expression of immature neuron markers. We also found that Sox11 overexpression led to the retardation of morphological maturation of neurons. These results suggest that Sox11 inhibits the maturation of post-mitotic neurons in the cerebral cortex during development.

Title: Modulation of dendritic differentiation by dopamine D1 receptor agonists

Authors: K. M. MONEY[1], *G. D. STANWOOD[2];
[1]Neurosci. Grad. Program, [2]Pharmacol., Vanderbilt Univ. Sch. of Med., NASHVILLE, TN

Abstract: Dopamine (DA) receptor signaling modulates the development of normal brain structure and function and is implicated in the pathophysiology of psychiatric diseases including schizophrenia. The striatum and frontal cortex receive significant dopaminergic innervations even prior to synaptogenesis, express high levels of DA receptors, and appear to be involved in

the developmental origins of psychiatric disease. DA receptor activation affects developmental processes in these regions, altering dendritic trajectories *in vivo*, and neurite outgrowth *in vitro*. This regulation appears to depend both on the brain region and receptor subtype activated, suggesting complex neuronal heterogeneity in responses. Using a DA D1 receptor reporter line (Drd1a-tdtomato line 6), we have observed widespread late embryonic [embryonic day 16.5 (E16.5)] expression of the D1 receptor in both frontal cortex and striatum. We therefore designed a series of experiments to assess the effects of D1 receptor stimulation on neuronal differentiation. We prepared neuron-enriched dissociated cell cultures derived from the medial frontal cortex and striatum from E16.5 mice (C57Bl/6). Cultures were grown for several days in the presence and absence of the D1-like receptor agonist, SKF 38393. Neurite outgrowth, branching, and neuronal density were measured with HCA Vision software following immunostaining for specific neuronal markers. Dose-responsive curves were conducted in wildtype cultures, and Drd1a knockout mice were used to confirm D1 receptor-dependence. SKF 38393 induced dose-dependent increases in neurite outgrowth, branching, and cell density. Preliminary data suggests that at least some of these effects are not mediated exclusively by DA D1 receptors. Current studies are evaluating potential roles for "off-target" receptors in mediating the effects, and are testing additional D1-like receptor agonists. Our studies will define the mechanisms through which D1 receptor agonists alter neurite outgrowth and contribute to understanding how the D1 receptor contributes to the development of psychiatric disorders and brain DA homeostasis.

Title: Regulation of dendritic morphogenesis by Miro1-dependent mitochondrial transport

Authors: ***N. F. HIGGS**, A. F. MACASKILL, G. LOPEZ-DOMENECH, J. T. KITTLER; Univ. Col. London, London, United Kingdom

Abstract: The proper intracellular distribution of mitochondria is thought to be critical for normal brain development and function. Correct dendritic development is important for the formation of neuronal circuits. Dendritic arbors form a highly extensive, complex network that cannot be sustained by diffusion of energy from the soma alone. Mitochondria are highly dynamic organelles, important for providing energy, buffering intracellular calcium and playing a role in apoptosis. These organelles must be actively transported and localised within cells to match their energy and calcium buffering requirements, however the role of mitochondrial trafficking for correct neuronal development, and dendritic morphogenesis remain poorly understood. The mitochondrial GTPase Miro1 acts as a critical adaptor protein linking mitochondria to the kinesin and dynein motor proteins, for their microtubule dependent transport along axons and dendrites. We have investigated the role played by Miro1, for regulating mitochondrial distribution and neuronal morphology, in the dendrites of developing hippocampal neurons. Here we show using loss and gain of function approaches that Miro1 is important for correctly distributing mitochondria throughout dendritic processes. We also investigate how this trafficking affects dendritic morphogenesis and the architecture of the dendritic tree and show that the fine tuning of mitochondrial distribution by Miro1 is reciprocally important for correct dendritic development.

Title: Dynamic effects of CXCR4/SDF-1 in neuroblastoma neurite outgrowth

Authors: Y. S. SHAN[1], *C. M. VAN GOLEN[2];
[1]Dept Biol., [2]Asst Professor, Dept Biol, Delaware State Univ., DOVER, DE

Abstract: Neurite formation counts as one of the most important progressions in neuronal development and differentiation. The N-like character of neuroblastoma cells makes them ideal as models for neuritogenesis research. Studies in neuroblastoma suggest CXCR4 has a potential

role in regulating the neurite outgrowth, which is also well involved in neuroblastoma metastasis. Our recent data demonstrates CXCR4 is co-localized with IGF-1R in neuroblastoma cells and modulates neurite extension through actin reorganization, although the underlining mechanism has yet to be clarified. We hypothesize that at low level of SDF-1(ligand of CXCR4), migration is induced for neuroblastoma cells; upon increased activation of the receptor (higher level of SDF-1), CXCR4 is internalized, reducing the amount of receptor on the cell membrane, and the internalized receptor will then interact with actin to increase neurite extension. This will promote neuroblastoma cells to migrate toward favorable conditions, such as higher SDF-1 levels in bone marrow. Once the cells have reached the favorable conditions, they will remain in that environment because of the reduction of CXCR4 on membrane surface. Same progress can take place in neuronal migration in development. By testing the expression level of AKT/p-AKT and ERK/p-ERK using western blot, we were able to test if any downstream signaling pathways were involved during this internalization. Combine treatment of AMD3100 (inhibitor of CXCR4) and SDF-1, we were able to see how neuritogenesis was impact using neurite outgrowth kit and immunofluorescent microscopy. On the other hand, flow cytometry and immunoprecipitation were as well used to examine the CXCR4 expression/localization on the cell surface and if the formation of CXCR4/F-actin complex took place in cytoplasm.

Title: Na+/Ca2+ exchanger 1 (NCX1)Involvement in neuronal differentiation through ca2+-dependent Akt phosphorylation

Authors: A. SECONDO[1], A. ESPOSITO[1], R. SIRABELLA[2], F. BOSCIA[2], A. PANNACCIONE[2], P. MOLINARO[2], M. CANTILE[2], M. SISALLI[2], R. CICCONE[2], C. FRANCO[2], *A. SCORZIELLO[3], G. DI RENZO[2], L. ANNUNZIATO[2];

Abstract: Neuronal growth factor (NGF) induces differentiation of neurons by modulating intracellular Ca2+ ions. However, the role of the three isoforms of the main Ca2+-extruding system, the Na+/Ca2+ exchanger (NCX), in neurite outgrowth remains unexplored. We investigated whether NCX1, NCX2 and NCX3 isoforms could play a relevant role in neuronal differentiation through the modulation of intracellular Ca2+ concentration ([Ca2+]i) and Akt pathway. Here we show that during NGF-induced differentiation (a) NCX1 protein level increased, NCX3 decreased, whereas NCX2 remained unaffected. Moreover, NGF caused a progressive neurite elongation, a significant increase of the well known marker of growth cones GAP-43, an enhancement of endoplasmic reticulum (ER) Ca2+ content, and of Akt phosphorylation; (b) at the same time, NCX total activity increased as measured by Fura 2AM single-cells microfluorimetry, 45Ca2+ uptake and patch-clamp; (c) NCX1 significantly colocalized with Gap-43 in NGF-treated cells; (d) the knocking-down of NCX1 prevented NGF-induced GAP-43 expression and neurite outgrowth; (e) the overexpression of the neuronal splicing isoform of NCX1 (NCX1.4), even in the absence of NGF, induced an increase in Akt phosphorylation and in GAP-43 protein expression; (f) the overexpression of NCX1.4 induced a significant increase in endoplasmic reticulum Ca2+ content measured as ATP- and thapsigargin-induced Ca2+ release; and finally (g) either the [Ca2+]i chelator BAPTA-AM or the PI3'K inhibitor LY 294002 prevented Akt phosphorylation and GAP-43 protein expression rise in neuronal cells overexpressing NCX1. Interestingly, the knocking-down of NCX1 in primary cortical neurons prevented Akt phosphorylation and protein expression of the neuronal markers of differentiation GAP-43 and MAP-2. Collectively, these data showed that NCX1 participates to neuronal differentiation by Akt phosphorylation through the modulation of ER Ca2+ content and PI'3K signaling.

Title: EphA7 guides dendritic morphology and synaptogenesis in cortical neurons

Authors: *C. LEONARD;
Georgetown Univ., Washington, DC

Abstract: Intercellular communication is a critical process that regulates the development of neurons, from migration to synaptogenesis. In order to achieve the proper shape and connections, neurons must interact in a variety of ways to determine their fate. One group of molecules, the Eph receptors and their ephrin ligands, play versatile roles in development. EphA7, in particular, has been shown to influence parcellation of brain structures, retinotectal axon guidance, and topographic mapping between the cortex and thalamus. The role of EphA7 in dendritic arborization and synaptogenesis, however, is only beginning to be understood. Our lab demonstrates that EphA7 is required for multiple stages of cortical neuronal maturation. Analysis of EphA7 mRNA and protein expression show EphA7 is present in the cortical plate during embryonic development. At this time, the ligand ephrin-A5 is also expressed in the cortical plate, indicating potential interactions between EphA7 and ephrin-A5. When EphA7 is absent from cortical neurons *in vitro*, dendrites can no longer avoid ligand ephrinA5, resulting in altered cell shape. *In vitro* experiments reveal that when EphA7 is ectopically expressed in cultured neurons, dendrites are shorter and less complex compared to controls, while mice mutant for EphA7 have neurons with longer and more complex dendrites *in vivo*. These results suggest EphA7 and ephrin-A5 interactions regulate dendritic arborization in the cerebral cortex. Furthermore, EphA7 is necessary for the formation and function of excitatory synapses in the cortex. *In vitro* and *in vivo* analyses reveal that neurons lacking EphA7 have fewer mature postsynaptic markers and fewer dendritic spines compared to wildtype neurons. Additionally, electrophysiological recording from cultured cortical neurons demonstrates that neurons lacking EphA7 exhibit delayed maturation of synaptic function compared to wildtype neurons. Together these data suggest that EphA7 is necessary early for proper restriction of dendritic arbors and later for formation and function of excitatory postsynaptic sites. To our knowledge, this is the first evidence of dendrite-specific roles for EphA7 during neuronal maturation.

Ctr. for Child Mental Development, Univ. of Fukui, Fukui, Japan

Abstract: The cytoskeleton and its binding partners such as nonmuscle myosin IIB are essential components in the control of neuronal spine morphology. We previously reported that Filamin A-interacting protein (FILIP) binds to nonmuscle myosin IIB and changes its subcellular localization, from actin fibers to the cytosol, and the presence/absence of FILIP affects spine morphology. We studied how and what region of FILIP involved in these activities. We then identified binding partners of FILIP by using COS-7 cells and studied the effects of the binding partners on FILIP function in primary cultured hippocampal and piriform cortex neurons. We found that one chaperone protein bound to the FILIP C-terminal region, and was responsible for the FILIP-mediated change in intracellular localization of nonmuscle myosin IIB. Indeed, an inhibitor of this chaperone protein influenced FILIP-induced morphological changes in neuronal spines. Therefore, it is likely that this chaperone protein promotes FILIP-myosin IIB activity over FILIP-mediated morphological changes to spines. All experiments were conducted in accordance with the Regulations for Animal Experimentation of Hyogo College of Medicine.

Title: FLNA overexpression contributes to abnormal dendritic patterning in tuberous sclerosis complex

Authors: *L. ZHANG[1], C. M. BARTLEY[2], X. GONG[1], L. S. HSIEH[1], T. V. LIN[1], A. BORDEY[1];
[1]Neurosurgery, and Cell. & Mol. Physiol., [2]Neurobio., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Abnormal dendritic complexity is a shared feature of many neurodevelopmental disorders associated with neurological defects. Here, we identified a novel role for the actin-crosslinking protein filamin A (FLNA) in normal dendritogenesis and its contribution to dendritic dysmorphogenesis in tuberous sclerosis complex (TSC), a disorder of the PI3K-mTOR pathway. Both knockdown and overexpression of FLNA in wild type neurons *in vivo* led to a more complex dendritic arbor, suggesting that an optimal FLNA level is required for normal dendritogenesis. In TSC, loss-of-function mutations in Tsc1 or Tsc2 leads to neuron enlargement with increased dendritic complexity. In Tsc1null neurons short-hairpin RNA against FLNA normalized FNA levels and prevented abnormal dendritic arborization. In addition, decreasing FLNA levels in Tsc1null neurons restored the frequency of their synaptic currents consistent with dendritic normalization although resting membrane potentials and membrane resistance were not normalized. These data demonstrate that altered FLNA expression increases dendritic complexity and contributes to pathologic dendritic patterning in TSC.

Title: Activity-Dependent regulation of dendrite dynamics in developing *Drosophila* larval visual circuit

Authors: C. SHENG, J. YIN, C. LONG, D. TANG, *Q. YUAN;
NIH/NINDS, Bethesda, MD

Abstract: Neuronal plasticity accompanying development and experience-dependent processes facilitates the establishment and refinement of the nervous system, while presenting significant challenges to the functional stability of the neural networks. The nervous system uses a variety of compensatory mechanisms to cope with perturbations. Recent studies suggested that structural plasticity serves as a major component for neuronal homeostasis. Our previous studies have demonstrated experience-dependent plasticity in the developing *Drosophila* larval visual circuit, in which ventral lateral neurons (LNvs), the postsynaptic targets of larval photoreceptors, exhibit robust structural plasticity of their dendritic arbors when animals are subjected to different visual experience. These observations also established a genetically tractable model system for mechanistic studies on the activity-dependent regulation of developmental plasticity. To analyze the change of neuronal morphology with high spatial and temporal resolutions, we carried out two-photon live imaging of LNvs in the developing larval brain. We observed fast structural dynamics of dendritic arbors, which was strongly influenced by the visual experience of the animals and their developmental stages. In addition, to identify genetic factors involved in the activity-dependent regulation of dendrite morphology, we carried out non-biased genetic screens and cell type specific manipulations. Our study identified activity-dependent distribution of a synaptic cell adhesion molecule babos/CG3624 as a critical component involved in the regulation of dendrite dynamics. These findings provided evidences for novel cellular and molecular mechanisms underlying homeostatic structural plasticity in the developing central nervous systems.

Title: Regulation of dendrite and spine growth by a novel transducible protein mLLP

Authors: *N.-K. YU, B.-K. KAANG, H. KIM, J. SHIM, S. KIM;
Dept. of Biol. Sci., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Various transcriptional regulators are involved in neuronal morphogenesis and development. We report here that mLLP, a mouse homolog of ApLLP which was previously shown to be a transcription factor facilitating synaptic plasticity in *Aplysia* neurons, is a nuclear protein interacting with transcriptional regulators and can promote dendritic growth, spinogenesis, and synaptic transmission. mLLP protein can be internalized into cells when extracellularly applied and can affect the dendritic arborization. These data suggest a regulatory role for neural development by a novel transducible nuclear protein mLLP.

Title: Mutant SPT-dependent activation of ERM proteins mediates altered growth dynamics in sensory neurons: Implications for HSAN1

Authors: *B. JUN, A. CHANDRA, F. EICHLER;
Neurol., MGH, Boston, MA

Abstract: The enzyme serine palmitoyltransferase (SPT) is responsible for the first and rate-limiting step in the de novo synthesis of sphingolipids, namely the condensation of L-serine and palmitoyl-CoA. Mutations in the SPTLC1 gene encoding a subunit of SPT have been shown to cause hereditary sensory and autonomic neuropathy type I (HSAN1). Mutant SPT exhibit a shift in enzymatic specificity from the canonical amino acid substrate L-serine, to the alternative L-alanine. The effects of altered sphingolipid metabolism due to SPT mutation, and availability of SPT substrates upon the development of sensory neurons remain unknown. Recently, ERM (ezrin/radixin/moesin) cytoplasmic scaffolding proteins have been implicated in neurite guidance and cytoskeletal reorganization (Marsick et al., 2012a,b). Here, we show that dorsal root ganglia (DRG) isolated from transgenic SPTLC1C133W mice have increased neurite length and branching compared to wild-type. In addition, wild-type DRG displayed a similar increase in branching following L-alanine supplementation. The aberrant morphology observed in both the mutant DRG and L-alanine supplemented wild-type DRG occurred in conjunction with increased expression of phosphorylated-ERM proteins. However, as inhibition of SPT and sphingosine kinase (SphK), key enzymes in sphingolipid metabolism, diminished the aberrant morphology and pERM expression in those conditions, we cannot rule out that metabolites downstream of SPT could mediate its effects upon neuronal development.

Title: βPix heterozygote mice ($\beta Pix^{+/-}$) exhibit reduced dendritic spine formation and also defects in social behavior

Authors: Y. KWON[1], T. KANG[1], D. KIM[2], *D.-E. PARK[1];
[1]Sch. of Biol. Sci., Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Dept. of Biol. Sci., KAIST, Daejeon, Korea, Republic of

Abstract: βPix (Pak interacting exchange factor) is a guanine nucleotide exchange factor (GEF) for Rho family small GTPases, Rac1 and Cdc42. It has been implicated in the modulation of diverse cellular events such as remodeling of actin cytoskeleton, regulation of focal adhesion dynamics, and cell migration. To investigate the role of βPix *in vivo,* we have generated βPix knock-out mouse. βPix null ($\beta Pix^{-/-}$) mouse was early embryonic lethal at E8.5. At E8.5, $\beta Pix^{-/-}$ embryos exhibited a significant developmental delay and were smaller in size compared to wild-type littermates. $\beta Pix^{-/-}$ embryos have several defects, lack of chorion-allantoic fusion, deficient axial rotation, and impaired closure of the cephalic neural folds. In contrast, the heterozygote mice ($\beta Pix^{+/-}$) that exhibit a reduced level of βPix expression were viable and apparently normal. However, Golgi staining of brain sections revealed that the spine density of basal dendrites in hippocampal CA1 region was decreased and the extent of dendritic branching was also somewhat reduced compared to those of wild-type littermates. In behavioral analysis, the $\beta Pix^{+/-}$ mice showed a defect in social preference test. These results indicate that βPix plays essential roles in early embryonic development, thus resulting in embryonic lethality of $\beta Pix^{-/-}$ mice. In addition, the expression level of βPix is also important for normal brain development, thus resulting in the reduced spine density and dendritic branching that may cause defects in social behavior of $\beta Pix^{+/-}$ mice.

Title: Exploration of two different compensatory strategies for recovery from injury in the adult cricket CNS

Authors: *H. W. HORCH[1], L. SAIDENBERG[1], M. CHONG[1], B. FIORILLO[1], J. VERGARA-BENITEZ[1], A. ZHANG[1], A. PFISTER[2], O. ELLERS[1], A. JOHNSON[1];
[1]Bowdoin Col., BRUNSWICK, ME; [2]American Museum of Natural History, New York, NY

Abstract: The consequences of injury in adult central nervous systems (CNS) are often devastating and irreversible. The CNS of the cricket is unusual in that it is capable of compensatory plasticity after injury as demonstrated by deafferentation-induced compensation in two different sensory systems. Unilateral deafferentation of the auditory neurons of the prothoracic ganglia induces these cells to send dendrites across the midline, a boundary they typically respect, to form synapses with contralateral auditory afferents. In contrast, injury to the cercal escape system shows an entirely different type of recovery, consisting mainly of physiological instead of structural reorganization. Past experiments have shown that the morphological compensation of the adult auditory system is remarkably precise, reinstating interneuron-specific tuning curves within several days. Careful anatomical analysis indicates that female dendrites branch rapidly once across the midline but then stop adding branches by about 5 days. Male dendrites, in contrast, are slower to add branches once across the midline, but extend, on average, twice as many branches as female dendrites after several weeks. Auditory axons from the contralateral, intact side, also extend additional branches from processes that have crossed the midline, though there is no sexual dimorphism. Are there specific protein candidates that correlate with recovery in either of these two systems? Initial results indicate that semaphorins 1 and 2a may differentially correlate with the different strategies employed in these two systems. Expression of sema1 and sema2a were examined using *in situ* hybridization, Q-PCR , and immunohisotochemistry. In addition, we explore a causative role for these semaphorins by blocking this deafferentation-induced upregulation in sema levels, via dsRNA injections in adult animals, and examining recovery. Our findings indicate that changes in the expression levels of semaphorins after deafferentation may play important differential roles in the deafferentation-induced plasticity seen in these two systems.

Title: miR-125b mediated filopodial dynamics in developing dendrites

Authors: *R. IYER[1], T. KIM[2], G. POPESCU[2], M. U. GILLETTE[1];
[1]Cell and Developmental Biol., [2]Electrical & Computer Engin., Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: Neuronal dendrites possess a complex dendritic arbor, which in large part gives rise to the intricate circuitry found in the nervous system. The establishment of this arbor is a result of the interplay between intrinsic cellular machinery of neurons and external stimuli, allowing dendrites to find their intended axonal partners. However, the identity, localization, and function of this intrinsic cellular machinery is not well understood. Small noncoding RNAs around 22 nucleotides long, called microRNAs (miRNAs), serve as post-transcriptional regulators of gene expression. Recent studies have pointed to localized populations of miRNAs as putative computational integrators that help translate stimuli sensed by dendritic filopodia into appropriate decisions on protein expression. This enables local, rapid decision-making in dendrites, a key requirement to navigate the spatio-temporally variant signals they receive. Here we investigate the brain-abundant miRNA, miR125b, for its role in dendrite development. miR125b has been shown to be maximally expressed at the developmental period corresponding to filopodial outgrowth in dendrites. Overexpression of this miRNA in cultured neurons leads to longer, more filopodia-like spines along dendrites. To study the role of miR125b during development, we inhibit its activity in cultured hippocampal neurons from rat during various developmental milestones as dendritic filopodia explore their microenvironment and give rise to dendrite branches and spines. Using a combination of confocal microscopy and high-resolution image analysis, we study the effect of miR125b inhibition on filopodial structure and density as well as dendritic outgrowth. To understand the effect of miR125b in the dynamics of filopodia, we use an innovative imaging technique, Spatial Light Interference Microscopy (SLIM), an interferometry-based label-free, live imaging system that has topographic accuracy comparable to atomic force microscopy (Wang et al, Opt Express, 2011). Using SLIM, we characterize the rate of filopodial extension and retraction compared with stability in response to miR125b inhibition. These high-resolution analyses reveal fresh insights into the process by which neurons integrate multiple external signals to establish the appropriate connections. Such insights are critical to understanding the implicated role of miR125b in neurological disorders such as Fragile X Syndrome and Alzheimer Disease.

Title: CREB signaling affects survival and differentiation of immature neurons

Authors: ***T. SANTANA**, M. *COSTA;
UFRN, Natal, Brazil

Abstract: Introduction Cortical development demands appropriate proliferation, migration and differentiation of newly formed neurons in order to achieve the formation of a functional network. Dendritic branching defines the functionality of the cell and the efficiency of information transmission. CREB mediated transcription is an important mechanisms to control activity-dependent dendritic morphology development and neuronal. Here, we show that CREB also plays a role in these phenomena in early post-mitotic neurons, likely prior establishment of synaptic contacts. **Materials and Methods** Primary cerebral cortex cultures were derived from dorsolateral telencephalon of E14 embryos. Dissociated cells were plated at a density of 5×10^5 cells per well in a 24-well plate onto poly-D-lysine-coated glass coverslips in DMEM (10% FCS, 1% penicillin/streptomycin). Infection was performed 2 h after plating using retroviruses containing either the GFP, A-CREB (negative dominant of CREB) or CREB-FY (constitutively activated form of CREB) plasmid. 24 h after plating serum was decreased to 5 % by adding DMEM/B27. Phase contrast images were acquired every 2 minutes for 84 h (37°C, 5% CO2) for time-lapse video microscopy and single-cell tracking was performed using a computer program (TTT). After 7 div, cells were fixed in 4% PFA and processed for immunohistochemistry using antibodies against GFP and MAP2. Morphological analysis were done using ImageJ (v. 1.46e) and NeuronJ (v. 1.4.2) plugin. **Results** A-CREB significantly decreased (41%) the total length of neuronal processes. A-CREB also decreased significantly the total number of neuronal processes, probably due to reduction in the number of ramifications, once the number of primary neurites remains similar between groups. A-CREB decreased the number of bifurcations in 36%, although CREB-FY didn't increase values over control level. Expression of A-CREB leaded to a significant decrease in neuronal survival from 60 h on. Our

data indicate that signaling through CREB influences the morphology and survival of early post-mitotic cortical neurons prior establishment of fully functional synaptic contacts.

Title: Social anxiety and the dynorphin/kappa opioid system during withdrawal from repeated ethanol: Impact of age and sex

Authors: ***T. L. DOREMUS-FITZWATER**, E. M. TRUXELL, E. I. VARLINSKAYA; Psychology, Binghamton Univ., Binghamton, NY

Abstract: Although adolescents are primarily insensitive to a number of acute alcohol effects, accumulating evidence suggests that they may be unusually vulnerable to adverse consequence of repeated alcohol exposure later in life, with the emergence of anxiety disorders being one of these consequences. However, less is known regarding the more immediate impact of repeated ethanol exposure during adolescence. Thus, the present study was designed to assess social anxiety-like behavioral alterations in adolescent and adult male and female Sprague-Dawley rats shortly after termination of repeated ethanol exposure. Adolescent (P28-34) and adult (P63-69) rats were given ethanol (3.5 g/kg, 25% v/v in tap water; intragastrically) once-daily for 7 days, with controls receiving an isovolumetric amount of water. Animals were then tested in a modified social interaction test 48 hr after the final exposure, and social anxiety-like behaviors were indexed via decreased social investigation and/or social preference. Immediately after testing, trunk blood and brains were collected. Behavioral results demonstrated that adolescent males, but not their female counterparts, exposed to repeated ethanol exhibited pronounced social anxiety, as evident by significant decreases in both social investigation and social preference. Adult females exposed to ethanol also demonstrated social anxiety, but only when

indexed via social preference. In contrast, adult males were resistant to the social anxiogenic effects of ethanol withdrawal under these test circumstances. As age- and sex-related differences in the dynorphin/kappa opioid system are likely contributors to ethanol's effects on social anxiety-like behavior, a preliminary assessment of opioid-related gene expression in the anterior cingulated cortex (ACC) was conducted. While previous results demonstrated that adolescent animals non-manipulated prior to the social interaction test (or exposure to the test context) exhibited significantly lower preprodynorphin (PPD) gene expression than adults, in the current study, PPD gene expression was substantially higher in adolescents relative to adults. Furthermore, ethanol-exposed adolescent males demonstrated a trend for higher PPD gene expression than their water-exposed counterparts. Taken together the present results suggest that adolescent males are most sensitive to the detrimental effects of withdrawal from repeated ethanol under social test circumstances, with future studies needed to further investigate the role of the dynorphin/kappa opioid system in this vulnerability.

Title: Contribution of alpha-7 nAChR tone in sustaining the gain of GABAergic transmission in the adult prefrontal cortex

Authors: D. R. THOMASES[1], E. FLORES-BARRERA[1], J. P. BRUNO[2], R. SCHWARCZ[3], *K.-Y. TSENG[1];
[1]Cell & Molec Pharmacol, RFUMS/Chicago Med. Schl, NORTH CHICAGO, IL; [2]2Departments of Psychology & Neurosci., The Ohio State Univ., Columbus, OH; [3]Dept. of Psychiatry, Maryland Psychiatric Res. Center, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The functional maturation of GABAergic circuits in the prefrontal cortex (PFC) during the adolescent transition to adulthood is one key mechanism for enabling proper prefrontal processing of ventral hippocampal afferent information and for supporting PFC-dependent cognitive functions. It is thought that a dysregulation of such GABAergic control of PFC response underlies the adolescent onset of cognitive deficits in a variety of psychiatric disorders including schizophrenia (SZ). Thus, further understanding of the mechanisms contributing to the initiation and maintenance of proper GABAergic inhibition in the PFC is a critical step towards restoring normal cognition in SZ and related psychiatric syndromes. Here the role of alpha-7 nicotinic acetylcholine receptor (nAChR) regulation of PFC response to ventral hippocampal train stimulation (10, 20 & 40Hz) was assessed by means of local field potential (LFP) recordings combined with local infusions of selective antagonists *in vivo*. Results showed that single prefrontal infusion of 300nM kynurenic acid (KYNA; a tryptophan metabolite known to preferentially block alpha-7 nAChR activity) was sufficient to induce a state of frequency-dependent disinhibition in the adult PFC that resembles the pattern of response resulting from local GABAergic blockade. A similar pattern of LFP disinhibition was found following local prefrontal infusion of the alpha-7 nAChR antagonist MLA (300nM), suggesting that alpha-7 nAChR tone in the PFC is required to enable the normal prefrontal GABAergic response to ventral hippocampal drive. Patch-clamp recordings in adult PFC brain slices further support this view, as the frequency of GABAergic synaptic activity onto layer V pyramidal neurons is positively regulated by local alpha-7 nAChR tone. Accordingly, the frequency-dependent LFP deficit induced by KYNA or MLA was not longer observed when the GABA-A alpha-1 positive allosteric modulator Indiplon (10uM) was co-administered into the PFC *in vivo*. Together, these results indicate that an upregulation of prefrontal alpha-7 nAChR tone could play an essential role in sustaining the increasing functional capacity of GABAergic transmission in the PFC during the adolescent transition to adulthood.

Title: Adolescent, but not adult, binge ethanol exposure leads to persistent global reductions of choline acetyltransferase expressing neurons in brain

Authors: *R. P. VETRENO[1], M. BROADWATER[2], W. LIU[3], L. SPEAR[2], F. CREWS[3]; [1]Sch. of Med., Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; [2]Ctr. for Developmental and Behavioral Neurosci., Binghamton Univ., Binghamton, NY; [3]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: During the adolescent transition from childhood to adulthood, notable maturational changes occur in brain neurotransmitter systems. The cholinergic system is composed of several distinct nuclei that exert neuromodulatory control over cognition, arousal, and reward. Binge drinking and alcohol abuse are common during this stage, which might alter the developmental trajectory of this system leading to long-term changes in adult neurobiology. Experiment 1 tested the hypothesis that adolescent intermittent ethanol (AIE; 5.0 g/kg, i.g., 2-day on/2-day off from postnatal day [P] 25 to P55) leads to persistent, global reductions of choline acetyltransferase (ChAT) expression, an enzyme critical for acetylcholine synthesis. Immunohistochemical analysis found that AIE reduced ChAT-immunoreactive (+IR) cells in the basal forebrain that persisted from late adolescence (P56) into later adulthood (P220). In addition to the basal forebrain, ChAT+IR was decreased in cholinergic nuclei of the hindbrain and striatum of young adult (P80) rats exposed to AIE. To determine if the binge ethanol-induced ChAT decline was unique to the adolescent, Experiment 2 examined ChAT+IR in the basal forebrain following adolescent (P28 - P48) and adult (P70 - P90) binge ethanol exposure. Twenty-five days later, ChAT expression was reduced in adolescent, but not adult, binge ethanol-exposed animals. Administration of the Toll-like receptor 4 agonist lipopolysaccharide to young adult rats (P70) produces a similar reduction in ChAT+IR that mimicked AIE, but did not further reduce ChAT+IR after AIE exposure. Together, these data suggest that adolescent binge ethanol decreases adult ChAT expression, possibly through neuroimmune mechanisms, which might impact adult cognition, arousal, or reward sensitivity.

Title: Adolescent alcohol exposure decreases gabaa receptor mediated currents in the adult medial prefrontal cortex

Authors: *S. CENTANNI[1], H. TRANTHAM-DAVIDSON[2], J. CHANDLER[2];
[1]Neurosci., [2]Med. Univ. of South Carolina, Charleston, SC

Abstract: During adolescence, the prefrontal cortex (PFC) undergoes a critical period of cortical development and refinement of neuronal circuits that occurs in conjunction with the maturation of complex cognitive behaviors. Although accumulating evidence suggests that binge-like alcohol consumption during adolescence adversely affects the development of the PFC, little is known about the long-term consequences of this on PFC-dependent behaviors in adulthood. The goal of the current study was to investigate the effect of adolescent alcohol exposure (AIE) on the adult GABAergic system in the PFC. Whole-cell patch clamp recordings from prelimbic PFC (PrL-PFC) layer V pyramidal neurons was performed in slices obtained from adult rats (PD90-120) that had been subjected to 4 cycles of AIE exposure by vapor inhalation between PD28-42. Litter-matched controls received sham exposure. We observed no differences in paired-pulse ratio or sIPSC frequency in slices from AIE treated rats relative to controls. In contrast, AIE exposure resulted in a significant decrease in spontaneous IPSC (sIPSC) amplitude suggesting AIE alterations in postsynaptic $GABA_AR$. Miniature IPSC amplitude and frequency were unaffected suggesting that the observed reduction in sIPSC amplitude may not be a result of synaptic $GABA_AR$, but rather those $GABA_AR$ located outside of the synapse. Next, we isolated the tonic $GABA_A$ current by measuring the holding current at -70mV in the presence and absence of the $GABA_AR$ antagonist picrotoxin (100 μM). Tonic current amplitude was significantly attenuated in AIE-exposed rats relative to controls in adulthood and at PD45 and PD60. Furthermore, pharmacological stimulation of the exclusively extrasynaptic ∂-$GABA_AR$ using the selective agonist THIP (1μM) revealed that AIE exposure significantly reduced the currents specifically mediated by $GABA_ARs$ containing the ∂ subunit. Preliminary data suggests

that the effect of AIE on the ∂-$GABA_A$R-mediated currents evident in adulthood is not present at PD45 or PD60. Additionally, AIE had no effect on total ∂-$GABA_A$R expression or surface expression of ∂-$GABA_A$R in the adult mPFC. These findings suggest that AIE significantly compromises $GABA_A$R mediated tonic currents immediately after AIE exposure and continuing on into adulthood. Moreover, preliminary evidence suggests that the major contribution of specific $GABA_A$R subunits underlying the reduction in tonic current may differ between adolescence and adulthood. The net consequence of AIE on the GABAergic system in the mPFC may negatively impact cognitive functioning in the adult by disrupting the balance of excitatory-inhibitory neurotransmission in the mPFC.

Title: Adolescent intermittent alcohol exposure (AIE) alters adult HPA axis responses to an alcohol challenge

Authors: *S. O. LEE[1], S. IM[2], S. BAE[2], J. HONG[2], J. VAUGHAN[2], C. RIVIER[2], E. VUONG[2], M. L. LOGRIP[2,3];
[2]The Clayton Fndn. Labs. for Peptide Biol., [1]Salk Inst., La Jolla, CA; [3]Committee on the Neurobio. of Addictive Disorders, The Scripps Res. Inst., La Jolla, CA

Abstract: The hypothalamic-pituitary-adrenal (HPA) axis undergoes critical developments during adolescence. As a result, stressors experienced during this period potentially have long-lasting effects on the adult HPA axis function. We investigated the effects of adolescent intermittent ethanol (AIE) exposure in rats on the response to acute stress challenges in adulthood. We hypothesized that AIE would have long-lasting effects on the adult HPA axis, resulting in altered responses to an alcohol challenge or physico-emotional stressors, such as shocks or restraint. To test these hypotheses, male rats were exposed to alcohol vapor for 6 h per day from PND 28-42 (AIE), then acutely challenged with alcohol intragastrically (4.5 g/kg, ig), shocks (0.3mA, 1 sec, 2 shocks/min, 30 min) or restraint (15 min) on PND 70-71 or PND 90-91.

As previously reported, we observed blunted HPA axis responses to alcohol challenge due to AIE. Specifically, AIE tended to inhibit the alcohol challenge-induced plasma corticosterone (cort) levels and expression of CRF mRNA in the paraventricular nucleus (PVN) of PND 70-71 male rats, while AIE significantly blunted the alcohol challenge-induced plasma cort levels and elevation of AVP mRNA in the PVN of PND 90-91 male rats. Previously we have shown that these changes in PVN responsiveness may result from AIE-induced alterations in adrenergic neurons in brainstem regions C1-C3 known to project to the PVN. AIE elevated the numbers of PNMT-positive cell bodies in the C2 region of males on PND 70-71, while AIE increased PNMT-positive cell numbers in the C1 regions of males on PND 90-91. Unlike the alcohol challenge responses, no differential modulation of plasma cort or CRF/AVP mRNA levels was observed after shock or restraint challenges in AIE vs. control rats. Brainstem regions C1-C3 were also unchanged in response to the shock challenge at PND 70-71 and PND 90-91. Together, this data suggests that adolescent alcohol exposure produces alterations in HPA axis responsiveness to administration of an acute alcohol challenge that may be very long-lasting and stress-specific.

Title: Adolescent nicotine exposure induces binge ethanol consumption and nAChR density increases in the reward pathway

Authors: *A. R. REVITSKY[1], M. J. MARKS[2], L. C. KLEIN[1];
[1]Neurosci., The Pennsylvania State Univ., State College, PA; [2]Inst. for Behavioral Genet. and Dept. of Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: Despite the deleterious effects resulting from cigarette use almost 20% of the U.S. adult population currently smokes tobacco, and 80% of adult smokers begin smoking during adolescence (CDC, 2011; USDHHS, 1994). Adolescents consume ethanol more than any other drug of abuse, and binge drinking among teens has become increasingly popular over the years (CASA, 2011; SAMHSA, 2002). Nicotine and ethanol activate the mesolimbic dopamine pathway and increase synaptic dopamine levels in the nucleus accumbens, in part through stimulation of nicotinic acetylcholine receptors on dopamine neurons in the ventral tegmental area (Blomqvist et al., 1997; Corrigall et al., 1994). Because of the way these drugs affect the reward pathway, and the fact that the adolescent brain undergoes extensive psychological development and gross neuroanatomical changes during this developmental period, adolescent use of these two drugs is particularly concerning (Spear, 2000). Thus, it is necessary to investigate reward-related outcomes and potential neurobiological underpinnings that result from exposure to nicotine and alcohol in adolescence, especially in females where rates of use for both these drugs are increasing (CASA, 2011; Pogun & Yararbas, 2009). Twenty- six adolescent female mice were exposed to either water (n=12) or nicotine (n=14) via an oral administration paradigm (200ug/ml) for 7 days. All mice were exposed then to a 4-day drinking in the dark protocol. Adolescent mice exposed to nicotine consumed a significantly more ethanol (g/kg) and displayed higher blood ethanol concentrations than control mice [$Fs(1,25) \geq 4.21$]. Autoradiographic analysis of nAChR density in regions of the brain reward pathway revealed higher levels of epibatidine binding in frontal cortical regions in mice exposed to nicotine compared to control [$Fs(1,25) \geq 2.05$]. Additionally, BEC was a significant positive predictor of α–bungarotoxin binding in the cingulate cortex, striatum, and dorsal tegmental area [$\beta s \geq 0.47$]. Overall, findings from this study suggest that nicotine exposure during adolescence may increase subsequent binge ethanol consumption through increased activation of the brain reward pathway as indexed by increases in nAChR density. Additionally, ethanol may play a significant role in modulating activating of reward pathway through stimulation of these nAChRs in several reward pathway brain regions.

Title: The interaction of nicotine and stress during adolescence on long-term impairments on a hippocampus-dependent task

Authors: *E. HOLLIDAY[1], S. LOGUE[2], T. GOULD[2];
[1]Temple Univ., Philadelphia, ; [2]Temple Univ., Philadelphia, PA

Abstract: Despite the known risks associated with tobacco use and decline of tobacco consumption in the last 50 years, nearly 1 in 5 people in the United States are everyday smokers. One reason for the steadfast smoking prevalence rates is adolescent smoking. In rodent models, nicotine treatment during adolescence leads to impairments in hippocampus-dependent tasks later in life. Adult mice under the same treatment conditions do not display long-term cognitive impairments. The results from this study suggest that these long-term impairments result from an interaction between stress and nicotine during adolescence. This study examined the interaction of stress and nicotine in adolescent (p38) and adult (p54) C57BL/6 mice that were either shipped from an animal facility in Maine to our animal facility in Philadelphia (STRESS) or bred in our animal facility (NO STRESS). All animals were implanted with osmotic mini-pumps to deliver 12.6mg/kg of nicotine per day for a period of 12 days, at which time the pumps were removed. Thirty days later animals were trained and tested in our contextual fear conditioning paradigm. Only adolescent animals shipped in and administered nicotine showed long-term impairments. Additionally, blood was collected from animals not designated for behavioral tasks and serum was used for corticosterone analysis. Only adolescent animals in the shipped condition showed elevated levels of corticosterone. Non-shipped adolescents, non-shipped adults, and shipped adults all displayed similar concentrations of corticosterone. This study suggests stress and nicotine interact during adolescence, leading to long-term cognitive changes. These changes may broadly impact

Title: Effects of adolescent caffeine consumption on anxiety behaviors, plasma corticosterone, and neural activity

Authors: J. STAFFORD[1], C. E. O'NEILL[1], R. J. NEWSOM[1], S. C. LEVIS[1], T. SCOTT[1], *R. K. BACHTELL[2];
[2]Dept. of Psychology & Neurosci., [1]Univ. of Colorado, BOULDER, CO

Abstract: Caffeine is the most commonly used psychoactive substance worldwide, and consumption by children and adolescents has risen dramatically in recent years. Previous studies have found that energy drink use is associated with anxiety young adult males, and can induce panic attacks in patients diagnosed with panic disorder. These experiments examine the effects of adolescent caffeine consumption on anxiety related behaviors, basal and stress-induced plasma corticosterone (CORT), and stress-induced c-*fos* mRNA expression. Beginning on post-natal day 28 (P28), Sprague-Dawley rats consumed caffeine (0.3 g/L) for 28 days (P28-55). Age-matched control rats consumed water. Caffeine and water consumption were monitored throughout the procedure, with no significant differences between groups on fluid consumption or body weight gain. Following 28 days of caffeine consumption, the caffeine solution was replaced with water for the remainder of the experiment. Behavioral testing occurred at three different time points: during caffeine exposure (P52-55), short-term withdrawal (24 hrs) from caffeine (P56), and long-term withdrawal (1 week) from caffeine (P62-66). Animals exposed to caffeine during adolescence exhibited increased anxiety in the open field at both withdrawal time points, 24 hrs and 1 week post caffeine, but not during the caffeine exposure. Chronic adolescent caffeine consumption also decreased social interaction with age-matched conspecifics at both short- (24 hr) and long-term withdrawal (1 week), but not during caffeine exposure. Finally, caffeine-exposed rats demonstrated increased anxiety on an elevated plus maze at all three time points. Because systemic caffeine administration has been shown to increase plasma CORT levels, we examined the effect of adolescent caffeine consumption on basal and stress-induced CORT levels during caffeine withdrawal. Animals exposed to caffeine had increased plasma CORT at the circadian trough, however no differences were observed at the circadian peak. Stress-induced CORT was measured 30 min after animals were placed on a small pedestal elevated 2 feet off the ground for 5 minutes. Stress-induced CORT was significantly lower in animals exposed to caffeine during adolescence. Together these findings suggest that adolescent caffeine consumption alters emotional reactivity using behavioral and neuroendocrine measures. We are currently processing the tissue to examine stress-induced c-*fos* mRNA expression in several stress-responsive brain areas including the frontal cortex, the extended amygdala, lateral septum, and hypothalamic regions.

Title: Alterations in neuronal nitric oxide synthase in the hippocampus of female adolescent rats exposed to repeated ethanol administrations

Authors: I. KARPICHEV, L. MALAVE, S. CAIN, S. KRONENBERG, *R. SIRCAR;
The City Col. of New York, NEW YORK, NY

Abstract: Earlier, we have reported that ethanol impairs spatial learning and memory in adolescent female rat, and that the N-methyl-D-aspartate (NMDA) receptor is involved in mediating ethanol-induced memory deficits. In the brain activation of the NMDA receptor by stimulating the enzyme neuronal nitric oxide synthase (nNOS), produces nitric oxide (NO). NO has been shown to be important in synaptic plasticity, and learning and memory. Increasing evidence indicates that NO is involved in many of ethanol's effects such as ethanol consumption, ethanol tolerance, and ethanol withdrawal symptoms. The present study was undertaken to investigate the effects of ethanol exposure on hippocampal NOS in adolescent rats. Female adolescent rats were treated with ethanol (2 g/kg, i.p.) for five consecutive days. Animals were sacrificed at specific time points following ethanol administration, their hippocampi removed and frozen. Control rats received equivalent volumes of vehicle for the same number of days and sacrificed along with the ethanol-treated rats. Levels of nNOS in hippocampal lysates were measured using western blot analysis. The results showed that ethanol-treated adolescent female rats exhibited increased levels of hippocampal nNOS. These data indicate that hippocampal nNOS may be important in mediating some of the cognitive impairing effects of ethanol in adolescent rat.

Title: Intermittent ethanol exposure during adolescence: Effects on stress-induced social alterations in adulthood

Authors: *E. I. VARLINSKAYA, E. M. TRUXELL, L. P. SPEAR;
Dept Psychol, Binghamton Univ., BINGHAMTON, NY

Abstract: Binge patterns of alcohol consumption are common in human adolescents and may contribute to alcohol-related and affective problems later in life, with exposure to different stressors further exacerbating these alterations. Using a rat model of adolescence, we have shown long-lasting and sex-dependent detrimental consequences of repeated exposure to ethanol during the juvenile-early adolescent period. Males, but not females, demonstrated social anxiety-like behavioral alterations, indexed via significant decreases in social investigation and social preference when tested as adults. The present study was designed to assess whether the social anxiety-like behavior associated with adolescent intermittent ethanol (AIE) exposure can be further exacerbated by exposure to a stressor later in life. Adolescent male and female Sprague-Dawley rats were exposed intragastrically to ethanol (3.5 g/kg, 25% solution in tap water) or an isovolumetric amount of water every other day between postnatal days (P) 25-45, for a total of 11 exposures. Three weeks following AIE half of the animals from each adolescent exposure condition were restrained (stress condition) for 90 min/day for 5 days (P66-P70), whereas the other half remained non-stressed. Social behavior and social preference were assessed 30 min following the offset of the stressor on the last exposure day (P70, immediate stress effects) as well as 7 days following exposure to restraint (P77, delayed effects) in a modified social interaction test under familiar circumstances. Non-stressed males (but not females) repeatedly exposed to ethanol showed significant decreases in social behavior and social preference relative to water-exposed non-stressed controls at P70 and P77, an effect not evident in their stressed male counterparts. Socially suppressing effects of stress, both immediate and delayed, were evident only in water-exposed males and females, with adolescent exposure to ethanol curbing the sensitivity of animals to the social consequences of repeated restraint during adulthood. AIE and stress effects on EtOH intake under social circumstances (four same-sex littermates drinking together in a novel cage for 30 min) were assessed in these animals on P80-P91. Neither AIE nor stress had any effects on social drinking, however each independently increased adolescent-typical play fighting in males, but not females, under these social circumstances. Thus, although later stress did not exacerbate the social anxiety seen after AIE in males, both manipulations

reinstated adolescent-typical social facilitation in adult males drinking ethanol in a social context.

Title: The effect of adolescent intermittent binge ethanol on neurogenesis and oligodendrogenesis in the subventricular zone and anterior corpus callosum of adult rats

Authors: *W. LIU, F. T. CREWS;
Bowles Ctr. for Alcohol Studies, Univ. of North Carolina-Chapel Hill, Chapel Hill, NC

Abstract: Binge drinking is common in adolescent humans. Previous studies have found that adolescent intermittent binge ethanol (AIE) caused a persistent change in hippocampal neurogenesis lasting into young adulthood. The current study examined the effect of AIE compared with water controls on neurogenesis and oligodendrogenesis in the subventricular zone (SVZ) and anterior corpus callosum (acc) of adult rat brain. Male Wistar rats were bred and reared in our vivarium. On the day following birth (P1), litters were culled to 10 pups. At weaning on P21 (Postnatal days 21), male offspring were weight matched and pair-housed. Animals were assigned into four groups. Two groups of them were treated with ethanol (AIE, 5g/kg/day, i.g., P25-P55; 2 days alcohol, 2 days off) and the other two groups were given with water as controls. Animals of the four groups (two controls and two AIE) were injected with a single dose of BrdU (300 mg/kg, i.p.) at P57 and P95, respectively, and were sacrificed 2 hours later. The impacts of AIE on neurogenesis and oilgodendrogenesis were investigated using immunohistochemistry with quantification of immunoreactivity to BrdU, Nestin, sox2, DCX, Dlx2 (neurogenesis markers) and NG2 (oligodendrogenesis progenitor cells, OPCs), olig2 (OPCs and mature oligodendrocytes) and olig1 (oligodendrocytes). In the subventricular zone, AIE reduced neurogenesis marker, sox2+IR (18%, $p<0.05$), DCX+IR (32%, $p<0.001$), and Dlx2+IR (13%, $p<0.05$) at P95. There were no change with BrdU+IR and nestin+IR. The study has showed that there were age-related (from P57 to P95) decline in olig2+IR and NG2+IR cells in

control group, however, there was no age-related decline in AIE group. NG2+IR cells in AIE group showed significantly higher than in control group (56%, $p<0.001$) at P95. In anterior corpus callosum, where OPCs generated in the SVZ migrate into, AIE induced the increase in nestin+IR (33%, $p<0.05$), sox2+IR (33%, $p<0.01$), DCX+IR (78%, $p<0.05$), olig2+IR (59%, $p<0.01$) at P95, and olig1 at P57 (90%, $p<0.01$), compared with control group. These data indicate that adolescent intermittent binge ethanol persistently reduced neurogenesis in the forebrain subventricular zone and increased oligodendrogenesis in anterior corpus callosum of adult rats. Title: Adolescent binge exposure alters the adult brain response to stress

Authors: *T. J. WALTER[1], R. VETRENO[2];
[1]Univ. of North Carolina - Chapel Hill, Carrboro, NC; [2]Univ. of North Carolina - Chapel Hill, Chapel Hill, NC

Abstract: Binge drinking is common among adolescents and has several long-term effects that can last into adulthood. One of these effects is a change in brain stress response to alcohol during adulthood. This study sought to determine whether adolescent binge exposure changes the adult brain stress response to stressors other than alcohol. This was done by exposing adolescent male Wistar rats to either an intermittent adolescent ethanol (AIE) treatment or water treatment from post-natal day 25 to 55. On post-natal day 95, after a period of abstinence, the AIE-treated and water-treated rats were each subdivided into two groups - stressed or non-stressed - for a total of four groups: Water-No Stress, AIE-No Stress, Water-Stress, and AIE-Stress. The stressed groups received 2 hours of restraint and partial submersion in water. The rats were sacrificed two hours after the end of the stressor and immunohistochemical stains were performed on the brains. The neuronal response to stress was examined using c-Fos and EGR1, and the microglial response to stress was examined using CD11b. Five stress-responsive brain regions, the mPFC, vBNST,

PVN, CeA and PAG were examined. Stress significantly increased c-Fos in all regions. Furthermore, there was a significance treatment-by-stress effect for c-Fos in the PVN. Stress also significantly increased EGR1 in all regions, and AIE significantly decreased EGR1 in the CeA. The AIE-Stress group also showed significantly lower EGR1 in the CeA than the Water-Stress group. Stress significantly increased CD11b in all examined regions and AIE significantly increased CD11b in the mPFC, the CeA and PAG. There was no treatment-by-stress interactions for CD11b in any examined region. Pearson correlations between c-Fos densities in the different brain regions were used to examine connectivity of these regions at baseline and under stress. Similar analyses were performed by correlating EGR1 densities across brain regions. AIE caused subtle differences in correlations both at baseline and under stress. These results suggest that adolescent binge exposure causes some changes in the adult brain response to stress during adulthood.

Title: Corticosterone response to the route of ethanol administration in adolescent and adult animals

Authors: *J. HOFFMAN[1], R. M. PHILPOT[2], C. L. KIRSTEIN[3];
[1]Psychology, Usf-Psychology, Tampa, FL; [2]Mosani Col. of Med., USF, Tampa, FL;
[3]Psychology, USF-Psychology, Tampa, FL

Abstract: Nearly half (48.6%) of alcohol use involves individuals under the age of 20, indicating the critical importance of research that focuses on the effects of alcohol exposure during the adolescent period. Because of the short period of adolescent development in rodents, studies using these animals to model adolescent alcohol exposure are predominately restricted to alcohol administered by the experimenter, most frequently intraperitoneal (i.p.) injections or oral intragastric (i.g.) administration. Although the i.g. method of administration is physiologically more similar to human alcohol use than i.p. administration, it is often thought of as especially stressful. Since adolescent animals exhibit larger and/or more prolonged corticosterone (CORT) responses to stressors than adult animals, the use of a stressful route of administration could

confound the results of studies comparing adolescent to adult alcohol responses. Therefore, the present study determined whether alterations in circulating CORT levels are larger following acute i.p. or i.g administration of alcohol, whether this response is altered following chronic intermittent ethanol exposure (CIE) and whether these responses are similar in adolescent and adult animals. Blood was collected via tail nick from adolescent and adult male Sprague-Dawley rats prior to and 15, 30 and 60 minutes following i.p or i.g administration of ethanol (2g/kg), saline (i.p.) or water (i.g.). Animals were subsequently exposed to 2g/kg ethanol (i.p or i.g) for 21 days using a CIE schedule (2 days on/1 day off). On the final day of ethanol exposure, blood was again collected prior to and 15, 30 and 60 minutes following ethanol exposure. Results indicate that: 1) adolescents have significantly higher basal circulating CORT than adults; 2) adolescents manifest larger CORT responses (area under the curve) than adults to acute saline (i.p.) or water (i.g.); 3) compared to adults, adolescents exhibit significantly greater increases in CORT following acute i.p., but not i.g., ethanol administration and; 4) during adolescence, but not adulthood, both i.p. and i.g. CIE administration suppress basal and ethanol stimulated circulating CORT. These results indicate that the route of ethanol administration is a relevant consideration when comparing acute and CIE effects between adolescent and adult animals, in particular if experimental measures are affected by CORT.

Title: Interaction of developmental nicotine exposure and the nicotine risk variant in the alpha 5 nicotinic subunit changes nicotine seeking in adolescent mice

Authors: ***H. C. O'NEILL**, C. WAGEMAN, S. R. GRADY, M. J. MARKS, J. A. STITZEL; Inst. For Behavioral Genet. , Univ. of Colorado, Boulder, CO

Abstract: A single nucleotide polymorphism (rs16969968) in the nicotinic acetylcholine receptor (nAChR) alpha5 subunit (a D397N substitution) has been linked to early onset smoking behavior and increased risk for nicotine dependence. The interaction of this polymorphism and developmental exposure to nicotine (DNE) with subsequent adolescent nicotine consumption has not been investigated. Recently, we developed a knockin mouse with this human SNP to facilitate further investigation. Prior to breeding and until weaning of the pups at day PN21, dams drank nicotine (100 µg /ml) in 0.2% saccharin water (developmental nicotine exposed, DNE) or 0.2% saccharin water alone (vehicle) as their sole source of fluid. For adolescent drinking studies, at 30 days of age offspring were given a choice between water or nicotine (100-400 µg/ml nicotine, 4 days at each concentration). Adolescent vehicle offspring homozygous for the high risk allele (N397) drank more nicotine than adolescent vehicle mice homozygous for the wild-type variant (D397). Adolescent DNE N397 mice drank more nicotine at the highest dose than all other groups, while DNE D397 mice appeared to actively avoid nicotine resulting in significantly less nicotine consumption compared to all other groups. No difference between vehicle and DNE D397 mice were noted for nicotine-stimulated synaptosomal striatal dopamine (DA) release, while DA release was decreased significantly in DNE N397 mice compared to all other groups. No differences were noted between D397 and N397 vehicle alpha5*-nAChR binding sites measured by [125I]-epibatidine binding and DNE had no effect on these sites in either variant. These data suggest that decreased DA function in the striatum may lead to increased nicotine seeking in N397 DNE mice. Recent studies have implicated the habenula in nicotine aversion. Functional assays measuring synaptosomal nAChR-mediated 86Rb efflux indicated decreased function in the habenula in N397 DNE mice, indicating a potential mechanism for reduced aversion and thus increased intake of nicotine in these mice. Binding studies in the habenula demonstrated no significant changes in nAChR binding populations; however, an interesting trend towards decreased alpha3 beta4-nAChR binding was evident in N397 DNE mice. Together these data indicate interplay of mechanisms that may contribute to increased nicotine intake and decreased aversion in N397 DNE mice. Further studies are warranted to investigate mechanisms underlying increased aversion in D397 DNE mice.

Title: Age differences in conditioned place preferences and taste aversions to nicotine

Authors: *C. DANNENHOFFER, L. P. SPEAR;
Psychology, Binghamton Univ., Binghamton, NY

Abstract: Nicotine is an addictive substance that produces both rewarding and aversive effects within an individual simultaneously. These opposing effects can be examined in animal models using conditioned taste aversion (CTA) and conditioned place preference (CPP) paradigms. Given that adolescents and adults have been reported to respond differently to rewarding and aversive effects of drugs and other stimuli in humans and laboratory animals, the current experiment investigated age differences in nicotine sensitivity using a combined CTA and CPP procedure. Adolescent (P25-35) and adult (P70-80) male Sprague-Dawley rats were pair-housed in their home cage with ad lib food and water throughout the experiment. Every other day for 8 days, animals were first given 30 min access to supersac (3% sucrose, 0.125% saccharin in water) in the home cage, followed by injection with nicotine (0.0, 0.2, 0.4, and 0.8mg/kg; s.c.), and placement on one side of the CPP chamber for 20 min post-injection; on alternative days, water access was followed by saline injection and placement on the alternative side of the CPP chamber. On CPP test day, animals were allowed access to both sides of the apparatus and place preference was determined. CTAs were defined as attenuated supersac intake relative to saline controls over training/test days. Under these training/test conditions, adolescents displayed stronger CPP while tending to show weaker CTA than adults. To determine whether use of the combined CTA/CPP procedure contributed to the relatively modest age-associated attenuation in CTA seen in adolescents in this study relative to prior reports, a CTA alone group was added at each age, with animals remaining in the home cage post-injection. Analysis of data from this CTA-only condition revealed no age effects. The lack of notable age differences in nicotine CTA seen in these studies contrasts with prior studies showing attenuated nicotine CTA in adolescents relative to adults. Differences may be related to the low stressfulness of the CTA conditioning procedures used here: i.e., conditioning of pair-housed, ad libitum food/water animals in the home cage. While confirming the enhanced sensitivity of adolescents to the rewarding properties of nicotine, these data suggest that observed age differences in the aversive effects of nicotine may be dependent on testing conditions, perhaps including the relative stressfulness (i.e., deprived vs. non-deprived; home cage vs. novel context) of the training/test protocol. Title: Neuronal injury associated with prenatal exposure of wistar rats to crude extract of vernonia amygdalina (bitter leaf)

Authors: *W. G. BALOGUN[1], A. AMIN[2], A. E. COBHAM[1], A. O. ISHOLA[1], W. I. ABDULMAJEED[2], O. B. AKINOLA[1];
[1]anatomy, Univ. of Ilorin, Ilorin Kwara State, Nigeria; [2]Physiol., Univ. of Ilorin, Ilorin, Nigeria

Abstract: Background: Bitter leaf is widely consumed by pregnant women in Africa for the treatment of many diseases during the various phases of pregnancy. But whether this treatment is deleterious to developing prefrontal cortex requires clarification. AIM: This study investigated some histological and histochemical effects of prenatal exposure of aqueous bitter leaf extract on the developing prefrontal cortex. METHODS: Twenty-five pregnant Wistar rats with an average weight of 200g were randomly divided into five groups (n=5). The experimental groups were administered bitter leaf (400mg/kg) on the gestational days 1-7 (group B), 8-14 (group C), 15-21 (group D) and 1-21 (group E) while the control (group A) was given normal saline from gestational days 1-21. After parturition, the litters in each group were weighed and sacrificed by euthanized on postnatal day 35. The brain was weighed and the prefrontal cortices were excised, fixed in formol calcium and processed. Tissue sections were stained with: Feulgen reaction for DNA substances and Cresyl Fast Violet for Nissl substance. while the homogenate was used to assayed the level of GDP, LDH and ALP. RESULTS: Using CFV, there was partial loss of Nissl substances in the litters exposed to bitter leaf on E8-E14 and E1-21 while there was more DNA loss in the litters exposed to bitter leaf on E8-E14 and E1-21. The GDP, ALP and LDH levels in the litters exposed to bitter leaf on E8-E14 and E1-21 was statistically significant from the control group. CONCLUSION: The above findings suggest that prenatal exposure of young Wistar rats to oral bitter leaf at 400 mg/kg is associated with neuronal loss in the prefrontal cortex. Title: Timing deficits are improved by nicotine pre-treatment in the neonatal quinpirole model of schizophrenia

Authors: E. M. ODINEAL[1], M. I. PALMATIER[1], E. D. CUMMINS[1], A. B. SHEPPARD[1], *R. W. BROWN[2];
[1]Psychology, [2]East TN State Univ., JOHNSON CITY, TN

Abstract: Schizophrenia is a developmental disorder characterized by alterations in dopamine (DA) and glutamate neurotransmitter systems in the forebrain. Among the myriad symptoms of schizophrenia, deficits in time perception may be especially dependent on hyper-sensitivity of DA D2-like receptors. Our laboratory has developed a model of schizophrenia in which neonatal quinpirole (QUIN) treatment causes long-term increases in the sensitivity of dopamine D2-like receptors without a change in receptor number. The present study investigated the effects of neonatal QUIN treatment on timing using a peak-interval procedure in rats. From postnatal days (P)1-21 male rats received daily intraperitoneal injections of QUIN (1mg/kg) or saline (SAL). After weaning the rats were socially housed and raised to adulthood (P60). All rats were then shifted to single-housing, feed restricted, and shaped to press a nose-key for a sucrose reward. After initial shaping sessions, a peak-interval procedure was used in which most rewards were delivered approximately 60 s apart (fixed-interval or FI 60s, 28 trials each session). To measure the distribution of responses around the expected time of reward delivery, two peak trials were also included - these trials lasted 180s and no reinforcer was delivered. We hypothesized that anticipation of the reward would result in maximal response-rates approximately 60s into peak-interval trials. However, potent disruptions in timing were observed for rats that were exposed to neonatal QUIN - response rates increased and decreased sporadically with no clear peak during test-trials. After 6 initial acquisition tests, subcutaneous nicotine injections (0.4mg/kg) were administered 15 minutes prior to testing. Nicotine pretreatment resulted in a gradual increase in response rates and the development of a peak interval that was centered between 55 and 70 s. However, when nicotine was subsequently replaced with placebo, response-rates gradually

declined and returned to a temporally disorganized pattern. These findings indicate that hypersensitivity in DA D2-like receptors interferes with performance on the peak-interval task and that pre-treatment with nicotine improves performance and timing. These findings also suggest that nicotine alleviates cognitive or affective deficits that interfere with performance of reward-based cognitive tasks in schizophrenia.

Title: Neonatal quinpirole treatment enhances nicotine self-administration in adult rats

Authors: *E. CUMMINS, E. M. ODINEAL, A. B. SHEPPARD, M. I. PALMATIER, R. W. BROWN;
Psychology, East Tennessee State Univ., Johnson City, TN

Abstract: Individuals with schizophrenia are 3 to 4-fold more likely to smoke cigarettes than the general population, but no mechanism for this comorbidity has been delineated. One potential mechanism for increased smoking may be alterations in dopamine (DA) function - especially increased sensitivity of DA D2-like receptors. In our pre-clinical model of schizophrenia, neonatal quinpirole (QUIN) treatment results in long-term increases in the sensitivity of dopamine D2-like receptors and also increases behavioral and neurochemical responses to nicotine (NIC) in adulthood. The present study investigated whether neonatal QUIN treatment increased NIC self-administration in adult rats. Male rats were given single intraperitoneal injections of QUIN (1mg/kg) or saline (SAL) from postnatal days (P)1-21. Rats were then socially housed and raised to adulthood (P60). All rats were then shifted to single-housing, feed restricted and shaped to lever-press for a sucrose reward before being instrumented for intravenous (IV) NIC self-administration. Meeting the schedule of reinforcement on the active lever resulted in delivery of NIC (60 ug/kg/infusion, base) and a ‘time-out’ cue (30 s extinction of the houselight) - no additional reinforcers were available during the time-out. Responses on a

second inactive lever were recorded but had no consequence. The schedule of reinforcement during 60-min sessions was increased from an FR1 to FR5. During acquisition, no differences between neonatal QUIN and SAL rats were observed. Once stable responding on the FR5 schedule was observed, all rats were shifted to a progressive ratio (PR) reinforcement schedule in which each reinforcer earned increased the number of responses required to earn subsequent reinforcers. Breaking point (BP) was defined as the final ratio completed before 60 min elapsed with no infusions earned. This breaking point indicates the point at which the motivation to obtain NIC is outweighed by the amount of effort required to earn the next infusion. Under the PR schedule QUIN rats showed increased motivation to self-administer NIC compared to SAL controls across all NIC doses tested (7.5-60 ug/kg/infusion), no differences in responding for placebo (0 ug/kg/infusion) were observed. The findings confirm that developmentally-induced increases in DA D2-like receptor sensitivity enhances the motivation to self-administer NIC in adulthood and provides further validation of the neonatal QUIN model of schizophrenia. These findings also suggest that enhanced motivational effects of NIC may explain the robust comorbidity between schizophrenia and smoking.

Title: The role of the α7 and α4β2 nicotinic receptors in nicotine sensitization and neural plasticity of adolescent rats neonatally treated with quinpirole

Authors: *D. PETERSON, E. D. CUMMINS, C. M. BARDO, R. W. BROWN;
East Tennessee State Univ., Johnson City, TN

Abstract: Substance abuse comorbidity is a common problem in schizophrenia and other psychotic disorders. In addition, smoking typically begins in adolescence, a period of development in which substance abuse commonly initiates. Nicotine has been shown to increase dopaminergic activity, which mediates positive reinforcement and may reduce some of the

negative symptoms of schizophrenia as well as cognitive impairments associated with schizophrenia. Dopaminergic activity also mediates behavioral sensitization to psychostimulants, including nicotine. Previous research from our lab has shown that rats neonatally treated with quinpirole, a dopamine D_2/D_3 agonist, from postnatal days (P) 1-11, 1-21, or 21-35 produces an increase in the sensitivity of the D_2 receptor throughout the animal's lifetime. This increase in D_2 sensitivity is a hallmark characteristic of schizophrenia. The purpose of the current study was to examine the roles of the α7 and α4β2 nicotinic acetylcholine receptors (nAChRs) in nicotine sensitization in adolescent rats neonatally treated with quinpirole. Adolescent rats (tested from postnatal days 33-49 every second day) were neonatally treated with either quinpirole (1 mg/kg) or saline from postnatal day (P)1-21. Results revealed that neonatal quinpirole enhanced sensitization to nicotine as compared to animals neonatally treated with saline and administered nicotine, and that the α4β2 antagonist dihyro-beta erythrodine (DhβEl 1 and 2.5 mg/kg) was more effective at blocking nicotine sensitization than methyllycaconitine (MLA; 2 and 4 mg/kg), regardless of neonatal drug treatment. In fact, rats that received DhβE demonstrated activity levels below that of controls treated with saline. Interestingly, DhβE was more effective in blockade of increases in activity produced by nicotine in males as compared to females on the final day of sensitization. In contrast, MLA failed to block sensitization to nicotine in both males and females, regardless of neonatal treatment condition. Interestingly, MLA (2 and 4 mg/kg) effectively blocked the acute hypoactive response to nicotine in males, and the higher dose of MLA (4 mg/kg) reduced sensitization more effectively in males, although this was not blocked to control levels. Brain tissue from the nucleus accumbens (NAc), the dorsal striatum, and hippocampus will be analyzed for both brain-derived neurotrophic factor (BDNF) and the mammalian target of rapamycin (mTOR), a protein signal downstream of BDNF. These results indicate that the α4β2 receptor, a common target for smoking cessation treatments plays a critical role in nicotine sensitization in the neonatal quinpirole model of schizophrenia.

Title: Low constraint-associated D4 receptor variant does not elicit differential G-protein activation

Authors: *M. SANCHEZ[1,2], N.-S. CAI[1], S. FERRE[1], H. YANO[1];
[1]NIDA/NIH, BALTIMORE, MD; [2]Univ. de Barcelona, Barcelona, Spain

Abstract: Dopamine D4 receptors (D4R) are expressed in the prefrontal cortex and in the basal ganglia. They play a fundamental role in the modulation of cortico-basal ganglia circuits involved in intentional volitional control, which determines the personality trait constraint. The gene encoding the human D4R shows an interesting polymorphism that consists of a variable number of tandem repeat of 2 to 11 repeats of a 48-base pair unit in exon 3, which codes for the third intracellular loop of the receptor. The D4.7R variant (with 7 repeats) is associated with low constraint, which constitutes an endophenotype of ADHD, OCD and substance use disorders. D4R is coupled to Gi proteins and its activation leads to inhibition of adenylyl cyclase. It has been suggested that activation of the D4.7R produces a less efficient adenylyl cyclase signaling compared to the other D4R. However, since the second messenger readouts may vary depending on the cellular environments, these reports may have overlooked the expression differences of receptors and effector species such as G protein subtypes. Thus, we turned to a biophysical approach in order to study D4R-mediated specific and quantifiable effector activation for all G protein species expressed in the cortex and striatum. We set up a bioluminescence resonance energy transfer (BRET) assay that detects a conformational change between the α and the γ subunit of the G protein. Upon receptor activation, the G protein binds to the receptor and changes its conformation in such a way that a light donor fused to the α subunit and an acceptor fused to the γ subunit move away resulting in a decreased BRET signal. Using this technique, we have studied the activation of five Giα isoforms by the three main receptor variants found in humans (D4.4R, D4.7R, D4.2R, in order of global allelic frequency) in response to its endogenous ligands and selective agonists and antagonists. On the contrary to reported studies, our results indicate that three D4R variants couple to all tested Gi protein subtypes to virtually the same extent. Therefore, using this controlled expression method, we have demonstrated for the first time that D4.7R variant does not present differences in G-protein coupling or activation. We are also implementing a BRET-based arrestin recruitment assay to look for differential effects for the different variants. The lack of differences in the signaling properties of the D4R variants when expressed alone will support a main role of the reported differential biochemical properties of heteromers of D4R variants with D2R (or other receptors) in the differential modulation of cortico-basal ganglia circuits and the personality trait constraint.

Title: Development of novel Gs / Golf biosensors: Gs-Golf functional selectivity in dopamine D1 receptors

Authors: *H. YANO[1], D. PROVASI[2], M. FILIZOLA[2], A. BONCI[1], S. FERRE[1], J. A. JAVITCH[3,4];
[1]Natl. Inst. On Drug Abuse, Natl. Inst. of Hlth., Baltimore, MD; [2]Mount Sinai Sch. of Med., New York, NY; [3]Columbia Univ., New York, NY; [4]New York State Psychiatric Inst., New York, NY

Abstract: Numerous neurotransmitters and neuromodulators mediate their effects directly through G protein-coupled receptors (GPCRs). Therefore, understanding the structure-function relationship of GPCRs is key to better development of neuropharmacological agents. Conformational changes associated with GPCR activation have been revealed in remarkable details by the crystal structure of agonist-bound beta2 adrenergic receptor coupled to Gs. However, the extent to which conformational changes are conserved in other G protein species and how different agonists may lead to different conformations remain to be determined. We are working to develop assays that can answer these questions. The dopamine D1 receptor can couple to both Gs and Golf (89% identical to Gs). As the expression patterns of Gs and Golf greatly differ in the brain and Golf is enriched in the striatum, the discovery of Golf-selective ligands would provide a novel tool for exploring the relevance of the various signaling pathways and thereby help to advance therapeutics for neuropsychiatric disorders. We first investigated conformational changes in the Gs heterotrimer after activation of D1R. Using a library of novel Gs biosensors with either luciferase or GFP inserted at various positions throughout the structure, we studied conformational changes by bioluminescence resonance energy transfer (BRET) and

compared the results to the crystal structures of the inactive and active conformations. We also studied conformational changes in the Gs protein induced by other receptors. Finally, taking advantage of the significant homology, we constructed Golf biosensor constructs and subsequently validated them in BRET-based assays of receptor activation. Our studies using these biosensors show for the first time that conformational changes within the Gs heterotrimer are very similar for different Gs-coupling receptors. Also comparison between the Gs and Golf sensor readouts suggests that activation of Gs and Golf lead to similar conformational changes. Using this set of biosensors, efficacy of ligands and activation preference between Gs and Golf can be addressed. This enables the screening of functionally selective D1 ligands that differentially target these related G proteins.

Title: Dopamine- and glutamate-containing axon terminals are segregated in distinct domains in dopamine neurons and regulated by striatal neurons

Authors: G. M. FORTIN[1], M.-J. BOURQUE[1], Z. SANEEI[1], C. PACELLI[1], R. K. VARASCHIN[1], N. GIGUERE[1], M. BRILL[1], S. SINGH[3], P. W. WISEMAN[3], *L.-E. TRUDEAU[2];

Abstract: A subset of midbrain DA neurons has been shown to express the type 2 vesicular glutamate transporter (VGLUT2), supporting their capacity for glutamate release from some of their axon terminals. Glutamate release from DA neurons is found mainly by neurons of the VTA and can be detected at terminals contacting ventral but not dorsal striatal neurons, suggesting the possibility that target-derived signals regulate the neurotransmitter phenotype of DA neurons. Whether glutamate can be released from the same terminals that release DA or from a segregated subset of axon terminals is also undetermined. Here we examined the localization of VGLUT2 both *in vitro*, in a primary co-culture system with ventral or dorsal striatal neurons, and *in vivo* in mouse striatal brain sections obtained from either conditional VGLUT2 knockout (cKO) mice or DAT-Cre mice expressing a floxed fluorescent reporter protein selectively in DA neurons. We find that while VGLUT2 is colocalized with tyrosine hydroxylase (TH) in a subset of terminals when mesencephalic DA neurons are cultured alone, VGLUT2 is mostly segregated from TH when DA neurons are cultured with ventral, but not striatal neurons. In striatal brain sections, we also confirm that VGLUT2 is found in axonal varicosities emanating from DA neurons but expressing very little if any TH. More advanced image analysis using the 2-color SpIDA technique also confirms low or random colocalization of TH and VGLUT2 signal *in vivo*. Our work unveils a fundamental feature of dopamine-glutamate cotransmission and suggests that striatal neurons can regulate the neurotransmitter phenotype of DA neurons.

Title: Neuro-modulatory role of the D2-like dopamine auto-receptor in *C. elegans*

Authors: ***S. MANDALAPU**, R. FORMISANO, M. MERSHA, P. HAN, H. S. DHILLON; Dept of Biol. Sci., Delaware State Univ., Dover, DE

Abstract: Dopamine influences a wide range of neural processes and is implicated in several neurological disorders. Degeneration of dopaminergic neurons in the midbrain of Parkinson's disease patients leads to decreased dopamine levels that may involve D2-like auto-receptors. In *C. elegans,* the D2-like dopamine receptor DOP-2 has been proposed to be the dopamine auto-receptor that modulates dopamine release during the process of associative learning. Our goal is to understand the auto-receptor functional of DOP-2 in modulating dopamine levels in the synaptic cleft. Work in our lab has shown that DOP-2 physically interacts with GPA-14 an inhibitory G-alpha subunit (Gαi), and that both *dop-2* and *gpa-14* deletion mutants habituate at a significantly faster rate as compared to wild-type. Furthermore, *gpa-14* deletions also show associative learning deficits similar to those reported for *dop-2* previously. In addition to dopamine, our results indicate that a TRP cation channel may be modulating DOP-2 auto-receptor function. Preliminary results for the *dop-2* and *trp-4* mutants show faster habituation and in the *trp-4;dop-2* double mutants the habituation is the same as the single mutants. We thus hypothesize that *dop-2* and *trp-4* act in the same pathway to modulate neurotransmitter release. Besides the genetic and behavioral approach outlined above, we are also using fluorescence recovery after photobleaching (FRAP) to test our hypothesis. Results from our experiments will provide insight into the molecular mechanisms involved in the modulation of the dopamine neurotransmitter release.

Title: Coordination and remodeling of cortico-limbic network dynamics by dopaminergic neuronal activity

Authors: *H. K. DECOT[1], W. GAO[2], P. A. KANTAK[3], Y.-C. J. KAO[4], M. DAS[4], J. H. JENNINGS[1], I. B. WITTEN[5], K. DEISSEROTH[6], Y.-Y. I. SHIH[4], G. D. STUBER[3]; [1]Neurobio., [2]Radiology, [3]Psychiatry, [4]Neurol., Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; [5]Psychology, Princeton Univ., Princeton, NJ; [6]Bioengineering, Stanford Univ., Stanford, CA

Abstract: Ventral Tegmental Area (VTA) dopaminergic neurons encode reward prediction errors and signal the incentive salience of sensory cues. Burst firing of these neurons result in phasic dopamine release in cortical and limbic terminal fields such as the medial prefrontal cortex (mPFC) and nucleus accumbens (NAc), which acts to modulate postsynaptic neuronal firing to promote changes in motivated behavioral output. However, it remains unclear how VTA dopaminergic activity affects large-scale brain network functional connectivity. This project aims to investigate whether the selective activation of DA neurons within the midbrain alters the functional connectivity between these neurons and their postsynaptic target regions, as well as global patterns of brain connectivity to provide clinically relevant insight into the effects of dopaminergic dysregulation on neural circuit mechanisms in the intact brain. To target DA neurons within this region, tyrosine hydroxylase (TH)-Cre adult Long Evans rats were microinjected into the ventral midbrain with a Cre-inducible adeno-associated virus carrying the gene encoding channelrhodopsin-2 (ChR2), a light-gated cation channel fused to an enhanced yellow fluorescent protein (EYFP) (THVTA::ChR2 rats) or only EYFP (THVTA::control rats). Chronic optical fibers were stereotactically implanted bilaterally above the VTA to permit light delivery to selectively activate DA neurons within this region. Single shot, single sampled GE-EPI sequences were acquired using a Bruker 9.4T MR scanner and custom surface coil. Data were averaged across subjects in order to provide group-averaged fMRI activation maps. Selective optogenetic activation of DA neurons within the midbrain not only caused significant regional CBV increases in downstream targets of the VTA including the dorsal striatum and nucleus accumbens in THVTA::ChR2 rats ($p<0.05$ corrected for multiple comparisons) but also coordinated dynamic shifts in global patterns of functional connectivity. Intravenous application of the D1 receptor antagonist, SCH23390 significantly attenuated the optical stimulation mediated CBV responses within these forebrain targets. In addition, pairing VTA dopamine neuronal activity with somatosensory stimuli dramatically enhanced the neuronal representation of the sensory stimulus and also remodeled functional connectivity. These data suggest that aberrant DA neuromodulation may alter the neuronal activation patterns seen within cortico-limbic networks, providing mechanistic insight into how DA signaling alters global patterns of brain connectivity.

Title: Dopamine, MMP activity, and NMDA stimulated calcium signal in striatal neurons

Authors: Y. LI[1], J. G. PARTRIDGE[2], S. VICINI[2], *K. CONANT[3];
[1]Neurosci. (Georgetown University), Georgetown Univ. and State Key Lab. of Biotherapy, West China Hospital, Sichuan Univ., Washington (U.S.A.) and Chengdu (China), DC; [2]Pharmacol., [3]Neurosci., Georgetown Univ., Washington, DC

Abstract: Dopamine is a neuromodulator known to influence glutamatergic transmission in striatal spiny neurons. While dopamine signaling may activate varied effectors of excitatory transmission, interactions with dopamine D1 receptor (D1R) bearing neurons in particular may stimulate PKA dependent phosphorylation of glutamate receptor subunits. Herein we focus on the question of whether D1 receptor activation stimulates superimposed changes in matrix metalloproteinase (MMP) activity to further influence glutamatergic transmission in the striatum. MMP levels are increased in the background of excess dopaminergic activity and these proteases are increasingly recognized as important effectors of glutamatergic transmission. We observe that dopamine and a D1R agonist, SKF81297, increase MMP activity in extracts from striatal slices as determined by cleavage of the substrate β-dystroglycan. Using transgenic mice engineered to express the calcium indicator protein GCaMP3 in D1R or D2R cell populations, we also observe that SKF81297 pretreatment of slices (10 μM, 40 min) can potentiate NMDA stimulated intracellular calcium increases in both cell types. The change in D2R cells is of particular interest in that it is consistent with the possibility that one or more soluble factors may be released from D1R bearing cells to in turn influence NMDA receptor dependent changes in neighboring cells. Present studies are underway to determine the extent to which specific MMPs contribute to D1R enhancement of NMDA function in subpopulations of striatal neurons.

Title: Heterogeneous evoked dopamine plasticity in the rat striatum

Authors: S. H. WALTERS, *A. C. MICHAEL;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Fast scan cyclic voltammetry (FSCV) enables real-time quantitative measurements of subsecond concentration changes of several neurotransmitters in living brains. Our laboratory has previously published (Moquin 2009) unique, domain-correlated, differential evoked dopamine response plasticity at the timescale of seconds. This observation was obtained at microcylinder electrodes, which spatially average the response from a large number of dopamine terminals. We hypothesized that additional forms of plasticity might be observed at microdisk electrodes, which sample the response from a smaller number of terminals, and are less prone to "average out" physiological variability. Measurements within and across animals in the *in vivo* anesthesized rat striatum revealed the existence of multiple discrete response patterns to consistent stimulus conditions, which we confirmed to be a feature of the recording site rather than an instrumental artifact. This confirms our hypothesis that the differential response stability is a form of localized differences in dopamine response plasticity. Combined mathematical modeling and experimental efforts to elucidate the mechanism or mechanisms of the observed dopamine response plasticity are ongoing.

Title: Applying label-free dynamic mass redistribution technology to analyze ligand efficacy on dopamine D1 receptor signaling in living cells

Authors: *N. CAI, H. YANO, M. SANCHEZ-SOTO, X. GUITART, A. H. NEWMAN, S. FERRE;
NIDA/NIH, BALTIMORE, MD

Abstract: Both the canonical dopamine D_1 receptor (D_1R) agonist SKF-38393 and the canonical D_1^R antagonist SCH 23390 are benzazepine derivatives that have been widely used as pharmacological tools and radioligands. Intriguingly, both have been reported to be partial agonists on adenylyl cyclase signaling. We first addressed the validity and degree of the partial agonism of SCH-23390 by using label-free dynamic mass redistribution technology in transfected HEK-293 cells, which measures G protein-mediated signaling. As expected, agonist-like responses were obtained with dopamine and, with lower efficacy, with SKF-38393 in cells stably transfected with D_1R, but not in non-transfected cells. Similarly, SCH-23390 showed an agonist-like concentration-response in D_1R-transfected but not in non-transfected cells, albeit with lower efficacy than SKF-38393 in D_1R-transfected cells. In agreement with previous studies, and only in D_1R-transfected cells, the non-selective dopamine receptor antagonists flupenthixol and (+)-butaclamol showed an inverse-agonist-like response and they antagonized the effects of dopamine, SKF-38393 and SCH-23390. As SKF 38393 and SCH 23390 have been widely reported to have opposing effects on locomotor activity in the experimental animal, these data suggest a role of G protein-independent signaling in the locomotor effects of D_1R ligands. To expand on these findings, we analyzed the efficacies of a series of previously synthesized benzazepine derivatives and discovered varying partial agonist efficacies in D1R-transfected cells that were also counteracted by flupenthixol and (+)-butaclamol. Behavioral evaluation of these compounds is in progress to determine if G protein-independent signaling plays a significant role on D_1R-mediated locomotor activation.

Title: The roles of voltage-gated calcium channels (VGCCs) in the control of striatal dopamine release are variable and dynamically regulated

Authors: *K. BRIMBLECOMBE[1], C. GRACIE[2], S. J. CRAGG[2];
[1]DPAG, [2]Dept. of Physiol. Anat. and Genet., Univ. of Oxford, Oxford, United Kingdom

Abstract: Voltage-gated calcium channels (VGCCs) operate differently in dopamine (DA) neurons of Substantia nigra pars compacta (SNc) compared to ventral tegmental area (VTA), neurons which are respectively sensitive and resistant to degeneration in Parkinson's disease. There is still much to understand about the VGCCs on the vast striatal axonal arbors of DA neurons that control striatal DA release. Previous studies will have been confounded by the VCGGs that operate on cholinergic interneurons and regulate ACh release, which in turn modulates and drive DA release. We have investigated which VGCC subtypes on DA axons operate in dorsal and ventral striatum to control DA release. We used fast-scan cyclic voltammetry (FCV) at carbon-fibre microelectrodes in mouse acute striatal slices to determine the roles of VGCCs subtypes in striatal DA release using specific blockers of N, P/Q, L, and T-type channels (ω-Conotoxin GVIA, 100 nM; ω-Agatoxin IVA, 200 nM; Isradipine, 5 μM; and NNC 55-0396, 1 μM respectively), in the presence of the nicotinic receptor antagonist DHßE (1 μM) to remove the confounding effects of ACh on DA terminals. We determined that at 2.4 mM extracellular Ca2+, N>P/Q>T and L-type channels control DA release in dorsal striatum whereas only N>P/Q-type channels contribute in ventral striatum. However, "silent" L- and T-type channels in ventral striatum had a role unmasked by increasing extracellular Ca2+. We also reveal that DA release in response to tonic versus phasic patterns of activity is a general function of calcium availability and not in fact dependent on specific VGCC subtypes operating at specific frequencies. Furthermore, data suggest that auxiliary α2δ subunits also modulate the VGCCs that control DA release . In summary the VGCCs that control striatal release are of many types, and are dynamically involved according to striatal region, Ca2+ concentration, auxiliary subunits and stimulation frequency.

Title: Physiological relevance of dopamine 2 receptor functional selectivity assessed in mice

Authors: S. M. PETERSON[1], D. J. URBAN[1], N. M. URS[1], O. LICHTARGE[2], *M. G. CARON[3];
[1]Cell Biol., Duke Univ. Med. Ctr., Durham, NC; [2]Baylor Col. of Med., Houston, TX; [3]Duke Univ. Ctr., DURHAM, NC

Abstract: Schizophrenia symptoms are alleviated with antipsychotics, a class of drugs that preferentially target the dopamine 2 receptors (D2Rs). However atypical antipsychotics such as aripiprazole and clozapine have partial agonist activity and weak antagonistic activity when compared to typical antipsychotics such as haloperidol and display fewer extrapyramidal side effects, potentially due to their distinct D2R pharmacology. D2R belongs to the superfamily of G protein-coupled receptors, are highly expressed in the striatum in indirect pathway medium spiny neurons (MSNs), and mediate the neuronal function of dopamine. D2R signals through many diverse intracellular signal transduction molecules including the inhibitory class of G proteins and the multifunctional adaptor β-arrestin. D2R's inhibition of cAMP and neuronal excitability through G proteins have long been established, while there is evidence that β-arrestin can function as a scaffold of signaling kinases and phosphatases. In order to gain a better understanding of the function of D2R and facilitate manipulation of each signaling pathway, we used the Evolutionary Trace approach to generate functionally selective receptors. Two mutants, termed [Gprot]D2R and [βarr]D2R, capable of functioning through either the G protein or β-arrestin interaction pathways and were used to catalog cellular signaling *in vitro*. In addition, using adeno-associated viral constructs, these D2R mutants were overexpressed in the indirect MSNs of the striatum as well as re-expressed in these MSNs with endogenous D2R removed by Cre recombinase. Amphetamine-induced locomotor activity in mice, a model to assess the activity of antipsychotics, was used to assess the behavioral outcome of these manipulations. [βarr]D2R expressing mice had enhanced amphetamine induced hyperlocomotion when compared to [Gprot]D2R, wild-type D2R or a control inactive D2R protein. Thus functional selectivity of D2Rs may provide an approach to identify selective behavioral consequences and previously unappreciated molecular targets for the development of more efficacious therapies for dysfunction of the brain dopamine system.

Title: Dopamine regulates CREB nuclear activity via EPAC2 in retinal cells

Authors: *R. PAES-DE-CARVALHO, C. E. NOGUEIRA, R. SOCODATO;
Neurobio., Fluminense Federal Univ., Niteroi, Brazil

Abstract: Cell communication in the CNS occurs mainly at synapses where electrical signals in the pre-synaptic terminal are translated in the release of neurotransmitters and activation of post-synaptic receptors. Synapses undergo dramatic morphological and biochemical modifications and such synaptic plasticity occurs in many neurological functions like learning, memory and cognition. Dopamine is an important neurotransmitter in several CNS areas and previous works showed its ability in regulating neurite outgrowth and growth cone motility in retinal neurons. Dopamine regulates two classes of receptors classified as D1-like and D2-like receptors, which are respectively coupled to activation or inhibition of adenylyl cyclase and cAMP accumulation. A classical cAMP/PKA pathway promotes the phosphorylation of the transcription factor CREB (cyclic AMP responsive element binding protein), which is also modulated by calcium/calmodulin kinase and the ERKs pathway. The accumulation of cAMP also stimulates the guanine nucleotide exchange factor EPAC (exchange protein activated by cAMP), which regulates ERK activity through the small GTPase Rap1. Therefore, this pathway could potentially modulate CREB activation. The aim of the present work was to study the signaling pathways involved in CREB phosphorylation induced by dopamine in retinal cells. Retinal cells were obtained from 8-day-old chick embryos and cultured for 3 days. Cultures were washed with Hanks saline, incubated for different times with dopamine and then processed for western blot or fixed for immunocytochemistry and confocal image analysis. Dopamine stimulated CREB

phosphorylation at Ser133 in a concentration and time-dependent manner. Maximal stimulation was attained with 1 μM dopamine after 15 minutes of incubation. The same phosphorylation level was observed after 20 minutes but completely disappeared after 45 or 60 minutes of incubation. Confocal microscopy showed that dopamine increased pCREB in cell nuclei and that this effect was reduced by infection of cultures with lentiviruses carrying shRNAs specific for EPAC2. Interestingly, ERK2 phosphorylation also increased in cell nuclei after stimulation with dopamine and could be inhibited by knocking down EPAC. Moreover, CREB phosphorylation was completely inhibited when ERK2 was knocked down with specific shRNAs. In conclusion, our present data show that dopamine increases CREB phosphorylation in cultured retinal cells and that EPAC2 is part of a signaling pathway promoting activation and migration of ERK2 into the cell nucleus where it activates the transcription factor CREB.

Title: Allosteric regulation of phosphodiesterase-2 controls dopamine-induced GluA1 membrane insertion

Authors: R. S. SONG, B. MASSENBURG, *S. R. NEVES;
Pharmacol., Mount Sinai Sch. of Med., New York, NY

Abstract: The strength and duration of synaptic transmission is largely determined by the number of post-synaptic AMPA receptors (AMPARs). Modulation of synaptic strength is achieved by changing AMPAR numbers in a process that requires receptor trafficking from intracellular vesicles to the plasma membrane. Trafficking of GluA1-containing AMPARs is regulated by PKA, a cAMP-dependent kinase. Phosphodiesterase-4 (PDE4), an enzyme that degrades cAMP, regulates PKA activity and controls dopamine-induced GluA1 membrane insertion. Here we asked whether additional PDEs expressed in medium spiny neurons also regulate GluA1 membrane insertion. Our approach combines live-cell imaging of cAMP and cGMP dynamics, along with GluA1 trafficking measurements and computational modeling of

signaling to explore the contribution of each PDE to GluA1 trafficking in striatal neurons. We found that inhibiting PDE1, a cAMP/cGMP PDE, resulted in a counterintuitive decrease in dopamine-induced cAMP levels and GluA1 membrane insertion. This decrease was due to the allosteric activation of PDE2 by cGMP, as simultaneous inhibition of both PDE1 and PDE2 abolished the decrease in GluA1 membrane insertion. Moreover, PDE1 regulation of GluA1 trafficking was limited to distal dendritic segments, suggesting selective spatial control. These results show that the interplay of multiple PDE activities can lead to unanticipated regulation of dopamine-induced GluA1 trafficking.

Title: Histamine H3 receptor modulation of dopamine release in mouse striatum

Authors: ***R. K. VARASCHIN**[1], L.-É. TRUDEAU[2];
[1]Pharmacol., [2]Pharmacol. and Neurosciences, GRSNC, Univ. de Montréal, Montréal, QC, Canada

Abstract: Histamine H3 receptors are widely distributed in the mammalian brain. Activation of these Gi-coupled receptors reduces neuronal activity and inhibits release not only of histamine itself, but also of acetylcholine, glutamate and serotonin. Although these receptors are abundantly expressed in the dorsal and ventral striatum, their modulatory role on activity-dependent dopamine (DA) release has not been directly evaluated. Here, we employed pharmacological tools and the fast-scan cyclic voltammetry technique to address the hypothesis that histamine H3 receptor activation diminishes DA release in the dorsal and ventral striatum. Acute brain slices from C57/BL6 mice were obtained using a protective slicing method. A stimulating bipolar electrode was placed either in the dorsal or ventral striatum and slices were stimulated every 2 min. Slices were then perfused with histamine (10 μM), the selective H3

agonist alpha-methyl-histamine (1 μM) or vehicle. In the dorsal striatum, neither histamine nor alpha-methyl-histamine had any significant effect on evoked DA overflow. In the ventral striatum however, alpha-methyl-histamine reduced the amplitude of DA overflow by about 50 %, whereas histamine only induced a modest, non-significant reduction. None of the drugs affected vesicle mobilization, as estimated by comparing responses to pairs of stimuli at 100 Hz. These results lead us to speculate that histamine is an important modulator of DA release in the ventral striatum. Interestingly, in this region, histamine H3 receptors may also be expressed post-synaptically by medium spiny neurons and cholinergic interneurons. Therefore, at least two converging mechanisms may account for histamine H3 modulation of DA release: one direct, implicating H3 receptor-mediated inhibition of DA release from dopaminergic axons; and another indirect, involving H3 receptor-mediated inhibition of cholinergic interneurons, otherwise known to positively modulate DA release. Experiments are currently being undertaken to evaluate these two possibilities. These findings may serve as proof-of-principle for the development of novel pharmacotherapeutic strategies to treat diseases where DA release in this region is abnormal, such as in drug addiction.

Title: The effect of flow rate on D2 receptor modulation of dopamine release measured in brain slices with fast-scan cyclic voltammetry

Authors: M. BURRELL, *J. LIPSKI;
Dept Physiol, Univ. Auckland, Auckland, New Zealand

Abstract: Fast-scan cyclic voltammetry (FSCV) has been widely used to measure stimulated release and uptake of dopamine (DA) and some other neurotransmitters in brain slices and *in vivo.* In contrast to constant potential amperometry (CPA), a technique in which calibration highly depends on flow rate, calibration performed in solutions with FSCV is relatively flow-independent. However, the flow dependence of the effects of stimulated DA release in brain

slices has not been systematically studied, in spite of the fact that many studies used ACSF flow rates as low as 1 ml/min, which may compromise oxygen delivery to the slice and affect DA overflow and activation of D2 autoreceptors. Our aim was to assess the effect of different ACSF flow rates through the recording chamber (volume, 1.2 ml) on the inhibitory action of D2 receptor activation during DA release evoked by bursts of electrical stimuli (2 s,10 Hz) delivered in dorsal striatum in submerged brain slices (300-350 μm; 32 ± 0.5°C) obtained from P21-28 Wistar rats. DA release was detected with FSCV using cylindrical carbon fibre microelectrodes (7 μm diameter) placed in the immediate vicinity of bipolar stimulating electrodes. At relatively high flow rate (3.5 ml/min), there was no significant effect of sulpiride (10 μM, n=4) or raclopride (1 μM, n=4) on the peak amplitude or the area under the curve (AUC) of stimulated DA release. However, the amplitude and the AUC were increased when flow rate was reduced to 1.0-1.75 ml/min (both $p<0.005$; combined sulpiride and raclopride effects). Reduction of flow rate from 3.5 to 1.0-1.75 ml/min did not increase the amplitude and AUC of burst stimulation-induced DA release in the absence of D2 receptor block. Our data show that flow rate should be taken into consideration when studying the effects of released DA using FSCV. Although high flow rates (>3 ml/min) are recommended for electrophysiological studies performed in brain slices to maintain network activity (eg. Hajos et al. 2009 Eur J Neurosci 29:319), they may reduce the inhibitory effect of D2 autoreceptor activation on DA release. This could be due to the reduced activation of these receptors by accelerated DA diffusion, and/or by hyperoxygenation and increased level of reactive oxygen species (eg. Matott et al. 2014 Neuroscience 270:98).

Title: Computational modeling suggests low striatal dopamine release probability

Authors: *K. ROONEY, L. J. WALLACE;
Pharmacol., The Ohio State Univ., Columbus, OH

Abstract: The hypothesis being evaluated is that dopaminergic receptors at varying locations near a dopamine release site might be exposed to different concentrations of dopamine. Such a study is important as dopamine in the striatum signals saliency of the current environmental

input and is involved in the learned formation of appropriate responses. One key component of background information to support the hypothesis is that the majority of dopamine signaling appears to involve a volume or neighborhood phenomenon rather than a synaptic paradigm. Given published densities of dopaminergic varicosities in the dorsal striatum, the volume associated with a release site is about 10 μm3. Potential dopamine targets in such a volume include D1 receptors on medium spiny neurons and D2 receptors on medium spiny neurons, cholinergic interneurons, and dopamine axon terminals. A computer model using the program MCell was developed to estimate extracellular dopamine and potential gradients in such a volume. The model contained a dopamine release site and a ring of 1800 dopamine transporters located at a distance of about 4 μm from the release site. Kinetic values for dopamine transporter were determined from studies simulating uptake experiments. The number of dopamine molecules in a single vesicle was calculated to be about 1500 based on the concentration of dopamine in rodent brain and an estimate of 250 vesicles per varicosity. Simulations of a firing rate of five per second with each event releasing the contents of a single vesicle resulted in an average extracellular concentration of 10 μM, much greater than the approximately 5 nM reported by no-net flux micro-dialysis. Less than 5 dopamine molecules would need to be released per firing event to create a 5 nM extracellular concentration, which is less than 0.3% of the number of dopamine molecules in a single vesicle. These data suggest that if no-net flux micro-dialysis is an accurate measure of extracellular dopamine, then dopamine signaling is characterized by probability of a vesicle release associated with each firing event less than 1% and/or a mechanism such as kiss and run releasing a very small fraction of vesicular contents. Additional modeling experiments simulated published data of dopamine transients elicited by electrical stimulation of striatal slices. The results suggest that a single supra-maximal electrical pulse can release 88% of the contents of one vesicle from each varicosity. This result also suggests that dopamine signaling involves a very small fraction of available dopamine.

Title: Hyperactivity and working memory deficits induced by prenatal nicotine exposure are associated with dopamine D1 and D4 receptor dysfunction

Authors: K. P. LEE[1], N. PINEDA[1], T. BRUNE[1], K. PATEL[1], A. GANNON[1], T. J. SPENCER[2], J. BIEDEMAN[2], P. G. BHIDE[1], *J. ZHU[1];
[1]Ctr. for Brain Repair, Biomed. Sci., Florida State Univ. Col. of Med., Tallahassee, FL; [2]Clin. and Res. Programs in Pediatric Psychopharmacology and Adult ADHD, Massachusetts Gen. Hospital, Harvard Med. Sch., Boston, MA

Abstract: Attention deficit/hyperactivity disorder (ADHD) affects about 5-10% of children worldwide. ADHD symptoms include inattention, hyperactivity, impulsivity, and deficits in executive function/working memory, with often a predominance of only a subset of the symptoms. Stimulant medications such as methylphenidate and amphetamine remain the most commonly prescribed drugs for ADHD treatment. Stimulants block dopamine reuptake, increase extracellular dopamine levels and thereby mitigate ADHD symptoms. However, stimulant medications are not equally effective against the full set of ADHD symptoms, nor is the dopamine receptor signaling mechanism(s) underlying the therapeutic effects of stimulant treatment fully understood. Here we report that hyperactivity and working memory deficits in a prenatal nicotine exposure (PNE) mouse model of ADHD are associated with impairment of specific dopamine receptor signaling mechanisms and that these symptoms can be treated by rectifying the specific impairments. We have reported previously that PNE is associated with locomotor hyperactivity and deficits in working memory/attention. Here we used a Y-maze test to assay separately working memory/attention performance (spontaneous alternation) and locomotor activity (number of arm entries). Selective dopamine D1 or D4 receptor agonists were administered 30 minutes prior to the Y-maze assay in PNE and control mice. The selective D1 receptor agonist, A-77636 (0.1 or 1μg/kg, i.p.) reduced the total number of arm entries dose-dependently (Mean±SEM, 0, 0.1 vs. 1μg/kg: 56±4, 45±3 vs. 40±2, one-way ANOVA, $F_{(2,20)}$=19.68, P<0.001), but had no significant effect on spontaneous alternation (55±2, 55±3 and 56±3, $F_{(2,20)}$=-24.54, P>0.05). Administration of the selective D4 agonist, PD168,077 (1, 10, 20mg/kg, i.p.), however, improved spontaneous alternation dose-dependently, (0, 10, 20 mg/kg: 67±3, 62±4, and 48±3, $F_{(2,31)}$=9.13, P<0.001), but did not have significant effects on the total number of arm entries (51±5, 54±4, and 56±5, $F_{(2,31)}$=1.23, P>0.05). Thus, hyperactivity and working memory deficits appear to be dissociable at the level of individual dopamine receptor function in the PNE mouse model of ADHD. Our data provide novel insights into the molecular mechanisms associated with individual components of the ADHD symptomatology, and underscore the potential for developing personalized treatments that target specific symptom domains.

Title: Influence of dopamine d1 receptor recycling in its heteromerization with type-2α corticotropin hormone receptors

Authors: *H. E. YARUR, K. GYSLING;
PUC, Santiago, Chile

Abstract: G-protein coupled receptors (GPCR) are involved in many physiological responses and are the target of more than 50% of the drugs present in the market. Heteromerization of GPCRs is a phenomenon known as the interaction of at least two GPCRs. In our laboratory, we have shown that type-2 corticotropin hormone receptors (CRHR2α) and dopamine D1 receptors (D1R) are capable of heteromerize after heterologous co-expression. D1R expressed alone is readily trafficked to the plasma membrane while CRHR2α is observed mainly in the endoplasmic reticulum. Interestingly, we have observed a change in the subcellular localization of both receptors when they are co-expressed. We hypothesize that the known recycling capacity of D1R influences its heteromerization with CRHR2α. For this purpose, we are evaluating the interaction of CRHR2α with a mutated form of D1R lacking its recycling domain, using protein immunoprecipitation and inmunofluorescence microscopy. We expect that the lack of D1R recycling domain will diminish the level of D1R/CRHR2 heteromerization and the consequent observed change in their sub-cellular localization induced by the heteromerization.

Title: Dopamine and serotonin alter neuronal excitability of lateral orbitofrontal cortex neurons

Authors: *S. NIMITVILAI, J. J. WOODWARD;
Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: The orbitofrontal cortex (OFC), a brain region within the prefrontal cortex (PFC), plays an important role in integrating sensory information, and participates in learning, prediction and decision making for emotional and reward-related behaviors. The OFC reciprocally interacts with several brain areas, including the dorsal and ventral striatum, medial PFC (mPFC), amygdala, dorsal raphe nucleus and midbrain. Many studies have revealed that the OFC is extensively innervated by monoamines, including serotonin, dopamine and noradrenaline. Dysfunction of the OFC is associated with numerous neuropsychiatric disorders such as schizophrenia, obsessive-compulsive disorder and alcohol and substance abuse disorders, and drugs that target monoamine receptors have been used in the treatment of these psychiatric diseases. However, little is known about how monoamine neurotransmitters modulate excitability of OFC neurons. In this study, we addressed this question and used whole-cell patch-clamp electrophysiology to examine the effects of serotonin and dopamine on current evoked firing of neurons in deep layers of the lateral OFC. Dopamine decreased the evoked excitability of OFC neurons in a concentration-dependent manner and this effect was largely reversed by a D2 receptor antagonist. Similarly, serotonin produced a reduction in number of spikes of OFC neurons and the role of 5-HT1 and other 5-HT receptor subtypes were examined. These data suggest that the intrinsic activity of lateral OFC neurons is reduced by either dopamine or serotonin and suggest that dysfunction of either of these neuromodulators may underlie some of the changes in OFC observed in various neuropsychiatric diseases including alcohol dependence. Title: Calcium levels determine differential signaling of adenosine A2A-dopamine D2 receptor heteromers in striatal neurons

Authors: *S. FERRE[1], D. AGUINAGA[2], E. MORENO[2], A. CORTES[2], J. MALLOL[2], V. CASADO[2], C. LLUIS[2], E. CANELA[2], P. MCCORMICK[2,3], G. NAVARRO[2];

Abstract: The pharmacological significance of the adenosine A2A receptor (A2AR)-dopamine D2 receptor (D2R) heteromer is well established, but the physiological factors that control its biochemical properties are still unknown. Using resonance energy transfer techniques and proximity ligation assay and determining adenylyl cyclase and MAPK signaling in HEK-293T transfected cells and striatal neurons in culture, we demonstrate a significant role of Ca2+ in the regulation of A2AR-D2R heteromer function. This is mediated by allosteric modulations mediated by the neuronal Ca2+-binding proteins NCS-1 and calneuron-1, which exert differential effects on the antagonistic modulation that A2AR exerts on D2R-mediated MAPK activation and adenylyl-cyclase inhibition. In transfected cells, NCS-1 and calneuron-1 compete for the same receptor epitopes to interact with A2AR-D2R heteromers. In striatal neurons, different Ca2+ levels promote the binding of either NCS-1 or calneuron-1 to the A2AR-D2R heteromer and its functional modulation. Preferential activation of A2AR in the A2AR-D2R heteromer leads to both cAMP accumulation and MAPK signaling. Upon co-activation of A2AR and D2R, the presence of low Ca+2 levels, with the corresponding binding of NCS-1, leads to only MAPK signaling; with high Ca+2 levels, co-activation leads to a very diminished cAMP and MAPK signaling response. In this way, A2AR-D2R heteromer constitutes a cellular device that provides a fine-tune modulation of adenosine and dopamine signals that, depending on the concentration of each neurotransmitter and the Ca+2 levels, determines the degree of adenylyl-cyclase or MAPK signaling. The results also shed light on the physiological role of reciprocal

antagonistic interactions within the A2AR-D2R heteromer, considered as a relevant target for the treatment of neuropsychiatric disorders.

Title: Computational model evidence for a complex containing DAT, VMAT, and D2 receptors and for pH regulation of dopamine leak from storage vesicles

Authors: ***L. J. WALLACE**, K. H. CIERNIAK, A. T. ZURLINDEN, A. D. KLAUSING; Ohio State Univ., COLUMBUS, OH

Abstract: The combination of an antipsychotic drug and an inhibitor of dopamine transporter (DAT) exerts several effects on dopamine nerve terminals (varicosities) that have not yet been explained. The goal of this project is to explain these effects using computer simulation models of dopaminergic varicosities. The simulation model utilizes rate equations for dopamine synthesis and metabolism and for transport of dopamine and its metabolite, DOPAC, between compartments. Drug effects are simulated by changing values of parameters thought to be impacted by the drugs. When such changes failed to provide a model output that matches published experimental data, additional changes were made using a trial and error process until model output matched experimental data. A set of parameters was found that provided model output closely matching published data for extracellular dopamine, extracellular DOPAC, tissue dopamine, tissue DOPAC, and rate of dopamine synthesis. The results document that : • D2 receptor antagonism increases extracellular dopamine by 63% with a compensatory increase in rate of dopamine synthesis • Some but not all antipsychotic drugs increase the rate of passive diffusion of dopamine out of storage vesicles. Rate of dopamine synthesis increases proportionally to the rate of increase of diffusion • D2 receptor antagonism decreases rate of DOPAC disappearance by 50% • DAT inhibition decreases rate of dopamine removal from signaling space • DAT inhibition decreases rate of secretion of dopamine by 70% • Combination of drugs reverses decreased rate of secretion elicited by inhibitors of DAT alone • Combination

of drugs decreases rate of dopamine storage by vesicular monoamine transporter (VMAT) by 60% We postulate the following biological explanation for these observations. (1) Some (but not all) antipsychotic drugs are lipophilic weak bases. These accumulate in storage vesicles, partially alkalinize the vesicle, and increase amount of diffusible neutral dopamine. Some tyrosine hydroxylase is located on storage vesicles, and activity of this enzyme increases in proportion to increases in rate of passive diffusion of dopamine out of vesicles. (2) DAT, VMAT, and D2 receptors exist in a complex such that pharmacological inhibition of both D2 receptors and DAT results in decreased activity of VMAT.

Title: The adenosine A2A receptor-dopamine D2 receptor heterotetramer: Understanding the molecular mechanisms of caffeine

Authors: *J. BONAVENTURA[1,3], G. NAVARRO[3], K. AZDAD[4], W. REA[1], V. CASADÓ[3], M. BRUGAROLAS[3], E. ANGELATS[3], J. MALLOL[3], E. I. CANELA[3], A. CORTÉS[3], C. LLUÍS[3], N. D. VOLKOW[2], S. N. SCHIFFMANN[4], V. CASADÓ[3], S. FERRÉ[1];
[1]NIDA/NIH, Baltimore, MD; [2]NIDA/NIH, Rockville, MD; [3]Univ. de Barcelona, Barcelona, Spain; [4]Universtité Libre de Bruxelles, Bruxelles, Belgium

Abstract: G-protein coupled receptors (GPCRs) form homomers and heteromers. The pentameric structure constituted by one GPCR homodimer and one heterotrimeric G protein may provide a main functional unit, and it is being hypothesized that GPCR heteromers are

constituted by heteromers of homodimers. Allosteric mechanisms determine a multiplicity of possible unique pharmacological properties of GPCR heteromers. Binding of a ligand to one of the receptors in the heteromer can modify the affinity of ligands for the other receptor. The most reproduced allosteric modulation of ligand-binding properties in a GPCR heteromer is the ability of adenosine A2A receptor (A2AR) agonists to decrease the affinity of dopamine D2 receptor (D2R) agonists in the A2AR-D2R heteromer. Since this mechanism could not explain recent results of PET experiments showing that caffeine significantly enhances binding of the D2R antagonist [11C]raclopride in human striatum, we evaluated other possible allosteric interactions in the A2AR-D2R heteromer involving antagonists. Experiments were performed in membrane preparations from sheep and human striatum and from HEK-293T cells transfected with D2R and wild type or mutant A2AR. The same as for A2AR agonists, A2AR antagonists (and caffeine) reduced D2R agonist (and antagonist) affinity, and this effect was significantly attenuated upon concomitant exposure to an A2AR agonist and an A2AR antagonist. Similar interactions of A2AR and D2R ligands were observed at the level of cell signaling (MAPK activation), striatal neuronal function (patch-clamp experiments) and locomotor activity (in rats) and indicated an additional modulation of the intrinsic efficacy of D2R agonists by A2AR agonists and antagonists. Our results indicate the presence of two binding sites for A2AR ligands, corresponding to two orthosteric sites, in the A2AR-D2R heteromer. Only their occupancy with either an A2AR agonist or antagonist, but not their simultaneous occupancy with an A2AR agonist and an A2AR antagonist, leads to allosteric modulations of D2R ligands. These results also suggest that A2AR-D2R heterotetramers constitute main functional units, which was supported with BRET experiments with double bi-molecular complementation of bioluminescent and fluorescent proteins.

Title: Decreasing the availability of intracellular calcium enhances potency and efficacy of dopamine on D2 autoreceptor-mediated currents in DBA/2J mouse brain slices

Authors: *A. J. AVELAR[1], A. SHARPE[2], M. J. BECKSTEAD[1];
[1]Dept. of Physiol., UT Hlth. Sci. Ctr. San Antonio, San Antonio, TX; [2]Univ. of the Incarnate Word, San Antonio, TX

Abstract: Dopamine neurons in the substantia nigra are involved in the initiation of voluntary movement and reward-related processes. D2-type autoreceptors on these neurons powerfully inhibit cell firing and have been negatively associated with psychostimulant use. Previous work from our lab suggests that intracellular calcium inhibits maximal autoreceptor-mediated outward currents in dopamine neurons from mouse brain slices. Additionally, we have observed that methamphetamine self-administration decreases maximal D2 autoreceptor-mediated outward currents in a calcium-dependent manner. However, since under physiological conditions only some of the autoreceptors are activated at any given time it is important to determine the effects of calcium on outward currents induced by lower concentrations of agonist. The objective of this study was to investigate the calcium dependence of the concentration-response curve for dopamine activation of D2 dopamine autoreceptor-mediated outward currents in naive and methamphetamine self-administration mice. To address this, we performed whole-cell patch-clamp electrophysiology of dopamine neurons in horizontal brain slices from DBA/2J mice to record outward currents from D2 autoreceptor opening of G protein coupled inwardly rectifying potassium (GIRK) channels. Naïve and methamphetamine self-administering mice were used to compare concentration-response curves between groups. The internal solution of the recording pipette contained either 10 mM BAPTA (high calcium chelation) or 0.025 mM EGTA (control conditions, low calcium chelation). Dopamine iontophoresis (1M) indicated the maximal D2 autoreceptor-mediated outward current that could be obtained from each cell, and bath perfusion of dopamine (3-300 μM) was used to construct agonist concentration-response curves. We tested the hypothesis that calcium chelation produces a leftward shift in the dopamine concentration-response curve at D2 autoreceptors. Our results show that decreasing the availability of intracellular calcium enhances both the potency and efficacy of dopamine on D2 autoreceptor-mediated currents. This calcium-mediated regulation of dopamine neuron physiology could have implications for the effects of psychostimulants on dopaminergic neurotransmission.

Title: Dopamine-induced synaptic plasticity is mediated by molecular interaction of ghrelin and dopamine-1 receptor in hippocampal neurons

Authors: *A. KERN, R. G. SMITH;
Metabolism & Aging, The Scripps Res. Inst., Jupiter, FL

Abstract: Employing *ghsr-IRES-tau-GFP* mice we found that ghrelin receptor (GHSR1a) and dopamine-1 receptor (DRD1) are co-expressed in dentate gyrus, CA1, CA2 and CA3 regions of hippocampus. We detected dependence on GHSR1a for DRD1 agonist-mediated expression of early response genes associated with synaptic plasticity, as well as phosphorylation of CaMKII, translocation of pCaMKII, exocytosis of glutamate receptors and induction of synaptic plasticity. In neurons co-expressing GHSR1a and DRD1 the DRD1 agonist, SKF81297, activates non-canonical DRD1 signal transduction via $G\alpha_q$-PLC-IP_3-Ca^{2+}; and independent of ghrelin, $G\alpha_s$ coupling and signaling through cAMP. This non-canonical pathway is inactive in hippocampal neurons from *Ghsr-/-* mice and is blocked by a neutral GHSR1a antagonist in neurons of *Ghsr+/+* mice. Confocal FRET microscopy is consistent with formation of trimeric complex in hippocampal cell bodies and neurite processes composed of GHSR1a:DRD1 heteromers in close proximity to $G\alpha_q$ (5.45 nm). The dynamic molecular interaction between GHSR1a and DRD1 was confirmed by using single molecule TIRF microscopy in real-time at the plasma membrane of hippocampal neurons. The molecular interaction between GHSR1a and DRD1 increased in the presence of SKF81297. Our demonstration that SKF81297-induced synaptic plasticity in hippocampal neurons is dependent on forming GHSR1a:DRD1 heteromers to result in DRD1 coupling to $G\alpha_q$ at the expense of $G\alpha_s$, is a new finding with profound implications for mechanisms involved in learning and memory. These results also provide an allosteric basis for indirectly fine-tuning dopamine action in GHSR1a:DRD1 expressing neurons using GHSR1a antagonists.

Title: Genetic predictors of *in vivo* human DOPA decarboxylase activity

Authors: *D. P. EISENBERG[1], J. C. MASDEU[1], P. D. KOHN[1], C. HEGARTY[1], B. KOLACHANA[2], D. R. WEINBERGER[3], K. F. BERMAN[1];
[1]Section on Integrative Neuroimaging, CBDB, [2]CBDB, NIMH, NIH, DHHS, Bethesda, MD; [3]Lieber Inst. for Brain Develop., Baltimore, MD

Abstract: BACKGROUND: DOPA decarboxylase (DDC) is an important enzyme in the synthesis of neuroactive molecules, including dopamine, serotonin, and trace amines. Rare genetic mutations abolishing the activity of this enzyme result in a syndrome that includes marked mental and motor developmental delays. Common genetic variation in DDC has been suggested to contribute to risk for several neuropsychiatric conditions and to illness onset in schizophrenia, in which DDC activity is exaggerated. Yet, it is unknown whether common variation in the DDC gene impacts its product's function *in vivo*. METHODS: To address this knowledge gap, we performed both DDC genotyping and DDC (18F-DOPA) PET studies in 119 healthy adults (59 women, 60 men) under 55 years of age. Twenty three markers across DDC with minor allele frequencies greater than 5% and providing coverage of HapMap annotated common variants in the CEU sample (at r-squared greater than 0.8 by 2- and 3-marker tagging as implemented by Haploview) were genotyped from peripheral blood samples with Taq-Man 5'-exonuclease assay. Haplotypes were created using PHASE software. For PET studies, after carbidopa pretreatment and at least 6 hours of fasting, 8-16 mCi of 18F-DOPA were injected intravenously and 90 minutes of dynamically binned images were acquired. These scans were attenuation-corrected, realigned, and coregistered to a structural MRI obtained in a separate session. Four regions of interest (ROIs) - dorsal caudate, dorsal putamen, ventral striatum (including nucleus accumbens) and midbrain - and one cerebellar reference region were delineated on each individual's structural MRI and applied to their PET data. The Patlak-Gjedde graphical method was employed using PMOD software to calculate the specific uptake constant Ki. General linear model analyses were performed in SPSS. RESULTS: Five haplotypes with frequencies of greater than 5% were generated and were independent of age and sex. Haplotype 2 and haplotype 4 provided nominal predictive value for specific tracer uptake, which, in post-hoc univariate tests, were shown to be driven largely by associations with midbrain ($p=0.004$)

and ventral striatum (p=0.01) Ki. DISCUSSION: Common variation in DDC predicts measureable differences in central 18F-DOPA uptake, suggesting a possible impact on DDC cis-regulation and warrenting genetic investigation of its potential molecular underpinnings. By offering evidence for functional effects of DDC polymorphisms in the living human brain, this study lays groundwork upon which to pursue hypotheses linking this candidate gene and aspects of neuropsychiatric conditions with mesolimbic involvement.

Abstract: Introduction: Aging is a complex, biological progression that increases the likelihood of developing neurodegenerative diseases such as Alzheimer’s and Parkinson’s disease. Neurotrophic factors provide an avenue of study into the aging process, as these secreted peptides promote survival, differentiation and maintenance of neurons, as well as the establishment of synaptic connections during development. The loss of neurotrophic support for specific neurotransmitter populations could confer susceptibility to various neurodegenerative disorders. Conserved dopamine neurotrophic factor (CDNF) is a novel neurotrophic factor that

has not yet been investigated in the aging process. Several scientists have proposed that the circulating blood may act as a "sentinel tissue", reflecting states of health or disease within the body for which human brain tissue biopsy samples are unavailable. Therefore, the objective of the present study was to measure CDNF levels in peripheral whole blood of healthy individuals, to examine CDNF mRNA expression in the human population over the course of development. Methods: Venous whole blood was collected from 26 healthy individuals at St. Josephs Healthcare in Hamilton, Ontario (all protocols approved by Hamilton Integrated Research Ethics Board and the Research Ethics Board at McMaster University). Whole blood mRNA was purified and extracted from PAXgene blood RNA tubes. CDNF mRNA gene expression was analysed using real-time reverse-transcriptase polymerase chain reaction (RT-PCR). PCR forward (F) and reverse (R) CDNF primers were as follows (5' 3'): F AAAGACGCAGCCACAAAGAT, R AGGATCTGCTTCAGCTCTGC. Results: Patients were divided into 3 age groups; A) Children [0-18 (n=6)], B) Young adults [18-50 (n=16)], and C) Older adults [50+ (n=5)]. One-way ANOVA was used to determine differences in CDNF mRNA expression levels between groups. Results indicated a trend towards decreasing CDNF levels with aging (p=0.07). Conclusions: This preliminary result suggests that CDNF mRNA levels may decrease with aging. Reductions in CDNF over the course of development may be particularly important in Parkinson's disease, a disorder stemming from dopamine degeneration. While larger studies are awaited to confirm this hypothesis, the examination of CDNF levels in peripheral blood may serve as a viable biomarker in the understanding of the selective dopaminergic degeneration within this disorder. This study was supported by: Canadian Institutes of Health Research (CIHR), Natural Sciences and Engineering Research Council (NSERC), and the Ontario Mental Health Foundation (OMHF).

Title: Hypoxia induces rapid production and release of enkephalins and cytokines in mouse pheochromocytoma cells

Authors: *M. J. EVINGER[1], A. S. CALERO[2], H. H. VILLANUEVA[2], P. GIRI[2], J. F. POWERS[3], A. S. TISCHLER[3];
[2]Pediatrics, [1]Stony Brook Univ., Stony Brook, NY; [3]Pathology, Tufts Univ. Sch. of Med., Boston, MA

Abstract: Adrenal chromaffin cells function as O_2 sensors during the third trimester of pregnancy and early post-natal life prior to maturation of the sympathetic nervous system. The ability to detect and mount appropriate physiological responses is important for neonate survival of apnea and hypoxic events frequently encountered during labor, delivery and early postnatal life. Mouse pheochromocytoma cells (MPC 10/9/96CR) are one of several adrenergic chromaffin-like cell lines characterized by epinephrine production and release (Powers et al., *Cell Tissue Res*., 2000). Complementing our previous demonstration that hypoxia is a potent stimulator of PNMT gene expression in these cells (Evinger et al., *Ann N Y Acad Sci.* 2002), this study hypothesizes that reduced oxygen concentrations[O_2] are likewise a significant stimulus for release of other chromaffin cell products important for survival of hypoxic episodes. Using MPC 10/9 cells subjected to 10% [O_2](hypoxia) for specific intervals, we demonstrate that hypoxia induces rapid and robust release of the catecholamine epinephrine with concentrations in media increasing from 0 to 25 ng/ml following 15 min incubation at 10% [O_2]. Hypoxia-stimulated production and release of enkephalin (ENK) parallels that of catecholamines: a ~2-fold increase of Met-ENK is detected by ELISA in the medium within 15 min. Following an initial decrease in cellular ENK content, the amount of ENK in MPC 10/9 cell extracts then rises by an average of 50% by 60 min. Synthesis of preproenkephalin mRNA likewise increases up to 3-fold within 30 min exposure to 10% O_2. Additionally, hypoxia stimulates production and release of chromaffin cell cytokines IL-1α and IL-1β from MPC 10/9 cells, with significant changes in IL-1β detectable within 15 min, as revealed using antibody-coupled Luminex detection . A compensatory increase of the cytokine mRNAs occurs following incubation in reduced [O_2]. Therefore, hypoxia-stimulated release of ENK and of cytokines IL-1α and IL-1β parallels the effects of reduced [O_2] on MPC 10/9 cell catecholamine content. Thus, in addition to metabolic enhancement provided by chromaffin cell catecholamine release, hypoxia evokes significant release of opioid peptides capable of modulating reflex-regulated cardiac contractility (especially during asphyxia-induced hypotension) and pro-inflammatory cytokines with associated influences on peptide hormone, catecholamine and steroid production. As seen in effects on CNS neurons, hypoxia evokes the rapid release and compensatory re-synthesis of adrenal medullary factors that enhance metabolic and physiological survival during neonatal O_2 deprivation.

Title: NOP-eGFP mice: Immunohitochemical characterization of the NOP-eGFP distribution in the spinal cord and DRG

Authors: *A. OZAWA[1], J. WU[1], D. MERCATELLI[1], G. BRUNORI[1], S. LOW[2], G. SCHERRER[2], B. L. KIEFFER[3], L. TOLL[1];
[1]Torrey Pines Inst. For Mol. Studies, Port St Lucie, FL; [2]Stanford Univ. Sch. of Med., Palo Alto, CA; [3]Douglas Institute, McGill Universit, Montreal, QC, Canada

Abstract: NOP receptors and N/OFQ are found throughout the brain, in the spinal cord, dorsal root ganglia, and a variety of peripheral tissues. The NOP-N/OFQ system regulates a wide range of biological actions including nociception. To better characterize the anatomical distribution patterns of the receptor, immunohistochemical experiments are conducted on mice in which the NOP receptor is replaced by an active NOP-eGFP receptor C-terminal fusion protein. Tissue sections from the dorsal root ganglia and spinal cord are stained with anti-GFP antibodies, as well as with antibodies to NF200, CGRP, PKCγ, and with biotinylated IB4. In the DRG, NOP-eGFP receptors are expressed on large, medium, and relatively small NF200+ (myelinated) cells that are mostly CGRP-, suggesting that they are not the peptidergic Aδ nociceptors. This also implies that the NOP-eGFP receptors might be on myelinated low-threshold mechanosensory neurons, including down-hair afferents. Down-hair afferents are the most sensitive mechano-sensitive somatosensory neurons and contribute to touch perception. They have myelinated axons and relatively small diameter cell bodies, and are NF200+. These cells contain neither mu nor delta receptors. They project to the ventral border of inner lamina II of the spinal cord where PKCγ+ spinal neurons are located. There are also a number of small cells that are NOP-eGFP+, NF200-, CGRP+ (or mu receptor positive): these are likely the typical peptidergic nociceptive C-fibers. Small cells are also observed that stain only for NOP-eGFP, implying the possibility that these cells might be involved in nonpeptidergenic nociceptive responses. In the spinal cord, NOP-eGFP receptors are highly expressed in laminae I-III, where CGRP (lamina I and lamina II

outer) immunoreactive terminals, PKCγ (ventral border of lamina II inner) interneurons and the terminals of IB4 positive neurons (dorsal border of lamina II inner) are located; immunoreactivity extends into lamina X. A moderate GFP immunoreactivity also appears ventrally throughout the spinal cord. This expression pattern of NOP-eGFP in spinal cord is consistent with the previously reported *in vitro* autoradiography in rat spinal cord. In most of the cells visualized, whether they are from the spinal cord, DRG, or brain, NOP receptors appear to be located throughout the cell, rather than being localized to the plasma membrane. In summary, immunohistochemical characterization provides us with information regarding the cell types containing NOP receptors in DRG and the lamina location in the spinal cord. It will be useful information for understanding the mechanism by which NOP receptors alter a nociceptive response.

Title: Hippocalcin signaling underlying slow afterhyperpolarization in hippocampal neurons

Authors: *N. I. KONONENKO[1,2], A. DOVGAN[1,2], V. CHERKAS[1,2], T. TSUGORKA[1,2], P. BELAN[1,2];
[1]Inst. Physiol, Kiev, Ukraine; [2]Key State Lab. of Mol and Cell Biol, Kiev, Ukraine

Abstract: Hippocalcin (HPCA) is a neuronal Ca2+ sensor protein that mediates many cellular functions. In particular, it is thought that HPCA mediates expression of a slow afterhyperpolarization (sAHP) in response to an increase in a free intracellular Ca2+ concentration ([Ca2+]i) in a neuronal dendritic tree. In the current work, we studied molecular mechanisms of sAHP induction by HPCA in cultured hippocampal neurons. First, we pharmacologically and electrophysiologically characterized channels underlying sAHP in these

neurons. We demonstrated that sAHP was mediated by potassium Ca2+-dependent conductance, which was not significantly reduced by a specific KCNQ channel blocker, XE991, indicating that this class of potassium channels does not contribute to sAHP current (IsAHP). Interestingly, that well-known sAHP inhibitors, UCL2077 or UCL1848 also did not affect IsAHP. At the same time, IsAHP was almost completely inhibited by activation of M1 cholino- or beta-adrenergic receptors. By means of loss of function and overexpression strategies we demonstrated that amplitude of IsAHP is strongly correlated with a level of HPCA expression implying that HPCA does function as a Ca2+ sensor for the sAHP in the hippocampal neurons. Simultaneously recording IsAHP and HPCA-YFP translocation induced in the same neuron by activation of voltage-gated Ca2+ channels we demonstrated overlapping of their time courses in certain sites of dendritic tree. It suggested that HPCA insertion into the plasma membrane in these sites may induce IsAHP. Using modification of FRET approach, which allowed us to measure HPCA concentration in the plasma membrane, a direct correlation between this concentration in the apical part of dendritic tree and IsAHP value was observed during the current decay. These results strongly suggest that the HPCA bound to certain sites of apical dendrite induces potassium Ca2+-dependent conductance responsible for sAHP and that sAHP conductance is proportional to HPCA concentration in these sites. It should be noted that a proportion of neurons revealing HPCA insertion into the plasma membrane upon an increase of [Ca2+]i did not produce a measurable IsAHP. It suggests that HPCA insertion into the plasma membrane in these neurons occurs in sites lacking the respective potassium conductance. All these findings demonstrate that sAHP is a complex phenomenon, in which HPCA integrates spatio-temporal changes of [Ca2+]i into its widespread insertion into the dendritic plasma membrane. This, in turn, results in activation of K+ conductance only in the sites where the respective still unidentified potassium channels are located.

Title: A novel mechanism for stress-induced analgesia: Involvement of orexin, substance P, and mGluR5 in the periaqueductal gray

Authors: *L.-C. CHIOU[1,2,3], Y.-C. CHIU[2];
[1]Dept. of Pharmacol., Natl. Taiwan University, Med. Col., Taipei, Taiwan; [2]Grad. institute of Pharmacol., Taipei, Taiwan; [3]Grad. institute of Brain and Mind Sci., Taipei, Taiwan

Abstract: Substance P has been known to be antinociceptive at the supraspinal level, primarily mediated by the neurokinin-1 receptor (NK1R). However, its action mechanism(s) remain unclear. An electrophysiological study in the ventrolateral periaqueductal gray (vlPAG) showed that substance P can activate glutamatergic neurons to release massive glutamate that activate perisynaptic $mGluR_5$, yielding endocannabinoids (eCBs) that inhibit GABA release via presynaptic cannabinoid 1 receptors (CB1Rs), producing retrograde disinhibition. Previously, we found orexin A induced antinociception also through eCB-mediated retrograde disinhibition in the vlPAG.[1] Both orexins and substance P are involved in stress-induced analgesia (SIA). Therefore, we investigated whether orexin A induces analgesia through releasing substance P in the vlPAG via this glutamate-$mGluR_5$-eCB-CB1R signaling cascade, and if this mechanism contributes to SIA. Intra-vlPAG microinjection (*i.pag.*) of substance P (5 nmol) significantly increased the paw withdrawal latency in the hot plat test in C57BL/6 mice (male, 8-12 weeks). This antinociceptive effect was blocked by *i.pag.* MPEP (50 nmol, an $mGluR_5$ antagonist) and AM251 (30 nmol, a CB1R antagonist), respectively. As reported previously, *i.pag.* orexin A (1 nmol.) also produced significant antinociceptive effect. Interestingly, this antinociceptive effect was blocked by *i.pag.* L-703,606 (10 nmol, an NK1 receptor antagonist) or MPEP. Interestingly, a 30-min restraint stress in mice significantly increased the withdrawal latency, and this SIA was blocked by *i.pag.* L-703,606 and MPEP. Both antagonists did not affect spontaneous locomotor activity in mice. Besides, substance P levels, measured by enzyme immunoassay, in vlPAG homogenates were significantly elevated in restrained mice, as compared to un-restrained ones (95.4±13.1 *vs.* 55.7±2.0 pg/μg protein, $p<0.05$). It is suggested that during stress, hypothalamic orexin neurons are activated, and released orexin A induces analgesia through releasing substance P that produces disinhibition via NK1Rs in the vlPAG by releasing glutamate to activate the $mGluR_5$-eCB-CB1R signaling cascade. Title: Nuclear export of OGFr is dependent on a nuclear export signal

Authors: N. P. KREN, I. S. ZAGON, *P. J. MCLAUGHLIN;
Dept Neural & Behav Sci., Penn State Univ. Coll Med., HERSHEY, PA

Abstract: The opioid growth factor (OGF) - OGF receptor (OGFr) axis regulates cell replication during normal development, tissue homeostasis, and neoplasia. Unlike classical opioid receptors, OGFr is not a transmembrane receptor, but does share some pharmacological properties with mu, delta, and kappa opioid receptors. OGFr binds the pentapeptide OGF, chemically termed [Met5]-enkephalin, to activate cyclin-dependent inhibitory kinas pathways and repress cell replication. This function of Gofer is dependent on nuclear localization. OGFr has three nuclear localization signals, and transport into the nucleus is mediated by karyopherinβ and Ran. Mechanisms of OGFr export from the nucleus are unknown. A variety of techniques were utilized to determine whether OGFr is actively exported from the nucleus. An evolutionarily conserved region of OGFr has 1 predicted nuclear export signal (NES) comprised of four leucines at residues 217, 220, 223 and 225. OGFr-eGFP was overexpressed in COS-7 cells, lacking other classical receptors, in order to visualize nuclear trafficking. Treatment with leptomycin B, an inhibitor of CRM-1 (chromosome region maintenance 1), demonstrated accumulation of OGFr-eGFP as well as endogenous OGFr in the nucleus, indicating that OGFr is exported in a CRM-1 dependent manner. Site-directed mutagenesis of specific leucines 217, 220, 223, and 225 individually or in combination resulted in decreased nuclear to cytoplasmic ratios, rather than accumulation within the nucleus. There are two plausible explanations for this unexpected result 1) OGFr could homodimerize with endogenous OGFr and be exported by the functional NES found in endogenous OGFr or 2) OGFr could be degraded within the nucleus. When cells expressing deltaNES were treated with leptomycin B nuclear accumulation increased by 22%, indicating that receptor dimerization may be only partially responsible. In similar experiments utilizing COS-7 cells expressing deltaNES treated with MG132, a proteasome inhibitor, there was no effect on nuclear localization, indicating that degradation does not account for exclusion of deltaNES from the nucleus. In conclusion, OGFr is actively exported from the nucleus by the nuclear export signal identified as residues 217-225, however regulation of this event warrants further studies.

Title: Netupitant and palonosetron trigger NK_1 Receptor internalization in NG108-15 cells

Authors: ***C. ROJAS**, A. G. THOMAS, M. STATHIS, B. S. SLUSHER;
Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Current therapy for chemotherapy induced nausea and vomiting includes the use of both 5-HT_3 and NK_1 receptor antagonists. Acute emesis has largely been alleviated with the use of 5-HT_3 receptor antagonists while an improvement in preventing delayed emesis has been achieved with NK_1 receptor antagonists. Delayed emesis however, remains a problem with a significant portion of cancer patients receiving highly emetogenic chemotherapy. Like other drugs in its class, palonosetron, a 5-HT_3 receptor antagonist, has shown efficacy against acute emesis. However, palonosetron has also shown consistent improvement in the suppression of delayed emesis. Since both 5-HT_3 and NK_1 receptor antagonists are often simultaneously administered to patients, the question remains if palonosetron's effect on delayed emesis would remain distinct when co-administered with an NK_1 receptor antagonist. Recent mechanistic studies using NG108-15 cells have shown that palonosetron and netupitant, an NK_1 receptor antagonist currently in phase 3 clinical trials, exhibited synergistic effects when inhibiting the Substance P response. The present studies showed that both netupitant and palonosetron induced NK_1 receptor internalization in NG108-15 cells and that when used together receptor internalization was additive. Palonosetron-induced NK_1 receptor internalization was dependent on the presence of the 5-HT_3 receptor. Results provide a possible explanation for palonosetron's enhancement of the inhibition of the SP response and suggest that the effect of palonosetron and NK_1 receptor antagonists on prevention of delayed emesis could be additive.

Title: Hippocampome.org: A neuroinformatics tool for biomarker profiling

Authors: *C. WHITE, C. L. REES, D. W. WHEELER, D. J. HAMILTON, A. O. KOMENDANTOV, S. VENKADESH, G. A. ASCOLI;
Krasnow Inst. for Advanced Study, George Mason Univ., Fairfax, VA

Abstract: Comprehending the dynamics of complex biological systems like the mammalian brain requires understanding the cells involved. Fundamental to this endeavor is knowledge of the molecular biomarkers they express. These biomarkers may enable the chemical identification of neuron types while providing informative signatures of functional mechanisms. A wealth of relevant literature on this topic exists; however, its optimal utilization requires that it be collected, organized, and integrated in easily accessible, centralized locations. Hippocampome.org provides such an opportunity by characterizing the morphology, electrophysiology, and biomarker expression of neuron types in the rodent hippocampal formation (dentate gyrus, CA1, CA2, CA3, subiculum, and entorhinal cortex). This knowledge base defines neuronal types on the basis of their primary neurotransmitter and the anatomical distributions of their axons and dendrites. The scientific literature then is mined for experimental biomarker data from individual morphologically-defined neurons corresponding to these types. Hippocampome.org also includes data on spatial expression patterns within the hippocampal subregions and layers that can be linked to specific neuron types by their somatic location. Hippocampome.org contains information on over 60 biomarkers. Those with expression information known for the most neuron types include the calcium binding proteins, calbindin, calretinin, and parvalbumin and the neuropeptides, cholecystokinin and somatostatin.

Approximately two-thirds of the more than 100 neuron types in the current instantiation of Hippocampome.org have expression information for at least one biomarker. From these data, potentially unique biomarker profiles can be identified for some hippocampal neuron types.

Title: Neuropeptide release in response to mechanical stimulation of cultured dorsal root ganglion cells

Authors: *E. G. TILLMAAND[1,2], C. A. CROUSHORE[3,1], S. S. RUBAKHIN[1], T. A. SAIF[4], J. V. SWEEDLER[3,2,1];
[1]Beckman Inst. For Advanced Sci. and Technol., Urbana, IL; [2]Neurosci., [3]Chem., [4]Mechanical Sci. and Engin., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: The pervasiveness of peptides as intercellular signaling molecules in the nervous system, along with their involvement in multiple disease states, underscores the importance of understanding key processes responsible for their function, including constitutive and/or stimulated release from healthy and pathologically modified cells. While the responses of neurons to chemical stimulation have been studied in detail, responses to mechanical stimuli are not as well understood. Results of recent investigations show that cells can specifically respond to mechanical stimuli and environments (Engler, AJ et al. Cell. 2006) and that tension plays a role in neuronal function (Ahmed, WW et al. Cell Mol Bioeng. 2012). However, the role of mechanical stimuli in the modulation of intercellular communication mechanisms remains elusive as studies linking neuropeptide release to changes in the mechanical environment are lacking. Here, we study dorsal root ganglion (DRG) cell neurochemistry as a function of changes

in mechanical environment. Toward this end, DRG cells are isolated from male Sprague-Dawley rats and cultured on a polydimethylsiloxane (PDMS) mechanical platform. After approximately 14 days in culture, tensile strain is applied to the PDMS substrate and, therefore, to the cultured cells. Samples of the extracellular media containing released peptides are collected before, during, and after the mechanical stimulation. Off-line matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS) is used to study the peptide profile of the releasates and results are compared with that of DRG cells stimulated via an increase in extracellular K+. A number of signals within the peptide molecular mass region are observed, with current efforts aimed at identifying the peptides using liquid chromatography coupled to tandem mass spectrometry. Several peptides have been tentatively identified including those derived from proteins involved in neuronal functions such as S100-beta and various splice forms of Myelin Basic Protein S, and those involved in receptor signaling. Interestingly, application of the two different stimuli to the DRG cells (mechanical versus chemical) resulted in the release of distinct peptide profiles with some overlap, suggesting that there are may be unique signaling pathways for the two methods of stimulation. By coupling the mechanical strain system with mass spectrometric microanalysis, we are able to focus on mechanically induced peptide release in order to further our understanding of the roles mechanical forces play in cell-to-cell communication.

Title: Dopamine D3, but not D2 or D4 receptor subtypes, mediate the inhibition of the vasodepressor sensory CGRPergic outflow in pithed rats

Authors: *G. MANRIQUE-MALDONADO, A. H. ALTAMIRANO-ESPINOZA, E. RIVERA-MANCILLA, B. VILLANUEVA-CASTILLO, C. M. VILLALÓN; Farmacobiología, Cinvestav-IPN, México, D.F., Mexico

Abstract: Primary sensory nerves play an important role in the modulation of several physiological functions including vascular tone, contributing to blood pressure control by the release of vasodilator neuropeptides, primarily calcitonin gene related peptide (CGRP). Indeed, electrical stimulation of the perivascular sensory outflow in pithed rats results in vasodepressor responses mainly mediated by CGRP receptor stimulation. Moreover, our group has recently reported that these vasodepressor responses are inhibited by prejunctional (quinpirole-sensitive) D_2-like receptors. Since D_2-like receptors consist of the D_2, D_3 and D_4 subtypes, this study was designed to identify, by using selective antagonists, the specific subtypes (D_2, D_3 and/or D_4) involved in the above quinpirole-induced inhibition. For this purpose, after anaesthesia, 40 male Wistar rats were pithed, artificially ventilated and pretreated intravenously (i.v.) with 25 mg/kg gallamine, i.v. continuous infusions of 2 mg/kg.min hexamethonium (to block autonomic ganglia) and 20 µg/kg.min methoxamine (for maintaining an increased arterial blood pressure at around 130 mm Hg). Then, the animals were divided into 8 groups (n=5 each) that subsequently received: (i) nothing (control group); (ii) saline (0.02 ml/min); (iii) quinpirole (D_2-like receptor agonist; 0.1 µg/kg.min); (iv) saline (0.02 ml/min) + ascorbic acid 5% (vehicle to dissolve the antagonists; 1 ml/kg); (v) quinpirole + ascorbic acid 5%; (vi) quinpirole + L-741,626 (D_2 antagonist; 300 µg/kg); (vii) quinpirole + SB-277011-A (D_3 antagonist; 300 µg/kg); and (viii) quinpirole + L-745,870 (D_4 antagonist; 100 µg/kg). Based on functional studies in pithed rats, the doses of these antagonists are high enough to completely block their respective receptors without modifying *per se* the electrically-induced vasodepressor responses. Under these conditions, electrical stimulation (0.56, 1, 1.8, 3.1 and 5.6 Hz; 50 V and 2 ms) of the thoracic spinal cord (T_9-T_{12}) resulted in frequency-dependent vasodepressor responses which: (i) remained unchanged during saline infusion or after i.v. bolus injection of ascorbic acid 5%; and (ii) were inhibited by quinpirole. Moreover, quinpirole-induced inhibition was: (i) unaltered after i.v. treatment with ascorbic acid 5% or the antagonists L-741,626 (D_2) and L-745,870 (D_4); and (ii) abolished after SB-277011-A (D_3). In conclusion, our results suggest that quinpirole-induced inhibition of the vasodepressor sensory CGRPergic outflow is mainly mediated by activation of prejunctional dopamine D_3 receptors, with no clear-cut evidence for the role of prejunctional D_2 or D_4 receptor subtypes.

Title: Expression and actions of AT1, AT2 and Mas receptors in the guinea pig intrinsic cardiac plexus

Authors: E. N. POWERS[1], K. A. LUCKETT[1], S. A. ROSEN[1], E. M. SOUTHERLAND[2], J. L. ARDELL[2], *J. C. HARDWICK[1];
[1]Ithaca Col., ITHACA, NY; [2]East Tennesse State Univ., Johnson City, TN

Abstract: The intrinsic cardiac (IC) nervous system integrates inputs from multiple sources to coordinate cardiac function. These inputs include parasympathetic efferent, sympathetic efferent and sensory afferent fibers in addition to local hormonal factors. A major local factor is angiotensin II (Ang II) which is found in the blood and is also produced by proteases within the cardiac interstitium. Ang II acts via AT1 or AT2 receptors. In addition, Ang II can be cleaved by ACE2 to formed Ang(1-7), a peptide that has been found to have significant effects on neurons via activation of Mas receptors. In this study, we looked at the expression of the different angiotensin peptide receptors and their actions on neurons of the guinea pig intrinsic cardiac plexus. All three receptors, AT1R, AT2R, and MasR, were detected in homogenates of the isolated cardiac ganglion by Western blot analysis. Previous studies showed that AT2R can increase the neuronal responses to adrenergic and muscarinic signals. Using a whole mount *in vitro* preparation of the cardiac plexus, intracellular voltage recordings were made from individual IC neurons. We found that Ang(1-7) synergistically increases neuronal excitability responses to NE and muscarinic agonists. We also examined the effects of Ang II on synaptic function in the ganglion by stimulating intraganglionic fibers leading to IC neurons of interest. Application of Ang II reduced the synaptic efficacy, as indicated by a reduced number of postsynaptic action potentials generated with increasing frequency suprathreshold stimulation. Addition of the AT1R antagonist losartan inhibited this effect. To examine potential changes in AngII receptor function with chronic heart disease, myocardial infarction (MI) was surgically induced in animals, and the cardiac ganglion examined 8 weeks later. Western blot analysis showed a decrease in AT1R expression in ganglia from MI animals, with no significant change in either AT2R or MasR expression levels. However, prior functional studies of the effects of Ang II on IC neurons demonstrated a MI-induced loss in sensitivity to exogenous Ang II application. Combined, these results indicate that MI induces a down regulation in presynaptic AT1 receptors, as well as a decrease in signaling via AT2R. Thus, increases in Ang II production, such as occurs with chronic heart disease, can result in significant alterations in function within this ganglion.

Title: Adaptive changes in lampyridae illuminate evolutionary trends: A study of toxin resistance in sodium-potassium pumps

Authors: *L. COBBS[1], P. ANDOLFATTO[2];
[1]NYULMC, New York, NY; [2]Princeton Univ., Princeton, NJ

Abstract: Two Lampyridae species, Photinus and Photuris, have evolved the ability to safely produce and consume, respectively, lucibufagin, a cardiac glycoside toxin which targets the alpha subunit (ATPα) of sodium-potassium protein pumps. Photuris, the consumers of exogenous lucibufagin, have accumulated adaptive mutations in their ATPα to resist cardiac glycoside binding. The path of Photuris ATPα's evolution has been shaped by negative pleiotropic constraints and gene duplication events. Previous studies have examined how these constraints and forces direct the speed and orientation of evolution, but debate continues over early models of gene duplicate maintenance and the significance of negative pleiotropy. I examined the amino acid sequences, cardiac glycoside binding affinities, and tissue-specific expression patterns of Photuris' ATPα gene copies to better parse the constraints and forces guiding adaptive evolution. My findings show that Photuris have employed many of the same molecular strategies to evolve lucibufagin resistance as other insects which also safely consume cardiac glycosides. This parallelism across ecological systems suggests that there are general rules governing adaptive evolution. Independent of ecological context, it seems that gene duplication eases constraints imposed by negative pleiotropy to allow for fixation of nonsynonymous mutations. In addition to providing insight into evolutionary dynamics, my

findings have implications for treatment of human diseases involving the sodium-potassium pump, including Digitalis therapy for Congestive Heart Failure and several neural disorders.

Title: Activation of M_3 muscarinic acetylcholine receptors protects against interferon-β-induced neuronal cell death

Authors: *M. C. OLIANAS, S. DEDONI, P. ONALI;
Dept Biomed. Sciences, Section of Neuroscience., Univ. Cagliari, Monserrato, Italy

Abstract: The clinical use of type I interferons (IFNs), such as IFN-α and IFN-β, is known to be frequently associated with the occurrence of central nervous system (CNS) side effects, including anxiety, confusion, cognitive deficits, mania, psychosis, depression and suicidal behaviour. In addition, chronically elevated IFN-α production in the CNS is considered a pathogenic factor in Aicardi-Goutieres syndrome, a genetically determined encephalopathy. At the cellular level, long-term exposure to type I IFNs induces neuronal cell death through activation of apoptosis. In the present study we used the SH-SY5Y cell line as a human neuronal cell model to identify neurochemical mechanisms capable of preventing type I IFN neurotoxicity. We found that cell treatment with either carbachol (CCh), a cholinergic receptor agonist, or oxotremorine M, a selective muscarinic acetylcholine receptor (mAChR) agonist, markedly suppressed IFN-β-induced neuronal cell death. The neuroprotective effect of CCh was antagonized by 4-DAMP, a M_3 mAChR preferring antagonist, but not methoctramine, a M_2 mAChR preferring antagonist, or MT-7, a selective M_1 mAChR antagonist. Concurrent cell treatment with CCh inhibited IFN-β-induced cytochrome c release from mitochondria, caspase activation and cleavage of poly-(ADP ribose) polymerase. CCh induced a long-lasting activation of either p38 or ERK 1 and 2 (ERK1/2) MAP kinases. Pharmacological inhibition of ERK1/2 but not p38 MAP kinase prevented the antiapoptotic effect of CCh. These data indicate that in SH-

SY5Y neuronal cells activation of M_3 mAChR counteracts IFN-β-induced neuronal apoptosis through activation of ERK1/2 pathway.

Title: M4-muscarinic receptors attenuate dopamine release via production of H2O2 in direct pathway medium spiny neurons

Authors: ***D. J. FOSTER**, Z. XIANG, P. J. CONN;
Vanderbilt Ctr. For Neurosci. Drug Discovery, Nashville, TN

Abstract: Two seminal clinical studies have demonstrated that the M1/M4 preferring agonist xanomeline can provide significant therapeutic efficacy in treating psychosis in patients with Alzheimer's disease or scizhophrenia. Unfortunately gastrointestinal side-effects, likely mediated by M2/M3 receptors, have removed xanomeline from consideration for clinical use. Here we utilize a subtype-selective M4 positive allosteric modulator (VU0467154) to elucidate the role of M4 in regulating striatal dopamine release. Application of the non-selective muscarinic receptor agonist Oxo-M decreased electrically-evoked striatal dopamine release as monitored via fast scan cyclic voltammetry in acute brain slices. The inhibition of dopamine release induced by sub-maximal Oxo-M concentrations was potentiated by inclusion of VU0467154, demonstrating that M4 activation reduces dopaminergic signaling. In the striatum M4 is found primarily on direct pathway medium spiny neurons and is also reported to be expressed on cholinergic interneurons and cortical afferents. However, M4 is not thought to be located on dopamine terminals, raising the question of how M4 activation alters dopamine overflow in acute striatal brain slices. Hydrogen peroxide (H2O2) produced in medium spiny neurons has been shown to inhibit dopamine release via activation of KATP channels on dopamine terminals. By monitoring

H_2O_2 directly in striatal slices with the fluorescent indicator H2DCFDA, we found that activation of M4 led to an increase in striatal H_2O_2 production. Furthermore, M4-mediated inhibition of dopamine release was potentiated by mercaptosuccinate (an inhibitor of H_2O_2 degredation) and attenuated by glybenclamide (a KATP blocker). These results demonstrate that M4 activation attenuates dopamine release via H_2O_2 production in direct pathway medium spiny neurons, a signaling pathway that may be of therapeutic interest to developing novel treatments for schizophrenia.

Title: Evaluation of the therapeutic efficacy of M1 muscarinic acetylcholine receptor potentiation in chronic phencyclidine-treated mouse model of schizophrenia

Authors: *A. GHOSHAL, J. M. ROOK, J. W. DICKERSON, R. D. MORRISON, S. R. STAUFFER, C. K. JONES, J. S. DANIELS, C. M. NISWENDER, C. W. LINDSLEY, Z. XIANG, P. J. CONN;
Pharmacology, Vanderbilt Ctr. for Neurosci. Drug Discovery, Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Current available treatments for schizophrenia reduce the positive symptoms of the disease, but have no clear efficacy in reducing the negative and cognitive symptoms. Interestingly, a recent clinical study suggested that the M1/M4-preferring muscarinic acetylcholine receptor (mAChR) agonist xanomeline may have efficacy in reducing all symptom clusters in schizophrenia patients. However, xanomeline and other mAChR agonists induce profound adverse effects due to the absence of subtype selectivity and have failed to advance in further clinical development. In recent years, our lab and others have developed highly selective positive allosteric modulators (PAMs) of M1 that provide unprecedented subtype selectivity and are now advancing in preclinical and clinical development. In this study, we have characterized a highly selective and systemically active M1 PAM, VU0453595. It induces a robust potentiation of ACh-induced activation of M1 but has no activity at M2-M5. It also strongly potentiates an M1-dependent long term depression (LTD) mediated by 50 μM carbachol (CCh) observed at the layer II/III to layer V synapse of the rodent medial prefrontal cortex (mPFC). VU0453595 has an excellent pharmacokinetic profile with significant brain penetration and has robust efficacy in improving cognitive function in multiple rodent models. Moreover, this compound does not cause any adverse effects associated with previous M1 agonists. In this study, we also used VU0453595 to investigate its efficacy in a preclinical rodent model of schizophrenia. Chronic NMDA receptor antagonism has been shown to be a reliable model for the negative and cognitive symptoms of schizophrenia. We found that daily treatment of rats with phencyclidine (PCP; 10 mg/kg) for 7 days induced profound electrophysiological and behavioral deficits. This treatment caused deficits in M1 receptor-mediated LTD in the mPFC induced with 50 μM CCh application. However, other responses to M1 activation in mPFC pyramidal neurons remained unaltered after the PCP administration as no deficits were observed in CCh-induced increases in spontaneous EPSCs and a CCh-induced inward current. We also observed profound cognitive deficits, including recognition memory, after chronic PCP treatment. Interestingly, pretreatment of 10 μM VU0453595 reversed the LTD deficits in the PCP-treated mice. Ongoing studies are looking at the behavioral efficacy of VU0453595 in the chronic PCP mouse model of schizophrenia. These results provide critical data in validating the potential utility of M1 PAMs as a novel therapeutic approach for treatment of negative and cognitive symptoms in schizophrenia patients.

Abstract: There is evidence to suggest that selective enhancement of cholinergic transmission through the M1 muscarinic acetylcholine receptor (mAChR) may reduce or ameliorate the loss of cognitive function that is observed in patients with Alzheimer's disease. Previous efforts to develop compounds that selectively activate M1 receptors have failed in clinical trials due to a true lack of specificity and adverse effects associated with the activation of other mAChR subtypes. We have focused our efforts on the development of novel compounds that do not activate G-protein coupled receptors (GPCRs) directly, but rather act at allosteric sites on the receptor to potentiate the activation of the receptor by its endogenous ligand; in the case of the M1 receptor, acetylcholine (ACh). Even activation through the allosteric site does not guarantee that these compounds will not display adverse effects as demonstrated with other classes of GPCRs, such as metabotropic glutamate receptor subtype 5 where allosteric agonist activity or positive allosteric modulation (PAM) coupled with agonist activity (ago-PAM) was shown to be correlated with the induction of seizures; however, PAM activity alone did not result in the induction of seizures. In addition, previous research has demonstrated that allosteric modulators may display signaling bias which could have fundamentally different effects on CNS function and affect their utility as therapeutics in a compound dependent manner. We were interested in determining if M1 allosteric agonist activity can be correlated to adverse effects observed with administration of a set of M1 modulators. We utilized cells lines in which the M1 receptor was expressed using an inducible promoter. With increasing levels of receptor expression, there was

a shift from pure PAM activity to ago-PAM activity, but the level of receptor expression that was needed to induce the shift varied depending on the compound tested. Furthermore, the potency of the PAM response did not change significantly with the change in receptor expression. *In vivo* studies in rodents assessed the adverse effect liability of various M1 PAMs from multiple distinct chemical scaffolds relative to the degree of agonist activity observed in *in vitro* assays. Further studies are underway to gain insight into the role of receptor expression in allosteric modulator activity to avoid the potential for adverse effects.

Abstract: Despite significant research there remains a major unmet medical need in the treatment of Alzheimer's disease. Current marketed drugs (e.g. Donepezil, Aricept®) function through inhibition of acetylcholinesterase activity resulting in widespread enhanced cholinergic activity. However the cognitive benefits from targeting this mechanism are modest and are accompanied by a range of dose-limiting cholinergic side effects due to the non-specific activation of all muscarinic receptor sub-types. Pre-clinical and clinical evidence suggests that specific activation of the muscarinic M_1 receptor activation plays a critical role in the beneficial elemnts of acetylcholinesterase inhibitors in Alzheimer's disease whereas activation of muscarinic M_2 and M_3 receptors are responsible for many of the side effects. Our objective has been to utilise a novel structure based drug discovery approach to design highly selective agonists for the M_1 receptor devoid of dose limiting activity at other muscarinic receptors.

Heptares' have solved the structure of the muscarinic M_1 receptor in an agonist conformation with multiple agonist ligands and the structural insights gained from this work have been instrumental in the design of highly selective M_1 agonists with good ligand efficiency and drug-like properties. The lead compound emonstrates ~1000fold selectivity against the muscarinic M_2, M_3 and M_5 receptors and is active in a primary rat hippocampal CA1 cell firing model. Oral administration at 3, 10 and 30mg/kg reversed a scopolamine deficit in a rat passive avoidance model and increased discrimination following a delay induced deficit in the rat novel object recognition model with an ED_{50} of approximately 4mg/kg. In addition these effects were additive with donepezil. This work has led to the first highly selective M_1 agonist candidate that entered Ph I clinical trials in late 2013.

Title: Novel bitopic ligands for the M_1 muscarinic acetylcholine receptor

Authors: *B. J. DAVIE, S. N. MISTRY, C. VALANT, B. CAPUANO, P. J. SCAMMELLS, A. CHRISTOPOULOS;
Monash Inst. of Pharmaceut. Sci., Parkville, Australia

Abstract: Molecules capable of simultaneously interacting with the orthosteric pocket and an allosteric site of a G protein-coupled receptor are termed 'bitopic ligands'. Rationally designing such hybrid molecules by linking a high potency orthosteric pharmacophore to a subtype-selective allosteric pharmacophore may result in a high affinity/potency and more selective drug. The objective of this project is to synthesize and pharmacologically evaluate putative bitopic ligands for the M_1 muscarinic acetylcholine receptor (M_1 mAChR); a prospective therapeutic target for the treatment of the cognitive deficits experienced in Alzheimer's disease and schizophrenia. Iperoxo, a highly potent non-selective orthosteric mAChR agonist, and BQCA, a highly selective M_1 mAChR positive allosteric modulator, were selected as our building-block molecules. In order to rationally design bitopic ligands, we first investigated the effect of alkyl linkers of various lengths on each pharmacophore. Six compounds were synthesized and pharmacologically evaluated for the preservation of their respective orthosteric and allosteric binding and functional profiles, in M_1 mAChR-expressing Chinese Hamster Ovary cells, using both [^{3}H]NMS radioligand binding and ERK1/2 phosphorylation assays. Interestingly, despite most of our novel analogues showing diminished agonist and allosteric properties, they all appeared to retain their overall respective pharmacological profiles, indicating that the introduction of linkers is tolerated. Encouraged by these results, the synthesis of complete hybrid orthosteric/allosteric molecules for the M_1 mAChR was subsequently undertaken. We can conclude from our preliminary results that our novel putative bitopic ligand design exhibiting a linker between orthosteric and allosteric pharmacophores for the M_1 mAChR is synthetically accessible, and may lead to the generation of a ligand able to bridge both the orthosteric pocket and an allosteric site of the receptor via a bitopic mode of binding. Future work will require [^{3}H]NMS radioligand dissociation kinetics assays and mutagenesis studies to conclusively confirm a bitopic mode of action for these hybrid molecules. Bitopic ligands may be useful pharmacological tools to further study the M_1 mAChR, and potentially pave the way towards novel, improved therapeutics for cognitive deficits.

Title: Mutations enable positive allosteric modulation by benzyl quinolone carboxylic acid (BQCA) at non-M1 muscarinic receptors

Authors: *J. ELLIS, G. J. ELMSLIE;
Psychiatry and Pharmacol., Penn State Univ., Hershey, PA

Abstract: The muscarinic acetylcholine receptors (mAChRs) comprise a family of G-protein-coupled receptors, all of which are expressed in the CNS. Physiological, behavioral, and knock-out mouse studies all suggest that these receptors play crucial roles in many CNS functions and disorders. Unfortunately, the structures of the five subtypes of mAChRs are very highly conserved in the transmembrane regions where ACh binds; this has hampered the development of subtype-selective agonists and antagonists. Additionally, the mAChRs also play essential roles in the autonomic system; this means that non-selective muscarinic agents have serious dose-limiting side effects. One approach to developing ligands with sufficient selectivity has been to target allosteric sites on the receptors, which are typically much less conserved than the orthosteric site. BQCA is a premier example of a positive allosteric modulator that is highly selective for the M_1 mAChR, which is a subtype whose enhancement is likely to benefit cognitive deficits, including those of Alzheimer's Disease. BQCA enhances the potency of ACh by 100-fold or more at M_1, while having no effect at the other subtypes. Such selectivity can be due either to highly selective affinity for M_1 or to neutral cooperativities at the other subtypes, and it is of significant interest to determine which mechanism is at work for this prototypical agent. We have used mutagenesis to identify residues that are key to the selective PAM activity. In agreement with others, we found that the aromatic nature of $M_1Y^{5.29}$ is essential (superscript numerals refer to the system of Ballesteros and Weinstein); Y=>A mutation abolishes activity, while Y=>F preserves it. Of the five subtypes, only M_5 lacks Y or F at this site. We found that the M_5Q=>$Y^{5.29}$ mutant displays modest PAM activity. Additionally, the PAM activity of the double mutant M_1E=>$A^{7.32}$,E=>$A^{7.36}$ is markedly attenuated, whereas the M_5YEE mutant has PAM activity equal to M_1. (The M_2EE mutant also exhibits moderate PAM activity). Finally, the interactions between BQCA and ACh in inhibiting the binding of the labeled orthosteric antagonist [^{3}H]N-methylscopolamine to M_1 vs M_1AA and M_5Y vs M_5YEE were evaluated using a mathematical allosteric model. The mutations caused marked changes in the cooperativity between BQCA and ACh, but did not alter the affinity of BQCA for the receptor. This indicates that the region near the top of TM7 that contains $E^{7.32}$ and $E^{7.36}$ is not part of the binding site. In agreement with this, BQCA was not found to be competitive with the allosteric modulator W84, which has previously been shown to bind within this region.

Title: Development of M5 muscarinic antagonists: Interaction of GZ-002-05 with muscarinic receptor subtypes

Authors: *W. S. MESSER, JR[1], T. YANG[2], C. MITCHELL[3], G. ZHENG[4];
[2]Pharmacol., [3]Neurosci., [1]Univ. of Toledo, TOLEDO, OH; [4]Pharmaceut. Sci., Univ. of Arkansas for Med. Sci., Little Rock, AR

Abstract: Selective antagonists for M_5 muscarinic receptors might be useful in the treatment of drug abuse. GZ-002-05 was identified previously as a novel, M_5-selective muscarinic antagonist. Muscarinic receptor selectivity was characterized by studying the effects of acetylcholine in the presence or absence of the compound using CHO cells expressing human M_1, M_3, or M_5 receptors. A [^{3}H] arachidonic acid release assay measured receptor activity and helped delineate the nature of the interaction(s) between the compound and muscarinic receptor subtypes. At M_1 receptors, 10 μM GZ-002-05 did not change the maximal response elicited by acetylcholine, however, it lowered significantly the EC_{50} value for acetylcholine from 1.8 μM to 36 μM. The data suggest a competitive interaction at M_1 receptors. In contrast, at 10 μM GZ-002-05 changed neither the maximal response nor the EC_{50} value of acetylcholine at M_3 receptors, suggesting that the compound did not influence agonist activation of M_3 receptors at that concentration. At M_5 receptors, 10 μM GZ-002-05 reduced the maximal response produced by acetylcholine (72 ± 8.8% of control stimulation) with no significant effect on the EC_{50} value, suggesting that the compound does not interact in a competitive manner at M_5 receptors. Overall, the results indicate unique mechanisms of interactions with muscarinic subtypes. The data suggest that GZ-002-05 may be useful as a lead compound in the development of potential therapeutic agents, however, further work is needed to understand how it acts at each muscarinic receptor subtype.

Abstract: Neuromodulators have profound effects on circuits and behavior, but the dynamics of their intracellular effectors has remained unclear. The adenylate cyclase/cyclic AMP/protein kinase A (PKA) module is a critical intracellular effector. This module is regulated by multiple behaviorally important neuromodulator receptors. Furthermore, PKA activity is necessary for the induction of many forms of synaptic plasticity and for the formation of long-term memory. In order to monitor PKA activity in brain tissue, we have developed a PKA activity sensor for quantitative analysis of endogenous GPCR signaling via 2-photon fluorescence lifetime imaging microscopy. We have used the PKA reporter to examine cholinergic modulation of PKA activity in the mouse hippocampus. Our results reveal new mechanisms for cholinergic action, with implications on synaptic transmission and plasticity.

Title: Modulatory effects of activation of presynaptic metabotropic glutamate receptors on the inhibitory responses in thalamic relay cells in the mouse

Authors: *T. LIU, I. PETROF, S. M. SHERMAN;
Neurobio., Univ. of Chicago, Chicago, IL

Abstract: We have previously shown that activation of presynaptic group II metabotropic glutamate receptors (mGluRs) reduces the gain of GABAergic inputs in both primary visual and auditory cortices (V1 and A1). In the present study, we sought to determine if activation of mGluRs can also affect the inhibitory input in thalamus. We used whole cell recording in a slice preparation in the mouse and studied two GABAergic inputs to relay cells: that of the thalamic reticular nucleus (TRN) to cells of the ventral posteromedial nucleus (VPM), activated by glutamate uncaging and electrical stimulation in TRN, and that of interneurons to cells of the lateral geniculate nucleus (LGN), activated disynaptically by electrical stimulation of the optic tract. We tested effects of mGluRs on these inputs by applying various agonists to the slice. In the pathway involving stimulation in TRN and recording in VPM, we found that activation of mGluRs significantly reduced the amplitude of IPSCs evoked from TRN inputs to VPM cells. Because the effects were not blocked by the addition of GDPβS to the recording electrode, and because mGluR agonists did not affect responses to photostimulation of GABA in a low Ca^{2+} and high Mg^{2+} bathing solution, we conclude that the reduction of the amplitude of GABAergic IPSCs was due to activation of presynaptic mGluRs. Furthermore, using specific mGluR agonists, we found that both group I and group II mGluRs were involved in these effects. Similar results were found in the interneuron inputs to LGN cells. Here, activation of presynaptic group I (especially type 1) and group II mGluRs significantly reduced the amplitude of evoked IPSCs. However, activation of type 5 mGluR increased the frequency of spontaneous IPSCs but not their amplitude in LGN cells, which we interpret to be via dendrodendritic synapses (F2 terminals). Nonetheless, it appears that groups I and II mGluRs may generally reduce the amplitude of evoked GABAergic IPSCs of axonal inputs to thalamic relay cells, operating through presynaptic mechanisms, and this extends our previous findings in cortex.

Title: mGluR2/3 influences in prefrontal cortex - potential for therapeutics

Authors: *L. E. JIN[1], M. WANG[1], Y. YANG[1], D. OTTENHEIMER[2], J. STEIN[2], C. D. PASPALAS[1], A. F. ARNSTEN[1];

Abstract: Schizophrenia is a complex mental disorder associated with impaired dorsolateral prefrontal cortical (dlPFC) function and abnormal glutamatergic transmission. Drugs acting on the group II metabotropic glutamate receptors (mGluR2/3) are of particular interest to the treatment of schizophrenia, especially as mGluR3 have been genetically linked to the illness. mGluR2/3 couple to Gi/Go and inhibit cAMP signaling. In rodent hippocampus, presynaptic mGluR2/3 reduce excitability by inhibiting neurotransmitter release, while postsynaptic mGluR2/3 have an opposite effect, increasing neuronal excitability by inhibiting K+ conductance. However, there is little knowledge of how mGluR2/3 influence higher cortical circuits in primates. Layer III dlPFC circuits in primates mediate the persistent activity needed for working memory via NMDA synaptic connections on spines. These circuits are of key interest, as they are greatly afflicted in patients with schizophrenia, causing dlPFC hypo-activity and cognitive impairments. We here present immuno electron microscopy data from monkey dlPFC layer III circuits showing mGluR2/3 on both pre- and postsynaptic sites, as well as on astrocytes that envelope the axospinous glutamate synapses. To test the roles of mGluR2/3 in regulating working memory, we recorded single-units in monkey dlPFC while the animals performed a spatial working memory task. Compounds targeting mGluR2/3 were applied by iontophoresis during recording. Low doses of the mGluR2/3 agonist, (2R,4R)-APDC, significantly improved the spatially-tuned persistent firing that is needed for working memory. At higher doses, the persistent firing was eroded, producing an inverted-U dose-response. These physiological data suggest that postsynaptic mGluR2/3 may be positioned on spines to inhibit cAMP-K+ channel signaling and strengthen dlPFC network firing at low doses, while firing may be decreased by presynaptic inhibition of glutamate release at higher doses. An inverted-U dose-response was also seen at the behavioral level in monkeys following systemic administration of APDC, with enhancing effects on working memory performance at low doses, and mixed effects

or impairment at higher doses. No evidence of side effects was observed. Local infusion of low doses of (2R,4R)-APDC into rat medial prefrontal cortex also improved working memory performance. Overall, the data indicate that mGluR2/3 modulate working memory circuits in PFC, and if their beneficial actions can be isolated, may have therapeutic potential in treating cognitive deficits in schizophrenia.

Title: Activation of metabotropic glutamate receptor 3 (mGlu3) is required for the induction of long-term depression in medial prefrontal cortex and fear extinction learning

Authors: *A. G. WALKER, C. J. WENTHUR, Z. XIANG, C. W. LINDSLEY, P. J. CONN; Pharmacol. & VCNDD, Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: There has been growing interest in the role of group II mGlus (mGlu2 and mGlu3) in the regulation of cognition. In rodents, pharmacological activation of mGlu2/3 in medial prefrontal cortex (mPFC) results in long-term depression (LTD) that is expressed postsynaptically. Interestingly, anatomical studies have indicated that mGlu2 and mGlu3 have distinct pre- and postsynaptic expression, suggesting they may differentially influence neurophysiology and behavior. Unfortunately, the individual contributions of mGlu2 and mGlu3 to cognition and LTD have yet to be investigated, largely due to a lack of compounds that can differentiate between the subtypes. We recently reported a series of selective mGlu3 negative allosteric modulators (NAMs) and have performed a series of studies to determine the role of mGlu3 in LTD and cognition. We recorded extracellular field excitatory postsynaptic potentials (fEPSPs) from layer V of mouse prelimbic mPFC in response to stimulation of layer II/III. Application of the mGlu2/3 agonist LY379268 (LY268; 30-100nM for 10 min) produced a

concentration dependent inhibition of the fEPSP slope with LTD observed at 100nM. Analysis of paired-pulse ratios (PPR) demonstrated that the initial inhibition was accompanied by a robust increase in PPR that decreased to baseline levels during the LTD phase, indicating it is expressed postsynaptically. LTD was blocked by the mGlu2/3 antagonist LY341495 (500nM), but not AP5, indicating NMDA receptor activation is not required. When LY268 was applied in the presence of a selective mGlu3 NAM, VU0469942 or VU0477950 (10uM), only transient inhibition, but no LTD was induced. Moreover, LY268 induced LTD in slices from mGlu2, but not mGlu3 knockout mice. To test the hypothesis that mGlu3 mediated effect is postsynaptic in nature, we monitored intracellular calcium (Ca2+) in layer V pyramidal neurons. Experiments were performed in the presence of tetrodotoxin to isolate postsynaptic receptor actions. Application of LY268 induced an increase in Ca2+ that was attenuated by VU0469942. Taken together, these data indicate that postsynaptic mGlu3 activation is required for induction of LTD in mPFC by an mGlu2/3 agonist. We also tested the effects of the mGlu3 NAM VU0477950 on fear extinction, a cognitive behavior dependent upon mPFC. Relative to vehicle, animals treated with VU0477950 (3-100mg/kg i.p.) displayed a dose dependent delay in fear extinction learning. Thus, our physiology and behavioral experiments provide evidence that mGlu3 strongly influences the function of circuits governing cognition and indicate this receptor as a putative target for treatment of disorders of impaired cognition.

Title: Sleep-deprivation induces changes in GABA-B and mGlu receptors and reduces the depressant action of agonists at the above receptors on excitatory postsynaptic potentials in rat hippocampal CA1 neurons

Authors: A. KWOK, J. HWANG, H. AZIZI, R. TADAVARTY, *B. SASTRY;
Univ. British Columbia Fac Med., Vancouver, BC, Canada

Abstract: Sleep is a necessity for a majority of animal species and it facilitates memory consolidation. Sleep-deprivation (SD) adversely affects synaptic plasticity and memory consolidation. Previous studies in our laboratory indicate that SD induces an increase in the expression and heterodimerization of $GABA_B$-R1 and mGlu1αR in the CA1 region of rat hippocampus. In the current study, we examined if the SD induced changes in $GABA_B$ and mGlu receptors translate into alterations in the actions of applied agonists. We also tested if the changes recover with time. Experiments were conducted on 3-4 week old male Wistar rats that were (a) allowed to normally sleep, (b) SD for 12 hrs, and (c) SD but allowed to recover for 48 hrs. Field excitatory postsynaptic potentials (EPSPs) were recorded from the CA1 pyramidal layer in response to the stimulation of stratum radiatum, in the hippocampal slice preparation. Agonists were applied to the slice-superfusing medium. The presence of $GABA_B$-R1, $GABA_B$-R2 and mGlu1αR was assessed using immunohistochemistry. $GABA_B$-R1 immunoreactivity in the CA1 pyramidal neurons was enhanced following SD but returned to control levels with a 48 hr recovery from SD. $GABA_B$-R2 expression was not changed following SD, but with the 48 hr recovery, CA1 interneurons showed more staining and pyramidal neurons less staining than in control or SD slices. Immunoreactivity for mGlu1αR, which was increased in SD rats, returned to controls with a 48 hr recovery from SD. We examined the actions of baclofen (GABA-B agonist; 0.25, 0.5, 1.0, 5.0 and 10 μM) and 1-Amino-1,3-dicarboxycyclopentane **(**ACPD, broad spectrum mGluR agonist; 1, 5, 10, 20 and 40 μM). In hippocampal slices from normally sleeping rats, ACPD depressed the EPSP in a dose dependent manner (EPSP as a % of pre-drug control in 10 μM ACPD: 33.95 $\pm$ 8.93, n=8). In SD animals, the depressant action was reduced (EPSP in 10 μM ACPD as a % of control: 57.28 $\pm$ 10.76, n=9). After a 48 recovery from SD, the EPSP was depressed more than in SD (EPSP in μM ACPD as a % of control: 51.82 $\pm$ 11.92, n=6). In slices from normally sleeping animals, baclofen depressed the EPSP in a dose dependent manner (EPSP in 0.5 μM baclofen as a % of pre-drug control: 49.40 $\pm$ 8.62, n=6). In SD animals, the depression was reduced (EPSP in baclofen as a % of control: 90.99 $\pm$ 3.16, n=8). After a 48 recovery from SD, the EPSP was depressed more than in SD animals (EPSP in baclofen as a % of control: 66.06 $\pm$ 5.04, n=6). In conclusion, $GABA_B$-R1 and mGlu1αR and the actions of applied mGlu and $GABA_B$ agonists change following a 12 hr SD and the changes subside with a 48 hr recovery from SD.

Title: Metabotropic glutamate group II receptors modulate presynaptic release of GABA in nociceptive thalamus

Authors: *K. A. ASSERI;
Dept. of Anesthesiology, Pharmacol. and Therapeut., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Metabotropic glutamate receptors (mGluRs) belong to the family C of G-protein coupled receptors. Activation of group II mGluRs inhibits neurons by altering Ca2+ and K+ conductances. Group II mGluRs may regulate release of neurotransmitters at central synapses. Ventrobasal thalamic nuclei process somatosensory information including pain impulses. A mixed group I/II mGluR agonist was used in previous thalamic studies to assess mGluRs involvement in extracellular responses. We examined the analgesic effects of the selective group II agonist (LY354740) on ventrobasal neurons. We hypothesize that this inhibitory action would decrease the release of GABA by activating group II mGluRs on nerve terminals on thalamocortical neurons of ventrobasal nuclei. Whole-cell patch clamp recordings were performed at 23-25°C from Sprague-Dawley rat (P11-12) brain slices. The main sensory input (medial lemniscus) and ventrobasal neurons were visually identified with a differential interference contrast microscope. Inhibitory postsynaptic currents (IPSCs) were evoked by electrical stimulation of medial lemniscus. Kynurenic acid was applied to block ionotropic glutamatergic transmission, isolating the IPSCs. Internal cesium was used to block postsynaptic actions of agonist. Drugs were applied in the bathing solution. When applied alone, group II mGluR agonist (LY354740) had no effects on active or passive membrane properties in 32 neurons. In a concentration-dependent manner, LY354740 reduced the peak amplitude of evoked IPSCs without affecting the decay time constants. With or without action potential-evoked release, LY354740 respectively reduced the frequency of spontaneous and miniature IPSCs. These reductions were blocked by co-application of LY341495, a selective group II mGluR antagonist. When applied alone, LY341495 increased the amplitude of lemniscal IPSCs and increased the frequency of miniature IPSCs, suggesting tonic activation of group II mGluRs. All IPSCs were antagonized by the GABAA antagonist bicuculline. The studies demonstrate that activation of group II mGluRs decreases the release of GABA in ventrobasal nuclei. As heteroreceptors, presynaptic group II mGlu receptors may regulate the release of GABA in thalamic neurons, providing potential target for antinociceptive drugs.

Title: Modulation of striatal synaptic transmission by group I metabotropic glutamate receptors

Authors: *K. A. JOHNSON, D. M. LOVINGER;
Lab. for Integrative Neurosci., NIAAA/NIH, Rockville, MD

Abstract: Group I metabotropic glutamate receptors, which include subtypes mGlu1 and mGlu5, modulate glutamatergic and GABAergic transmission in the CNS via diverse, synapse-specific mechanisms. Activation of postsynaptic group I mGlu receptors has been shown to reduce both glutamatergic and GABAergic transmission in medium spiny neurons (MSNs) in the dorsal striatum via retrograde endocannabinoid signaling and activation of presynaptic CB1 receptors. Interestingly, mGlu receptor-mediated suppression of GABA transmission occurs at more hyperpolarized membrane potentials ("down" state), whereas group I mGlu receptors only substantially inhibit glutamate transmission at slightly depolarized ("up" state) membrane potentials. While group I mGlu receptor-mediated suppression of GABA transmission is readily reversible, we and others have observed long-term depression (LTD) of glutamatergic transmission following treatment of mouse striatal slices with the group I mGlu receptor-selective agonist DHPG. Intriguingly, the differential state-dependence and time course of synaptic modulation suggest that divergent mechanisms contribute to mGlu receptor-induced retrograde endocannabinoid signaling at different inputs to MSNs. Previous studies indicate that activation of striatal group I mGlu receptors with the selective agonist DHPG increases production of 2-arachidonoylglycerol (2-AG) but not anandamide, suggesting that 2-AG is the primary mediator of group I mGlu receptor-induced suppression of synaptic transmission. To test this hypothesis, we evaluated the ability of DHPG to inhibit glutamatergic transmission in mice lacking diacylglycerol lipase α (DGLα), the enzyme primarily responsible for 2-AG production in the striatum. Surprisingly, DHPG produced a significant inhibition of glutamatergic transmission in slices obtained from DGLα knockout mice, suggesting that alternative mechanisms contribute to the ability of group I mGlu receptors to modulate synaptic

transmission in MSNs. Ongoing studies will further elucidate the mechanisms underlying the state-dependent and input-specific modulation of neurotransmission in MSNs by group I mGlu receptors.

Title: Adaptive changes in the expression of grm4 and grm5 genes in the striatum following induction of parkinsonism in mice

Authors: M. CANNELLA[1], M. MOTOLESE[1], D. BUCCI[1], G. MOLINARO[1], A. TRAFICANTE[1], J. MARROCCO[2], V. BRUNO[1,3,2], F. NICOLETTI[1,3,2], *G. BATTAGLIA[1]; [1]Neurosci., I.R.C.C.S. Neuromed, Pozzilli, Italy; [2]I.R.C.C.S. Neuromed, Sapienza University, Italy, and Univ. of Lille, France, LIA (International Associalted Laboratories), Roma, Italy; [3]Physiol. and Pharmacol., Univ. Sapienza, Roma, Italy

Abstract: It is generally believed that neuroadaptive changes occurring in the indirect pathway of the basal ganglia motor circuit delay the onset of motor symptoms associated with parkinsonism. The identification of these changes may add further insights into the pathophysiology of parkinsonism and better define the time window of intervention with different classes of antiparkinsonian agents. Parkinson's disease (PD) is characterized by the progressive loss of nigro-striatal neurons that lead to a decreased activity of the direct pathway and an increased activity of the indirect pathway, with ensuing inhibition of thalamocortical neurons and motor dysfunction. Activation of mGlu4 metabotropic glutamate receptors inhibits GABA release at the synapse between striatal projection neurons and neurons of the external globus pallidus. This is the first synapse of the indirect pathway of the basal ganglia motor circuit, which is overactive in PD. Drugs that activate mGlu4 receptors cause a robust depression of inhibitory synaptic transmission in the external globus pallidus, relieve motor symptoms and induce neuroprotective effects in animal models of parkinsonism. It is generally believed that during the early "compensated" phase of PD a number of mechanisms reduce the activity of the indirect pathway. We examined the transcripts of mGlu4 receptors and other proteins involved in the regulation of basal ganglia motor circuit in mice challenged with the parkinsonian toxin, 1-

methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP, 30 mg/kg, i.p.) and with the dopamine receptor blocker, haloperidol (1 mg/kg, s.c.). We observed an up-regulation of mGlu4 receptors, CB1 receptors and preproenkephalin-A few days after MPTP and haloperidol injection and a decrease of A2A and mGlu5 receptors. To examine whether the increase in mGlu4 receptor transcript could represent an early compensatory mechanism, we measured the catalepsy in wild-type and mGlu4 receptor knockout mice at different time points (30 min, 1 h, 2 h, and 4 h) after haloperidol injection (0.5 and 1 mg/kg, s.c.). Wild-type and mGlu4 receptor knockout mice showed the same response to haloperidol at 30 min and 1 h (1 mg/kg); in contrast, catalepsy remained high at 2 and 4 h in mGlu4 receptor knockout mice as opposed to wild-type mice. The lower dose of haloperidol (0.5 mg/kg) induced a much higher response and catalepsy in mGlu4 knockout mice at all time points as compared to wild-type mice. These data suggest that an up-regulation of mGlu4 receptors in striatal projection neurons contributes to restrain the activity of the indirect pathway in the early phases of parkinsonism.

Title: Corticostriatal metaplasticity of group I metabotropic glutamate receptors contributes to habit learning

Authors: B. GRECO[1], A. CAVACCINI[1], A. ROCCHI[1], M. TRUSEL[1], V. PAGET-BLANC[1], M. PENNUTO[2], *R. TONINI[1];
[1]Ist. Italiano Di Tecnologia, NBT, Genova, Italy; [2]Ctr. for Integrative Biol., Trento, Italy

Abstract: Goal-directed control of actions is the ability to adapt the behavior to obtain specific outcomes and to efficiently respond in changing situations. With repetition, actions become more automatic and habitual and are mainly driven by contextual stimuli. Neuronal projections from the limbic and associative cortical areas to the medial part of the dorsal striatum (*cognitive*

control system) are involved in the goal-directed actions and behavioral flexibility, while projections from sensory motor cortices to the dorsolateral striatum (*habit system*) in motor planning and habit formation. Recent theories propose that the cognitive control system and the habit system interact to determine action control. Neuromodulation of these systems could be important in the formation of goal-directed and habitual behaviors, and in the emergence of pathological behaviors such as drug addiction or compulsive disorders. Our study aimed at elucidating the role of synaptic neuromodulators in the neuronal processes underlying the shift from flexible goal-directed actions to habitual strategies that occurs naturally following repeated practice. To this end, we assessed the synaptic and behavioral impact of different training regimes of instrumental conditioning of nose poke for food reward, which promote either goal-directed (short-training) or habitual behavior (over-training). In the dorsolateral striatum (DLS), long-term depression (LTD) depends on the synaptic neuromodulator endocannabinoids (eCBs), released upon activation of group I metabotropic glutamate receptors (mGluR1/5) and activation of dopamine D2 receptors. In over-trained habitual mice, we found that eCB-mediated LTD, induced upon pharmacological activation of mGluR1/5, was specifically lost at cortical connections to the striatal medium spiny neurons of the striatopallidal pathway. This associated with reduced efficacy of the intracellular cascades downstream from mGluR1/5 activation, raising the possibility that training-induced metaplasticity of mGluR1/5 signaling and adaptations of eCB pathway may contribute to habit formation. At the behavioral level, to test whether mGluR1/5 receptors were actively recruited during instrumental learning, we used a selective mGlur5 antagonist, either administered systemically or selectively within the DLS during training. We found that *in-vivo* treatment with the antagonist restored aspects of goal-directed behavior in over-trained mice. All together, our data indicate that the functional interplay between mGluR5- and eCB signaling modulates the shift from goal-directed to habitual behavior under physiological conditions.

Title: Activation of metabotropic glutamate receptor 1 overcomes NMDA receptor-mediated excitotoxicity

Authors: *H. A. HATHAWAY, S. PSHENICHKIN, J. T. WROBLEWSKI;
Pharmacol., Georgetown Univ., Washington, DC

Abstract: Glutamate is the predominant excitatory neurotransmitter in the mammalian brain. As such, glutamate-induced signal transduction is vital for the survival and health of neurons, especially during development. A frequently utilized model to study developmental elimination of neurons is primary cultures of cerebellar granule cells. In this system, high extracellular potassium (25 mM KCl, K25) maximizes cell viability, whereas reduction of potassium to physiological levels (5 mM KCl, K5) causes apoptosis by a mechanism that is analogous to removal of trophic support. Using this model of potassium deprivation in cerebellar granule cells, we have previously shown that addition of bath glutamate protects neurons from K5 toxicity, as measured by MTT assay to quantify cell viability. This neuroprotective action of glutamate is specifically mediated by activation of metabotropic glutamate 1 (mGlu1) receptors. Activation of mGlu1 receptors stimulates numerous signal transduction cascades, including canonical Gq-coupled hydrolysis of membrane phosphoinositides. We have found that mGlu1 receptor-meditated neuroprotection occurs via a Gq protein-independent mechanism. Additionally, some agonists of mGlu1 receptors (eg quisqualate) have maximum efficacy for stimulating phosphoinositide hydrolysis but no efficacy for protecting neurons from K5 toxicity, whereas glutamate has full efficacy for both of these mGlu1 receptor-mediated outcomes. Although glutamatergic signaling can be neuroprotective, under pathophysiological conditions (such as traumatic brain injury or ischemia) excess quantities of glutamate are released into the extracellular space and cause cell death. This excitotoxicity is mediated by NMDA receptor activation and subsequent increases in intracellular calcium. As cerebellar granule cells express both NMDA receptors and mGlu1 receptors, we hypothesized that neuroprotective mGlu1 receptor activation overcomes excitotoxic NMDA receptor activation in our model. To study this we measured viability of cerebellar granule cells in the presence of glutamate. Here we report that under these conditions a reduction of mGlu1 receptor activity, either by pharmacological blockade or reduced receptor expression, results in a decrease in cell viability that is blocked by antagonism of NMDA receptors.

Neuromed, Sapienza University, Italy, and Univ. of Lille, France, LIA (International Associalted Laboratories), Roma, Italy

Abstract: Recent evidence suggests that epigenetic mechanisms play a critical role for risk, onset, and progression of ischemia. Epigenetics refers to functionally relevant modifications of the genome that do not involve changes in DNA sequence, and include chemical marks that regulate gene transcription. At molecular level epigenetic phenomena are mediated by a variety of mechanisms including DNA methylation and histone acetylation. In our study we aimed at identifying epigenetic marks of ischemic brain damage, and examining the possibility that a pathological gene programming induced by ischemia can be targeted by specific drugs. We used the 4-vessel occlusion (4VO) model of transient global ischemia in rats. Rats subjected to 4VO show selective degeneration of hippocampal CA1 pyramidal neurons, whereas neurons of the CA3 region are relatively spared. We examined the expression of DNA-methyltransferases (DNMTs) and histone deacetylases (HDACs), in CA1 and CA3 regions at different time that precede neuronal death following ischemia/reperfusion (6, 12 and 24 hours). We found that global ischemia caused a substantial increase in DNMT3a and HDAC2 expression in the vulnerable CA1 region at 12 hours after reperfusion. We then examined the expression profile of different metabotropic glutamate (mGlu) receptor subtypes, which have an established role in mechanisms of neurodegeneration/neuroprotection. We found that global ischemia caused a substantial and CA1 region-specific down-regulation of mGlu2 receptors, which are known to be regulated by HDAC2. Other mGlu receptor subtypes were unchanged. This suggests an hypothetical epigenetic cascade in which global ischemia up-regulates HDAC2 in vulnerable neurons, thereby suppressing the expression of mGlu2 receptors. These changes may be compensatory because pharmacological amplification of mGlu2 receptor function with a positive allosteric modulator enhanced neuronal death in the CA1 region. We are currently examining whether blockade of the residual mGlu2 receptors with a negative allosteric modulator protects vulnerable CA1 pyramidal neurons against ischemic damage.

Title: mGlu1 receptors epigenetically restrain the expression of mGlu5 receptors in the cerebellum

Authors: *S. NOTARTOMASO[1], C. ZAPPULLA[1], G. MASCIO[1], M. MOTOLESE[1], M. CANNELLA[1], P. SCARSELLI[1], R. GRADINI[1], G. BATTAGLIA[1], V. BRUNO[1,2,3], F. NICOLETTI[1,2,3];

Abstract: We moved from our recent finding that mGlu1 metabotropic glutamate receptors are down-regulated in Purkinje cells of mutant mice modeling type-1 spinocerebellar ataxia (SCA1). Surprisingly, the loss of mGlu1 receptors was associated with the appearance of mGlu5 receptors in Purkinje cells of these mice. Expression of mGlu5 receptors was prevented by treatment of SCA1 mice with the mGlu1 receptor enhancer, RO0711401 (Notartomaso et al., Mol. Brain, 2013). mGlu5 receptors are found in Purkinje cells in the first two weeks of postnatal life. Afterwards, their expression declines, as shown by immunohistochemistry, immunoblotting, and measurements of mRNA levels by quantitative PCR. At the same time, expression of mGlu1 receptors is increased in Purkinje cells. Cerebellar maturation from PND9 to PND18 was associated with an increased methylation of the Grm5 gene promoter and a reduced methylation of the Grm1 gene promoter. We measured polyphosphoinositide (PI) hydrolysis in cerebellar slices using DHPG as a mixed mGlu1/5 orthosteric agonist, and dissecting the mGlu1 and mGlu5 component of the stimulation with the aid of two selective negative allosteric modulators (MTEP for mGlu5 and JNJ6259658 for mGlu1 receptors). DHPG-stimulated PI hydrolysis was prominent at PND9, when both mGlu1 and mGlu5 receptors contributed to the action of the agonist. At PND16, the residual stimulation by DHPG was exclusively mediated by mGlu1 receptors. However, in mice pre-treated systemically with JNJ6259685 for 7 days, mGlu5 receptors were still functional at PND16. In adult mice, systemic treatment with JNJ6259685 restored the expression of mGlu5 receptors in Purkinje cells, and caused a substantial reduction in Grm5 methylation. These findings suggest that expression of mGlu5 receptors in Purkinje

cells is down-regulated by an epigenetic mechanism that is triggered by the activation of mGlu1 receptors. Perhaps this mechanism is relevant to processes of developmental plasticity that rely on the activation of mGlu1 receptors, such as the elimination of supernumerary climbing fibers.

Title: The role of metabotropic glutamate receptor signaling in sleep regulation in *Drosophila* melanogaster

Authors: ***S. LY**[1,2], N. NAIDOO[1], A. I. PACK[1];
[1]Ctr. for Sleep and Circadian Neurobio., [2]Neurosci. Grad. Group, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Metabotropic glutamate receptors (mGluRs) modulate a wide range of processes in the central nervous system such as synaptic plasticity and neuronal signaling. In this study, we investigated the role of mGluR signaling in sleep and wake regulation in *Drosophila* melanogaster. While mammals express multiple forms of mGluRs, *Drosophila* melanogaster contains just one mGluR, known as DmGluRA, that is homologous to mammalian Group II mGluRs. We investigated the behavioral sleep effects of pharmacologically inhibiting DmGluRA by feeding female wCS10 flies food containing LY341495, a type II mGluR antagonist. LY341495-treated flies display total sleep reductions that are attributed to fewer and short sleep bouts during the day. Additionally, we examined the binding dynamics of DmGluRA and Homer, a sleep- and wake-regulating adaptor protein that links mGluRs to ionotropic glutamate signaling as well as to calcium signaling in the endoplasmic reticulum. Co-immunoprecipitation of DmGluRA and Homer confirm that DmGluRA and Homer physically interact in *Drosophila*. Furthermore, preliminary western blot analysis shows that levels of Homer/DmGluRA protein interaction are higher during the day than during the night. Our results indicate that mGluR signaling modulates daytime sleep in *Drosophila* and suggests that its involvement in sleep regulation may be mediated by binding to Homer proteins during the day.

These results have important implications for our understanding of the molecular mechanisms underlying sleep and wake and provide a link between sleep and other biological processes in the brain that depend on mGluR and Homer signaling.

Title: mGluR-dependent modulation of synaptic transmission in the lateral habenula

Authors: ***K. VALENTINOVA**[1,2], I. MOUTKINE[1,2], M. MAMELI[1,2];
[1]Inst. Du Fer À Moulin, Paris, France; [2]INSERM/UPMC, Paris, France

Abstract: The lateral habenula (LHb) is an excitatory structure controlling monoamine systems implicated in the encoding of motivational states. In this context, the excitatory inputs - from the globus pallidus - and inhibitory inputs - from the ventral tegmental area - onto LHb neurons drive avoidance, and reward-related behaviors respectively. Therefore fine tuning of excitatory and inhibitory transmission may control LHb neurons function and subsequent behaviors. However the cellular determinants modulating both excitatory and inhibitory synaptic inputs onto LHb neurons remain elusive. The group I metabotropic glutamate receptors (mGluRs) modulate synaptic transmission across the central nervous system. Further, mGluRs have been implicated in pathologies associated with LHb dysfunction, including depression, anxiety and addiction. Our hypothesis is that metabotropic glutamate receptors may represent a common substrate for the control of synaptic transmission onto LHb neurons. We employed patch-clamp recordings in brain slices from mice to test whether and how mGluRs regulate excitatory and inhibitory synaptic transmission onto LHb neurons. To assess whether mGluRs are present in the LHb we performed RT-PCR from microdissected LHb, which shows expression of both mGluR1 and mGluR5. Moreover, the selective agonist (RS)-3,5-dihydroxyphenylglycine (DHPG, 50 μM) induces an inward current, suggesting a functional expression of mGluRs in the LHb. We then

recorded evoked excitatory postsynaptic currents (EPSC) over time in voltage clamp mode from LHb neurons at -50 mV. We found that DHPG leads to a long-lasting depression of AMPA-mediated EPSCs (eLTD). Similarly, when recording evoked inhibitory PSC (IPSC), DHPG induces a long lasting reduction of GABAa currents (iLTD). We found different expression mechanisms underlying eLTD and iLTD. DHPG-induced eLTD occurs along with an increased paired-pulse ratio, indicative of a reduced neurotransmitter release. Further eLTD requires CB1 receptors (CB1R), as it is blocked by the CB1R antagonist Ness0327 (0.5 μM). Conversely, iLTD occurs in the presence of the CB1R antagonist, despite the functional expression of CB1Rs at GABAergic synapses. Indeed, the CB1R agonist WIN-55,212-2 (5 μM) decreased the IPSCs. These results suggest that the group I mGluRs reduce AMPA and GABAa-mediated synaptic transmission via different cellular mechanisms. In conclusion, mGluR modulation of synaptic transmission may represent a molecular mechanism relevant for LHb function in encoding motivation in physiological and pathological conditions.

Title: Production of xanthurenic acid from 3-hydroxykynurenine in rat and human brain *in vitro* and *in vivo*

Authors: *K. V. SATHYASAIKUMAR, M. TARARINA, H.-Q. WU, R. SCHWARCZ; Maryland Psychiatric Res. Center, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Xanthurenic acid (XA), a metabolite formed from 3-hydroxykynurenine (3-HK) in the kynurenine pathway, has been proposed to function as a modulator of glutamatergic neurotransmission in the central nervous system, since it inhibits the vesicular glutamate transporter (Neale et al., Neuropsychopharmacology, 2013) and is an agonist of Group II (mGlu 2 and mGlu 3) metabotropic glutamate receptors (Fazio et al., Curr. Neuropharmacol., 2012). The goal of the present study was to evaluate 3-HK as a substrate for the neosynthesis of XA and to identify the nature of the responsible enzyme(s) using rat and human brain tissue homogenates. In addition, we used rat cortical slices to study the mechanisms that modulate XA synthesis and examined the *de novo* synthesis of XA from 3-HK by microdialysis *in vivo*. XA

was identified and quantified by HPLC with electrochemical detection (Okech et al., BBRC, 2006). All experiments were designed in analogy to studies of the *de novo* synthesis of kynurenic acid (KYNA) from kynurenine (see Schwarcz et al., Nature Rev. Neurosci., 2012, for review). *In vitro*, production of XA from 3-HK was temperature-dependent and linear with time and substrate concentration. Synthesis in various rat brain regions was similar to the pattern seen in KYNA synthesis from kynurenine. XA production was enhanced in the quinolinate-lesioned striatum, indicating a non-neuronal localization of the synthesizing machinery. Use of BFF122 (Amori et al., JNC, 2009), a selective inhibitor of kynurenine aminotransferase II (KAT II), revealed that the majority of XA production in rat brain was catalyzed by KAT II (85% inhibition in tissue homogenate; 78% inhibition in slices). Similar results were obtained using human prefrontal cortex homogenates (74% inhibition), and confirmed using partially purified rat KAT II and recombinant human KAT II. Release of newly produced XA from cortical slices was influenced by ionic milieu, buffer composition and co-substrates. Thus, deletion of Na^+ increased XA release (+54%), while addition of 50 mM K^+ (-43%) or 50 µM veratridine (-72%) reduced XA release in cortical slices. Addition of the co-substrates pyruvate (+ 205%) or α-ketoglutarate (+109%) significantly increased XA release. *In vivo*, newly produced XA was recovered in striatal microdialysate samples after focal perfusion with 3-HK (10 µM). Basal values of XA in microdialysate were <4 nM. Jointly, these data confirm the cerebral production of XA from 3-HK both *in vitro* and *in vivo*. Further studies are needed to examine the role of this KAT II-catalyzed XA formation in the regulation of kynurenine pathway flux and function in physiology and pathology.

Abstract: Side effects of drugs are the major drawback for the use of any medicine in clinics, and depend mainly on small therapeutic windows and off-target actions. Obtaining a fine control over the temporal and spatial activity of a drug would allow precise dosing and localization of active drugs, respectively. These optimal therapeutic conditions cannot be achieved with any existing drug. Light can help solving the limitations of classical pharmacology. Optopharmacology is a recently developed technique that consists of attaching a light-sensitive moiety (usually azobenzene) to ligands that control endogenous proteins, so that drugs can be made available with the spatiotemporal precision of light. Still, optopharmacology was never applied before to the most interesting targets for drug development: allosteric modulators of G protein-coupled receptors (GPCRs). We report here the synthesis and characterization of the first light-sensitive allosteric modulator of the metabotropic glutamate receptor 5 (mGlu5), a class C GPCR, by a novel optopharmacological design. Instead of assembling azobenzene next to the ligand, like in previous optopharmacology, we integrated azobenzene inside a known allosteric ligand of mGlu receptors by simple substitution of few atoms in the parent compound. One of the obtained molecules (Alloswitch-1) was active with nanomolar potency and light wavelength-specificity as a negative allosteric modulator (NAM) of mGlu5. In cultured cells, Alloswitch-1 counteracts calcium oscillations induced by activation of both heterologous and endogenous mGlu5 receptors in the dark, and different light conditions (violet and green light) can be used to switch these oscillations on and off reversibly. In Xenopus tropicalis tadpoles, Alloswitch-1

controls the motility of animals in a light- and concentration-dependent manner. Alloswitch-1 is a novel and powerful tool for the optical control of an endogenous GPCR. Moreover, the uncommonly high success rate of our novel design strategy suggests that it can be extended to allosteric modulators of other GPCRs.

Title: Preso1 bidirectionally regulates group I mGluR phosphorylation

Authors: ***J.-H. HU**[1], P. F. WORLEY[2], D. A. HOFFMAN[1];
[1]NICHD, Bethesda, MD; [2]Johns Hopkins Univ., Baltimore, MD

Abstract: Group I metabotropic glutamate receptors (mGluR1/5) are enriched at excitatory synapses in the brain where they are important in neural plasticity and behavioral responses

including drug addiction, fear conditioning, inflammatory pain, and schizophrenia. Phosphorylation of mGluR1/5 at Homer binding site (TPPSPF), and subsequent Pin1 binding and isomerization of S-P bond are required for synaptic plasticity and cocaine motor sensitization. Therefore, it is a central goal to understand mechanisms that control dynamic mGluR5 phosphorylation. Here, we report that the scaffold protein Preso1 controls both phosphorylation and dephosphorylation of mGluR5. Previously, we reported that Preso1 scaffolds kinases that phosphorylate mGluR5 including CDK5 and Erk, and that Preso1 is required for activity-dependent mGluR5 phosphorylation. However, how mGluR5 is dephosphorylated remained elusive. Treatment of neurons with okadaic acid, a PP2A inhibitor, increases mGluR5 phosphorylation. PP2A dephosphorylates mGluR5 at the Homer binding site when expressed with mGluR5 in HEK293T cells. Furthermore, we identified the C-subunit of PP2A as a binding partner of Preso1 using Preso1 PDZ and FERM domains as bait in a yeast two hybridization screen. Binding is confirmed by co-IP when expressed in HEK293T cells. These data suggest that Preso1 not only serves as a scaffold protein for kinases but also for phosphatase. This dual functionality is similar to AKAPs. In support of the notion that Preso1 plays a role in recruiting PP2A to dephosphorylate mGluR5 in striatum, preliminary data shows that mGluR5 phosphorylation persists longer in striatum after cocaine administration in Preso1 KO mice compared to WT littermates. Moreover, behavioral analysis reveals that increased cocaine motor sensitization in Preso1 KO mice compared to WT littermates. Taken together, these biochemical and behavioral data suggest that Preso1 bidirectionally regulates mGluR5 phosphorylation by anchoring both kinases and phosphatase.

Title: Proper localization and function of trpm1 depends on LRIT3 expression in rod depolarizing bipolar cells

Authors: *R. G. GREGG[1], J. NOEL[2], K. M. HEATH[3], N. HASAN[3], T. RAY[4], M. A. MCCALL[5];
[1]Biochem & Mol Biol, Univ. Louisville, LOUISVILLE, KY; [2]Anat Sci. & Neurobio., [4]Biochem & Mol Biol, [5]Ophthalmology & Visual SCiences, [3]Univ. of Louisville, Louisville, KY

Abstract: The retina processes light information through parallel ON and OFF pathways. Type 1 congenital stationary night blindness (CSNB1) is a human retinal disorder caused by disruption of ON pathway signaling within depolarizing bipolar cells (DBCs). In patients and mouse models, CSNB1 is characterized by night blindness and the absence of an ERG b-wave. Both patients and mice have normal photoreceptor function (ERG a-wave), but lack ON bipolar cell (BC) depolarization in response to light, due to absence of key components in the mGluR6 G-protein coupled cascade that ends with gating of the TRPM1 channel. CSNB1 mouse models have intact retinal morphology. Using a zinc-finger nuclease (ZFNs) strategy, we constructed a mouse lines with mutations in exon 2 of the leucine-rich repeat, immunoglobulin-like domain and transmembrane domain-containing protein 3 precursor (LRIT3). ZFNs injected into fertilized single cell embryos make double strand breaks in the target sequence, resulting in non-homologous end joining, and mutations, which can create null alleles. Using procedures approved by the University of Louisville Institutional Animal Care and Use Committee, we characterized LRIT3 mutant retinal function with ERG and rod DBC whole cell patch clamp as well as retinal morphology with immunohistochemistry. Similar to the published results in humans (Zeitz et al., 2013) with mutations in LRIT3, the dark- and light-adapted ERGs from the LRIT3$^{-/-}$ mice have a normal a-wave, although their b-wave is absent, a phenotype shared with other mouse models of CSNB1. Currents evoked in LRIT3$^{-/-}$ rod DBCs using either CPPG to gate the TRPM1 channel through the mGluR6 receptor or capsaicin to directly gate the TRPM1 channel produced small residual currents, similar to those found in TRPM1$^{-/-}$ rod DBCs and significantly smaller than WT. Consistent with these physiological differences between LRIT3$^{-/-}$ and WT mice, TRPM1 expression is absent from the LRIT3$^{-/-}$ DBC terminals. We conclude that LRIT3 is necessary for TRPM1 localization to DBC dendritic terminals and the absence of TRPM1 in LRIT3$^{-/-}$ retina leads to their CSNB1 phenotype. Title: Significant differences in the structure and function of excitatory synapses in the rhesus monkey lateral prefrontal versus primary visual cortex

Authors: *J. I. LUEBKE, M. MEDALLA;
Anat. & Neurobio., Boston Univ. Sch. of Med., Boston, MA

Abstract: Excitatory synaptic response properties of layer 3 pyramidal neurons in the rhesus monkey lateral prefrontal cortex (LPFC) differ markedly from those in the primary visual cortex (V1). Spontaneous excitatory postsynaptic currents (EPSCs), exhibit significantly higher frequency, greater amplitude and slower rise and decay times in LPFC neurons, which computational models predict are due to higher gAMPA in LPFC than in V1 neurons (Amatrudo et al., 2012). Here, we sought to determine whether these distinct synaptic responses are due to differences in firing rates of presynaptic neurons, in postsynaptic entities, and/or in presynaptic entities. When action potentials were blocked with TTx, whole cell voltage clamp recordings revealed that, as with sEPSCs, TTx-insensitive miniature EPSCs exhibit significantly higher frequency, greater amplitude and slower kinetics in LPFC compared to V1 neurons demonstrating that differences in synaptic responses are not due to differences in the firing rates of presynaptic neurons. We next examined the size and distribution of spines across LPFC versus V1 neurons with confocal microscopy. As previously shown, LPFC neurons possessed significantly higher densities of spines of all subtypes compared to V1 neurons. K-means cluster analysis of spine head widths was used to separate the total population into small (< 0.52 um) and large spines. The mean spine width of large spines was significantly larger across the entire dendritic arbors of LPFC vs. V1 neurons. Electron microscopic quantification of asymmetric synapses in layers 2-3 neuropil demonstrated that while there was no difference in synapse density in LPFC and V1, there was a higher proportion of perforated axospinous synapses in LPFC (34 ± 1%) compared to V1 (20 ± 5%). The mean postsynaptic density (PSD) surface area of axospinous synapses was significantly greater in LPFC (0.11 ±0.01 μm2) compared to V1 (0.08 ±0.01 μm2), and perforated synapses were about twice as large. Consistent with the differences in spine and synapse size, the mean volume of axonal boutons in L2-3 of LPFC was significantly larger than of V1, due specifically to the population of boutons forming perforated synapses. In the LPFC there were approximately 1.6x more vesicles per bouton than there were in V1 boutons and the mean number of synaptic vesicles per bouton forming a perforated synapse was almost twice as high (LPFC, 746 ± 62 vs. V1, 438 ± 44). Taken together, these data are consistent with the idea that significantly more frequent and higher amplitude synaptic

currents in LPFC compared to V1 neurons are due, at least in part, to larger and more powerful synapses in LPFC.

Title: Distribution of dendritic spines and inhibitory inputs on layer 2 and layer 3 pyramidal neurons of the rhesus monkey anterior cingulate cortex

Authors: *M. MEDALLA, J. P. GILMAN, J. WANG, J. I. LUEBKE;
Anat. & Neurobio., Boston Univ. Sch. of Med., BOSTON, MA

Abstract: The role of the primate anterior cingulate cortex (ACC) in cognition remains poorly understood, but depends on pyramidal neurons that participate in diverse cortico-cortical and cortico-subcortical networks. The functional output of pyramidal neurons is largely determined by their intrinsic dendritic structure and excitatory and inhibitory synaptic connections, which are laminar specific. We compared the morphological features of layer 2 (L2) and layer 3 (L3) pyramidal neurons in the monkey ACC using intracellular filling, immunohistochemistry and confocal microscopy. The distribution of dendritic spines- the principal recipients of glutamatergic inputs- and inhibitory VGAT+ terminals apposed to distinct neuronal compartments was quantified. Dendritic arbors of L3 were larger and more complex than L2 neurons, exhibiting longer total dendritic lengths, more branch points, and spanning larger convex hull volumes and laminar extents. However the two populations do not differ significantly with regard to the distribution of dendritic spines or putative inhibitory inputs. Dendritic spine density along apical and basal dendritic arbors of both L2 and L3 neurons was lowest in the proximal third, highest in middle third, and progressively declined across the distal third of the arbors. Furthermore, the proportions of spine subtypes did not differ, being comprised of ~80% thin; ~10% mushroom; and ~8% stubby. The density of inhibitory VGAT+

appositions on apical and basal arbors was also similar between L2 and L3 neurons, which was highest in the proximal third and progressively declined distally. Majority (~72%) of these dendritic VGAT+ appositions were found along dendritic shafts and the rest were found on spines. VGAT+ puncta on spines were observed most frequently on thin spines, the most prevalent subtype. However thin spines with VGAT+ appositions comprise only a small (~14%) proportion of the total population of thin spines. In contrast, mushroom spines were selectively targeted by inhibitory inputs since 27-44% of mushroom spines (depending on layer and arbor) had VGAT+ appositions. In addition, VGAT+ appositions were present along axon initial segments (~30 μm from soma) in higher densities than along dendrites (L2: 0.7 ± 0.01 apps/μm axon vs. 0.4 ± 0.07/μm dendrite; L3: 0.8 ± 0.04 vs. 0.4 ± 0.05/μm). Moreover, axonal VGAT+ apposition density was significantly higher for L3 versus L2 neurons. In conclusion, this study provides detailed information on the topology of synaptic inputs to principal neurons in the primate ACC for the first time; such information is essential for a basic understanding of network function in this important brain area.

Title: Mechanisms underlying spreading depolarization-induced dendritic beading

Authors: A. B. STEFFENSEN[1], J. SWORD[2], D. CROOM[2], S. A. KIROV[2,3], *N. MACAULAY[1];
[1]Univ. of Copenhagen, Copenhagen, Denmark; [2]Brain and Behavior Discovery Inst., [3]Dept. of Neurosurg., Georgia Regents Univ., Augusta, GA

Abstract: Spreading depolarizations (SDs) are waves of sustained neuronal and glial depolarization that propagate a massive disruption of ion gradients through the brain. SD is

associated with migraine aura and it was recently recognized as a novel mechanism of injury in stroke and TBI patients. SD leads to neuronal swelling and dendritic beading as assessed in real time with 2-photon laser scanning microscopy (2PLSM). Pyramidal neurons do not express aquaporins and thus display low inherent water permeability. Yet, SD rapidly induces focal swelling (beading) along the dendritic shaft. The molecular mechanism by which dendrites bead during SD remains elusive. To address this issue, we induced SD in mouse hippocampal slices by focal KCl-microinjection and visualized the ensuing dendritic beading by 2PLSM. We confirmed that dendritic beading failed to arise during large (100 mOsm) hyposmotic challenges, underscoring that neuronal swelling does not occur as a simple osmotic event. SD-induced dendritic beading was not prevented by pharmacological interference with formation of actin and stability of microtubules thus dendritic beading may entirely result from excessive water influx. Dendritic beading was strictly dependent on the presence of Cl- in the ACSF and accordingly, combined blockade of two Cl- -coupled transporters (K+/Cl- and bicarbonate cotransporters) in addition to a lactate transporter, led to a significant reduction in dendritic beading without interfering with SD. Furthermore, our *in vivo* 2PLSM data showed a strong inhibition of dendritic beading upon pharmacological blockage of these three cotransporters. We therefore propose that SD-induced dendritic beading takes place as a consequence of the altered driving forces for these cotransporters. As some of these transport mechanisms share the ability to transport water during their translocation mechanism, they may thereby generate dendritic beading by a mechanism independent of osmotic forces.

Title: Triple miRNA Shank knockdown shows that Shank-cortactin interactions control actin dynamics to maintain flexibility of neuronal spines and synapses

Authors: *H. D. MAC GILLAVRY[1], J. M. KERR[2], N. A. FROST[3], T. A. BLANPIED[4]; [1]Dept. of Cell Biol., Utrecht Univ., Utrecht, Netherlands; [2]Porter Neurosci. Res. Ctr., NINDS, Bethesda, MD; [3]Dept. of Neurol., UCSF Sch. of Med., San Francisco, CA; [4]Dept. of Physiol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The spine actin cytoskeleton forms a complex filamentous network required for maintenance of synaptic architecture and plasticity of excitatory transmission. However, we have little understanding of the molecular intermediates that permit spatially restricted control of actin polymerization over synaptic structure and function. The family of Shank scaffolding molecules (comprising Shank1, 2 and 3) are among the core components of the postsynaptic density (PSD). Shank proteins have multiple protein interaction domains that link surface glutamate receptors to other scaffolding molecules within the PSD, as well as to the actin cytoskeleton via diverse actin-binding proteins. Furthermore, Shank proteins are generally found in the deeper layers of the PSD facing the spine interior, and are thus ideally positioned to control actin cytoskeleton-PSD interactions. However, determining the function of Shank proteins in neurons has been complicated because the different Shank isoforms share a very high degree of sequence and domain homology. Therefore, to control spine Shank content while preventing potential compensatory effects, we developed a miRNA-based knockdown strategy to reduce the expression simultaneously of all synaptically targeted Shank isoforms in hippocampal neurons. Using this approach, we achieved a strong (>75%) reduction in total Shank protein levels at individual spines, prompting a ~40% decrease in mushroom spine density. Furthermore, miRNA-based Shank knockdown reduced spine actin levels and increased sensitivity to the actin depolymerizing agent Latrunculin A, an effect restored by re-expression of full-length miRNA-resistant human SHANK2. Interestingly, a SHANK2 mutant lacking the proline-rich cortactin binding motif (SHANK2-ΔPRO) was unable to rescue these defects, suggesting that Shank-cortactin interactions are required for the maintenance and stability of the spine actin cytoskeleton. Furthermore, Shank knockdown reduced cortactin levels in spines and increased the mobility of spine cortactin as measured by single-molecule tracking PALM, suggesting that Shank proteins recruit and stabilize cortactin at the synapse. Consistent with this model, we found that Shank knockdown significantly reduced spontaneous remodeling of synapse morphology, a phenomenon dependent on actin dynamics, and this could not be rescued by the SHANK2-ΔPRO mutant. We conclude that beyond their role as stable scaffolding molecules within the PSD, Shank proteins are key intermediates between the synapse and the spine interior that, via cortactin, permit the actin cytoskeleton to dynamically regulate synapse morphology and function.

Title: Syntaxin 4 is a postsynaptic t-SNARE required for synaptic growth and plasticity in *Drosophila*

Authors: ***K. P. HARRIS**[1], Y. AKBERGENOVA[1], R. W. CHO[1], Z. D. PICCIOLI[1], N. PERRIMON[2], J. LITTLETON[1];
[1]Biology; Brain and Cognitive Sci., MIT, Cambridge, MA; [2]Dept. of Genet., Harvard Med. Sch., Boston, MA

Abstract: Postsynaptic cells can induce synaptic plasticity through the release of retrograde signals in response to presynaptic activity. We have previously identified a calcium-dependent retrograde signaling pathway that is mediated by postsynaptic Synaptotagmin 4 (Syt4) at *Drosophila* neuromuscular junctions (NMJs). We hypothesize that Syt4 acts as a Ca2+ sensor to control the release of retrograde signals, similar to the role of Syt1 in presynaptic vesicle fusion. However, little is known about how postsynaptic exocytosis is regulated and what cargo molecules are trafficked in the Syt4 pathway. Further analysis of Syt4-mediated signaling will enhance our understanding of how synaptic growth and plasticity are regulated. To identify genes involved in Syt4 trafficking, we assembled a UAS-RNAi transgenic collection targeting 450 gene products that are resident at synapses and/or involved in membrane trafficking. Syt4 decorates the postsynaptic membrane of the NMJ, overlapping with glutamate receptor fields opposite active zones. Candidate UAS-RNAi constructs were co-expressed with fluorescently tagged Syt4 and animals were examined for changes in Syt4 distribution. We identified several candidates that regulate Syt4 distribution at the NMJ, including the t-SNARE Syntaxin 4 (Syx4). RNAi knockdown of Syx4 results in a reduction in Syt4 levels at the postsynaptic membrane and abnormal accumulation of Syt4 in the cytoplasm. To further explore the function of Syx4, we generated *loss-of-function* mutants. These animals exhibit a reduction in the number of boutons at the NMJ and the number of active zones per bouton, indicating impairment of synaptic structural plasticity. Syx4 protein is enriched postsynaptically at the NMJ, and postsynaptic

expression of Syx4 is sufficient to fully rescue Syx4 mutant defects. These observations are consistent with a role for Syx4 as a t-SNARE for postsynaptic exocytosis. Current studies are aimed at identifying additional retrograde signaling pathways that may be perturbed upon loss of Syx4 function. We observe a reduction in the delivery of Neuroligin (Nlg) to the postsynaptic membrane in Syx4 mutants and strong genetic interactions between Nlg, Neurexin (Nrx) and Syx4, consistent with Syx4 playing a role in regulating the important Nlg-Nrx trans-synaptic adhesion complex. We will continue to investigate the mechanism by which Nlg, Nrx and Syx4 interact, as well as other signaling pathways that may be disrupted in Syx4 mutants. We anticipate this approach will expand our understanding of postsynaptic regulation of synaptic plasticity.

Title: The cell-autonomous role of MEF2C in postnatal neocortical circuit and synapse development *in vivo*

Authors: *K. E. RAJKOVICH, K. W. LOERWALD, J. R. GIBSON, K. M. HUBER; Neurosci., UT-Southwestern Med. Ctr., Dallas, TX

Abstract: Neocortical circuits are sculpted by genetic programs and neuronal activity during development, and aberrant formation of these circuits is associated with neurodevelopmental disorders such as autism. Proper neocortical circuit development requires an appropriate balance of synapse proliferation and elimination: processes regulated by circuit activity and experience. The MEF2 family of activity-dependent transcription factors regulates excitatory synapse number and function in other brain regions. Although there are four MEF2 genes (*Mef2a-d*),

Mef2c accounts for ~75% of MEF2 expression in neocortex and is an autism-linked gene. Many studies show MEF2 genes to regulate synaptic structure and function in several brain areas, but the nature of this regulation is controversial. Previous studies from others and our group suggest that MEF2 negatively regulates synapse number. Therefore, we initially hypothesized that *Mef2c* deletion in neocortex should increase synapse number and function in neocortex. However, these studies employed *in vitro* and global deletion strategies where primary functions of MEF2 may be obscured by secondary, indirect changes. We examined the postsynaptic, cell-autonomous role of endogenous MEF2 genes in regulating synaptic pathways in acutely prepared cortical slices. Sparse AAV-Cre-mediated deletion of *Mef2c* within the postnatal mouse somatosensory (barrel) cortex allows a within-animal comparison of $Mef2c^{flx/flx}$ and *Mef2c*-deleted neurons. We use this preparation to perform intracellular patch clamping and morphological imaging experiments in L2/3 pyramidal neurons to determine the effects of postnatal *Mef2c* deletion on synaptic structure and function. *Mef2c* deletion downregulates evoked synaptic transmission over several synaptic pathways in L2/3 pyramidal neurons and requires experience-dependent neural activity to drive this effect, as assessed by laser-scanning photostimulation (LSPS) with glutamate uncaging. *Mef2c* deletion does not affect short-term plasticity, suggesting a postsynaptic locus for *Mef2c*-dependent regulation of synaptic transmission. Interestingly, *Mef2c* deletion enhances spontaneous synaptic transmission. Finally, *Mef2a/d* deletion does not affect these processes. Our data reveal that *Mef2c*-mediated synaptic regulation in the neocortex is complex. Here we study the cell-autonomous, postsynaptic role for endogenous *Mef2c* in the mammalian postnatal neocortex: a brain region where little is known about how MEF2 isoforms regulate neural circuit development *in vivo*.

Title: Transmembrane-agrin overexpression in the adult murine cortex and hippocampus results in decreased dendritic spine density and altered spine morphology

Authors: *A. SCHICK[1], S. PFEIFFER[2], J. SCHICK[2], S. KRÖGER[1];
[1]LMU Dept Physiol., Munich, Germany; [2]Helmholtz Inst., Munich, Germany

Abstract: The heparan sulfate proteoglycan agrin is a well-characterized regulator of synaptogenesis at the neuromuscular junction. Its role in the developing and adult central nervous system is less well understood. Evidence however is accumulating that agrin also plays a role as synapse organizer in the CNS. Previously we demonstrated that overexpression or aggregation of the transmembrane form of agrin (TM-agrin), the predominant isoform of agrin in the CNS, results in the formation of numerous filopodia-like processes on axons and dendrites *in vitro*. We also showed that a partitioning of TM-agrin into lipid rafts, the activation of the Src family kinase Fyn and subsequently the activation of MAPK are prerequisites for the formation of these processes. The TM-agrin-induced processes appeared very similar to those extended by dendrites as precursors for spine synapses. We therefore investigated the role of TM-agrin-induced processes and their role in synapse development and plasticity in the CNS *in vivo*. To this end we generated knock-in mice that conditionally overexpress TM-agrin in the cortex and hippocampus, driven by a CamKII-CreERT2 promoter. Initial examination of adult TM-agrin overexpressing mice showed that they are healthy, normal in size, and do not show any obvious behavioral abnormalities despite a more than 10-fold increase in TM-agrin protein in whole brain membrane preparations. Upon examination of neuronal morphology, we observed a 33% decrease in spine density on CA1 pyramidal neurons. However, the decrease in spine number per dendrite length did not equally affect all types of spines. Instead stubby spines, which represent a subpopulation of transitory immature spines, showed an increase in 13% on TM-agrin overexpressing pyramidal neuron dendrites. Likewise, in the cortex of these mice we observed a decrease in the number of PSD95 immunoreactive punctae of approximately 20%. Taken together, these results show that overexpression of transmembrane-agrin in adult mice has an effect on spine density in the cortex and hippocampus. This further supports the hypothesis that agrin is an important regulator of synapse type and density in the adult CNS.

Abstract: Background: ASD is a neurodevelopmental disorder that has a complex etiology. Studies show that abnormal synaptic functions in the brain may be involved in the pathogenesis. Several synaptic proteins including Neuroligin3 and 4, CNTNAP2 and the SHANK family (SH3 and multiple ankyrin repeat domain) have been implicated in ASD from genetic studies. These findings support an emerging synaptic hypothesis in the pathophysiology of ASD. The SHANK proteins act as synaptic scaffolding, organizing the cytoskeletal and signaling complex at the postsynaptic density of excitatory synapses. SHANK2 has been identified as a strong causative gene in ASD. Small de novo microdeletions along with nonsense and missense point mutations have been identified within the *SHANK2* gene in individuals with ASD and intellectual disability (Berkel et al 2010).These results indicated a role of SHANK2 haploinsufficiency in the pathophysiology of ASD and intellectual disability, and provide an excellent opportunity to model SHANK2 causing ASD using a transgenic mouse model. **Objective:** The overall goal of my research project is to gain insights into the function of Shank2 and the pathophysiology of ASD using a model organism. I will generate and characterize Shank2 mutant mice. **Results:** 1) *In vitro* studies indicate that a human SHANK2 mutation may result in defects in protein trafficking. 2) Using SHANK2 protein domains as bait for yeast-two-hybrid screen, I identified an interacting protein containing a conserved ubiquitin ligase domain, MindBomb2 (MIB2). The ubiquitination of Shank family proteins has been suggested previously. The preliminary data support the co-localization and interaction of tagged Shank2 and MIB2 in HEK293 cells. *In vitro* data suggests MIB2 promotes the ubiquitination and degradation of Shank2. Data from MIB2 mutant animals indicate an increase in SHANK2 protein levels. 3) Using a gene targeting approach, I have obtained Shank2 exon 24 deletion mice (Δe24). I have analyzed the DNA and RNA of Shank2 and confirmed the complete excision of exon 24. Western blot shows an absence of the Shank2 protein in the Δe24 mice. I have begun biochemical analysis of the proteins in the post synaptic density and an extensive analysis of behavior, electrophysiology, and neuronal morphology is ongoing. **Conclusions:** 1) I have identified a ubiquitin ligase that potentially plays a role in SHANK2 regulation. 2) I generated a mouse with a deletion mimicking mutations seen in patients with ASD. 3) I identified behavioral phenotypes in Shank2 Δe24-/- mice that are significantly different that the WT behaviors and have begun pharmacological treatment.

Title: Extracellular phosphorylation regulates EphB trafficking and EphB-NMDAR interaction

Authors: N. XIA[1], *K. HANAMURA[1], S. I. SHEFFLER-COLLINS[2], M. B. DALVA[1]; [1]Neurosci., Thomas Jefferson Univ., Philadelphia, PA; [2]Neurosci. Grad. Group, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: EphBs are trans-membrane receptor tyrosine kinases. When EphBs are activated by ephrin-B ligands and remain on the cell surface, they can recruit and maintain NMDARs to synaptic sites. In contrast, endocytosed EphBs generate repulsive responses. However, whether the localization of EphBs and interaction with the NMDAR are regulated by the same mechanism is unknown. Protein phosphorylation is a fundamental mechanism regulating cellular function. While the intracellular phosphorylation has been extensively studied, the function of extracellular phosphorylation is less well understood. We find that phosphorylation of a tyrosine residue in the extracellular fibronectin type III repeat domain of EphB2 receptor regulates both receptor trafficking and its ability to interact with the NMDAR. Using mass spectrometry, site-directed mutagenesis and phospho-specific antibodies, we identify a specific phosphorylation site on EphB2 that undergoes phosphorylation in a ligand-dependent fashion. The phosphorylation of EphB2 occurs on the cell surface as surface staining of live cultured neurons shows that amount surface phosphorylated EphB increases upon ligand stimulation. In contrast, pretreatment with a membrane impermeable kinase inhibitor blocks the increase in surface EphB phosphorylation. We next examine the functional significance of EphB2 extracellular phosphorylation. In the absence of NMDAR, EphB2 extracellular domain phosphorylation results in EphB2 internalization and degradation, indicating that ecotodomain phosphorylation may regulate trafficking and membrane retention of the receptor. In the presence of the NMDAR, EphB2 extracellular domain phosphorylation drives the EphB2-NMDAR interaction

both in HEK293T cells and neurons. Finally to begin to test whether extracellular phosphorylation might be a general mechanism for protein-protein interaction, we identify and test putative NMDAR interacting proteins. Using sequence alignment and homology, we predict that EphA8 should also interact with the NMDAR. Experiments in HEK293T cells validate that EphA8 can interact with the NMDAR. Taken together, our results suggest that extracellular phosphorylation might be an underappreciated mechanism in regulation of protein interaction and protein trafficking.

Title: Distinct roles of Shank family proteins in regulating glutamatergic synaptic transmission

Authors: R. SHI, P. REDMAN, Y. LIU, M. LIU, K. JONES, *W. XU;
MIT, Cambridge, MA

Abstract: Scaffold proteins in the postsynaptic density (PSD) of excitatory glutamatergic synapses have been shown to be important in regulating synaptic transmission. Defects in many scaffold proteins, including the Shank family of proteins, have been associated with neurological, neurodevelopmental, and neuropsychiatric diseases, but how these proteins regulate glutamate receptor-mediated synaptic transmission remains elusive. Here, we investigate the role of the Shank proteins in regulating synaptic transmission, and seek to determine any functional differences among Shank family members. Using an shRNA-mediated knockdown of Shank proteins, combined with dual whole-cell patch clamp in hippocampal slice culture, we show that knockdown of Shank1 or Shank2 reduced AMPAR-mediated evoked excitatory postsynaptic currents (eEPSCs). Our experiments further suggest that this reduction in AMPAR eEPSCs was likely mediated by a reduction in the number but not the strength of

AMPAR-containing synapses. Simultaneous knockdown of both Shank1 and Shank2 also decreased NMDAR eEPSCs, indicating further synaptic defect. However, knockdown of Shank3 showed no effect on synaptic transmission in our system, potentially due to a late developmental onset of Shank3 expression. Taken together, our results suggest that distinct Shank family members contribute differently to maintain glutamatergic synaptic function.

Title: S-nitrosylation of Cdk5 and its activator p35 in neuronal morphogenesis and synaptic function

Authors: ***P. ZHANG**[1,2,3], W.-Y. FU[1,2,3], A. FU[1,2,3], N. IP*[1,2,3];
[1]Div. of Life Sci., HKUST, HONG KONG, China; [2]Mol. Neurosci. Center, HKUST, Hong kong, China; [3]State Key Lab. of Mol. Neuroscience, HKUST, Hong kong, China

Abstract: Cyclin-dependent kinase 5 (Cdk5), a proline-directed serine/threonine kinase, plays important roles in neural development such as neuronal migration, neurite outgrowth and synapse formation. Unlike other cyclin-dependent kinase family members, which are regulated by cyclins, Cdk5 is activated through its association with the neuronal-specific activators, p35 and p39. We have previously demonstrated that Cdk5 can undergo S-nitrosylation at Cys83 which reduced its kinase activity and regulated the morphology of dendritic spines, where most excitatory synapses reside. We report here that p35 can also be S-nitrosylated *in vitro*. S-nitrosylation of Cdk5 and p35 could both be detected in mouse brains, and the specific modification was abolished in mice lacking neuronal nitric oxide synthase (nNOS). Importantly,

enhanced Cdk5 activity together with increased phosphorylation of various specific Cdk5 substrates was observed in the brains of nNOS-knockout mice, suggesting that S-nitrosylation is responsible for negatively regulating Cdk5 activity *in vivo*. Furthermore, we showed that blockade of NO production in cultured hippocampal neurons resulted in synaptic failures. More importantly, inhibition of Cdk5 activity partially rescued the synaptic deficits upon NO production blockade. Taken together, our findings reveal a new regulatory mechanism for Cdk5 that is essential for neuronal morphogenesis and synaptic functioning.

Title: Pharmacological characterization of novel neuroactive steroid modulators of NMDA receptors

Authors: M. A. ACKLEY, G. M. BELFORT, G. MARTINEZ-BOTELLA, F. G. SALITURO, A. J. ROBICHAUD, *J. J. DOHERTY;
Sage Therapeut., Cambridge, MA

Abstract: NMDA receptors are intimately involved in neuroplasticity throughout the brain and as such, represent targets of interest for drug development for neuropsychiatric diseases. Positive modulators of NMDA receptors are of interest for their potential to alleviate cognitive deficits in diseases such as schizophrenia, whilst recent clinical evidence with Ketamine suggests a novel role for inhibitors of NMDA function for treatment resistant depression. We recently reported that the endogenous neurosteroid, 24(S)-hydroxycholesterol directly modulates the NMDA receptor and positively impacts plasticity in the hippocampus (Paul et al, 2013). Subsequently, we have developed a range of both positive and negative allosteric modulators of NMDA receptors based on this endogenous molecule. We have characterized the electrophysiological properties of these novel positive and negative allosteric modulators in heterologous cell lines expressing human GluN1/GluN2A subunits as well as confirming activity at native rodent NMDA receptors using primary hippocampal neuron cultures We have also undertaken a series of mechanistic experiments in the hippocampal neurons to determine the potential for use dependence, the rate of modulatory onset and the mechanism by which these compounds affect

the Glutamate concentration-response curve. Furthermore, we characterized the subunit selectivity of a subset of modulators in *Xenopus laevis* oocytes that expressed human GluN1 along with GluN2A, 2B, 2C or 2D. The data presented demonstrate that our neuroactive steroid chemistry platform supports the development of both positive and negative allosteric modulators displaying a range of activities at NMDA receptors. Compounds within this class may represent novel therapeutics for a range of neuropsychiatric diseases characterized by NMDA receptor hyper- or hypo-function.

Title: No effect of DHA on synaptic transmission and plasticity in mice

Authors: *G. N. NIKOLAJSEN, M. J. WEST, M. S. JENSEN;
Biomedicine, Aarhus Univ., Aarhus C, Denmark

Abstract: Epidemiological and clinical trials suggest that insufficient consumption of the omega-3 fatty acid, docosahexaenoic acid (DHA), during pregnancy, is associated with poor cognitive development. In this regard, it has been suggested that DHA deficiency may affect normal synaptic plasticity. Previous studies of the effects of DHA on synaptic functions have been performed in rat hippocampal slices. It was reported, that rats kept on a DHA deficient diet had a significant lower level of long term potentiation (LTP). In this study, we investigated

DHA's influence on synaptic transmission and plasticity in wild type (Wt) mice and a transgenic (Tg) mouse model of Alzheimer Disease (AD) like amyloidosis. Female Wt and APPswe/PS1deltaE9 mice were given an enriched or DHA free diet during breeding. This Tg mouse shows an age related increase in Abeta42 (Aβ42) levels from 4 months of age but no changes of synaptic transmission when fed a normal diet. Only female offspring were used for this study, which were kept on the same diet as their parent through life. This resulted in 4 different experimental groups at 7 months of age (: DHA-Wt, DHA-Tg, non-DHA-Wt and non-DHA-Tg mice with 8 subjects within each group. In the present study, synaptic transmission was evaluated by recording field excitatory postsynaptic potentials (f-EPSP) and input/output responses to Schaffer collateral stimulation. Synaptic plasticity was evaluated by LTP recordings induced by theta burst stimulation. The results showed that a DHA deficit or enriched diet from embryo stage had no significant effect on LTP in these 7 months old female mice, regardless of genes. These findings suggest that DHA consumption in mice do not have the same impact on the synaptic plasticity as in rats. Moreover, the expression of amyloid does not seem make the mouse more responsive to a DHA deficient diet.

Title: Innexins function as plasmamembrane unpaired channels in native *C. elegans* touch neurons

Authors: *R. SANGALETTI, G. DAHL, L. BIANCHI;
Physiol. and Biophysics, Univ. of Miami, Miller Sch. of Med., Miami, FL

Abstract: Cell-to-cell communication is mediated by intercellular protein complexes named gap junctions. In vertebrates, gap junctions are formed by connexon hemichannels, each consisting of homo or heteromers of connexin proteins. In invertebrates gap junctions are formed by evolutionarly-unrelated proteins called innexins, which share with connexins general membrane topology. At the sequence level, innexins share homology with another family of proteins in vertebrates, called pannexins. However, pannexins have been shown to form unpaired plasma membrane channels that mediate release of ATP and ions into the extracellular space, rather than

forming gap junctions. Since, innexins and pannexins share sequence homology, it was postulated that innexins may also function as plasmamembrane channels. However, no activity of innexins as plasma membrane channels has been documentated to date in native *C. elegans* cells. We show here that, *C. elegans* gentle body touch neurons express a channel sensitive to mechanical stimuli. This channel has a large conductance (~1 nS), is voltage-independent, non-selective, is blocked by innexin/pannexin inhibitors and is permeable to fluorescent dyes such as Ethidium Bromide. Moreover, we show that this channel functions also in a K+-selective, voltage-dependent subconductance state. Based on its functional and pharmacological features, we conclude that the mechanosensitive channel expressed in *C. elegans* touch neurons is an innexin. We thus propose that innexins form unpaired plasmamembrane channels in *C. elegans* touch neurons. Single cell RT-PCR and further *in vivo* analysis will be performed to identify the gene/s responsible for the channel activity detected in touch neurons. The identification of unpaired innexins in *C. elegans* opens a new venue for exploiting the genetic tractability of this powerful model system to further our understanding of the still elusive physiological role of the homologous vertebrate proteins pannexins in the context of a whole organism.

Title: Effects of NO-dependent signalling on electrical synaptic transmission in spinal cord neurones and HeLa cells stably expressing Cx36

Authors: A. D. WHYMENT[1], *N. E. DALE[2], D. SPANSWICK[3,4,1];
[1]NeuroSolutions Ltd, Coventry, United Kingdom; [2]Univ. Warwick, Coventry, United Kingdom; [3]Dept. of Physiol., Monash Univ., Melbourne, Australia; [4]Med. Sch., Univ. of Warwick, Coventry, United Kingdom

Abstract: Our knowledge of the role of chemical synaptic transmission and nitric oxide (NO) is extensive, however, the same cannot be said of electrical synapses although recent research has begun to recognise this mode of communication is more vastly more widespread than originally thought. A potential relationship between NO and gap-junctions in the CNS and elsewhere has been suggested for decades by the significant correlation of gap-junction mRNA and NO

synthase distribution. HeLa cells stably expressing Cx35, the mammalian homologue of Cx36, show NO-donors potently uncouple these cells. Recently, the importance of nitrite and nitrate has transformed with the realisation that these putative inert anions are stored in tissues and physiologically recycled in blood and tissues to produce NO and bioactive nitrogen oxides. Here we have used whole-cell patch-clamp recording techniques to investigate the effects of NO-dependent signalling on electrical synaptic transmission in spinal cord neurones and HeLa cells stably expressing Cx36. Simultaneous whole-cell recordings were made from 5 pairs of electrotonically coupled sympathetic preganglionic neurones (SPNs). The mean coupling coefficients (CC) and junctional conductances (Gj) were 0.22 ± 0.02 and 0.91 ± 0.06 nS, respectively. In the presence of SNOG (200 μM n = 5), mean CC and Gj were reduced to 0.16 ± 0.03 and 0.66 ± 0.15 nS, respectively. Application of NO donors activated three species of ion channels; most importantly an intermediate non-selective 140 pS channel which we believe to be a gap junction hemi-channel. Thus, the effects of NO and its precursors were tested on Cx36 hemi-channels expressed in HeLa cells. SNOG (200 μM, n = 8) reduced peak current amplitude to 66.1 ± 9.4% of control levels. Nitrite (200 μM, n = 8) reduced peak current amplitude to 58.2 ± 7.4% of control values. The potassium channel blocker barium (200 μM, n=5) slightly reduced peak current to 93.4 ± 12.4% of control values and reduced the effect of nitrite to 79.6 ± 12.4% (n=6). These data support the notion that NO acts to inhibit electrotonic coupling within SPNs and has a direct effect on Cx36 hemi-channels and suggest a pivotal role for nitrite in its own right as a signalling anion and not simply an alternative source for NO. This has important implications for the control of autonomic function, including heart rate, blood pressure and energy homeostasis.

Title: Roles of electrical synapses in gamma-band activity of sensory and association cortex

Authors: *B. W. CONNORS, G. T. NESKE, A. U. SUGDEN, S. R. CRANDALL, S. J. CRUIKSHANK;
Dept of Neurosci., Brown Univ., PROVIDENCE, RI

Abstract: Electrical synapses formed by connexin36 (Cx36)-containing gap junctions are extensive in the cerebral cortex, connecting many neighboring inhibitory interneurons of the same subtype; they are effective, passing a significant fraction of their voltage signals; and they are ubiquitous across species. Various theoretical and experimental investigations suggest that electrical synapses promote spike synchrony during current injection into interneuron pairs, and during pharmacological activation of interneuron subtypes *in vitro*. One natural form of synchronous activity in cerebral cortex is the gamma oscillation, in which the local field potential (LFP) and inhibitory synaptic inputs are characterized by a high power in the 30-80 Hz range. The activity of fast-spiking (FS) interneurons has long been considered critical to the generation of this oscillation, and gamma-band power in the hippocampus is reduced in Cx36 knockout (KO) mice. These results and the electrical coupling of FS cells suggest that electrical synapses may play an important role in gamma-band activity in the neocortex. We have measured the effects of Cx36 on the roles of electrical synapses in complex forms of cortical activity where recurrent excitatory and inhibitory synaptic conductances are activated. Acute slices of wild-type (WT) and Cx36 KO mice were compared using different cortical areas and gamma-inducing protocols. In barrel cortex (a primary somatosensory area), gamma-frequency activity was generated during the “Up” periods of slow oscillations. In dorsal postrhinal cortex (dPOR) (a visuospatial association area) gamma-frequency activity was induced by asynchronous optogenetic activation of excitatory cells. In layers 4 and 5 of barrel cortex, there was a small but significant decrease in the gamma power of inhibitory postsynaptic currents (IPSCs) recorded in pyramidal cells of the Cx36 KO compared to WT. Phase-locking of pyramidal cell spikes and the gamma-band LFP, phase-locking of IPSCs and the LFP, and correlations between IPSCs of pyramidal cell pairs were equally strong in Cx36 KO and WT; IPSC correlations were temporally sharper in WT neurons, however. During optically evoked gamma-band activity in dPOR, there were no Cx36-dependent differences in the power, frequency, or correlations of IPSCs recorded in pyramidal cell pairs. We will further investigate the Cx36-dependence of optically evoked gamma-band activity in barrel cortex. Our results to date suggest that electrical synapses contribute to certain temporal features of gamma activity, but also that robust gamma oscillations can persist in the absence of electrical synapses.

Title: Efficacy and modulation of spike timing at asymmetrical electrical synapses in the thalamic reticular nucleus

Authors: J. SEVETSON, *J. S. HAAS;
Dept. of Biol. Sci., Lehigh Univ., Bethlehem, PA

Abstract: Neurons of the thalamic reticular nucleus (TRN) provide the main source of inhibition to thalamocortical relay cells and are interconnected by electrical synapses based on connexin36 gap junctions. While the effects of electrical synapses in synchronizing coupled neurons have been described, their efficacy as synapses and modulatory effects on spike timing in coupled neighbors have been underappreciated. Here, using dual-cell recordings, we show that spiking activity in one TRN cell modulates perithreshold spike timing in a coupled neighbor by 10s of ms. Further, we characterize asymmetry as a fundamental property of electrical synapses, and demonstrate that asymmetry also impacts modulation of spike times. Finally, we evaluate the systematic effects of electrical synaptic asymmetry in a two-cell network model with an asymmetrical electrical synapse, which we provide with inputs of varied amplitude and timing. Together, these results demonstrate that asymmetry of electrical synapses alters the dynamic range and computational role that these synapses play within a neuronal network. In the TRN, this directionality of electrical synaptic signaling could be an organizing principle for tuning its responses to arising sensory inputs.

Title: A synaptic excitatory/inhibitory sequence mediated by voltage-gated channels and gap junctions

Authors: P. F. APOSTOLIDES, *L. O. TRUSSELL;
Oregon Hearing Res. Ctr., Oregon Hlth. Sci. Univ., PORTLAND, OR

Abstract: Gap junctions act as lowpass filters of electrical signals and are theoretically better suited to transmit slow voltage changes such as subthreshold synaptic events rather than fast, supra-threshold spikes. However, most previous studies investigating electrical coupling have focused primarily on transmission of action potentials. It is thus unclear whether the propagation of non-spike mediated events such as excitatory postsynaptic potentials (EPSPs) through gap junctions represents a physiologically relevant signal in electrical networks. We examined this problem in the dorsal cochlear nucleus using patch-clamp recordings from brain slices taken from P15-25 mice. Excitatory synapses made by parallel fibers onto the fusiform principal cells activated a TTX-sensitive Na+ conductance which dramatically prolonged the EPSP. Moreover, during the prolonged depolarization a resting HCN conductance was deactivated, leading to a delayed AHP associated with the EPSP. In this way, intrinsic currents markedly reshaped subthreshold EPSPs. Most interestingly, these subthreshold voltage changes resulting from activation/deactivation of Na+ and HCN channels then generated a slow (>100 ms) excitation/inhibition sequence in the GABAergic stellate cells that we previously showed to be electrically-coupled to fusiform cells (Apostolides & Trussell 2013). This electrical transmission accounted for the majority of glutamatergic signaling to stellate cells, such that a subthreshold EPSP in a single fusiform cell can drive spikes in coupled interneurons. Thus, the interaction between a principal cell's synaptic and voltage-gated channels determines the spike activity of an inhibitory network without firing a single action potential in the principal cell.

Title: Common and uncommon mechanisms of LTD at electrical synapses in the TRN

Authors: ***J. SEVETSON**, J. BRAGUE, J. HAAS;
Biol. Sci., Lehigh Univ., Bethlehem, PA

Abstract: Neurons of the thalamic reticular nucleus (TRN), which provide the main source of inhibition to thalamocortical relay cells, express a high density of connexin36-based gap junctions. Long-term depression (LTD) of electrical synapses in the TRN has been demonstrated following paired activity (Haas et al., Science 2011) and after activation of mGluR receptors by afferent stimulation (Landisman and Connors, Science 2005), but the interactions and downstream mechanisms of these two induction paradigms remain unknown. Using dual whole-cell recordings *in vitro*, we demonstrate occlusion of LTD following the sequential applications of paired bursting and of the mGluR agonist ACPD in pairs of coupled TRN neurons. Further, application of the specific T-type calcium channel antagonist TTA-A2 blocked bursting-induced LTD but did not block mGluR agonist-mediated LTD. Together, these data provide support for a signaling model of induction with separable components, whereby activity-induced depression is mediated by calcium entry while afferent activity-induced depression is independent of calcium entry. We hypothesize that the two induction mechanisms converge at a shared downstream pathway, and we are currently investigating the components of that pathway. Thus, our results provide a crucial link between electrical synaptic plasticity and the well-characterized mechanisms underlying plasticity at chemical synapses.

Title: Expression profile of connexin 26, -30, -31.1, -36, -43 and -45 in mouse SN and VTA

Authors: *A. HERNANDEZ SANCHEZ, J. A. MENDEZ;
Inst. de Fisica, Univ. Autonoma De San Luis Potosi, San Luis Potosi, Mexico

Abstract: Dopamine (DA) neurons of the substantia nigra (SN) and ventral tegmental area (VTA) participate in hedonism, memory and reward processes. However, within both SN and VTA there are other neuronal populations: GABA, DA/Glutamate (Glu) co-releasing and pure (Glu) neurons. It has been previously shown that DA neurons have the ability to communicate between them through electrical synapses. However, the connexin repertoire of DA neurons in mice is not known. Remarkably, identical electrical activity during appetitive and aversive learning has been shown in both DA and non-DA neurons in the VTA. One possibility to explain this would be electrical coupling through gap junctions. As first action to explore that possibility we determined the expression of 6 connexins (Cx26, Cx30, Cx31.1, Cx36, Cx43 and Cx45) by multiplex RT-PCR in both SN and VTA from new born (p0) up to postnatal day 120 (p120). Using the expression levels of each connexin at p90 as control, we found the highest expression level of Cx26, Cx30 and Cx43 in both SN and VTA at p120: 3.2, 2.5 and 3 times in SN and 6.1, 4.3 and 45.7 times in ATV for Cx26, Cx30 and Cx43 respectively. In addition, Cx36 showed its maximal expression level in p0 mice in SN (27.2 times) whereas in VTA the peak was at p15 (3.87 times). The expression levels of Cx31.1 as well as of Cx45 did not change significantly through all ages tested. Interestingly, we found that the expression of Cx26 at p0 and of Cx45 at p120 was null in VTA whereas in SN was highly expressed, perhaps this differential expression pattern can be used as a tool to readily establish the boundaries between SN and VTA in immunohystochemical experiments. To extend these observations, we are currently using single cell multiplex RT-PCR in acutely dissociated cells to determine the expression profile of these connexins in specific neuronal cell types in the adult mice.

Title: Organotypically cultured hippocampal networks emit spontaneous neuronal activity similar to *in vivo* ongoing activity

Authors: *K. OKAMOTO[1], T. ISHIKAWA[1], R. ABE[1], D. ISHIKAWA[1], C. KOBAYASHI[1], M. MIZUNUMA[1], H. NORIMOTO[1], N. MATSUKI[1], Y. IKEGAYA[1,2];

Abstract: Spontaneous neuronal activity prevails in virtual all brain regions *in vivo* and even in brain slices *in vitro*. But its function, influence, or spatiotemporal patterns are not fully understood. Acute brain slice preparations exhibit a fewer level of spontaneous activity because of massive cut of neurites during slicing. Organotypic slice cultures self-restore neurites and synaptic connections and remodel the network complexity through the intrinsic rules of neural plasticity. Therefore, cultured slices could offer a better opportunity for investigating some aspect of spontaneous activity. In hippocampal networks, we compared spontaneous activity patterns among acute slices, cultured slices, and *in vivo* networks. Using functional multineuron calcium imaging and cell-attached patch-clamp recordings, we found that the mean firing rates of individual neurons of slice cultures did not differ from those of the *in vivo* hippocampus and were higher than those of acute slice neurons. Using whole-cell voltage-clamp techniques, we isolated spontaneous excitatory and inhibitory postsynaptic conductances (sEPSGs, sIPSGs) and measured five parameters, i.e., mean, coefficient of variance, skewness, kurtosis, and synaptic event frequency. The sEPSG parameters of slice cultures were similar to those of *in vivo* recordings, whereas the sIPSG parameters were not. We then used Soft Confidence Weighted (SCW), a machine learning technique, and tried to classify our datasets. We exposed SCW to the parameters of EPSGs or IPSGs of all datasets of *in vivo* and acute networks and then asked it which the parameters of a given cultured slice are similar to those of either *in vivo* neurons or acute slices. In both EPSGs and IPSGs, SCW judged almost all slice culture datasets as '*in vivo*-

like'. These results suggest that hippocampal slice cultures resemble the *in vivo* hippocampus, rather than acute slices, in terms of spontaneous activity.

Title: Non-parabolic unfolding of neuronal avalanches suggests preferred spatial pathways in cortical dynamics

Authors: *S. R. MILLER[1,2], S. YU[2], D. PLENZ[2];
[1]Univ. of Maryland Col. Park, College Park, MD; [2]Section on Critical Brain Dynamics, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Agreement between the theory of criticality and experimental neuroscience has been established in terms of observed scale-invariance for neuronal avalanches, which constitute spontaneous activity cascades in the cortex during rest. Similarly, pharmacologically-validated optimization of certain aspects of information processing during avalanche dynamics, such as dynamic range, information capacity, and the transient formation of phase-coupled neuronal groups, are in line with a balanced critical regime of neuronal activity. Given that evidence for emergent critical dynamics in the mammalian cortex is gaining increasing traction in the research community, it is worthwhile to consider how the brain might leverage neuronal avalanches to store, transmit, and process information. A major information aspect introduced by neuronal avalanches is related to their instantaneous spatial spread, e.g. the number of sites visited per time step as an avalanche unfolds. From graph theoretical studies, we expect critical dynamics on a neural network with random small-world connectivity to generate avalanches with a characteristic parabolic spread; avalanches will typically initiate at a single site, engage more and

more sites as they unfold, and eventually contract spatially and terminate. However, experimental findings presented here illustrate that neuronal avalanches recorded in cortical layers 2/3 of awake Macaque monkeys (n=2) do not appear to follow a parabolic function. Instead, neuronal avalanches recorded *in vivo* have a flattened spread such that (1) they visit significantly fewer sites during their unfolding than expected from a homogeneous network architecture, and (2) they display considerable variability around a characteristic mean function that is independent of avalanche life time. These stochastic features were especially evident for avalanches with long life times. These results suggest avalanches unfold along preferred pathways, indicating a heterogeneous functional architecture of the cortex.

Title: Signal propagation in small neuron networks with memory function - Characterization and modeling

Authors: ***L. DEMKO**, H. DERMUTZ, C. FORRO, S. WEYDERT, T. ZAMBELLI, J. VOROS;
Lab. of Biosensors and Bioelectronics, ETH Zurich, Zurich, Switzerland

Abstract: Understanding how the human brain stores and processes information is undoubtedly one of the grand challenges of this century. Despite of the vast amount of technical possibilities we still have very little understanding (and especially consensus) about e.g. learning, which might be partially due to the lack of well-defined, small "study networks" of real neurons that can be reproducibly and quantitatively analyzed at a few or single neuron level over extended periods of time. Apart from the experimental approach, modeling has always played a key role in understanding neural coding and signal transmission. However, in spite of the large variety of existing models there is still very little correlation with experimental results, and model based predictions for large networks are far from reality. In order to gain insight into the information

processing and neurocomputation of small networks, we study and model small neuronal systems with simple but controlled topology, how the activity changes as a function of it, study the effect of directional connections, and how these networks react to different stimuli. First we start with the experimental characterization of signal propagation between small groups of neurons with or without directional connections, by measuring the delay time between the neuronal activities of the different groups. When changing the network topology from simple linear feed-forward type to circular ones including loops, we expect to observe activity dependent systematic changes in the delay times due to long-term potentiation (memory effect). As for the theoretical aspect, we try to make one step above the classical models that operate with different synaptic strengths and transfer probabilities, and construct a simplified model based on our observations of rather deterministic firing patterns in the above mentioned small networks. The model assumes that the flow of information (activity) between groups of neurons can be described by delay times representing the time needed for the information traveling from one group of neurons to the other. This delay time what is in the focus of our approach is a property that is easily measurable by common techniques such as patch clamping or multi-electrode arrays as a part of the characterization step, but it is also possible to study its time dependence during and after the different stimulation protocols, providing a genuine way to bridge the gap between experiments and theory. Our model enables us to design simple networks with memory effect, a feature being the ultimate target of our experimental investigations with small neuronal networks.

Title: Dynamic coherent structures in slow-wave activity of primate visual cortex

Authors: *R. TOWNSEND[1], S. SOLOMON[2], P. R. MARTIN[3,2], S. G. SOLOMON[4], P. GONG[1];
[1]Sch. of Physics, [2]Sch. of Med. Sci., [3]Save Sight Inst., The Univ. of Sydney, Sydney, Australia; [4]Exptl. Psychology, Univ. Col. London, London, United Kingdom

Abstract: Many complex physical and biological systems self-organize into dynamic spatiotemporal patterns known as coherent structures. In neural systems, only synchronized nerve cell activity and, more recently, simple planar travelling waves are typically considered. Here, we characterize complex coherent structures in slow-wave (<10 Hz) neural activity, which is considered important for key brain functions including memory consolidation and sleep. We made multi-electrode local field potential (LFP) recordings from the middle temporal area of visual cortex in 6 sufentanil anaesthetized marmoset monkeys, during presentation of a spatially uniform gray field (60 Cd m^2) presented on a video monitor. By adapting techniques established for the analysis of turbulence in fluids, we describe a rich repertoire of patterns present at sub-millimeter spatial scales, and sub-second temporal scales. The most commonly observed patterns were planar travelling waves (30% of measurement time) and widespread synchronous activity (17% measurement time). In addition, 11% of measurement time was characterized by more complex coherent structures. These include waves that radiate from, converge to, or spiral around phase singularities within the local nerve cell network, typically persisting for 10-100 ms before dissipating or drifting out of the recording area. Because our approach provides a physical framework for analyzing these patterns, we are able to quantify their dynamic properties including durations, rates, speeds, and spatiotemporal evolution. We show there are preferred paths of change from one coherent structure to another, indicating deterministic elements in pattern evolution. We also show that the presence of coherent structures is associated with a reduction in power of slow-wave activity and is reflected in simultaneously recorded action potentials. Slow-wave brain activity must thus be understood in context of complex and dynamic local processes, rather than simple synchronous activation of nerve populations within relevant brain regions.

Title: Dendritic calcium signaling in basket cells and its role during network activity

Authors: *S. DELATTRE, D. DIETRICH, E. A. MATTHEWS;
Dpt of Neurosurg., Bonn, Germany

Abstract: Inhibitory basket cells have a key role in synchronizing pyramidal cells during network activity. Basket cells are subdivided into two classes: parvalbumin (PV) containing basket cell and cholecystokinin (CCK) containing basket cell. These two cells types, however similar in morphology and location, have different roles, electrophysiological characteristics and molecular contents. Particularly, CCK basket cells have no reported calcium binding protein whereas PV is present in the other basket cell type. Because calcium has an important role in excitability and plasticity, we therefore investigated the different calcium buffering and diffusion environments in these basket cells, and the potential role that calcium plays in dendritic signaling. GFP positive interneurons in hippocampal slices from the mouse line Tg(Gad2-EGFP)DJ31Gsat were patched in current clamp mode and somatic action potentials (APs) were elicited with current injection. In the same set of cells, OGB6F dye concentration was varied ("added buffer" approach) and dendritic calcium transients were quantified based on confocal laser scanning microscopy. Endogenous buffering capacity was calculated from both the decay time constant and the inverse amplitude of the transients according to the single compartment model. Previous work has shown that PV basket cells display a buffering capacity of $\kappa \approx 210$ and contain a mobile endogenous buffer[1]. In the current study, CCK basket cells were found to have a buffering capacity of $\kappa = 150 \pm 25$ and no mobile endogenous buffers were detected as expected. Dendritic spread of calcium transients induced by back propagating APs was also investigated in the CCK basket cell. In CCK basket cells calcium transients penetrate up to 90 µm into their dendrites with stable amplitude (% Δ F/F) 22 ± 3 with 300µM of calcium dye OGB6F. This behavior could support spike timing dependent plasticity and might influence network activity. We furthermore investigated the calcium transients during oscillatory activity in a submerged slice preparation. We hypothesize that calcium signaling in dendrites of CCK basket cell mimics the oscillatory activity of the slice. 1 Aponte, Y., Bischofberger, J. & Jonas, P. Efficient Ca2+ buffering in fast-spiking basket cells of rat hippocampus. *The Journal of physiology* **586**, 2061-2075, doi:10.1113/jphysiol.2007.147298 (2008).

Title: Sensorimotor function is implemented by a coordinated interplay of brief neuronal activations that traverse space and time

Authors: *W. G. COON[1,2], A. GUNDUZ[3], P. BRUNNER[1,4], B. PESARAN[5], G. SCHALK[1,6,4]; [1]Neural Injury & Repair, Wadsworth Ctr., Albany, NY; [2]Biomed. Sci., State Univ. of New York, Albany, Albany, NY; [3]Biomed. Engin., Univ. of Florida, Gainesville, FL; [4]Neurol., Albany Med. Col., Albany, NY; [5]Ctr. for Neural Sci., NYU, New York, NY; [6]Biomed. Sci., State Univ. of New York, Albany, NY

Abstract: Behavior arises from neuronal population activity that occurs across distant areas of the brain. The fleeting nature of this activity has been recognized at least since Sherrington likened the brain to an “enchanted loom” bustling with “millions of flashing shuttles.” Charting the trajectory of these flashing shuttles, i.e., of neural activity traversing space and time, and examining its relation to behavior, is of central importance to advancing our understanding of brain function. Studies over the past decades have been successful in identifying the locations of neuronal populations involved in specific behaviors, or in characterizing the specific relationship of individual populations of neurons to task-related variables. They have only been marginally successful in characterizing the spatial and temporal sequence of distant populations of neurons that together implement a behavior such as the translation of a visual stimulus into a button press. Superficially, this issue appears to be largely due to limitations of traditional imaging techniques. More fundamentally, it is also caused by the significant inter-trial variance of the timing of neuronal activity, which greatly reduces the temporal resolution of our observations when standard analytic methods (ex. across-trial averaging) are employed. For these reasons, it remains largely unknown how neuronal activity traverses space and time, and how it relates to behavior or to other physiological mechanisms such as modulatory oscillatory activity. In our

study, we set out to begin to address this critical problem. To do this, we recorded electrocorticographic (ECoG) signals in four human subjects while they performed a visuomotor response task: subjects pressed a button as soon as they detected a change in a visual stimulus. We then applied a novel detection technique to identify the time of activity onset and offset in neuronal populations in single trials. The results show that population activity at each location was typically much briefer (mdn = 42.5ms) than implied by previous studies. Furthermore, they demonstrate that variance in the timing of population activity is strongly related to variance in the timing of the behavior ($r2 = 0.32$, $p < 0.001$). Finally, our results reveal an intriguing preference of the timing of the onset of cortical activity to the first half of the trough of underlying oscillatory activity in the alpha band (binomial test, $p < 0.001$). Our results document this effect across all subjects and across many brain regions. This result provides tantalizing evidence for a general physiological mechanism that governs the activation and/or synchronization of distant neural populations.

Title: Synaptic depression enables reliable sequential activity cascades in recurrent networks

Authors: *M. M. BIHUN, M. H. HENNIG;
Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: A growing body of research reports the sequential activation of neural assemblies, suggesting that some brain computations are performed through sequence-based dynamics. Hippocampal replay, songbird, neural activity found in posterior parietal cortex and hippocampus during working memory tasks are just a few examples. It remains unclear how

those sequences are generated and a number of models have been proposed. Kremkow et al. (J. Neurosci 2010) demonstrated that timing differences between correlated excitation and inhibition - temporal gating - can control the propagation of spiking activity transients. We adapted this mechanism in the following scenario. We simulated a recurrent balanced network of 20,000 conductance-based leaky integrate-and-fire with sparse connectivity (5%) and embedded a chain of gates, exploiting the temporal gating principle. The chain consisted of 3 to 20 gates to test whether this framework can underlie the generation of sequential activity in the spiking networks. We found that this connectivity enables, in principle, reliable feed-forward propagation and transient amplification along such a chain. However, in a recurrent network the synchronous activity in a chain can also excite the rest of the network, which then leads to instabilities such as persistent oscillatory activity. If the total excitation is weaker to compensate for such effects, the network elevates its activity only during the signal propagation which is followed by the period of hyperpolarization of most of the neurons. On the network level it can be interpreted that the activation of a chain destabilizes and then transiently shuts down the whole network which then recovers to its normal, low firing rate activity. We next investigated the possible role of two mechanisms in stabilising network activity under these conditions. Spike Frequency Adaptation did not prevent the network from entering the oscillatory regime but allowed it to escape it and return to its normal state. Short-term plasticity in a form of synaptic depression allowed the network to remain in its stable state and shortened the hyperpolarization following chain activation. Next, we embedded multiple chains to test the robustness of this framework. If the chains are non-overlapping, the signal propagation is successful in all of the chains. When the chains have too many shared neurons, the signal gets disrupted and may lead to simultaneous activation of two or more chains. The next step is to find the conditions that allow for reliable signal propagation in such overlapping chains.

Title: Rate and size modulation of neuronal avalanches during motor and cognitive tasks in macaque monkeys

Authors: *S. YU[1], S. CHOU[1], A. R. MITZ[2], R. SAUNDERS[2], D. PLENZ[1];
[1]Section on Critical Brain Dynamics, [2]Lab. of Neuropsychology, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: All cortical functions, even simple ones, engage large, spatially distributed groups of neurons, yet the precise spatiotemporal organization of such group activity is unclear. During well-controlled behavioral studies, neurons often modulate their firing rates in relation to significant behavioral events, supporting the idea of a rate code, which may not require precise temporal coordination of neuronal activities. In contrast, firing of neuronal pairs often undergoes transient phase-locking in relation to behavioral events, supporting a precise temporal code. So far, it is unclear how both frameworks can be reconciled at the level of large neuronal groups. Here we address this issue by studying neuronal avalanches in behaving monkeys. Neuronal avalanches are cascades of neuronal activity in superficial layers of cortex with spatiotemporal organization precisely governed by power laws. We recorded neuronal avalanches in 2 monkeys engaged in 2 different tasks using chronically implanted 10 by10 microelectrode arrays (monkey 1: pre-motor cortex; monkey 2: dorsal-lateral prefrontal cortex). Monkey 1 self-initiated the touching of a sensor pad for rewards. Monkey 2 performed a visual-motor mapping task in which food rewards were retrieved from dispensers according to a visual cue. We recorded the local field potential (LFP, 1-100 Hz) and spiking activity (300-7500 Hz) for 0.5-1 h during which the monkeys performed 150-300 trials. In both monkeys, neuronal firing correlated with distinct behavioral aspects (e.g., hand movement, cue presentation, cue identity), demonstrating that the areas recorded from participate in task encoding. For avalanche analyses, negative deflections in the LFP on the array (nLFPs; -2.5SD) were concatenated into spatiotemporal patterns. We found that pattern rate and size were strongly modulated by behaviorally relevant events (e.g., cue presentation, movements). Despite non-stationary rates and sizes, the size distribution of patterns invariably obeyed a power law over the duration of the trial, demonstrating that the patterns emerged from avalanches. The power law was abolished using a shift-predictor, which randomizes individual recording sites across trials and, therefore, controls for nLFP rate modulation during trials but destroys fine temporal correlations between sites. These results, for the first time, demonstrate that neuronal dynamics organize as avalanches during well-defined behavioral episodes. It extends our previous work based on resting state activity to behavior activity and introduces a precise spatiotemporal coordination of neuronal population activity that underlies cortical functions.

Title: Selective activation of columnar neural population by lateral inhibition in a realistic model of primary motor cortex

Authors: *J. IGARASHI, J. MOREN, J. YOSHIMOTO, K. DOYA;
Neural Computation Unit, Okinawa Inst. of Sci. and Technol., Kunigami-Gun, Okinawa-Ken, Japan

Abstract: Spatially arranged columns in the neocortex has been considered to process information with interacting neighboring columns through horizontal connection. In order to understand how the horizontal interaction regulates the activity of columns in motor control, we developed a model of the primary motor cortex (M1) including realistic spatial distribution of the neural connectivity. The constructed model consisted of layer 2/3, 5A, 5B, and 6. We used integrate-and-fire neuron model for excitatory and inhibitory neurons in each layer. The connection probability among neurons across/within layers was based on experimental reports using laser scanning photo stimulation on M1 [1]. First, to investigate the contribution of horizontal connection in the model, we gave stimulation to neurons within a 90 micrometer diameter sphere centered in layer 2/3 and recorded the synaptic currents from the cells at different horizontal distances. Both excitatory and inhibitory synaptic currents decreased with the distance from the stimulus site, with less than 50 % at 400 micrometer, which was similar to the experimental result observed in the barrel cortex. We next investigated interaction among neural populations by stimulating two neighboring sites (diameter 90 micrometer) in layer 2/3 simultaneously. With different strengths of stimulus to two sites, inhibition from strongly stimulated site prevented the neurons in the other site from firing. The result suggests that the neural population in layer 2/3 comparable to column size may have the ability to generate lateral inhibition. Finally, assuming sensory input to layer 2/3, and top-down input to layer 5B, we tested simultaneous stimulation to layer-2/3 and layer-5B cells of two neighboring columnar populations, with different intensity for layer-2/3 subpopulations and the same subthreshold intensity for layer-5B subpopulations. Selective activation of the layer-2/3 subpopulation receiving strong stimulus occurred due to lateral inhibition, which resulted in selective activation of a layer-5B subpopulation including corticospinal neurons. These results suggest that the

horizontal connections in M1 may enable selection of motor outputs by lateral inhibition among columns. [1] Kätzel D. et al. 2011. Nature. Neuroscience. 14: 100-107.

Title: Crosstalk between Nrf2 anti-oxidative signal pathway and mitochondria

Authors: ***J. SUN**, J. W. SIMPKINS;
Physiol. & Pharmacol., Univ. of West Virginia Robert C. Byrd Hlth. Sci. Ctr., Morgantown, WV

Abstract: The accumulation of reactive oxygen species (ROS) in the neurons contributes to the development of many neurodegenerative diseases. The elimination of oxidative stress partly depends on the transcription factor nuclear factor E2-related factor 2 (Nrf2)-antioxidant response element (ARE) signal pathway which induces the expression of various anti-oxidative protein. Nrf2 is a transcription factor and regulates ARE-containing gene expression which is a cis-acting regulatory element that controls the transcription of phase II detoxification enzymes and antioxidant protein levels, such as glutathione synthesis. Activation of Nrf2-ARE signaling system is dependent upon redox homeostasis in cells. Under normal conditions, Keap1, as an adaptor that binds to Nrf2, causes Nrf2 ubiquitination and its rapid degradation. Under oxidative stress, the binding between Nrf2 and Keap1 is disrupted; then Nrf2 translocates into the nucleus and binds to ARE that promote the transcription of ARE-driven genes. Tertiary-butylhydroquinone (tBHQ) is a well-known phenolic compound that causes Nrf2 nuclear localization and activation of Nrf2-ARE pathway. We investigated the effect of activation of the Nrf2-ARE pathway by tBHQ on mitochondrial function under oxidative stress *in vitro*. Glutamate toxicity in HT22 cells, a hippocampus neuronal cell line, is a commonly used *in vitro* oxidative stress model. We found that tBHQ exerted a complete protective effect against glutamate toxicity. This neuroprotection was effective even with an 8 hours treatment delay with

tBHQ. tBHQ treatment prevented the increase in ROS and mitochondrial membrane potential disruption caused by glutamate. Also, glutamate impaired mitochondrial respiration and ATP production; a functional deficiency that was inhibited by tBHQ. In addition, We demonstrated that tBHQ suppressed mitochondrial-mediated apoptosis which contributed to its neuroprotective effect. Apoptosis-inducing factor (AIF), located in mitochondria, translocates to the nucleus and induces cell death. To be released from mitochondria, AIF is cleaved by clapain and this process is suppressed by calpastatin. We found that tBHQ prevented glutamate-induced translocation of AIF. There was no significant change of calpain level. However, glutamate suppressed calpastatin activity which indirectly promoted calpain activity and led to AIF cleavage, effects that were prevented by tBHQ. In conclusion, tBHQ rescues cells from glutamate toxicity through maintaining mitochondrial function and inhibiting mitochondrial-mediated apoptosis.

Title: Inference of neural pathways in a dynamical connectome of the *C. elegans* worm

Authors: *E. SHLIZERMAN;
Univ. of Washington, Seattle, WA

Abstract: The nervous system of the nematode Caenorhabditis elegans (*C. elegans*) is comprised of 302 neurons for which electro-physical connectivity map (i.e. connectome) is fully resolved. Although the static connectome is available, inference of dominant neural pathways that control sensorimotor responses is challenging since neurons are dynamical objects and interactions within the network are also dynamic. In our study, we construct a Probabilistic Graphical Model (PGM) for the *C. elegans* connectome that represents the 'effective connectivity' between the neurons (correlations) and takes into account the dynamics. The structure of the PGM is learned using Bayesian methods capable of learning the structure of an undirected graphical model from a collection of time series. The collections are obtained by a systematic excitation of neurons in a recently developed computational dynamical model for the *C. elegans* that simulates single neural responses and interactions between the neurons (synaptic and gap). Bayesian inference methods applied to the constructed PGM allow us to extract neural

pathways in the connectome of *C. elegans* responsible for experimentally well characterized movements of the worm such as forward and backward locomotion. In addition, we show that the framework allows for inference of pathways that correspond to movements that were not fully characterized in experiments and to perform 'reverse-engineering' studies in which a typical setup on the motor neurons layer is imposed and dominant pathways that propagate to the sensory layer through the interneurons layer are being identified.

Title: Exosomes with cell signaling capabilities can be isolated from neuronal cells following *in vitro* differentiation under feeder and serum free conditions

Authors: *R. L. WEBB[1,2,3], H. M. REISS[2,3], E. T. JORDAN[2,3], F. GOODFELLOW[2,3], S. L. STICE[2,3];
[2]Regenerative Biosci. Ctr., [3]Animal and Dairy Sci., [1]Univ. of Georgia, Athens, GA

Abstract: Exosomes are small, concave secretory vesicles originating from the fusion of intracellular multivesicular bodies with the plasma membrane. These vesicles range in size from 50-100 nm, and contain cargoes implicated in intercellular signaling mechanisms, including lectins, lipids, proteins, and various species of regulatory RNAs. While the role of exosomes in cellular signaling has been best described in terms of antigen presentation for immune cells, it is becoming ever more apparent that exosomes are secreted by many types of cells, including cortical neurons, astrocytes, and oligodendrocytes of the central nervous system. We hypothesize that exosomes confer paracrine benefits on neural stem cells and play a critical role in both optimal *in vitro* neural cultures conditions and in therapeutic outcomes of neural stem cell treatments. The objective of the current study was to determine if it was possible to isolate exosomes from human stem cells of a neural lineage, specifically neural progenitor cells and / or differentiated post-mitotic neuronal cells. Exosomes were purified from neural progenitor cells (SOX 1+and 2+, OCT4-; hNP1™ ArunA Biomedical), derived from human pluripotent stem cell

lines or differentiated neuronal cells (β-III tubulin (Tuj1) +, MAP2+, Oct4-; hN2™ ArunA Biomedical). While preliminary data indicate that neural progenitor cells secrete fewer exosomes than SY5Y neuroblastoma cells or other cell types, we were able to purify exosomes using either polymer extraction methods or ultracentrifugation. Coomassie staining of purified fractions revealed a broad range of proteins expressed in the neural progenitor population compared to the differentiated neuronal cells, a finding that will be further investigated using silver staining and mass spectroscopy to develop a profile of proteins. Under *in vitro* conditions, treatment of cells with purified exosomes resulted in an approximate 3 fold increase in intracellular calcium following addition of human differentiated neuronal cell exosomes compared to those from SH SY5Y cells, as measured with Molecular Devices Calcium 6 FLiPR assay. This detects calcium flux as a result of activation of either ionotropic or metabotropic glutamate receptors, the receptor class that mediates the majority of excitatory neurotransmission, and a receptor class implicated in several pathological conditions. Future studies will evaluate the biochemical properties of these exosome populations in greater detail with the goal of determining the mechanism and potential benefits that exosomes confer on human neural cells.

Title: Processing of theta input differs markedly at the individual stages of the piriform-hippocampal network

Authors: ***B. H. TRIEU**[1], E. A. KRAMAR[1], Y. JIA[1], W. WANG[1], C. D. COX[1], D. T. PHAM[1], C. M. GALL[1,2], G. LYNCH[1,3];

[1]Anat. and Neurobio., [2]Neurobio. and Behavior, [3]Psychiatry and Human Behavior, Univ. of CA - Irvine, Irvine, CA

Abstract: The series of steps leading from the lateral olfactory tract through piriform/entorhinal cortex and the primary intra-hippocampal circuit constitutes one of the best defined, many stage networks found in the forebrain. We have conducted a first test of whether individual components in the extended network perform different types of signal processing. Theta is a prominent rhythm in the piriform-hippocampal system and so we applied 20 second trains of 5Hz stimulation to each of five stages in the piriform/hippocampal system. Dramatic regional differences in synaptic responses were found. Two connections exhibited a brief facilitation (lateral olfactory tract to piriform, lateral perforant path), one steadily declined during the train (piriform associational), a third showed progressively greater facilitation (mossy fibers), and a fourth generated a biphasic pattern (CA3 to CA1). Transmitter mobilization and adenosine modulation were strikingly different between the relays and contributed to the observed variations in theta processing. Factors potentially involved in the neurobiological differentiation between network elements, including vesicle loading proteins and key elements in the 'tripartite synapse', were identified. Notably, input / output (number of stimulated axons / size of EPSP) relationships described a third discriminative dimension. This third vector likely reflects relative anatomical divergence of projections to the target fields and may contribute to regional differences in LTP. Simulations based on the above results describe a network whose initial stages (piriform cortex, dentate gyrus) respond to external information with a brief surge of activity which is followed by delayed elaboration in the output components (pyramidal cell fields of hippocampus). We propose that these differences in signal processing play important roles in pattern separation by the former structures and pattern completion by the latter.

Title: The hippocampo-septal feedback state-dependently modulates the medial septum

Authors: *L. NIKITIDOU, E. PAPP, T. F. FREUND, V. VARGA;
Inst. of Exptl. Med., Budapest, Hungary

Abstract: Theta rhythm in the limbic system is a highly regular oscillation in the 4 -10 Hz frequency range strongly associated with information acquisition, memory formation and sensory-motor integration. The reciprocal inhibitory connection between the medial septum (MS) and the hippocampus comprises the backbone of the theta generating circuitry. GABAergic MS neurons are thought to generate the pacemaking input to the hippocampal inhibitory network. According to theoretical and *in vitro* studies, somatostatin (SOM)-containing hippocampo-septal (HS) neurons may synchronize the MS pacemaker cells. However, the hippocampus is capable of autonomously generating theta oscillations *in vitro*. Thereby, theta rhythmicity would emerge from the communication of the MS and hippocampal oscillating networks, but the role of the HS pathway in this dialogue is still unknown. Here, we aim to disentangle the action of the HS feedback, by recording the response of MS neurons to the selective manipulation of HS fibers, in urethane-anesthetized as well as in freely moving mice. To selectively manipulate HS fibers or terminals, SOM-expressing hippocampal neurons were in SOM-Cre transgenic mice transduced by a Cre-dependent adeno-associated viral vector encoding channelrhodopsin 2. Activation of either HS axon terminals in the MS or passing fibers in the fimbria vigorously inhibited theta-coupled MS neurons and resulted in a 5 - 100 ms post-pulse inhibitory period. HS-elicited inhibition was weaker during sensory evoked theta oscillations compared to non-theta states. Surprisingly, the majority of neurons were activated by 5 and 10 Hz stimulation despite exhibiting post-pulse inhibition. The response of the activated neurons was strongly state-dependent, as characterized by resistance to perturbation during theta oscillations as opposed to significant alteration of firing pattern in non-theta states. In a freely moving mouse HS fiber stimulation at high frequency (20 or 50 Hz) blocked the firing of MS units during non-theta or still theta whereas it failed to alter neuronal activity during movement theta epochs. Thus, the HS feedback modulates the medial septal network in a state-dependent manner.

Title: Signal and noise correlations in a recurrent network of neurons in culture

Authors: *J. BARRAL[1], T. TCHUMATCHENKO[2], A. REYES[1];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Max Planck Inst. for Brain Res., Frankfurt, Germany

Abstract: Neighboring neurons share common synaptic inputs, potentially leading to correlated spiking activity (so-called noise correlation). In addition, spiking activity may be correlated in the presence of a global drive to the network (so-called signal correlation). Both experimental results and theoretical analyses suggest that noise correlation may be attenuated actively via the arrival of strongly correlated inputs. This decorrelation mechanism is made possible by the cancellation of synchronous excitatory and inhibitory inputs at resting membrane potential. Here, we used a network of cortical neurons in culture to examine whether active decorrelation operates equally on signal and noise correlations and whether it depends on network state and neuronal distance. Cultures containing excitatory and inhibitory neurons were made from tissue excised from mouse cortex and transfected with channelrhodopsin. We developed an innovative optical device to stimulate optogenetically a large neuronal population with both spatial and temporal precision. Using an ultra-fast video-projector, we stimulated 10 to ~50 neurons with independent trains of light pulses that evoked action potentials with high temporal resolution. With this preparation, we systematically varied the spatial correlation of the stimulated neurons, their firing rates and the spatial extent of the activated network. We experimentally examined correlations between inhibitory and excitatory inputs in the recurrent network when a sub-population was activated by a given spatiotemporal pattern. We showed that active decorrelation operates in recurrent networks of neurons in culture. A systematic delay between excitation and inhibition guarantees that some correlated activity persists and can be modulated by an external input. In particular, the correlation between post-synaptic potentials increases with the firing rate and with the spatial correlation of the stimulated neurons. Comparison to simulations of integrate-and-fire neuron networks highlighted the generic properties of active decorrelation and its robustness. Although signal and noise are both actively decorrelated, signal correlation remains dominant, allowing information to be encoded by the correlated activity of neurons. Additionally, we observed that signal correlation remains high even for distant neurons while noise correlation decays rapidly, consistent with noise correlation arising from local shared inputs. Hence, signal-to-noise ratio increases with distance, suggesting that signal is better transmitted between spatially disparate neurons.

Title: Propagation of neuronal activity by electrical field

Authors: *C. QIU, M. ZHANG, D. DURAND;
Biomed. Engin., Case Western Reserve Univ., Cleveland, OH

Abstract: The propagation of 4-AP induced epileptiform neuronal activity in the hippocampus exhibits a speed of approximately 0.1m/s and could propagate without synaptic transmission or gap junctions. This non-synaptic propagation could not be explained by diffusion since it is too slow, suggesting that there exists another mechanism for such type of propagation. Electrical field effect is a highly possible candidate as it can modulate the spiking patterns and timings of single neuron or network firing activity. We developed a simulated CA1 pyramidal network model with cells connected solely through field effect and tested the hypothesis that electrical field alone can cause neuronal activity to travel with a speed of 0.1m/s. The results showed that with 4-AP/No [Ca] and normal aCSF cell kinetics, field effect could mediate transverse propagation with a speed of 0.12 ± 0.097 m/s and 0.11 ± 0.034 m/s, respectively, upon spiking initiation of the first row cells. The network activity under both conditions resulted in an endogenous network field amplitudes of ~2-~5mV/mm, matching the weak field measured in unfolded hippocampus or cortex in-vitro. Increasing the extracellular resistivity by 40% caused an exponential increase of speed and linear increase of network field amplitude; additionally, an inversely linear relationship was observed between the field amplitude and propagation delay time. Changing the membrane capacitance and resistance did not significantly change either the speed or the field amplitude. Finally, simulation results predicted that smaller extracellular space would generate higher propagation speeds. Experiments in hippocampal slices confirmed this prediction when the osmolarity was changed to affect the extracellular space. Taken together, these results show that despite its weak amplitude, the field effect can be solely responsible for neuronal activity propagation with a speed of 0.1m/s in both pathological and physiological

conditions. The main parameter affecting the speed of propagation is the amplitude of the field.

Title: Electrical coupling and synchronized activity within iPSC-derived neuronal networks

Authors: M. W. TOIVONEN[1], Z. ZHU[1], X.-H. ZENG[1], J. TURECEK[2], V. Z. HAN[1], *J. P. WELSH[1];
[1]Ctr. for Integrative Brain Res., Seattle Children's Res. Inst., Seattle, WA; [2]Neurobio., Harvard Univ., Boston, MA

Abstract: We examined the synaptic properties of cultured neurons derived from induced pluripotent stem cells (iPSCs). Fibroblasts from adult C57BL/6 mouse tail were reprogrammed into iPSCs by forced expression of OCT4, SOX2, KLF4, and c-MYC and subsequently differentiated into neuronal networks by culturing with N2 medium (DMED/F12 with 1% NEAA, 2 mM L-Glutamine, 2% B27, 1% FBS). iPSC-derived neuronal networks were studied over days 12-20 of differentiation with immunostaining and dual whole-cell patch-clamp electrophysiology. iPSC-derived neurons uniformly expressed the neuronal marker MAP2 in

dendrites. In addition, iPSC-derived neurons expressed the neuronal gap junction protein connexin36 in nearly all somata and dendrites and GABA in 18% of the neuronal somata. As has been reported with single neuron recordings, iPSC-derived neurons often exhibited spontaneous spiking and spontaneous EPSPs and IPSPs. Dual recordings were obtained in neuron pairs having interwoven dendrites whose somata were separated by no more than 70 μm. Of 141 dual recordings, 21% showed synchronized spontaneous spiking and/or subthreshold activity that was blocked by 20 μM CNQX, indicating a necessary role for glutamatergic synaptic transmission. Cross-correlation of synchronized spiking showed high temporal variability, with spike bursts of one neuron randomly leading or lagging the other by 400 μs to 50 ms (Cv=0.58 ± 0.12 SEM). Direct chemical synaptic transmission was observed in 5% of neuron pairs in which depolarizing current injected into one neuron evoked a direct spike and a following spike in the neighboring neuron with high probability (75 ± 13%), stereotypic latency (9.95 ± 0.5 ms), and low temporal variability (Cv=0.15 ± 0.02). Of note, 3.6% of neuron pairs showed electrotonic coupling as measured by membrane potential hyperpolarization to -300 or -500 pA injected into the neighboring neuron. Coupling coefficients and gap junctional conductances ranged from moderate (3.4% and 130 pS) to very strong (38% and 6.5 nS) with means of 13.3 ± 4.3% and 1.5 ± 0.8 nS and medians of 7.3% and 300 pS, respectively. Electrical coupling among iPSC-derived neuron pairs had a median symmetry of 1.37, but could be perfectly symmetric (1.02) or strongly asymmetric (3.7). The study indicated that monosynaptic chemical and electrical synaptic transmission integrate in iPSC-derived neuronal cultures and contribute to activity synchronization.

Abstract: High-density 2D microelectrode arrays offer an unique way to simultaneously record spike and local field potential (LFP) activity along the cortical surface. Here, with 4 mm × 4 mm 100-electrode Utah arrays in human and monkey neocortex, we analysed spontaneous high-frequency LFP oscillations (>20 Hz) during wakefulness and the different stages of sleep. In both monkey and humans, narrow-band beta (20-35 Hz) and gamma range (40-80 Hz) were identified during slow-wave sleep and they were also present, but generally less pronounced, during waking and REM sleep. Very frequently, in all states, beta and gamma patterns appeared at about the same time on the array, forming large spatially coherent patterns separated by many seconds with less activity. We applied phase-based analysis methods to precisely quantify the propagation of these beta/gamma patterns. We found that that beta and gamma oscillations formed waves of activity that propagate over the array with a velocity of 20-30 cm/s, close to axonal propagation velocity. After separation of units between “regular-spiking” (RS) and “fast spiking” (FS) neurons based on spike waveform and duration from a large number of cells (up to 180), we found that a strong increase in firing of specific FS cells during beta/gamma patterns. Furthermore, specific correlated firings of spatially distant neurons (>1 mm) were detected during these high-frequency patterns, suggesting that fast oscillations mediate neuronal synchronizations between large-scale patches of cortex. Altogether, these findings confirm and extend earlier animal studies reporting high-frequency oscillations during sleep. In addition, we report that FS cells play a key role in the generation of high-frequency oscillation. Furthermore, beta/gamma waves have been found to organize and modulate cortical population activity on the mesoscopic scale. The partial overlap between the spatial distribution of high-frequency oscillations during sleep and wakefulness suggests that these waves are of similar nature and that, during sleep, they may restore wake-like patterns that support the consolidation of information related to the experiences of the previous awake period.

Title: Propagating waves from local field potentials in multi-electrode recordings in human and monkey cortex match the properties found in voltage-sensitive dye imaging

Authors: *A. DESTEXHE[1], L. MULLER[1], G. BENVENUTI[2,3], F. CHAVANE[2,3];
[1]CNRS, Gif-sur-Yvette, France; [2]INT, CNRS, Marseille, France; [3]Aix Marseille Univ., Marseille, France

Abstract: The existence of propagating waves, either spontaneous or stimulus-evoked, in neocortex during the awake state has been a subject of recent interest [1,2,3]. Here, following work done previously in voltage-sensitive dye imaging of the primary visual cortex in the awake monkey [3], we apply an analysis method for non-parametric, automated detection of propagating waves to multielectrode (Utah) array recordings taken from the neocortex of monkey (primary visual cortex), and compare to recordings in human (middle temporal gyrus; data from [4]). In the spontaneous activity during wakefulness, we detect transient, intermittent propagations occurring in the local field potential (LFP) across the biological frequency range. After selecting the propagation epochs within the highest confidence interval, we observe that the speed distribution falls naturally into the range of the horizontal fibers (0.1 - 0.5 m/s), suggesting a similar propagation substrate as that observed previously in voltage-sensitive dye imaging data [3]. With this in mind, we go on to compare the spatiotemporal dynamics on the array across various states of arousal. One question raised by our earlier VSD analysis is the extent to which the wave evoked by a small visual stimulus is supra- or sub-threshold. Specifically, because neurons during awake, "activated" cortical states sit a few millivolts below threshold [5,6], operating in a fluctuation-driven regime [7,8], the transient depolarization

detected in the VSD signal as the wave passes may change the background spiking probability in the local circuit. To address this, we analyzed the relationship between single- and multi-unit activity (SUA/MUA) and LFP. We study the spatiotemporal dynamics of this relationship to determine the coupling of spiking activity with transient propagating waves, and compare the results with computational models of spiking neurons. In conclusion, we show here that a combination of multi-electrode recordings, time-series analysis and computational modeling provides a powerful set of tools for quantifying the spatiotemporal dynamics of the awake state in human and monkey. 1. Abstract: We investigated the local field potential (LFP) contribution associated with a single spike in human and non-human-primate cortex. The data were recorded from the temporal cortex of patients who underwent a surgical treatment for the localisation of the epileptic foci [2] and from the motor cortex of macaque monkeys [3]. The LFP and spiking activity were recorded with a 10-by-10 array of intracortical electrodes (Utah array, interelectrode distance 400 μm). Spikes of single neurons were discriminated by semi-automatic clustering and the cell type was determined based on a spike waveform [2]. The average of LFP segments triggered on spontaneous spikes (LFP-STA) showed components that were non-causal, i.e. preceding spike occurrence, and non-local, i.e. appearing with no delay at large distances. We investigated whether this spatial and temporal spread could be explained by the morphology, the volume conduction and/or network interactions. We developed a simple statistical model of the LFP generated by a population of correlated Poisson-like neurons. The contribution of each spike to the LFP was described by a LFP kernel. In a population of independent neurons we could perfectly recover this contribution by means of the LFP-STA, but correlations made the LFP-STA non-causal and spatially non-local. Its width and amplitude depended on the jitter, correlation coefficient and the number of contributing neurons. Based on realistic values of the parameters we estimated that in presence of correlations the LFP-STA is about 100-1000 times larger the LFP-STA in an uncorrelated population. To test whether the correlations could explain the spatial and temporal broadening of the experimental LFP-STA we estimated the spatial co-variance matrix from the on-going LFP. By inverting the matrix we derived spatio-temporal filters, which disambiguated the local (<800 μm) LFP components triggered by a single neuron. The amplitude and spatial reach of these components were larger for putative inhibitory neurons compared to excitatory neurons. These differences might be are related to axon morphology and/or synaptic connectivity. We conclude that while the contribution of a single neuron is local and does not exceed the area within a radius of 800 μm, the LFP is spatially and temporally extended due to the neuronal correlations and volume conduction. The local LFP contributions are dominated by inhibitory neurons confirming results of *in vitro* experiments [1]. [1] M. Bazelot et al. J. Physiol. (Lond.), 588:2077, 2010. [2] A. Peyrache et al. Title: Mechanisms of memory destruction in an *in vitro* model of interictal epileptiform discharges

Authors: *M. R. DRANIAS, A. M. J. VANDONGEN;
Neurosci. and Behavioral Disorders (NBD), Duke-NUS Grad. Med. Sch., Singapore, Singapore

Abstract: Brief synchronizing bursts of epileptiform activity known as interictal epileptiform discharges (IEDs) can cause transient cognitive impairments (TCI) in the absence of overt seizures. We show that stimulus information represented in networks of living neurons is also disrupted by brief synchronizing bursts of neural activity (SNBs), analogous to IEDs, and demonstrate some of the mechanisms of this disruption. Experiments were performed using primary cultures of E18 dissociated rat cortical neurons transfected with ChannelRhodopsin-2 and plated on multielectrode arrays. These optogenetically modified networks encode and maintain stimulus information for as long as one second and while stimulus information persists in memory, additional stimuli elicit an adapted response that reflects the identity of the prior stimulus. On each trial we presented either one stimulus or two sequential stimuli. On trials interrupted by SNBs, stimulus-specific information tends to be lost. To better understand this process, we investigated how the timing of SNBs impacts stimulus adaptation in the sequential stimulus task and the changes in entropy associated with SNBs. SNB timing was analyzed by breaking trials into encoding, delay and readout phases. The adapted response of the network to a second stimulus is lost regardless of timing. Examination of the pattern of network activity indicates SNBs do not interfere with stimulus processing by acting like white noise, rather some networks have a single stereotyped response and others several. An inverse relationship was found to hold between normalized entropy of an SNB and the overall mean firing rate of the network across a trial. This indicates the more excitable a network, the more stereotyped its response. These results are consistent with past experiments, predict how neural circuits *in vivo* will behave during IEDs, and provide a model useful for identifying drugs and human genetic mutations that modulate short-term memory and TCI.

Title: A predictive filter for input comparison in the CA1 microcircuit

Authors: *A. D. MILSTEIN, J. C. MAGEE;
Magee Lab., Hhmi/Janelia Farm, Ashburn, VA

Abstract: Spatial and temporal features of synaptic inputs engage integration mechanisms on multiple scales, including presynaptic release sites, postsynaptic dendrites, and networks of inhibitory interneurons. Here we investigate how these mechanisms cooperate to filter synaptic input onto CA1 pyramidal cells. We find that inputs from CA3 onto proximal dendrites as well as inputs from entorhinal cortex layer III (ECIII) onto distal dendrites sum sublinearly or linearly at low firing rates due to feedforward inhibition, but sum supralinearly at high firing rates due to presynaptic facilitation, producing a high-pass filter. However, during punctuated bursts of inputs that mimic theta rhythmic activity, additional nonlinear integration mechanisms in dendrites are balanced by the recruitment of additional feedforward and feedback inhibition, resulting in suppression of dendritic complex spikes. We show that a particular subpopulation of inhibitory interneurons expressing neuropeptide Y (NPY) contributes prominently to this predictive filter by integrating both CA3 and ECIII input pathways and potently inhibiting CA1 pyramidal cell dendrites.

Title: Lipopolysaccharide-induced calcium oscillations in neonatal rat nucleus tractus solitarius (NTS) *in vitro*

Authors: M. R. CUSTER, N. OSMAN, *C. G. WILSON;
Ctr. for Perinatal Biol., Loma Linda Univ., Loma Linda, CA

Abstract: Lipopolysaccharide (LPS) is commonly used to induce an inflammatory response in animal models. In premature infants, systemic infection (sepsis) causes tachypnea and an increase in the number of apneas over time. The mechanism by which sepsis alters breathing control centrally is unknown. Our laboratory has previously shown that LPS instilled into the airway of 10 day old rats causes changes in IL-1beta expression in brain stem regions associated with breathing control, including the rostral medulla, NTS, and the hypoglossal (XII) motonucleus. We hypothesized that expression and release of cytokines in the brain stem alters neuronal activity in these brain stem areas which, in turn, alters breathing rhythm. To test this hypothesis, we performed experiments using confocal imaging to evaluate changes in calcium flux in neurons within the NTS before and after exposure to LPS (75 micrograms/200 mL ACSF). We cut acute organotypic slices (300 microns) from brain stems of postnatal day 1 to 5 rat pups. These slices included the preBötzinger complex, XII motoneurons, and the NTS. Fluo-4-AM was used to label the slices, prepared in DMSO/Pluronic and incubated for 1 hour (14 micrograms dye/mL of ACSF) and then the slices were transferred to a Zeiss LSM-710 confocal microscope for imaging of calcium transients. NTS neurons showed an increase in rhythmic calcium oscillations within 10 min after LPS infusion. Baseline burst duration averaged 0.02 ± 0.03 (SD) per minute and increased to 0.56 ± 0.16 bursts per minute. After 30 min, burst frequency declined to 0.19 ± 0.21 per min and continued to fall to 0.01 ± 0.03 after 50 minutes of exposure. The changes in network activity we observed may be the underlying substrate for the changes in breathing pattern seen in sepsis. Changes in the NTS network may gate afferent input information carried via the vagus nerve to the CNS and gating of these afferent inputs may be critical to the breathing changes we have previously observed in our rat models.

Title: TIMP-1 modulates chemotaxis of human neural stem cells through CD63 and integrin signaling

Authors: H. SHIN, *M. LEE;
Brain Dis. Res. Ctr., Sch. Med. Ajou Univ., Suwon, Korea, Republic of

Abstract: **Hee Sun Shin**[1], Soo Youn Lee[1], Jung Mi Kim[1], Soo Young Cho[2, 3], Hyun Suk Kim[1], Jeong Yong Jeon[1], Rukhsana Kausar[1], Seon Yong Jeong[4], Young Seek Lee[5] and Myung Ae Lee[1] [1]Department of Brain Science, Ajou University School of Medicine, Suwon, Korea [2]Mammalian Genetics Unit, Medical Research Council Harwell, Harwell, Oxford shire OX11 0RD, U.K. [3]Laboratory of Developmental Biology and Genomics, College of Veterinary Medicine, and Interdisciplinary Program for Bioinformatics, Program for Cancer Biology and BIO-MAX Institute, Seoul National University, Seoul, Korea [4]Department of Medical Genetics, Ajou University School of Medicine, Suwon, Korea [5]Division of Molecular Life Science, Hanyang University, Ansan, Korea The hNSCs (human neural stem cells) have the interesting characteristic of migration towards an intracranial glioma. However, the molecules and mechanisms responsible for tumour tropism are unclear. In the present study, we used microarray and proteomics analyses to identify a novel chemoattractant molecule, TIMP-1 (tissue inhibitor of metalloproteinase-1), secreted from human brain tumour tissues. We demonstrate that TIMP-1 significantly enhances hNSC adhesion and migration in a cell culture system. These effects were critically dependent on CD63, as shRNA-mediated ablation of CD63 expression attenuated the response. TIMP-1 significantly increased the number of FAs (focal adhesions) and cytoskeletal reorganization for cell migration in hNSCs, whereas knockdown of CD63 resulted in decreased hNSC spreading, FAs and migration, even after TIMP-1 treatment. In addition, TIMP-1 binding to CD63 activated β1 integrin-mediated signalling through Akt and FAK phosphorylation, leading to pattern changes in distribution of vinculin and F-actin (filamentous actin). Furthermore, inactivation of β1 integrin by use of a blocking antibody or inhibition of PI3K (phosphoinositide 3-kinase) signalling impaired the migration of hNSCs towards TIMP-1. Collectively, our results underline TIMP-1 as a novel and effective key regulator of CD63 and β1 integrin-mediated signalling, which regulates hNSC adhesion and migration.

Title: Visualizing an emotional valence map in the limbic forebrain by TAI-FISH

Authors: *H. HU;
Inst. of Neuroscience, Chinese Acad. of Sci., Shanghai, China

Abstract: A fundamental problem in neuroscience is how emotional valences are represented in the brain. Thus far, we know relatively little about how appetitive and aversive systems interact, and to what extent information regarding these two opposite values segregate and converge. Here we introduce an experimental strategy to simultaneously visualize the neural correlates of two stimuli of contrasting emotional valence across the whole limbic forebrain at single cell resolution. We discovered characteristic patterns of interaction - segregated, convergent and intermingled - between the appetitive and aversive neural ensembles. In the nucleus accumbens, we identified a mosaic pattern of activation by multiple pairs of positive and negative emotional cues, and unraveled previously unappreciated functional heterogeneity within the D1- and D2-type medium-spiny neurons. These results provide new insights into the coding of emotional valence in the brain, and demonstrate proof-of-principle of a powerful methodology for the simultaneous functional mapping of two distinct behaviors.

Title: Efficient discovery of functional brain networks in large multisubject fMRI datasets

Authors: *J. R. MANNING[1], R. RANGANATH[2], K. NORMAN[2], D. BLEI[2];
[1]Princeton Neurosci. Inst., [2]Princeton Univ., Princeton, NJ

Abstract: Standard approaches to examining functional connectivity patterns in fMRI datasets entail correlating the time series of activations (across images) of each pair of voxels. Because the size of the full brain connectivity matrix grows with the square of the number of voxels, this approach carries a substantial computational burden. For example, the voxel-to-voxel connectivity matrix for a 50,000 voxel image occupies several GB of memory. Comparing many such matrices (e.g. across experimental conditions or participants) requires an alternative approach. We will present a technique, called Hierarchical Topographic Factor Analysis (HTFA), that leverages the strong spatial correlations that pervade fMRI data to reduce the full brain connectivity network to a much smaller K-node network (where the number of nodes, K, is chosen by the practitioner). Our Bayesian inference procedure scales well, allowing researchers to discover networks in huge fMRI datasets, with dozens of subjects and thousands of images, even on modest computer hardware (e.g. a laptop computer). Unlike approaches that require pre-selecting seed regions or regions of interest, the locations (and sizes) of the nodes HTFA uncovers are determined automatically from the full dataset. We will present representative applications of HTFA to several existing fMRI datasets, illustrating how HTFA can be used to identify task-based differences in functional connectivity.

Title: Emergence of consciousness as a phase transition in information percolation

Authors: D. MOWREY, D. W. ZHOU, P. TANG, *Y. XU;
Anesthesiol., Univ. Pittsburgh Sch. Med., Pittsburgh, PA

Abstract: Mammalian brains have evolved to achieve great functional diversity using a limited set of structural motifs. The ways in which highly complex cognitive functions emerge from a finite number of network connections are not fully understood. We present a theoretical model to describe the fundamental processes of information transmission in a hierarchical network, whose edges are stochastically defined by a single parameter, p, representing information percolation probability. The system expands vertically in a layered fractal structure, with each layer forming a Watts-Strogatz small-world network. By treating neural activity as a time series of sensory information percolating from an input node to multiple nodes in an output layer, we reproduced major clinical electroencephalographic (EEG) characteristics found in the loss of consciousness during general anesthesia. As the percolation edge probability increases, the rapid convergence of output and input signal distributions exhibits a steep phase transition, with a concomitant increase in both the spectral power and signal synchrony in the α, β, and γ frequency range and a rapid decrease in information entropy, signifying information integration and the emergence of meaningful correlation among output nodes. Our results demonstrate that by modeling consciousness as information percolation we can capture emergent phenomena clinically observed along the pathway between the anesthetized and conscious states. Robustness of information integrity is maintained even in a sparsely connected network and shows a sharp transition consistent with the precipitous loss of consciousness during general anesthesia.

Title: Tight synchrony between fast spiking inhibitory interneurons during endogenous 20-80 Hz cortical network activity

Authors: *D. B. SALKOFF[1], D. MCCORMICK[2];
[1]Interdepartmental Neurosci. Program, [2]Neurobio., Yale Med. Sch., New Haven, CT

Abstract: The activated cortical state is associated with the generation of 20-80 Hz activity which has been proposed to be generated either through interactions between pyramidal neurons and inhibitory interneurons, between inhibitory interneurons themselves, or both. These models are differentiated by the mechanisms driving and synchronizing inhibitory interneurons (e.g. EPSPs, IPSPs, gap junction potentials). Here we investigated this question through dual whole cell recording from pairs of fast spiking (FS) inhibitory interneurons during the generation of spontaneous UP states (which contain high power at 20-80 Hz) in the mouse entorhinal cortical slice *in vitro*. Using the active slice preparation, we found that FS cells <150 um apart have tightly-synchronized spiking, with a width at half-maximum of ~3 ms in the cross-correlogram. Excitatory currents were measured in pairs of cells by holding voltage at -80 mV, and the similarity of currents was quantified by calculating the correlation coefficient (all pairs 0.26 +/- 0.15). Common excitatory input was an excellent predictor of the degree of spike synchrony, capturing 82% of the variance. Electrical coupling between the recorded FS cells was only a weak predictor of spike synchrony. These results suggest that nearby FS interneurons are driven to discharge in a synchronized manner through the arrival of excitatory postsynaptic potentials from one or more presynaptic pyramidal neurons. These results are consistent with 20-80 Hz activity being generated by an interaction of both pyramidal and fast spiking interneurons - a model that is also supported by results obtained from dual recordings from these two cell types. The network implications of tight, millisecond-precision synchrony in fast spiking interneurons is currently under investigation.

Title: Loss of network functionality due to a cumulative one-cell-at-a-time deletion of constituent neurons: A simulation and modeling study of pre-Bötzinger laser ablation experiments

Authors: *H. SONG[1], D. LAMAR[2], C. DEL NEGRO[3];
[1]The Col. of William and Mary, Williamsburg, VA; [2]Dept. of Biol., [3]Dept. of Applied Sci., The Col. of William & Mary, Williamsburg, VA

Abstract: The mammalian breathing rhythm originates from the pre-Bötzinger complex (preBötC) of the ventral medulla. The preBötC core consists of interneurons derived from progenitors that express transcription factor Dbx1. Experiments showed that cumulative deletion of ~15% of Dbx1 preBötC neurons stopped respiratory rhythm. Here we simulated these experiments to help explain rhythm cessation due to Dbx1 neuron ablations. We generated random directed graphs that model the preBötC. Each neuron was populated by the Rubin-Hayes (2009) preBötC neuron model. Synaptic connections were modeled as ionotropic glutamatergic synapses. Rhythmic model networks were subjected to cumulative ablations, which lead to irreversible rhythm cessation, like the experiments. By computing several metrics for graph connectivity, we found that the network remained intact even after the rhythm stopped, which led us to hypothesize that the network function depends on a subset of neurons whose specific properties are key rhythmogenic elements. We sought to identify that putative critical subset of neurons and the characteristic properties that distinguished them. In numerical simulations, we discovered a sub-network of neurons with a strong inward current (CAN current). Deleting this subset of neurons terminated the respiratory rhythm at lower cell-ablation tallies. One key feature for neurons in this CAN-subnetwork is high in-degree (i.e., a large number of incoming excitatory synapses). Furthermore, by monitoring the time for the first burst of each individual neuron in its pre-inspiratory phase (strongly correlated with leakage-K current) we also discovered that constituent deletions of random neurons would impair the recurrent excitation, eventually terminating the network functionality to generate a network-wide burst when the network fails to achieve some threshold rate of recurrent excitation. These simulation and modeling results suggest that neurons in the rhythm-generating network have heightened importance based on topological properties (i.e., high in-degrees) as well as high levels of CAN current and low levels of leakage-K current. The loss of respiratory rhythm would be largely attributed to the impairment of network excitability or the disturbance of the process of recurrent excitation.

Abstract: Synchronous neuronal activity in the hippocampus plays an important role in both physiological and pathological states. A number of studies have demonstrated that GABAergic inhibitory neurons regulate synchronous neuronal activities; however, less is known about the behavior of excitatory neurons in synchronous events. In this study, we monitored the spatiotemporal patterns of synchronous neuronal activities in the CA1 or CA3 pyramidal cell layer of acute hippocampus slices prepared from P6-8 rats using functional multineuron Ca^{2+} imaging. When GABAergic transmission was inhibited by bicuculline, synchronous Ca^{2+} elevations of CA1 spontaneously occurred in pyramidal cells. These activities were abolished by surgical incision of CA3-CA1 axonal pathways. We analyzed the behavior of individual neurons in synchronous Ca^{2+} activities and clarified that the onset times of individual neurons depended on the cell location relative to the stratum oriens (SO). Synchronous Ca^{2+} activities could be also induced by field stimulation of Schaffer collaterals, but they did not exhibit the location dependence of the onset time. In CA3, the onset times of Ca^{2+} activities did not strongly correlate with the distances from the SO. On the other hand, cells that showed earlier onset times were located close to each other, forming hot spot-like foci of activity initiation. Finally, we investigated the temporal fluctuations in synchronous Ca^{2+} activities. Synchronous events were classified into three groups depending on the propagation speed of their sequential activities, 1) compression, 2) normal, and 3) expansion. Synchronous Ca^{2+} activities fluctuated across these three states during our observation period of 24 min, and the state of an event could be predicted by the inter-event interval after the immediately preceding event. Thus, even without GABAergic transmission, the spatiotemporal patterns of synchronous neuronal activities are non-randomly organized, and the temporal states drift dynamically. Therefore, excitatory neurons may also serve as a regulator of synchronous neuronal activities.

Abstract: Sharp wave-ripples are transient oscillatory events in the hippocampus which are associated with the reactivation of neuronal ensembles within specific circuits during memory formation. Fast-spiking, parvalbumin-expressing interneurons (FS-PV-INs) are thought to provide fast integration in these oscillatory circuits by suppressing regenerative activity in their dendrites. Here, using fast 3D two-photon recording from multiple dendritic segments we challenge this classical view by demonstrating that passive, well-dampened FS-PV IN dendrites can be transiently activated by a high number of spatially and temporally coincident excitatory inputs. In this active state, several physiological properties of FS-PV INs are changed. For example, in contrast to the silent slice conditions, FS-PV INs now can generate propagating Ca2+ multiple dendritic hot-spots, propagate toward neighboring dendritic segments, and are mediated dominantly by L-type Ca2+ with membrane potential oscillations, that we call ‘interneuronal ripple oscillations’. These interneuronal ripple oscillations had the same frequency as the field potential oscillations associated with sharp wave-ripples, and controlled the phase of action potentials in FS-PV INs. Our results suggest that FS-PV IN dendrites could play a key role in mechanism of network oscillations.

Title: Low dose quinpirole affects cocaine-induced locomotion and slows down theta rhythm frequency in the rat ventral tegmental area

Authors: A. MONTEFORTE[1], S. KOULCHITSKY[1], T. BEEKEN[1], J. DETHIER[1], E. QUERTEMONT[1], E. BULLINGER[2], *V. M. SEUTIN[1];
[1]Univ. Liege, Sart Tilman / Liege, Belgium; [2]Otto-von-Guericke Univ., Magdeburg, Germany

Abstract: In any brain area, the simultaneous activity of large number of cells generates rhythms which rapidly fluctuate during wakefulness. This is also the case of the ventral tegmental area (VTA) where dopaminergic and GABAergic neurons are organized in “subnetworks” with specific inputs and outputs. How the brain coordinates the activity of various networks, such as the VTA network, to produce behavioral output is not clear. The VTA is involved in motor activity, motivation, reward and salience. Dopaminergic drugs such as cocaine induce locomotor activation and, in high and repeated doses, stereotypies. We previously showed that co-administration of a low dose of quinpirole (0.1 mg/kg, i.p.) and a moderate dose of cocaine (10 mg/kg, i.p.) alters the pattern of locomotor activation (as compared to the same dose of cocaine alone), making it look like a so-called locomotor stereotypy. In quantitative terms, co-administration of quinpirole modifies the relative amount spent at various speeds by the animal, with a clear and significant decrease in the relative amount of time spent at high speed. Using a telemetric recording system and 8-microelectrode-arrays spanning most of the extent of the VTA of freely behaving Wistar rats, we recorded the local field potentials (LFPs) within this area in order to test the hypothesis that this altered behavior could be due to changes in the activity of the VTA network. Indeed, the values of the LFP theta peak were significantly different

depending on the experimental conditions (AND when only considering very similar locomotor bouts). In control conditions, power spectrum analysis of the LPFs revealed a prominent peak in the theta frequency range during these periods (7.29±0.06 Hz). Injection of cocaine induced a shift of the peak of LFP theta power toward a slightly higher frequency (7.94±0.08 Hz). In contrast, when cocaine was co-administrated with a low-dose of quinpirole, the peak was shifted toward a lower frequency (~15% decrease, 6.65±0.10 Hz, $p<0.001$ vs cocaine alone). Our data show that an autoreceptor-selective dose of quinpirole markedly alters the quality of cocaine-induced locomotion and at the same time significantly decreases the macroscopic rhythm of the VTA network. To our knowledge, this is the first suggestion that a moderate shift in frequency of LFPs in the VTA is associated with a strong behavioral alteration. This reduced frequency may alter the ability of the VTA to communicate with its output structures.

Title: Cortical membrane oscillatory activities induced by light stimulations

Authors: ***T. OTSUKA**, Y. KAWAGUCHI;
Natl. Inst. For Physiological Sci., Okazaki, Japan

Abstract: The cortex outputs the information to several brain areas through different sets of pyramidal cells. It has been shown that cortical pyramidal cells form intra- and inter-laminar subnetworks, depending on pyramidal projection subtypes. To understand cortical information processing related to the high order brain functions, it is important to know how activities of individual pyramidal cell subnetworks are regulated. In the present study, we investigated optogenetically induced network activities in the rat frontal cortical slices. Channel rhodopsin was selectively expressed in L2/3 pyramidal cells by *in utero* electroporation. Whole-cell recordings were obtained from L5 pyramidal cells and Fast-Spiking (FS) interneurons, while light stimulation was applied to layer 2/3 to induce network activities. Membrane oscillatory

activities at the frequency around 30Hz were observed in both pyramidal and FS cells during light stimulations. Moreover, we compared activities induced by light stimulations in L5 pyramidal cells projecting to the ipsilateral pontine nuclei (CPn) and the contralateral cortex (COM), identified by retrograde fluorescent tracers. Oscillatory activities were frequently found in CPn cells. Cross-correlation analysis suggests that pyramidal and FS cells highly interact with each other during oscillations. Our results suggest that oscillatory activities, induced by L2/3 pyramidal cell stimulation, in the cortical circuits depend on the interaction between specific pyramidal cell subtypes and FS interneurons.

Title: Optogenetic activation of cholinergic neurons in the medial septum causes a scopolamine-sensitive reduction in theta power in hippocampus

Authors: *S. MONDRAGON[1], S. GLASGOW[3], S. WILLIAMS[2];
[1]Douglas Mental Hlth. Univ. Institute, McGill, Canada, QC, Canada; [2]Douglas Mental Hlth. Univ. Institute, McGill, Montreal, QC, Canada; [3]Dept. of Neurol. and Neurosurg., Montreal Neurolog. Institute, McGill Univ., Montreal, QC, Canada

Abstract: Cholinergic neurons in the medial septum-vertical limb of the diagonal band of Broca (MSvDB) are known to have an important role in memory formation and have been suggested to be an important player for theta rhythm generation. Although previous studies have focused on understanding how cholinergic neurons pace hippocampal theta oscillations, all cholinergic neurons are slow-firing and thus may not have the capacity to pace theta oscillations. Therefore, the function of these neurons, in modulating hippocampal activity remains unknown. We combined optogenetics with our recently developed *in vitro* septo-hippocampal preparation to address this question. For this study, we used ChAT-mhChR2-YFP BAC transgenic mice expressing channelrhodopsin-2/EYFP fusion protein (mhChR2:YFP) targeted selectively to cholinergic neurons. Characterization of septo-hippocampal neurons showed photocurrents of 190 +/- 50 pA (steady state: 160 +/- 50 pA) and depolarizations of 25 +/- 3 mV (n=9). Cholinergic neurons followed light stimulation from 1 to 20 ms pulse duration. Firing efficiency

increased with pulse size and stimulation response ratio reached peak value at 5, 10 and 20 ms, suggesting that cholinergic neurons could be finely activated with light. Surprisingly, optogenetic activation of cholinergic neurons caused a scopolamine sensitive reduction in theta power in the CA1 area in the intermediate hippocampus. In addition we found that MSvDB cholinergic neurons can directly modulate firing frequency hippocampal CA1 interneurons. Together, these results suggest that the role of slow firing septo-hippocampal neurons contribute negatively to theta oscillation power in the hippocampus.

Title: Transient competitive amplification in cortical circuits

Authors: *N. A. VASCONCELOS[1], J. BOURG[1], K. WIMMER[2], A. COMPTE[2], J. DE LA ROCHA[2], A. RENART[1];
[1]Champalimaud Neurosci. Programme, Champalimaud Ctr. for the Unknown, Lisbon, Portugal; [2]IDIBAPS, Barcelona, Spain

Abstract: Recurrent connections in cortical circuits might play a role in the selective amplification of different patterns of population activity. We explored this issue in population recordings of spontaneous activity from the auditory and somatosensory cortices of Urethane anesthetized rats during periods of cortical activation, which are also characteristic of attentive

wakefulness. PCA reveals that the correlation structure of the population is low-dimensional, with a gap in the amount of explained correlation between the first and subsequent principal components. The distribution of loadings onto the high-variance mode (PC1) across the population is wide and roughly centered at zero. Thus, the dynamics of the population is 'competitive': neurons with high positive or high negative loadings are negatively correlated with each other. Because PC1 is approximately orthogonal to the mean population activity, the population-averaged correlation is close to zero, as we showed previously (Renart et al., Science, 2010). What mechanisms could underlie the amplification of competitive fluctuations? We first show that randomly connected balanced networks do not generate competitive amplification. Competition in recurrent circuits has typically been modeled in a 3-population network with two excitatory populations interacting directly and through mutual inhibition (Wang, Neuron, 2002). Competition arises when the network operates close to a pitchfork bifurcation, so we refer to this mechanism as Normal Competitive Amplification (NCA). We developed a different mechanism using non-normal amplification (Murphy & Miller, Neuron, 2009) in the same 3-population network. When two eigenvectors of the effective connection matrix are approximately collinear with the competitive mode, strong amplification of competitive fluctuations arises in the absence of near-zero eigenvalues. Because the resulting strong fluctuations are short-lived, we refer to this phenomenon as Transient Competitive Amplification (TCA). We show that the TCA model requires asymmetric connectivity between the two competing populations. Then, using linear systems theory we examine the temporal structure of correlations in both models and compare them with those in our recordings. The TCA model naturally generates idiosyncratic but robust features of the real data, such as positive correlations within the two populations of clearly different magnitudes and a time delay in the negative correlations between them. Our work suggests that non-normal amplification indeed drives competitive spontaneous temporal fluctuations during states of cortical activation.

Title: Early brain network alterations are correlated with β-CTF in Alzheimer's transgenic mouse model

Authors: S. MONDRAGÓN-RODRÍGUEZ[1], *F. MANSEAU[2,1], N. GU[1], R. BOYCE[1], S. WILLIAMS[1];
[1]Dept. of Psychiatry, McGill Univ., Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada; [2]EBRI, Rome, Italy

Abstract: Alzheimer's disease (AD) is defined by the presence of amyloid-β (Aβ) and tau protein aggregates but increasing data suggests that early brain network alterations may be at the root for the pathogenesis of the disease. In the present study we performed extracellular field recording at the CA1/subiculum area in an *in vitro* complete hippocampal preparation from p30 J20-AD mice. We found that theta oscillation strength (a measure of rhythmicity) in J20 was significantly lower than that from the control group (tg: 16.3±1.3; ctrl: 32.8±3.6, t-test: $p<0.01$, n=10). In addition, J20 displayed significantly reduced theta-gamma cross-frequency coupling (CFC) at low (25-45 Hz) and high (150-250 Hz) gamma range, as the peak modulation index for low/high gamma were significantly reduced (low gamma: tg: 2.8±0.6; wt:14±2.9; high gamma: tg: 5.0±1.3; wt: 15.0±1.4, t-test: $p<0.01$, n=10). We then used optogenetics to explore the possible alterations in pyramidal cell and interneuronal network in CFC. Optogenetics was performed in offspring from CamKII-cre mice crossed with J20, injected with AAV2-Cheta-eYFP virus. Light driven pyramidal cell networks elicited theta oscillations (4-12 Hz) as well as nested low (25-50 Hz) and high gamma (150-250 Hz). However, we found that when driven with fixed frequency light stimulations, the J20 group showed significantly less CFC at all frequencies tested compared to controls. When applying sinusoidal injections of light of increasing frequencies (0-12 Hz) to drive the hippocampal network, it was found that the optimal CFC found between 4-6 Hz in controls was nearly absent in the J20 (n=8, $t<0.05$). Interestingly, the changes in CFC in the J20 mice were significantly associated with the Aβ precursor β-CTF (t-test: $p<0.005$, n=8). Despite the high β-CTF expression and the changes in network activity, no significant changes in learning and memory were noted at this age in the J20. In summary, our data suggests that brain network alterations precede the canonical Aβ protein deposition.

Title: Estimation of optimal neuron parameters to obtain minimal variability of periods in an oscillatory hybrid network

Authors: *R. M. HOOPER[1], R. A. TIKIDJI-HAMBURYAN[2], C. C. CANAVIER[2,3], A. A. PRINZ[4];
[1]Dept. of Biomed. Engin., Georgia Tech/Emory Univ., Atlanta, GA; [2]Dept. of Cell Biol. and Anat., [3]Neurosci. Ctr. for Excellence, Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA; [4]Dept. of Biol., Emory Univ., Atlanta, GA

Abstract: Rhythmic neuronal activity is a hallmark of many functions of the nervous system−including expression of motor patterns, cognition, memory, arousal, and sleep. Networks that give rise to this rhythmicity often consist of pacemaker neurons coupled to non-pacemaking neurons, and produce activity that is stereotyped and reliable, yet with some level of variability that appears to be specific to the requirements of each network; e.g. some circuits exhibit high levels of activity variability in order to accomplish some behavioral goal [1,2]. While it is understood that existence of synaptic feedback from non-pacemaking neurons to pacemaker neurons is one strategy by which networks can scale the level of activity variability [3,4], it is not understood how specific neuronal dynamics of networks influence variability scaling, or what the neuronal dynamics must be to induce minimal network variability. Here we show how network activity variability changes with altered phase response dynamics of non-pacemaking neurons, and using previously developed analyses [5] demonstrate a theoretical approach's predictive efficacy in hybrid networks established in the stomatogastric nervous system (STNS) of *Cancer borealis.* These hybrid networks consist of one biological pacemaker neuron (Anterior Burster/Pyloric Dilator complex [AB/PD]) and one artificial non-pacemaker neuron (designed to mimic the burst timing of the Lateral Pyloric [LP] neuron) established with dynamic clamp, which allows us to vary the phase response dynamics of the latter element. Qualitatively similar simulations are used in the theoretical approach. Our experimental results show that a network with a non-pacemaker neuron using a positive slope in the response interval to stimulus interval relationship (t_S-t_R curve) results in different network variability levels compared to both an isolated oscillator neuron or a hybrid network with a zero slope t_S-t_R curve. Initial theoretical predictions indicate that a negative slope in the non-pacemaker neuron t_S-t_R curve would result in opposite effects on network variability compared to the initially examined positive slope and zero slope t_S-t_R network configurations. This prediction was confirmed in further experiments. Finally, we use realtime t_S-t_R measurements of the pacemaker neuron and theoretical methods to estimate and implement a network with minimal activity variability. 1. Title: Analysis of single unit and neuronal activity in the human subthalamic nucleus during reach-to-grasp movements

Authors: *U. E. RAMIREZ PASOS[1], M. PÖTTER-NERGER[2], R. REESE[1], F. STEIGERWALD[1], *. VOLKMANN[1];
[1]Universitätsklinikum Würzburg, Würzburg, Germany; [2]Neurologische Klinik, Universitätsklinikum Schleswig-Holstein, Campus Kiel, Kiel, Germany

Abstract: The basal ganglia (BG) are involved in processing of goal-oriented behavior, motor preparation, and action selection. Electrophysiological studies of the human BG point to a decrease in subthalamic nucleus (STN) oscillatory LFP activity upon movement onset, chiefly in the beta range (13-30Hz). However, the simplicity of these movements (e.g. arm flexion, hand suppination) may not represent more complex human motor processing. We have employed the reach-to-grasp (RtG) paradigm as a more functionally relevant task to observe whether the STN processes movement differently according to the kinematic aspects of a complex motor task involving coordinated distal or proximal muscle activation. 12 parkinsonian patients reached toward a panel and pressed a grip device in response to a warning cue while single-unit activity was intraoperatively being recorded from their STN within the 300-10,000 Hz band at ~25kHz. On average the patient performed the task 10 times per depth of insertion. Ultrasound-emitting devices were attached to thumb, index finger, wrist, and elbow to reconstruct the position and velocity curves of the wrist markers as well as the distance between fingers. Neuronal background unit activity (BUA) has been interpreted as a marker for synchorinized activity of the local population in the neuron vicinity. Following Moran's (2008) method, background

activity was extracted from neuronal spike trains by removing spikes identified with a spike sorter and inserting random segments from the rest of the signal into the empty slots. The resulting BUA signals were then analyzed relative to each aspect of the movement (beginning of transport phase (TP); maximum velocity; end of transport phase; maximum grip opening; and grip closing) to identify spectral properties using SPM. We observed a significant activation of the alpha band shortly before the warning cue followed by suppression, which we interpret as a marker for motor preparation. In half of the subjects a broadband activation is present at the beginning of the TP ans likewise during maximum grip opening for 5/12 patients. For the end of the RtG movement broadband desynchronization is observed in 5/12 patients. The last results run counter to LFP studies which support the idea that movement initiation specifically suppresses beta activity in the subthalamic nucleus. This suggests that changes in the beta band in STN activity relative to movement may be only specific to synchronized post-synaptic potentials but not to BUA. Abstract: Neuronal oscillations have a close, nontrivial relationship with brain signal processing and behavior, and are regarded as a fundamental mechanism for temporal coordination and information integration. The Local Field Potential (LFP) is one of the electrophysiological signals that captures this phenomenon, since it corresponds to the sustained currents in the tissue, and its variations over time represent how a neuronal population respond as a whole to a given stimulus. It is, therefore, a preeminent signal when we aim to analyze the changes in connectivity between different cortical regions. More specifically, the LFP synchronization within and between different brain regions is taken as an indicative of a decision-making process, and its dynamics may reflect the integration of different neuronal ensembles towards accomplishing a specific goal. To date, it is not clear how different brain regions interact and encode information. In this work, the relation between motor and somatosensory cortices (M1 and S1, respectively) was studied during an active whisker discrimination task. Long-Evans rats were trained to discriminate between a wide or narrow aperture employing only their mystacial vibrissae to receive a water reward. Over the task execution, the LFPs of sensorimotor cortex were analyzed around the instant the rat broke the photo beam at the discrimination bars. We present temporal analysis through the variation of the Phase Locking Value (PLV) to unveil information dynamics and interactions between M1 and S1 neurons.

Title: Effect of median raphe manipulation on the hippocampal network

Authors: *A. DOMONKOS, L. NIKITIDOU, A. SZőNYI, C. CSERÉP, D. ZELENA, G. NYIRI, T. F. FREUND, V. VARGA;
Inst. of Exptl. Medicine, Hungarian Acad. of Sci., Budapest, Hungary

Abstract: The median raphe (MR) is a major source of the ascending serotonergic system involved in neuromodulation related to e.g. mood, fear and stress. Previous studies revealed the existence of a fast and vigorous glutamatergic component of the MR-hippocampal pathway. The aim of this study was to decipher the role of MR-manipulation in the regulation of hippocampal activity in acute and freely behaving (chronic) animals. Adeno-associated viral vectors containing channelrhodopsin 2 tagged with mCherry or YFP under the synapsin promoter were injected into the MR of C57Bl/6 mice. About 3-4 weeks after injection, a 32-channel 4-shank (Buzsáki) probe was implanted into the dorsal hippocampus for sampling hippocampal unit and field response to the optogenetic manipulation of the MR. In some cases, multiple single wires were implanted into different brain regions (prefrontal cortex, amygdala, dorsal and ventral hippocampus), instead of silicon probe. Different stimulation frequencies were tested in acute (urethane-anesthetized) and chronic (freely behaving) experiments. Preliminary data show layer-dependent response in the hippocampus during MR stimulation. However, the MR stimulation failed to induce state transitions in the hippocampus. In chronic recordings, pulses delivered in the MR at 20 Hz dramatically decreased the power of low-range theta oscillations in the hippocampus. Additionally, weak entrainment of the hippocampal network was detected during stimulation by 8 Hz. Importantly, the response amplitude was dependent on the testing environment (home cage vs. linear track). The correlation between evoked effect and precise localization of optic fiber and opsin-expressing cells will be analyzed. Additionally, selective optogenetic manipulation of serotonergic MR neurons will be also carried out to test the role of serotonergic component in the modulation of hippocampal activity.

Abstract: Tau aggregation is a pathological hallmark of various neurodegenerative disorders, including frontotemporal dementia spectrum disorders (FTD-s) and Alzheimer's disease (AD). Recently, an amino acid substitution in tau (A152T) was reported to increase the risk of both FTD-s and AD, but the underlying mechanisms are unclear. To investigate the effects of A152T-variant human tau (hTau-A152T) on the integrity, function and survival of neurons *in vivo*, we generated transgenic mice with doxycycline (DOX)-regulatable expression of hTau-A152T in excitatory forebrain neurons. By 2–4 months of age, brains of these mice showed an abnormal accumulation of misfolded and phosphorylated tau and reactive astrocytosis. Suppressing hTau-A152T expression with DOX reversed these abnormalities. hTau-A152T expressing mice had no behavioral deficits until they were 17 months old, when they showed impairments in the Morris water maze test. Electrophysiological analysis of acute hippocampal slices from 4–8 month-old hTau-A152T mice revealed decreased intrinsic excitability of granule cells in the dentate gyrus and increased synaptic transmission strength at the granule cell to CA3 mossy fiber synapse. Electroencephalographic recordings of brain oscillations in awake behaving mice revealed network hyperexcitability in hTau-A152T mice, including enhanced epileptiform activity in response to pentylenetetrazol challenge. In addition, we found evidence for co-pathogenic interactions between hTau-A152T and human amyloid precursor protein (hAPP) or amyloid- (A) peptides. Breedings between hTau-A152T mice and hAPP transgenic mice from line J20 yielded 128 offspring, but only two of these mice co-expressed hTau-A152T and hAPP/A, and both of them died shortly after weaning. To confirm that the above effects are specifically caused by the A152T substitution and not by overexpression of hTau, we generated transgenic mice expressing comparable levels of wildtype hTau. Side-by-side analyses of hTau-A152T and hTau-Wildtype mice are in progress. The findings we have obtained so far suggest that accumulation of hTau-A152T leads to age-related cognitive decline, possibly by changing synaptic functions and enhancing neural network excitability. These effects may also contribute to the ability of this tau variant to increase the brain's susceptibility to pathologically elevated levels of A and, possibly, to other factors involved in the pathogenesis of AD and FTD-s.

Abstract: Alzheimer’s disease (AD), frontotemporal dementia and related tauopathies are characterized by aggregation of hyperphosphorylated tau. Several animal models have been established to reproduce the pathology at the level of the hippocampus and amygdala, but age-dependent changes in tau phosphorylation and aggregation in the brainstem and their possible behavioral sequels have not been studied intensively. As the occurrence of disturbed eating behavior suggests an involvement of brainstem nuclei in the pathogenesis of AD, we analyzed the behavior and patterns of tau phosphorylation in the trigeminal motor nucleus of senescent human P301L tau-transgenic pR5 (pR5) mice. Male pR5 mice on a C57BL/6OlaHsd (Harlan) background and gender-matched non-transgenic littermates (non-tg) at the age of 6, 15 and 18 months were tested for behavioral performance (T-maze, Morris water maze, Open field, Object recognition test, RotaRod, Fitness Center). At the age of 8, 16 and 19 months, the animals were sacrificed and coronal brainstem sections were cut for immunohistochemical staining. The number of phospho-tau (AT8- and AT180-)immunoreactive neurons in the trigeminal motor

nucleus was quantified and normalized to the number of choline acetyltransferase or Nissl-stained cells. Behavioral testing revealed no significant age- or genotype-dependent differences. Likewise, body weight of pR5 mice was unchanged compared to non-tg mice. Therefore eating-related behavior seemed to be unaffected. However, histological analysis revealed a significantly higher proportion of both, AT8- and AT180-immunoreactive neurons in the trigeminal motor nucleus of older compared to younger pR5 mice (8 versus 16 months: $p<0.01$; 8 versus 19 months: $p<0.05$; performed by means of Student's t-test). No significant differences in the number of AT8- and AT180- immunoreactive neurons of the trigeminal motor nucleus were observed between 16- and 19-months-old pR5 mice. Our findings in the pR5 mouse model show for the trigeminal motor nucleus an age-related increase of the number of neurons that display tau hyperphosphorylation at the AT8- and AT180-epitopes between 8 and 16 months of age. Since there were no detectable behavioral alterations, this pretangle tau hyperphosphorylation state does not appear to affect the functionality of neurons.

Abstract: There is mounting evidence that soluble hyperphosphorylated tau species drive neuronal dysfunction and degeneration in tauopathy. Since the effect of progressive tau

pathology on intrinsic neuronal functions and synaptic plasticity still remains unclear, we investigated electrophysiological properties of hippocampal CA1 neurons in elderly tau transgenic mice. Electrophysiological recordings were performed in acute brain slices from P301L tau transgenic pR5 mice (tg) at the age of 13 to 17 months and age-matched non-transgenic littermate (nt) controls. Using the whole-cell configuration of the patch-clamp technique, intrinsic membrane properties and response to stimulation of the Schaffer collaterals were analyzed in a total of 25 neurons from tg and 12 neurons from nt animals. We found significant differences in the action potential firing threshold ($p<0.01$) and in the macroscopic activation kinetics of the hyperpolarization-activated inward current (IH; $p<0.05$). The higher firing threshold in tg (-47.2mV±11.8mV) in comparison to nt (-55.7mV±6.3mV) neurons may have substantial implications for the hippocampal network. The difference could represent a conceivable explanation for the pronounced loss of long-term potentiation detected in CA1 neurons of several tau transgenic models (Sydow et al. [2011] J Neurosci 31:2511-2525; Oddo et al. [2003] Neuron 39:409-421). The slowed macroscopic activation of IH in tg (84.7ms±92ms) versus nt (27.8ms±28ms) neurons may tend to facilitate temporal summation, possibly antagonizing the increased firing threshold. These results are in apparent contrast to former studies (Rocher et al. [2010] Exp Neurol 223:385-393; Crimins et al. [2012] Acta Neuropathol 124:777-795) where changes in the intrinsic properties of frontal cortical pyramidal neurons indicated an enhanced hyperexcitability in the rTg4510 mouse model of tauopathy. This may point to region-specific pathological changes in tau transgenic mice.

Abstract: Abstract: Aggregation of tau is a hallmark in many neurodegenerative diseases including Alzheimer's disease, certain forms of frontotemporal dementia, and progressive supranuclear palsy. Tau is a cytosolic, microtubule binding protein. In disease conditions, tau protein dissociates from microtubules and aggregates to forms neurofibrillary tangles in neurons and dystrophic neurites. We recently showed by continuous intracerebroventricular infusion of three anti-tau antibodies into the lateral ventricle of P301S transgenic mice that tau pathology was markedly reduced and there was improvement of cognitive deficits (Yanamandra et al. 2013). Of all anti-tau antibodies we administered, HJ8.5 was the most potent in reducing tau pathology in all methods we analyzed. In the current study, we administered two doses (10 mg/kg and 50 mg/kg) of the HJ8.5 antibody intraperitoneally (I.P.) to 6 month old P301S tau transgenic mice. Control mice received PBS injection. Mice received one I.P. injection weekly for a period of 12 weeks. After treatment, we performed immunostaining, biochemical analysis and behavioral tests. Quantitative immunostaining showed that 50mg/kg treatment of HJ8.5 reduced hippocampal CA1 cellular layer staining as assessed AT8-phospho tau antibody compared to PBS/vehicle treated controls. We also observed that both 10 mg/kg and 50 mg/kg treatment with HJ8.5 antibody significantly reduced the loss of cortical and hippocampal tissue volumes compared to control mice. By biochemical analysis, we found that mice treated with HJ8.5 at 50 mg/kg showed an increase in soluble and a marked decrease in insoluble total tau levels. HJ8.5 is a human specific tau antibody and it resulted in a substantial decrease in insoluble human tau by ~75% in the 70% formic acid soluble fraction. We also observed a strong correlation between the amount of brain atrophy and insoluble tau levels measured by ELISA. HJ8.5 50 mg/kg treated mice showed a decrease in motor deficits compared to the control group in both the inverted screen and ledge tests. Using *in vitro* BV2-microglial cell lines, we observed significantly higher uptake of P301S tau aggregates in the presence of HJ8.5 antibody. Overall, our results indicate that systemically administered anti-tau antibody HJ8.5 potently decreases insoluble tau, decreases brain atrophy, and improves motor function in a mouse model of tauopathy.

Title: Memory deficits correlate with tau and spine pathology in P301S MAPT transgenic mice

Authors: *H. XU[1,2], T. W. RÖSLER[1], T. CARLSSON[3], W. H. OERTEL[3], G. U. HÖGLINGER[1,2,3];
[1]Dept. of Translational Neurodegeneration, German Ctr. for Neurodegenerative Dis., Munich, Germany; [2]Dept. of Neurol., Tech. Univ. Munich, Munich, Germany; [3]Dept. of Neurol., Philipps-University, Marburg, Germany

Abstract: Back ground As a model of frontotemporal dementia and parkinsonism linked to chromosome 17 with tau pathology (FTDP-17-Tau), P301S *MAPT* transgenic mice (P301S mice) have been identified with onset of locomotor deficits since 5 months of age in previous studies. However, no cognitive deficit correlated with sub-cellular level of tau pathology and dendritic spine loss was reported on the model at early age. **Aim of the study** Our study investigated memory deficit of P301S mice in relation to pathological tau species and dendritic spine pathology throughout adulthood. **Methods and results** Behavior tests One group of P301S mice was investigated monthly with the rotarod test from 2 to 6 months of age. Another group of P301S mice was subjected monthly to the novel open field from 2 to 6 months of age and the Morris water maze test at 2.5 and 5.5 months. Same numbers of the wild type mice were taken as control for all the testing sessions and time points. Immunoblot and immunohistochemistry P301S and wild type mice ($n \geq 3$ per group and time-point) were sacrificed by an intraperitoneal (i.p.) injection of pentobarbital at (30 g/kg) at 2, 3, 4, 5, or 6 months of age. Soluble and sarkosyl-insobuble tau from the brain homogenates were analyzed using the following tau antibodies: AT180 (Thermo scientific, Waltham, MA) for PHF-tau; CP13 and MC1 (kindly provided by the Department of Pathology, Albert Einstein College of Medicine, NY, NY) for S202-pTau and conformationally changed tau, respectively. Post-fixed free floating sections

were immunostained with the same antibodies for tau and the anti-NeuN antibody (Millipore, Darmstadt, Germany) for neurons. Golgi staining and dendritic spine quantification P301S and wild type mice were sacrificed at 2.5 and 5.5 months of age by cervical dislocation. Brains were quickly removed and briefly cleaned with Millipore water. The GolgiStain^{TM} kit (FD NeuroTechnologies, Columbia, MD) was used following the manufacturer's guidelines. Dendrites with more than 10 μm length were reconstructed into 3D images and then quantified spine density, length, cross-sectional area, and volume using the Imaris software (Bitplane, Zurich, Switzerland). **Conclusion** Tauopathy-induced impaired synaptic connectivity in the hippocampus leads to memory deficit in P301S mice at an early age (< 2.5 month of age). This newly recognized behavioral deficit and suggested patho-anatomical substrate may be helpful as a read-out for the development of new therapeutic tau-targeting interventions.

Title: Riluzole attenuates spatial memory deficits in a TauP301L mouse model of Alzheimer's disease

Authors: *D. WEITZNER, M. REED, H. HUNSBERGER, C. RUDY;
Psychology, West Virginia Univ., Morgantown, WV

Abstract: Individuals at risk for developing Alzheimer's disease (AD) often exhibit neuronal hyperexcitability throughout the memory networks in the years preceding AD diagnosis. This hyperexcitability may be due to an increase in glutamatergic signaling, a hypothesis supported by our recent findings of increased glutamate release in the hippocampus of rTg(TauP301L)4510 mice, a commonly used tau mouse model of AD. Though TauP301L mice exhibit age-dependent memory deficits, neuron loss, and neurofibrillary tangle formation, the alterations in glutamate

signaling observed in these mice occurs early in the disease process, at a time prior to neuron loss or tangle formation, but coinciding with the onset of subtle memory deficits. The objective of this study was to examine whether riluzole, an FDA-approved disease-modifying drug for amyotrophic lateral sclerosis that effectively regulates glutamate levels, would attenuate the spatial memory deficits observed in TauP301L mice. To avoid alterations resulting from P301L tau expression during development, tau expression was suppressed until adulthood (approximately 2.5 months of age). Spatial reference memory was compared prior to the onset of P301L tau expression and at multiple time points after the onset of P301L tau expression. As anticipated, prior to the onset of P301L tau expression, there were no differences in memory between TauP301L mice and transgene negative littermates. In contrast, after the onset of P301L tau expression, our initial findings indicate TauP301L mice exhibit age-dependent memory deficits, an effect attenuated by riluzole. Thus, our findings could establish a potential therapeutic intervention for memory deficits and cell death caused by the accumulation of excess glutamate in the extracellular space.

Title: Beneficial effects of anatabine in a mouse model of tauopathy

Authors: *D. PARIS[1], D. BEAULIEU-ABDELAHAD[1], G. AIT-GHEZALA[1], V. MATHURA[1], M. VERMA[1], A. E. ROHER[2], F. CRAWFORD[1], M. MULLAN[1,3];
[1]Roskamp Inst., SARASOTA, FL; [2]The Longtine Ctr. for Neurodegenerative Biochem., Banner Sun Hlth. Res. Inst., Sun City, AZ; [3]Rock Creek Pharmaceuticals, Sarasota, FL

Abstract: We have previously shown that the natural alkaloid anatabine displays some anti-inflammatory and Alzheimer ß-amyloid lowering properties in the central nervous system associated with reduced STAT3, NFκB and microglial activation. Microglial activation and astrogliosis are preeminent in tauopathies and mitigation of neuroinflammation has been shown to delay the progression of tauopathies in animal models. We therefore investigated here the impact of a chronic oral treatment with anatabine in a mouse model of tauopathy (Tg P301S). We found that the incidence of paralysis and abnormal hind limb extension reflex was reduced in

Tg Tau P301S treated with anatabine suggesting that anatabine delays the disease progression in this model of tauopathy. Additionally, we show that anatabine suppresses tau phosphorylation (at multiple Alzheimer's disease pertinent epitopes) as well as tau oligomerization in the brain and spinal cord of Tg P301S further confirming this assumption. The reduction in pathological tau species observed in anatabine treated mice was accompanied by a reduction in microgliosis and STAT3 activation in the brain and spinal cord of Tg P301S revealing an anti-inflammatory activity of anatabine in Tg P301S mice. Additional data regarding the mechanism(s) of action of anatabine responsible for its beneficial activity against the development of tauopathy will be presented. Overall our data support further exploration of anatabine as a disease modifying agent for the treatment of tauopathies including Alzheimer's disease. Title: Aggrecan changes seasonally in hibernating ground squirrels: Insight into understanding Alzheimer’s disease

Authors: *K. B. BJUGSTAD[1], A. HINDLE[2], S. L. MARTIN[2];
[1]Medicine, Neuroscience, Bioengineering, [2]Cell and Developmental Biol., Univ. Colorado Denver, AURORA, CO

Abstract: The ability for hyperphosphorylated tau and amyloid-beta to aggregate into neurofibrillary tangles (NFTs) and amyloid plaques, the two hallmarks of Alzheimer's disease (AD) neuropathology, is dependent on the presence of sulfated proteoglycans in the brain's extracellular matrix (ECM). Phosphorylated tau is abnormally elevated in the brains of hibernating mammals, specifically during torpor, without evidence of tangle formation. Remarkably, tau phosphorylation returns to normal during each interbout arousal; this cycle between torpor and arousal repeats ~every two weeks throughout the 6-7 months of winter hibernation. Because of the prominent role that the ECM has in NFT formation, we hypothesized that the relative composition of the sulfated proteoglycans in the ECM of hibernating animals may differ from that of other animals, display a seasonal change, and/or change within torpor-arousal cycles. Septal brain ECM was assessed in summer active (SA) and two winter hibernating groups of 13-lined ground squirrels, Late-Torpor (LT) and Interbout Arousal (IBA); non-hibernating rats served as controls) Using immunohistochemistry, the relative abundance of 5 ECM proteoglycans was measured: brevican, agrin, aggrecan, glypican, and hyaluronic acid. There were no significant species differences between rats and ground squirrels, suggesting potential seasonal or euthermic changes in ground squirrel brain ECM would be small and within the natural variation of ECM expression. Analysis among ground squirrel groups revealed no significant differences in agrin, brevican, HA, or glypican. Aggrecan, however, was elevated in hibernating ground squirrels, especially in IBA animals, with a significant elevation compared to SA animals. It is possible that aggrecan cycles seasonally, allowing the brain to prepare for long-term hibernation. Human brain areas with aggrecan deficient ECM, such as the septum, typically contain greater tau pathology during AD. Identifying the proteoglycan changes that prevent tau pathology during hibernation may reveal a novel approach to understanding AD.

Title: Cellular and morphological changes in hippocampus (CA1) in rats exposed to Vanadium Pentoxide

Authors: *E. MONTIEL-FLORES, SR[1,2], V. ANAYA-MARTÍNEZ[2], A. GUTIÉRREZ-VALDEZ[2], J. SÁNCHEZ-BETANCOURT[2], J. ESPINOSA-VILLANUEVA[2], M. AVILA-COSTA[2];
[1]Neurophatolgy, UNIVERSIDAD ESTATAL DEL VALLE DE ECATEPEC, México, Mexico; [2]Neurosciences, Neuromorphology lab., UNAM-FES-Iztacala, Tlanepantla, Edo. de México, México, Mexico

Abstract: Vanadium (V) is a petroleum product widely distributed in nature, it is employed in the steel industry, car parts and as a pigment in paint manufacture. Its toxicity depends on its oxidation state, it seems that the vanadium pentoxide (V2O5) is the most toxic to the living cells. It has been reported that oral administration induces changes in motor activity and learning, in rats i.p. administration increases lipid peroxidation levels in cerebellum and the concentration of free radicals in hippocampus and cerebellum. Mice which inhale V2O5 presented reduced number of tubulin+ in Leydig and Sertoli cells; it has also been reported that inhaled V2O5 induces loss of dendritic spines, necrosis, and hippocampus neuropil alterations, and that these changes correlate with alterations in spatial memory. The purpose of this work is to characterize the morphological alterations and the number of cells with hyperphosphorylated tau-p-Ser262 that appears in the hippocampus (CA1) in rats exposed to V2O5. Male wistar rats inhaled 0.02 M of V2O5, 1 h two times a week for 6 months. The results show that tau protein is phosphorylated by V2O2, we observed significant increase in the number of immuno+ tau-pSer262 at 4, 16 and 24 weeks comparing to control group, also we observed morphological changes in the shape and size of nucleus, soma and dendrites of hippocampal cells. We consider that CA1 neurons hyperphosphorylation observed induced morphological alterations in cytoskeleton and these changes are similar to those reported in tauopathies such as Alzheimer's disease.

Title: Preventative effects of chronic treadmill exercise on cognitive and non-cognitive behaviors in P301S tau transgenic mice

Authors: *O. OHIA, S. MONTAZARI, C. VOLLERT, J. ERIKSEN;
Pharmacol. and Pharmaceut. Sci., Univ. of Houston, HOUSTON, TX

Abstract: Alzheimer's disease (AD), as well as other tau-related dementias, are neurodegenerative diseases that are characterized in part by the pathological development of neurofibrillary tangles. Based on recent clinical evidence in patients with neurodegenerative tauopathy, it is possible that introducing physical exercise can be instrumental in delaying the onset of behavioral impairments. In this study, 4-month old P301S tau transgenic mice were subjected to 6 months of forced treadmill exercise and evaluated for effects on cognitive and non-cognitive behaviors. Exercise significantly impacted the motor coordination and muscular strength of exercised P301S mice compared to their non-exercised counterparts. Additionally, mice were assessed on their performance in the light/dark avoidance test, elevated-plus maze, pre-pulse inhibition, contextual and cued fear conditioning and Morris water maze. We observed that exercise altered the cognitive and non-cognitive impairments displayed in P301S mice. We believe this research will lead to a more comprehensive understanding of how treadmill exercise may help to prevent or delay the onset of neurodegenerative disease.

Title: Tau reduction in adulthood in a new line of conditional knockout mice is safe and reduces seizure susceptibility

Authors: *Z. LI, S. BUCKINGHAM, A. HALL, S. WILSON, E. D. ROBERSON;
Neurobio., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Microtubule-associated protein tau is emerging as target for treatment of Alzheimer's disease and potentially for forms of epilepsy. Tau reduction from conception has been well demonstrated to confer resistance to seizures in various seizure models. This seizure protective effect could possibly arise from compensatory mechanisms during development triggered by tau knockout from conception. Therefore, targeting tau in adulthood to treat seizures and Alzheimer's disease may or may not be effective. To address this question, we developed an inducible tau knockout system. We maintained normal levels of tau during development to avoid potential developmental effects of tau reduction. We then induced tau reduction in adult mice and tested seizure susceptibility in two different models. Tau reduction in adulthood decreased the maximum seizure severity and prolonged the latency of seizures induced by pentylenetetrazol, an antagonist of $GABA_A$ receptors. Tau knockout in adulthood also decreased the severity of seizures induced by kainic acid, a glutamate receptor agonist. The severity of seizures correlated with residual level of tau; lower levels of tau were associated with lower seizure severity. Tau reduction in adulthood did not cause overt abnormalities, suggesting overall safety of tau knockout in adulthood. In summary, we conclude that tau reduction in adulthood effectively protects mice from seizures without causing major abnormalities. These data support the idea that tau could be effectively and safely targeted for treatment of seizures and Alzheimer's disease.

Title: A new reporter system of tau spreading *in vivo*: AAV-delivered human tau crosses synapses in mice

Authors: *S. WEGMANN, S. NICHOLLS, S. TAKEDA, Z. FAN, B. T. HYMAN;
Neurol., Mass Gen. Hosp. / Harvard Med. Sch., Charlestown, MA

Abstract: In Alzheimer's disease, the progressive deposition of tau protein in neurofibrillary tangels (NFTs) appears to follow a certain pattern. Starting in the entorhinal cortex, pathological tau aggregation next occurs in the limbic system, then cortical areas, and finally throughout the brain of AD patients. In recent years, mouse models that mimic such tau pathology spreading pattern have been evolved. In these mice, transgenic human tau expression is locally restricted to the entorhinal cortex. In old mice (>18 month), human tau is also found in neurons that do not express the transgene and are directly downstream of the EC, in the dentate gyrus, the hippocampus, and more frontal cortical areas suggesting that tau can cross synapses along the perforant pathway. However, drawbacks of this model remain: 1) late onset of tau spreading, 2) restriction to perforant pathway, and 3) technical difficulties in discriminating between tau expressing and tau recipient neurons. Here, to study tau spreading *in vivo* and *in vitro* more efficiently, we created a tau expression reporter system, eGFP-2a-huTau, in which eGFP and wild-type human full-length tau (441aa) are expressed as separate proteins in the the same cell. This construct allows direct indentification and *in situ* visualization of tau expressing cells without creating a bulky GFP-tau fusion protein that may show cellular functions and distribution distinct from "naked" tau. We expressed eGFP-2a-huTau in neurons to examine the cellular consequences of tau overexpression. Furthermore, using immunofluorescence labeling of human tau (N-terminal epitope), we were able to identify neurons that recieved human tau from neighboring neurons (huTau+/eGFP-) *in vitro* after >7 days in culture. Next, we packaged eGFP-2a-huTau under teh CBA promotor into an adeno associated virus (AAV) and delivered it stereotactically into the entorhinal cortex of wild-type mice. Postmortem analysis of eGFP and human tau in these brains showed strong expression of eGFP and tau in the injected brain areas, as well as tau spreading to neighboring neurons and neurons in more distal areas of the brain as early as 4-6 weeks after AAV delivery. Phosphorylated tau (PHF1, CP13) was found in tau expressing but not tau rececieving neurons. However, more detailed analysis of the tau found in downstream neurons is in progress. Our early data suggest that i) wild-type tau is able to travel from neuron-to-neuron and ii) the mechanism of tau traveling maybe independent of phoshprylation and aggregation. Our eGFP-2a-huTau construct resembles a great tool to study diverse questions in tau biology and disease both *in vitro* and *in vitro* in parallel.

Title: Phosphorylated tau levels in the brains of naked mole-rats (Heterocephalus glaber) are differentially elevated based on reproductive status

Authors: *C. M. DENGLER-CRISH[1], G. N. WILSON[2], M. A. SMITH[1], S. D. CRISH[1]; [1]Pharmaceut. Sci., Northeast Ohio Med. Univ., Rootstown, OH; [2]Biomed. Sci. Grad. Program, Kent State Univ., Kent, OH

Abstract: Previous studies have shown that naked mole-rats exhibit unusual accumulations of amyloid beta at young ages comparable those shown in advanced Alzheimer's disease (AD) transgenic mice *(Edrey et al. 2013; Neurobiol Aging 34: 2352)*. Our laboratory investigated whether hyperphosphorylated tau, a pathological marker of AD, was elevated in reproductively suppressed and recently reproductively-activated naked mole-rats (12-weeks after removal from reproductive suppression) using ELISA. Our results indicated that newly activated mole-rats exhibited higher total brain levels of tau isoform s396-404 than suppressed animals. These differences were also apparent when comparing cerebellum and cortex but were not shown to be different at the subcortical level. Conversely, total tau was higher in the reproductively suppressed animals in all three brain regions. Additionally, total tau levels as well as isoform s396-404 were elevated comparably to hTau (B6.Cg-*Mapt*$^{tm1(EGFP)Klt}$ Tg(MAPT)8cPdav/J) mutant mice that express elevated levels of hyperphosphorylated tau. These results suggest that, like amyloid beta, potentially damaging high levels of hyperphosphorylated tau are naturally expressed in naked mole-rat brains and this expression may vary as a function of reproductive experience.

Title: Metabolic phenotyping of Tg4510 tau transgenic mice indicates hyperactivity and circadian disruption

Authors: *A. JOLY AMADO, M. N. GORDON, D. MORGAN;
USF Hlth. Byrd Alzheimer's Inst., Tampa, FL

Abstract: Tau is a microtubule-associated protein which can aggregates into neurofibrillary tangles (NFTs) in age-related neurodegenerative diseases. Unexplained weight loss and cachexia are frequent clinical findings in patients with Alzheimer's disease (AD) and eating disorders have been reported in other tauopathies like Frontotemporal Dementia (FTD). However, the impact of tau pathology on energy homeostasis remains unclear. Transgenic Tg4510 mice overexpressing P301L tau exhibit pretangles, cognitive impairments and neuronal loss, which increase with aging. Mice also exhibit a significant decrease in body weight compared to their nontransgenic littermates (NTG). In this study, 2 and then 7 months old Tg4510 and nontransgenic mice were placed in metabolic cages which allow the continuous evaluation of food intake, locomotor activity and measurements of CO2 production and O2 consumption. At 2 months of age, Tg4510 exhibit no differences in food intake or body weight compared to NTG, but do display a significant increase in nocturnal total activity ($5.2x10^4$ +/-0.30 counts/12h vs $3.7x10^4$ +/-0.31 counts/12h in NTG) along with decreased O2 consumption and CO2 production compared to NTG. At 7 months of age, Tg4510 mice show a massive increase in total activity during both night ($12.7x10^4$ +/-2.4 counts/12h vs $2.4x10^4$ +/-0.2 counts/12h in NTG) and day ($10.9x10^4$ +/-2.6 counts/12h vs $1.9x10^4$ +/-0.2 counts/12h in NTG). Interestingly, both O2 consumption and CO2 production were now increased at 7 mo in tau mice compared to their nontransgenic littermates. In a different cohort, 7 months old Tg4510 revealed tau deposits, phosphorylated tau and NFTs in the hypothalamus, particularly in the ventromedial nucleus, which could be related to the metabolic disturbances observed. Our data suggest that tau protein accumulation in the hypothalamus may be involved in energy homeostasis deregulation observed in Tg4510 mice and tauopathies such as AD and FTD. Understanding the origin of energy balance disorders in tauopathies may suggest new drug targets to modify some of the behavioral characteristics of the disorder, and possibly have impact on the disease process as well, providing benefit to both patients and caregivers. Supported by NS 76308 and Alzheimer's Association.

Title: High-fat diet increases the expression and alternative splicing of tau in the brain of female mice independently from peripheral metabolic changes

Authors: M. TAKALO[1], *A. HAAPASALO[1], S. KEMPPAINEN[1], P. MÄKINEN[1], J. PIHLAJAMÄKI[1], H. SOININEN[1,2], M. LAAKSO[1], H. TANILA[1], M. HILTUNEN[1]; [1]Univ. of Eastern Finland, Kuopio, Finland; [2]Kuopio Univ. Hosp., Kuopio, Finland

Abstract: A number of epidemiological studies suggests that type 2 diabetes mellitus (T2DM) increases the risk of Alzheimer's disease (AD). However, molecular mechanisms underlying this co-morbidity are not well understood. Intraneuronal deposits of microtubule-associated protein tau are characteristic features of several neurodegenerative diseases, including AD. Moreover, abnormal splicing of tau exon 10 leads to the altered ratio of 4-repeat (4R) vs. 3-repeat (3R) tau isoforms in neurodegenerative diseases and T2DM.To investigate the effects of both genetically and high-fat diet (HFD)-induced diabetic phenotype on tau expression and exon 10 splicing, we used the well characterized AD mouse model (APdE9) with hyperglycemia induced by the overexpression of pancreatic insulin-like growth factor 2 (IGF2). Four genotype groups were included in the study; wild-type (AwIw), IGF2 overexpressing (AwI+), APdE9 overexpressing (A+Iw), and APdE9 x IGF2 co-overexpressing (A+I+) mice. Mice were fed either with standard chow or with HFD for four months. Before sacrificing, mice went through a behavioral test battery. Tau expression at mRNA level was assessed with quantitative PCR and capillary electrophoresis by using primers flanking exon 10. Tau phosphorylation and protein expression were assessed with Western blot. HFD significantly induced 4R-tau mRNA and protein

expression and tau phosphorylation in the temporal cortex of all female mice regardless of the genotype. The mRNA levels of 3R-tau were also significantly increased by the HFD, although the expression of 3R-tau was considerably lower as compared to that of 4R-tau. Moreover, HFD significantly increased the mRNA ratio of 4R-tau vs. 3R-tau in the temporal cortex of these mice. Increased 4R-tau and 3R-tau mRNA expression correlated with poor spatial memory and reduced exploratory activity. These effects were associated with diet-induced weight gain, but were independent of peripheral hyperglycemia, hyperinsulinemia, and insulin resistance. HFD did not affect neuroinflammation, activation of Akt/glycogen synthase kinase 3β signaling pathway, or the expression of tau exon 10 splicing enhancers in the temporal cortex of the mice. We are currently analyzing the brain metabolic profile of the HFD-fed mice in order to identify the specific lipid(s) responsible for the observed alterations in tau expression and splicing. Our findings provide experimental *in vivo* evidence that HFD, independently from diabetic or AD background, can modulate the expression and alternative splicing of tau. Thus, active dietary choices may modify tau-related pathological mechanisms.

Title: Neuroinflammation and cognitive impairments in a novel transgenic mouse model expressing a rare Tau mutation A152T in progressive supranuclear palsy

Authors: *A. SYDOW[1], K. HOCHGRÄFE[2], S. KÖNEN[1], D. MATENIA[2], O. PETROVA[3], E.-M. MANDELKOW[1,2,3];
[1]DZNE (German Ctr. Neurodegen. Diseases), Bonn, Germany; [2]Max-Planck-Institute for

Neurolog. Res. Cologne, Hamburg outstation, Hamburg, Germany; [3]CAESAR Res. Ctr., Bonn, Germany

Abstract: To mimic pathological hallmarks of genetically provoked tauopathies (e.g. progressive supranuclear palsy), we have generated a novel transgenic mouse model expressing human full-length Tau with a rare point mutation A152T (hTau40/A152T). The transgene is located inside the ROSA26 locus and the expression is controlled by the neuron-specific Thy1.2 promoter resulting in physiological expression levels in the brain and spinal cord of hTau40/A152T mice. The molecular ratios of Tau species (exogenous mutant Tau vs endogenous mouse Tau) are 1-2:1 (brain) and 3:1 (spinal cord), respectively. At young age immunohistological analysis of hTau40/A152T mice demonstrated the presence of pathological Tau conformation (MC1) and Tau hyperphosphorylation (pThr231/pSer235, pSer202/pThr205, pSer396/pSer404) combined with Tau missorting into the somatodendritic compartment of cortical and hippocampal neurons. The detection of Tau-aggregates by Gallyas silver staining and sarcosyl-extraction indicates a progressive co-aggregation of endogenous mouse Tau and exogenous human Tau with increasing age, leading to neuronal loss. Furthermore old hTau40/A152T mice show a prominent neuroinflammatory response as judged by activation of microglia and astrocytes and a rise of inflammatory markers such as inducible nitric oxide synthase (iNOS). In clear contrast to other Tau-transgenic models and Alzheimer disease patients with rather reduced protein clearance, hTau40/A152T mice show a strong induction of autophagy with increased levels of lysosomal (beclin, hsc70, LC3) and proteasomal (proteasome 26S subunit) markers in cortex and hippocampus. Although hTau40/A152T-expression induces Tau hyperphosphorylation and Tau aggregation in spinal cord and motor cortex, transgenic hTau40/A152T mice exhibit unaffected neuromotor performance similar to wild-type littermates as tested by a rotarod test. Importantly, deficits in spatial reference memory (Morris water maze) manifest in hTau40/A152T mice at the age of ~16 months and are accompanied by neurodegeneration as visualized by Fluoro Jade C staining. The pathophysiological characterization shows an excitotoxic phenotype including increased extracellular glutamate and intracellular calcium (see abstract by J. Decker et al.). In conclusion, the hTau40/A152T mouse model mimics pathological hallmarks of tauopathies (Tau hyperphosphorylation, Tau aggregation, neuroinflammation, cognitive decline) and offers potential to evaluate new therapeutic strategies and drug candidates against Tau-induced neurodegeneration.

Abstract: Aims: Generate and characterize a robust non-human primate model of progressive tauopathy by targeted overexpression of mutant or wild type human Tau protein in the hippocampus using adeno-associated viral (AAV) vectors. Background: Recently published results demonstrate the efficacy of lentiviruses to generate a genetic model of tauopathy in rodents. Longitudinal histopathological characterization revealed the presence of aggregates as early as 2 months and different stages of tau protein phosphorylation, conformational change and aggregation were clearly shown. This data supported the development of a non-human primate model of tauopathy where functional deficits could be explored longitudinally *in vivo*. Methods: Intracerebral stereotaxic injections of AAV vectors were performed under preoperative MRI guidance in 12 adult male macaques (M.fascicularis). Primates were injected into the hippocampus bilaterally with an AAV2/9 viral vector bearing a CBA promoter and overexpressing either the WT hTau46 (n=4), the hTau46 P301L mutated form of Tau (n=4) or a null GFP (n=4) where the reporter gene is transcribed but not translated. MRI was used to screen for potential inflammatory reactions and atrophy as well as individual determination of the targeted stereotactic coordinates. All primates were trained to perform a cognitive battery on tactile screens before and at 4, 8, and 12 months post-injection looking at working memory, spatial memory and executive function. Post-mortem histological analysis included MC1, AT8,

AT100, NeuN, GFAP, CD68, and Iba1. The control group is still ongoing. Results: Our preliminary results suggest that overexpressing either wild type or mutated forms of tau leads to a cognitive deficit that is detectable as early as 4 months after viral delivery and stabilizes at 8 months post-infection. The same animals showed no deficit in a visual discrimination task suggesting the specificity of the impairment in spatial, executive and recognition memory. MRI imaging did not evidenced inflammatory reactions or atrophy over time. Ongoing histological analysis confirms the presence of widespread AT8-positive inclusions in the hippocampus and connected regions like entorhinal cortex and the cingulate cortex. These results remain preliminary until the GFP group full data is available. Conclusion: This model of tauopathy based on the use of AAV9-CBA vector has good construct, neuropathological and functional validity and holds great promise for further investigation of therapeutic strategies and tau specific PET ligands in non-human primates.

Title: Cell-restricted deletion of MyD88 affects tau pathology in an hTau mouse model of tauopathy

Authors: N. MAPHIS[1], X. LI[3], B. LAMB[3], *K. BHASKAR[2];
[1]Mol. Genet. Microbiology, [2]Mol. Genet. and Microbiology, Univ. of New Mexico, Albuquerque, NM; [3]Cleveland Clin., Cleveland, OH

Abstract: Tangle pathology (including hyperphosphorylated and aggregated tau) is a major neuropathological hallmark of Alzheimer's disease (AD) and related tauopathies. Increasing evidence suggests that inflammatory processes in the brain precede tau pathology. A previous study from our group has demonstrated that enhancing neuroinflammation either via a Toll-Like Receptor-4 (TLR-4) ligand lipopolysaccharide (LPS) or genetic ablation of the *Cx3cr1* (fractalkine receptor) led to increased tau phosphorylation, aggregation and working memory impairment in a manner dependent upon the activation of interleukin-1 receptor (IL-1R)-p38 mitogen activated protein kinase (p38 MAPK) pathway. To block IL-1R and TLR-4 receptor signaling, we targeted and performed cell-specific deletion of MyD88 - a common adapter protein of IL-1 and TLR-4 receptors using Cre-LoxP technology. First, microglia-restricted deletion of MyD88 (Cd11bCreMyD88$^{f/f}$) was confirmed by isolation of microglia followed by qRT-PCR for MyD88 expression. Second, increased infiltration of CD45+ cells (peripheral monocytes) within the brains of Cd11bCreMyD88$^{f/f}$ mice was observed compared to MyD88$^{f/f}$ mice via flow cytometry. Third, in contrast to what was expected, microglia-restricted deletion of MyD88 led to enhanced AT8- and AT180-site tau phosphorylation. Fourth, gene expression and multiplex protein analysis comparing the CD11bCreMyD88$^{f/f}$ to MyD88$^{f/f}$ suggested alterations in key inflammatory cytokines and chemokines. Finally, we studied the effect of neuronal-restricted deletion of MyD88 in an hTau mouse model of tauopathy (hTau-*Mapt*$^{-/-}$/CamKII[[Unsupported Character - Symbol Font ]]CreMyD88$^{f/f}$) on tau pathology. Notably, we observed a drastic reduction in the levels of truncated neurotoxic tau in the cortex of hTau*Mapt*$^{-/-}$/CamKII[[Unsupported Character - Symbol Font ]]CreMyD88$^{f/f}$ mice compared to our hTau*Mapt*$^{-/-}$ mice, however there was no difference in the phosphorylated-specific tau at the AT8-, AT180- or PHF1-sites. Further studies on the characterization of truncated tau species and the effect of microglia-restricted (CD11b) deletion of MyD88 on tangle pathology and cognitive function are ongoing.

Title: Hypertension increases tau hyperphosphorylation and Aβ production in 3XTg-AD mice

Authors: *Y.-H. SHIH[1], C.-W. LEE[1], T.-W. LIN[1], S.-F. TSAI[1], Y.-M. KUO[1,2];
[1]Inst. of Basic Med. Sciences, Natl. Cheng Kung Univ., Tainan, Taiwan; [2]Dept. of Cell Biol. and Anatomy, Natl. Cheng Kung Univ., Tainan, Taiwan

Abstract: Objective: Epidemiological studies suggest chronic hypertension (HTN) is associated with late-onset AD. However, whether HTN is a cause for AD or merely a comorbid remains unclear. This study is to investigate the role of HTN in the pathogenesis of AD. Methods: We use the modified two-kidney one-clip (2K1C) to induce HTN in 3XTg-AD mice. The blood pressure and AD-related pathology in the hippocampus were measured 1 month after the surgery. Sham operation served as controls. Results: 2K1C resulted to blood pressure elevated and consistent after surgery 1 month compared to sham groups. The performance of learning and memory was impaired in object recognition test but not in radial arm water maze in HTN group. The level of hippocampal Aβ40 and Aβ42 was increased and positively correlated to mean blood pressure changed ratio. The p412-tau-postive stains were enhanced in the ventral parts of hippocampus. The level of GSK3β, a tau protein phosphorylation kinase, was unaffected by 2K1C. Conclusion: These results suggest that HTN may not cause AD, yet it may contribute and aggravate the pathogenesis of AD.

Title: Reduction/delay of phenotype in Tg4510 tauopathy model following gestational doxycycline treatment and removal of helicobacter infection

Authors: *D. M. BARTEN, A. EASTON, B. SNYDER, L. B. DECARR, C. BOURIN, G. HIRSCHFELD, G. W. CADELINA, S. KEENAN, D. BRYCE, A. CACACE, C. M. CONWAY,

M. K. AHLIJANIAN, N. DEVIDZE;
Exploratory Biol. & Genomics, Bristol-Myers Squibb, WALLINGFORD, CT

Abstract: The phenotype of transgenic mouse lines often varies between colonies of animals at different sites, or can drift over time within a colony. The Tg4510 bi-genic tauopathy mouse model overexpresses the tetracycline-controlled transcriptional activator (tTA) driven by the Cam kinase II (CamKII) promoter, which initiates transcription of the human tau-P301L transgene through the tetracycline operon-responsive element (TRE). Doxycycline (Dox) treatment of the mice reduces transgene expression by 75 percent. Unlike literature reports, the Tg4510 colony at our facility showed a significant loss of CA1 neurons as early as 2 months of age. Based on this neuropathology, it is not surprising that 2 month Tg4510 mice were cognitively impaired, although previous reports found no deficits at this age. Doxycycline treatment of the dams from inception to P21 (weaning) or P0 (birth) prevented this developmental loss of CA1 neurons. Tg4510 mice treated with Dox during development were studied longitudinally to determine the onset of behavioral deficits, tau pathology and neurodegeneration. A significant delay in the tauopathy phenotype was observed when transgene expression was reduced during gestation. In a separate observation, we noted that the founder animals and our colony harbor helicobacter. Helicobacter species infect the gastrointestinal tracts of many of species, including over 50% of humans. Most subjects/animals show no clinical signs, and it is widespread in many otherwise specific-pathogen free colonies. Breeders at the BMS colony treated with a combination of amoxicillin, clarithromycin, metronidazole, and omeprazole (BioServ) for several generations were found to be helicobacter-free using PCR analysis of feces. Helicobacter-free CamKII tTA female and TRE tau-P301L male mice were bred to generate Tg4510 bi-transgenic mice. Importantly, the Tg4510 mice themselves had no antibiotic treatment during gestation or later. Helicobacter-free Tg4510 mice showed reduced tau pathology compared to helicobacter positive mice, but they still retained developmental loss of CA1 neurons measured at 2 months of age. These data demonstrate the impact of transgene expression during gestation, as well as the effects of a peripheral bacterial infection on a central tauopathy phenotye in transgenic mice. These observations may help to explain the phenotypic variability observed between colonies of a single line of transgenic mice.

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder that is characterized by the progressive deposition of amyloid plaques and neurofibrillary tangles (NFTs), composed of tau. Accumulation of these lesions is associated with synapse loss, neuronal death, and subsequent cognitive decline. In early stages of AD, NFT pathology occurs in the entorhinal cortex and medial temporal lobe from where it spreads along synaptic connections throughout limbic and association cortices. Understanding how tau pathology spreads in AD may reveal new therapeutic targets for AD. However, the mechanism underlying inter-neuronal transfer of pathological tau is unknown: pathological aggregates may be directly transported between synaptically-connected neurons, pathological tau may provide a template for the recruitment and subsequent misfolding of non-pathological tau, or both. In order to test these possibilities, we generated a novel transgenic mouse model of tauopathy. rTgTauEC mice overexpress human tau harboring the P301L mutation in layer II of the entorhinal cortex (EC). In these mice, NFTs form first in the transgene-expressing neurons in the EC and then progress to neurons without detectable transgene expression, including neurons in the dentate gyrus (DG), hippocampus, and frontal cortex. We crossed these mice with mice lacking murine tau (TauKO) to generate a new line that expresses human P301L tau within the EC in the absence of endogenous mouse tau. We examined human tau localization in 18 month-old brain sections from three mice strains: rTgTauEC, TauKO, and TauKO x rTgTauEC. Brain tissue was sectioned by cryostat into 10 micron horizontal sections, and human tau was visualized by immunohistochemistry using TauY9 antibody. As expected, brains from both rTgTauEC and TauKO x rTgTauEC mice showed localized human tau expression in the EC. In addition, we identified human tau-positive neurons in hippocampus and somatosensory cortex, indicating propagation of tau in both mouse lines. Interestingly, the numbers of human tau-positive neurons in the DG was not significantly different between rTgTauEC and TauKO x rTgTauEC mice. Levels of phosphorylated human tau, as identified by phospho-specific tau antibodies were similar in both mouse lines. However, only rTgTauEC brains showed tau aggregates, as visualized by both immunoreactivity to Alz50 antibody and staining with thiazine red. We conclude that inter-neuronal propagation of pathological human tau does not require the presence of endogenous mouse tau, suggesting that recruitment of non-pathological forms of tau is not necessary for spreading of NFT pathology.

Title: Sustained oligomeric Aβ exposure decreases GLT-1 steady state levels in astrocytes without altering its transcription

Authors: *J. M. ZUMKEHR, C. HAWKINS, M. KITAZAWA;
Mol. and Cell Biol., UC Merced, Merced, CA

Abstract: The disruption of the glutamatergic neuronal network has been suggested to contribute to synaptic loss and cognitive decline in Alzheimer's disease (AD). Astrocytes play an important role in regulating this network through the expression of the glutamate transporter 1 (GLT-1). Impairment of glutamate uptake by astrocytes has been reported in AD and the knockdown of GLT-1 in AD mice exacerbates cognitive decline. We previously demonstrated that GLT-1 levels decreased in an age-dependent manner in 3xTg-AD mice and that the pharmacological up regulation of GLT-1 in these mice rescued cognition, restored synaptic density and ameliorated tau pathology without affecting Aβ pathology. Our *in vivo* evidence suggests that a functional loss of GLT-1 is mediated by Aβ toxicity. Therefore, we hypothesize that certain toxic Aβ assembly states downregulate GLT-1 in astrocytes and promote other AD neuropathology including tau and synaptic loss. To test our hypothesis, we examine the mechanistic link between GLT-1 and Aβ *in vitro*. We find that pathologically-relevant, naturally secreted Aβ oligomers from the conditioned media of 7PA2 cells significantly decrease the steady state levels of GLT-1 in the primary neuron and astrocyte cell co-culture system. Aβ oligomers, however, did not change mRNA expression levels of GLT-1 which suggest that Aβ oligomers functionally inactivate GLT-1 by facilitating its degradation. Our results also suggest that sustained Aβ oligomers exposure significantly decrease GLT-1 steady state levels in astrocytes which may lead to the development of tau pathology, synaptic loss and neuronal loss in AD.

Title: Toxic events of beta-amyloid oligomers on cortical neurons and protective effect of beta-Estradiol: A mechanistic study

Authors: *N. CALLIZOT, M. COMBES, P. POINDRON;
Neuro-Sys, Gardanne, France

Abstract: Alzheimer disease (AD) affects mainly people over the age of 65 years, suffering from different clinical symptoms such as progressive decline in memory, thinking, language, and learning capacity. The toxic role of beta amyloid peptide (Ab) has now shifted from insoluble Ab fibrils to smaller, soluble oligomeric Ab aggregates (AbO). Many evidences suggest that the neurodegenerative process would be due to the interaction of AbO with binding targets, activation of stress kinases, hyperphosphorylation of tau protein, caspase activation, loss of synapse, neuronal death, loss of cholinergic function, generation of reactive intermediates of oxygen (oxidative stress), or glutamate excitotoxicity. Urgent need for efficient new therapies is high, but could only be successful with an extensively comprehension of AbO degeneration process. In the present work, based on an *in vitro* primary cell culture treated with AbO preparation, we have carefully studied the cytopathological effects of AbO on neuronal death and then we have investigated the effect of 17-beta Estradiol (B-estr) on the degeneration process induced by AbO. Briefly we used rat cortical neurons (from E15). The cells were seeded in 96-well plates and intoxicated with AβO solution after 11 days of culture for 24 hours. B-estr was used at 100 nM (final concentration) and was added as pretreatment (1h before injuries). A co-incubation with selective inhibitors was performed for the mechanistic study. In parallel, western blotting (WB) analysis was done to quantify protein levels and their activation. We showed that B-estr was able to significantly protect neurons as well as glial cells from degeneration decreasing the caspase 3 activation and the massive mitochondrial stress (induced by AbO). Preservation of neurite network and synapsis integrity was also observed. Moreover, the large hyperphosphorylation of tau protein induced by AbO was significantly reduced with B-Estr. A mechanistic study was also performed co-incubating inhibitors of main survival pathways to try to better understand the mode of action of B-estr and the pathway involved in the AbO toxicity. We showed that the effects of b-Estr were fully abolished blocking the MEK pathway as well as the DNA repair pathway (PARP-g) or the mitochondrial anti-apoptotic pathway (Bcl2). Interestingly the effect was inexisting coincubating B-estr with TrK receptor or Ras/Raf inhibitors showing the predominant role of growth factors paythway in its neuroprotective effect. Finally, we showed a large inactivation of AKT protein in presence of AbO that was reversed even over activated in presence of B-Estr.

Title: Aβ1-42 reduces P-glycoprotein in the blood-brain barrier through RAGE-NF-κB signaling

Authors: *J. PARK, R. PARK, S.-Y. KOOK, S.-M. SON, S.-H. HAN, I. MOOK-JUNG; Dept. of biomedical science, Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: The reduced clearance of amyloid-β peptide (Aβ) from the brain partly accounts for the neurotoxic accumulation of Aβ in Alzheimer's disease (AD). Recently, it has been suggested that P-glycoprotein (P-gp), which is an efflux transporter expressed on the luminal membrane of the brain capillary endothelium, is capable of transporting Aβ out of the brain. Although evidence has shown that restoring P-gp reduces brain Aβ in a mouse model of AD, the molecular mechanisms underlying the decrease in P-gp expression in AD is largely unknown. We found that Aβ1-42 reduced P-gp expression in the murine brain endothelial cell line bEnd.3, which was consistent with our *in vivo* data that P-gp expression was significantly reduced especially near amyloid plaques in the brains of five familial AD mutations (5XFAD) mice, which are used as an animal model for AD. A neutralizing antibody against the receptor for advanced glycation end products (RAGE) and an inhibitor of nuclear factor-kappa B (NF-κB) signaling prevented the decrease in Aβ1-42-induced P-gp expression, suggesting that Aβ reduced P-gp expression through NF-κB signaling by interacting with RAGE. In addition, we observed that the P-gp reduction by Aβ was rescued in bEnd.3 cells receiving inductive signals or factors from astrocytes making contacts with endothelial cells (ECs). These results support that alterations of astrocyte-EC contacts were closely associated with P-gp expression. This suggestion was further supported by the observation of a loss of astrocyte polarity in the brains of 5XFAD mice. Taken together, we found that P-gp down regulation by Aβ was mediated through RAGE-NF-κB signaling pathway in ECs and that the contact between astrocytes and ECs was an important factor in the regulation of P-gp expression.

Title: Identification of 5-methoxyflavone as a novel DNA polymerase-beta inhibitor and neuroprotective agent against beta-amyloid toxicity

Authors: S. MERLO[1], L. BASILE[2], M. SORTINO[1], F. NICOLETTI[3], S. GUCCIONE[2], *A. G. COPANI[2];

Abstract: DNA replication is an obligatory step in the apoptotic pathway triggered by beta-amyloid in neurons. Neuronal DNA replication is unusual, since it is carried-out by DNA polymerase-beta (pol-beta), and likely lasts months before the occurrence of neuronal Death (reviewed in Copani et al., Curr Med Chem 2008). Pol-beta might therefore represent a relevant target for neuroprotection in Alzheimer's disease (AD). Known pol-beta inhibitors are not selective for the enzyme; dideoxycytidine, which we have shown to prevent beta-amyloid-induced DNA replication and apoptosis (Copani et al., Faseb J. 2002), is a preferential inhibitor of pol-beta over DNA polymerase-alpha and delta. We searched for selective pol-beta inhibitors by virtual screening of a database containing more than 4,000 natural and over 20,000 drug-like compounds. Twenty compounds were selected for their best-fit pose on the 8-kD domain of the enzyme. So far, we have tested nine of the selected compounds on both wild type and pol-beta-null mouse fibroblasts, which are hypersensitive to the DNA-methylating agent methylmethanesulfonate (MMS). Among the tested compounds, only 5-methoxyflavone was able to enhance cellular sensitivity to MMS in wild type but not in pol-beta null cultures, and the resulting sensitivity to MMS in wild type cells mimicked that observed in pol-beta null cells. Thus, 5-methoxyflavone was able to inhibit the base-excision repair activity of pol-beta required for MMS resistance. Similarly, the compound directly inhibited human pol-beta activity on a gapped DNA substrate. In pure cultures of rat cortical neurons, 5-methoxyflavone was devoid of intrinsic toxicity when applied for 48 hrs and up to a concentration of 10 microM. These cultures are a useful model to investigate potential inhibitors of beta-amyloid-induced DNA replication and apoptosis (Copani et al., Faseb J. 2002; Copani et al., J. Neurosci. 2006). Consistent with an inhibition of pol-beta, 5-methoxyflavone (5-10 microM) was able to reduce both the number of S-phase neurons and apoptosis triggered by soluble oligomers of beta-amyloid.

Title: Agonists of sigma1-receptor, donepezil and PRE-084, rescue hippocampal long-term potentiation impaired by beta-amyloid peptide

Authors: *E. I. SOLNTSEVA, N. A. KAPAI, O. V. POPOVA;
Brain Res. Dept., Res. Ctr. of Neurology, Rus Acad Med. Sci., Moscow, Russian Federation

Abstract: Donepezil is a potent acetylcholinesterase inhibitor used for the treatment of Alzheimer's disease (AD). Additional therapeutically relevant target for donepezil is sigma1 receptor (Sig1-R). Beta-amyloid peptide (Aβ) is believed to contribute to the pathogenesis of AD. In our previous work (Kapai et al., 2012) we have shown that donepezil antagonizes the suppressive action of Aβ(1-42) on long-term potentiation (LTP) in rat hippocampal slices. The purpose of the present study was to determine whether Sig1-R is involved into the mechanisms of donepezil action. For this purpose, we have tested whether agonist of Sig1-R PRE-084 mimics, and antagonist of Sig1-R haloperidol abolishes the effect of donepezil. Population spikes (PS) were recorded from the pyramidal layer of the CA1 region of rat hippocampal slices. LTP of PS was induced using a train of high frequency stimulation (100 Hz, 1 s). Drugs were applied by addition to the perfusate starting 15 min before and ending 5 min after the tetanus. In the control group, the amplitude of PS 30 min post-tetanus reached 153±10%. Aβ1-42 (200 nM) markedly suppressed the LTP magnitude or even caused the suppression of baseline PS (82±8%, $P<0.001$). This suppression of LTP could be markedly prevented when 1 μM donepezil was co-administered with Aβ (136±11%, $P<0.05$). Further, we co-administered three substances: Aβ, donepezil and 0.5 μM haloperidol, and have found that haloperidol antagonized the stimulating effect of donepezil on LTP (92±6%, $P<0.05$). Neither donepezil, nor haloperidol changed control LTP. Agonist of Sig1-R PRE-084 at concentration of 1 μM did not influence PS evoked by

single stimuli but significantly augmented the LTP (209.3 ± 15.5%, P<0.05). Then PRE-084 was co-administered with Aβ in the following concentrations: 0.1 μM, 0.5 μM, 1 μM and 10 μM. The drug was found to reverse LTP impairment in a dose-dependent manner. The concentration of 0.1 μM was not effective (79.8 ± 12.0%), while addition of higher concentrations of the drug to Aβ solution caused significant improvement of LTP. The LTP amplitude 30 min post-tetanus restored to 139.0 ± 11.5% for 0.5 μM (P < 0.05), to 172.4 ± 5.5% for 1 μM (P < 0.01) and to 183.0 ± 7.3% for 10 μM PRE-084 (P < 0.01). In conclusion, our observations show for the first time that selective agonist of Sig1-R PRE-084 can facilitate both control and Aβ impaired LTP, and this effect mimics the effect of donepezil. In addition to that, antagonist of Sig1-R haloperidol was found to abolish the stimulating effect of donepezil on LTP impaired by Aβ, which confirms the involvement of Sig1-R in the observed effect of donepezil.

Title: Mechanism of toxic effect of amyloid beta peptide on Kv1.1 channel activity

Authors: *K. DEBOEUF[1,2], M. ISLAM[2], M. PACE[2], B. HALLAHAN[3], J. FARLEY[1,2]; [1]Psychology, [2]Neurosci., Indiana Univ., Bloomington, IN; [3]Pharmaceut. Sci., Univ. of Kentucky, Lexington, KY

Abstract: Amyloid beta-peptides [e.g., Aβ (1-42)] have frequently been implicated in the pathogenesis of Alzheimer's disease. Previous studies have found that neurotoxic Aβ peptides lead to the eventual disruption of calcium (Ca2+) homeostasis and can even disrupt synaptic transmission long before cell death occurs. However, the precise mechanism of these effects remains unclear. Our work suggests that Aβ- suppression of voltage-dependent K+ channel activity is among the earliest key steps in these processes. Using Xenopus oocytes, we have elucidated a pathway in which Ca2+-dependent activation of protein phosphatase 2B (PP2B/calcineurin), protein kinase C (PKC), an as yet unidentified protein tyrosine kinase (PTK), and the small G-protein RhoA all participate to produce profound suppression of Kv1.1 activity. This pathway is recruited by a variety of stimuli that increase [Ca2+]i in oocytes, including exogenous and endogenous GPCRs that couple to Gq/11 -PLC, calcium ionophore

(A23187), and ligand-gated ion channels that flux Ca2+. Because Kv1.1 and related K+ channels are activated during an action potential, are potent regulators of Ca2+ influx during depolarization, and pharmacological inhibition of Kv channels is often neurotoxic, we speculate that Aβ could disrupt Kv channels and thus lead to hyperexcitability, altered synaptic transmission, disruption of Ca2+ homeostasis, and neurotoxicity. We assessed the effects of Aβ (1-42) peptide (monomers and low-n oligomers) on heterologously expressed Kv1.1 channels in oocytes. Low (1uM-10 nM) concentrations produced a rapid, dose-dependent, suppression of macroscopic Kv1.1 current: ~50% reductions within 30 m. Reverse sequence (40-1) control peptide, as well as solvent-alone, failed to suppress Kv1.1. Additional studies showed Aβ suppression was partially Ca2+-dependent, and was reduced by ~50% when oocytes were loaded with BAPTA-AM. Aβ suppression of Kv1.1 also involves PP2B, since it was partially blocked (~50%) by the PP2B-inhibitor, cyclosporine A. The Aβ-produced Ca2+ increase did not occur via Ca2+ influx (e.g., through Aβ-mega pores), since complete removal of extracellular Ca2+ failed to attenuate Aβ-suppression of Kv1.1. Instead, it appears that Aβ is releasing Ca2+ from internal stores. Current lab work suggests aging (1 hr vs. 12 hrs.) may affect Aβ aggregate forms (soluble monomers vs. low-n oligomers), thus altering the extent of Kv1.1 channel activity suppression. Preliminary single channel work suggests the possibility that Aβ-suppression of Kv1.1 may also involve direct protein-protein interaction of Aβ with Kv1.1 channel subunits.

Title: Role of somatostatin in β-amyloid induced cytotoxicity in human brain endothelial cells

Authors: S. PAIK, R. K. SOMVANSHI, C. SINGH, S. ZOU, *U. KUMAR;
Pharmaceut. Sci., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Introduction: We recently demonstrated that somatostatin (SST) improves inflammation induced impaired distribution of ZO-1 in human brain endothelial cells (hCMEC/D3). In addition, we have also described changes in SST release and accumulation in cultured cortical neurons in response to β-amyloid. In several neuropathological conditions including Alzheimer's disease (AD), impaired blood brain barrier (BBB) play crucial role in brain damage. However, nothing is currently known whether receptor proteins exert any role in the protection of BBB. Accordingly in the present study, we used human brain endothelial cells and β-amyloid as a model of AD and determined concentration and time-dependent effect of SST in response to β-amyloid induced toxicity. In addition, we also determined the changes in expression and distributional pattern of SSTR and NMDAR subtypes at the level of mRNA and protein, respectively. Methods: hCMEC/D3 cell line was used for the experiments. β-amyloid induced toxicity was determined by using MTT assay in presence or absence of SST in concentration dependent manner. To determine whether the cells were displaying apoptosis or necrosis, Hoechst and PI staining was used. Subcellular distribution of SSTRs and NMDARs was determined by using immunofluorescence staining. Quantitative expression of SSTRs and NMDARs was determined by qRT-PCR and western blot analysis. Results: MTT assay revealed that β-amyloid consistently elicited dose-dependent toxicity. Interestingly, SST showed biphasic effect against β-amyloid by displaying protection at low concentration (1nM), however, the protective effect was gradually decreased with increasing concentration of SST. In addition, we have also characterized that SSTR and NMDAR subtypes are expressed in hCMEC/D3 cell in a receptor specific manner. Conclusion: SST elicit protective role against β-amyloid induced toxicity in hCMEC/D3 cells via alteration of SSTR and NMDAR subtype specific interaction.

Title: H2o2-upregulated rage on ab-induced oxidative pathway and membrane phase changes in bend3 cells

Authors: *C. EST, H. WANG, J. LEE;
Univ. of Missouri - Columbia, Columbia, MO

Abstract: Although the implication of amyloid-β (Aβ) in the pathogenesis of Alzheimer's Disease is still a matter of debate, increasing evidence has shown that Aβ is a pivotal component which directly influences cellular membrane alterations and triggers cellular signaling cascades leading to responses such as neuro-inflammation. The overall goal of this study is to investigate the role of hydrogen peroxide (H2O2) upregulated RAGE (receptor for advanced glycation end products) on the Aβ induced oxidative pathway and membrane phase changes in mouse cerebral endothelial cells (CECs). b.End3 cells were treated with H2O2, 5 μM Aβ, or the two in succession. First, the levels of RAGE normalized by β-actin were determined by the immune-blotting of RAGE rabbit/anti-rabbit primary and secondary antibodies. Following a positive MTT analysis, the expression of Aβ-induced superoxide after H2O2 treatment was elucidated by fluorescent microscopy of dihydroethidium (DHE), a flourescent DNA probe. The intensity of fluorescence directly correlates to activity of reactive oxygen species (ROS). Next, cytosolic phospholipase2 (c-PLA2) expression was measured by Western blotting, as c-PLA2 is known to play a role in the mediation of the neurotoxic effects of Aβ. Lastly, fluorescent microscopy of Laurdan was utilized to determine cell membrane molecular order; two fluorescent images at different wavelengths are overlaid to determine the generalized polarization (GP), where a high GP indicates high molecular order, and a low GP indicates low molecular order. Analysis of RAGE levels shows a maximal expression at H2O2 concentrations of 25 μM, and this concentration was used in subsequent experiments. DHE experiments show that H2O2 increases ROS expression after 24 hours, but at a lower extent than a two hour treatment of Aβ. Interestingly, Aβ treatment immediately following the 24 hour H2O2 treatment increases ROS expression at levels significantly lower than either treatment alone. Further supporting these findings, the Laurdan data shows a decrease in GP initially following H2O2 treatment, then a shift towards high GP, maximizing at the 24 hour observation. However, the H2O2/Aβ successive treatment shifts back towards a slightly high GP, but with a significantly less ordered membrane than the 24 hour treatment H2O2. Controlling oxidative stress is considered to be an important therapeutic method for AD, and the data of this experiment shows that a mechanism must exist that counteracts the combined damage of H2O2 and Aβ in succession, so further research is necessary to elucidate the structure of this response, which may lead to strong candidates for therapeutic treatment.

Title: Changes to tight junctions in the blood-brain barrier mediated by $A\beta^{25-35}$-RAGE interaction

Authors: *S. M. LANTZ-MCPEAK[1], E. CUEVAS[1], H. R. HERNANDEZ[2], M. G. PAULE[1], S. F. ALI[1], S. Z. IMAM[1];
[1]Div. of Neurotoxicology, NCTR/FDA, JEFFERSON, AR; [2]Lab. de Fisiología Celular, Facultad de Ciencias Químicas, Univ. Autónoma de San Luis Potosí, San Luis Potosí, Mexico

Abstract: Due to its high-energy demands, sensitivity to reactive oxygen species (ROS) and apoptosis, the neuron is one of the cell types most vulnerable to mitochondrial damage. There have been numerous reports of associations between mitochondrial damage and diverse neurodegenerative diseases including Parkinson's disease (PD) and Alzheimer's disease (AD). Such associations are thought to be mediated by oxidative stress. Overproduction and accumulation of amyloid-β peptide (Aβ) is a hallmark pathologic feature of AD. Although $A\beta^{1-42}$ accumulates in the neuritic plaques in AD patients, it has been suggested that $A\beta^{25-35}$ is the toxic domain of this peptide. Recently, we demonstrated that microinjection of $A\beta^{25-35}$ into the rat hippocampus produced neurotoxicity mediated by the receptor for advanced glycation end products (RAGE). It has been demonstrated that RAGE interacts with Aβ and mediates Aβ transport across the blood-brain barrier (BBB), contributing to the deposition of Aβ in the brain. However, the molecular mechanisms behind the Aβ-RAGE interacts that underlie such transport is poorly understood. In order to determine whether the toxicity associated with $A\beta^{25-35}$-RAGE interactions involves tight junction disruptions in the BBB, a primary culture of rat brain microvessel endothelial cells (rBMECs) was prepared by enzymatic digestion and differential centrifugation as an *in vitro* model of the BBB. Confluent rBMEC monolayers (10-14 days) were treated with $A\beta^{25-35}$ or $A\beta^{35-25}$ (as control) at 20 μM for 24 hours. Changes in RAGE, occludin (OC), and claudin-5 (C-5) expression were determined utilizing Western blot techniques. Cytotoxicity was evaluated using an XTT assay and Mitotracker for assessment of mitochondrial function, detection of DCFH-DA to measure ROS production (oxidative stress), and an LDH assay for membrane integrity. Trans epithelial electric resistance (TEER) and fluorescein flux were used as indicators of rBMEC permeability. $A\beta^{25-35}$ treatment resulted in an increase in RAGE, OC, and C-5 expression, indicating disruption of tight junctions. Significantly decreased mitochondrial function and TEER, as well as increased oxidative stress and fluorescein flux were also observed. These data suggest that toxicity associated with the $A\beta^{25-35}$-RAGE interaction is mediated by oxidative stress, which ultimately leads to cell death and disruption of BBB integrity, thereby increasing the permeability of the BBB and decreasing its protective function.

This compromised functionality of the BBB warrants further studies using markers of $A\beta^{25-35}$ and RAGE to further elucidate their interaction and involvement in neurodegenerative diseases.

Title: Role of Adiponectin in the pathogenesis of Alzheimer's disease

Authors: *U. YUN, J. JEONG, U. YUN, Y. CHOI;
PHARMACY, SUNGKYUNKWAN UNIVERSITY, SUWON, Korea, Republic of

Abstract: Extensive epidemiological studies have shown that unexplained weigh loss is associated with the Alzheimer's disease but the mechanism linking AD and weight loss remains obscure. Currently, possibilities that hormones secreted from adipocytes may have roles in the development of Alzheimer's disease have suggested in several studies. The adipocyte-derived bioactive protein, adiponectin, is specifically expressed in adipose tissue. Adiponectin has attracted attention in recent years as therapeutic target for the metabolic syndrome. A recent finding revealing the correlation of elevated adiponectin levels in plasma and CSF to AD patients provides evidence suggesting adiponectin as a clue for linking AD. Adiponectin receptor 1 (ADR1) and adiponectin receptor 2 (ADR2) are the major receptors for adiponectin and can be activated by all forms of adiponectin found in the circulation. In the brain, ADR1 and 2 are expressed in the arcuate and the paraventricular nuclei of the hypothalamus, where they regulate feeding behaviors and cerebral cortical neurons. However, functions of adiponectin and ADRs in Alzheimer's disease are still poorly understood. In this study, we showed that adiponectin expression was consistently and significantly increased in the brains of Alzheimer's disease mouse model. It suggests that further studies of the functions of adiponectin signaling in Aβ metabolism and toxicity are warranted

Title: Differential membrane toxicity of Aβ fragments by pore forming mechanisms

Authors: *C. M. PETERS[1], E. FERNÁNDEZ-PÉREZ[1], D. BASCUÑÁN[1], M. ESPINOZA[1], C. OPAZO[2], L. G. AGUAYO[1];

Abstract: Introduction. Alzheimer´s disease (AD) is a progressive neurodegenerative pathology that affects the human brain and causes cognitive and behavioral disorders. A major characteristic of AD is the presence of β-amyloid peptide (Aβ) oligomers in the brain. We have previously shown that Aβ oligomers (Aβo) associate with the neuronal membrane and induce the formation of perforations, causing an influx of calcium ions and increasing the release of synaptic vesicles that leads to a delayed synaptic failure produced by vesicle depletion. Several studies suggest that Aβ fragments, produced in the brain by enzymatic processing, can produce toxic effects similar to those of Aβ42. Here, we evaluated three Aβ fragments from different regions of Aβ; Aβ1-28 from the N-terminal region, Aβ25-35 from the central region and Aβ17-42 from the C-terminal region. Materials and methods. With the aim of determining the role of the different regions of Aβ on neurotoxicity, we performed a series of experiments to evaluate the toxicity of Aβ fragments. We used patch clamp, immunofluorescence, western blot, calcium imaging and viability assays. Results. Our results show that Aβ readily associated to the plasma membrane of several cell types such as CA1 hippocampal neurons, primary hippocampal cultures and HEK cells after 1 h of incubation. Moreover, Aβ changed the normal membrane conductance inducing the formation of pore-like structures. The latter produce a delayed synaptic failure. Although all the tested fragments of Aβ were found to produce toxicity when we used MTT viability assays, only Aβ25-35 was able to induce membrane perforation. Moreover, Aβ25-35 increased the intracellular calcium levels in acute applications, observing similar results with Aβ42 and Aβ1-28, but not with Aβ17-42. Conclusion. We conclude that Aβ fragments produced

toxic effects similar to those observed with Aβ42. The results suggest that the center region of Aβ (25-35) is important for membrane perforation and calcium increase; the N-terminal region (1-28) contributes to the increase in intracellular calcium, but not in the membrane perforation, likely by interacting with calcium receptors; and the C-terminal region, represented with the fragment produced by the α-secretase (17-42), induced mitochondrial toxicity, but not membrane perforation and calcium increase, supporting the idea of less toxicity in the non-amyloidogenic pathway.

Abstract: Amyloid β protein (Aβ) plays a central role in pathogenesis of Alzheimer disease (AD). Recently nonfibrillar Aβ assemblies (termed oligomers), varying in size from dimers to multimers, are considered to play more proximal roles in AD. To elucidate the molecular identities of pathogenic Aβ oligomers and their neuronal targets leading to neurodegeneration in AD, we have previously isolated highly toxic spherical Aβ assemblies termed "amylospheroids" (ASPD) from AD patients' brains (Hoshi M et al. PNAS2003, Noguchi A et al. JBC2009). Patient-derived ASPD were toxic to human mature neurons and their amount in AD susceptible regions well correlated with pathological severity of AD. Furthermore, we found that ASPD bind to mature neurons specifically and cause severe neurodegeneration. In this study, as a first step to dissect the molecular mechanism of ASPD neurotoxicity, we examined whether ASPD exposure to mature neurons affected their intracellular free calcium level ($[Ca^{2+}]i$). Measurement of $[Ca^{2+}]i$ responses to ASPD showed that $[Ca^{2+}]i$ responses were enhanced in mature neurons treated with ASPD. The addition of EGTA, calcium chelator, abolished the progressive elevation of $[Ca^{2+}]i$ caused by the ASPD treatment and BAPTA-AM, $[Ca^{2+}]i$ chelator, blocked ASPD neurotoxicity. Taken together, ASPD neurotoxicity requires Ca^{2+} influx. Further studies using inhibitors against Ca^{2+} related channels, we found that N-type voltage gated calcium channels (VGCC) are involved in ASPD neurotoxicity. Interestingly, the abnormal Ca^{2+} overload induced by ASPD activated two tau protein kinase, CDK5 and GSK3β, and increased the phosphorylation of tau. ASPD binding to mature neurons is likely to cause such VGCC activation and eventual tau phosphorylation. However, whether or not ASPD directly bind to VGCC has remained to be elucidated. Therefore, we are currently searching for ASPD target protein(s) present on the mature neuronal surface, which are responsible for the above Ca^{2+}-mediated neurotoxicity of ASPD.

Title: Alzheimer's amyloid degradation by secreted lysosomal enzymes

Authors: *S. SOLÉ-DOMÈNECH[1], D. L. WAKEFIELD[2], E. CAPETILLO-ZARATE[1], D. CRUZ[1], B. A. BAIRD[2], F. R. MAXFIELD[1];

Abstract: In Alzheimer's disease (AD), some brain regions associated with neurodegeneration present abundant amyloid-beta (Aβ) fibrillogenesis. It is unclear how microglia or macrophages in the brain can proteolytically degrade Aβ fibrils (fAβ) and plaques that are significantly larger than these cells. A new possible mechanism is suggested by an earlier study published by our lab in which it was found that macrophages could degrade very large aggregates of LDL by creating an extracellular, acidic compartment that we called the "lysosomal synapse" into which lysosomal contents are secreted (Haka et al. 2009). To study the interaction of microglia and macrophages with fAβ, and in collaboration with the Cornell NanoScale Science & Technology Facility (CNF), we fabricate surfaces to present spatially defined fluorescently labeled streptavidin on glass cover slips which are thereafter incubated with Aβ-Cy3-biotin fibrils of 100-200nm in length. Biotinylated fAβ is captured by the multivalent streptavidin, thus immobilizing fAβ onto the glass surface (Fig. A). Macrophages and microglia, for which their lysosomes were previously labeled with FITC-dextran, are subsequently incubated on the fAβ-coated micro-pattern and imaged using Total Internal Reflection Fluorescence Microscopy (TIRFM). TIRFM reveals rapid FITC flashes (indicated by white arrowheads in Fig. B) at the pattern surface which are indicative of lysosomal content release. As FITC exits the lysosomes, it undergoes fluorescence increase associated with the transition from the acidic lysosomal environment to the more alkaline pH of the extracellular environment. Measurements from a reduced number of samples indicate that macrophages incubated on fAβ-coated surfaces present higher secretory activity when compared to those exposed to streptavidin-coated surfaces (Fig. C). The proposed studies are aimed at exploring new ground for treatments based on the use of therapeutic agents to increase lysosomal activity. These could potentially lead to an enhancement in microglia fAβ lysosomal degradation and clearance.

Title: Treatment of neurons with coconut oil and constituent fatty acids attenuates the effects of amyloid beta *in vitro*

Authors: *K. M. MEAROW[1], F. NAFAR[2];
[1]Div. Biomed. Sci., Mem. Univ. Newfoundland, St John's, NL, Canada; [2]Div. of BioMedical Sci., Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: Dietary supplementation has been studied as an approach to ameliorating deficits associated with aging and neurodegeneration. In particular, recent anecdotal evidence has touted the use of coconut oil as having major benefits in lessening the cognitive deficits associated with Alzheimer's disease. Coconut oil has a high percentage of medium chain triglycerides (MCTs, approx. 70% of C:6-12), with caprylic and capric acid comprising ~ 21% of these MCTs in

virgin coconut oil. While there is rather limited scientific evidence that such treatment would have a significant effect on disease, there is scientific basis behind the use of MCTs, such as those found in coconut oils. MCTs can be rapidly metabolized to induce metabolic ketosis and ketone bodies can then be used as an alternative to glucose for energy requirements. We recently reported that treatment of cultured cortical neurons with coconut oil could rescue the cells from the deleterious effects of Aβ exposure. In the current study we extend our investigation to include coconut oil and its major constitutent fatty acids caprylic/octanoic (C8) acid and lauric (C12) acid, as well as an examination of treatment timing and duration in cultures of neonatal cortical and hippocampal neurons. Cultures of cortical or hippocampal neurons were exposed to a variety of treatment paradigms. In initial experiments, cultures were concomitantly treated with Aβ and oil/FAs; subsequently we investigated treatment with Aβ for 1, 6 or 24 hrs followed by addition of oil/FAs for a further 24 hrs. Neuronal survival was assessed using standard survival assays, while confocal microscopy was employed to analyze mitochondrial parameters, cleaved caspase3 labelling, and axonal and dendritic morphology. Our preliminary results suggest that the complete oil is more effective than the individual FAs in ameliorating the toxic effects of Aβ on the neurons, based on survival assay and cleaved caspase3 labelling. In terms of the treatment timing, preliminary data suggest that the oil can rescue cells pre-exposed to Aβ for 1 or 6 hrs, but is much less effective when the pre-exposure has been 24 hrs. Continuing work is focused on mechanisms that may be involved in this protective influence.

Abstract: Alzheimer's disease (AD) is characterized by the presence of amyloid-β (Aβ) peptide plaques and believed to result from the misregulation of the production or clearance of Aβ. The rate-limiting step in the generation of Aβ is the processing of Aβ precursor protein (APP) by β-site APP-cleaving enzyme (BACE1). Elucidating how expression of these proteins is regulated will ultimately reveal new drug targets. Our aim is to utilize novel approaches to define the regulation of these gene products by microRNAs (miRNAs). MiRNAs are an abundant class of small RNAs that mediate potent inhibitory effects on global gene expression. Using multiple bioinformatic tools and a series of functional studies in neuronal and glial cultures, we previously reported specific microRNA species that regulate levels of APP and BACE1. Herein we present data demonstrating miR20b and miR-298 mediated regulation of APP alone or with BACE1. First, we prepared chimeric APP 3'-UTR and BACE1 3'-UTR reporter constructs downstream of a reporter *Renilla* luciferase gene and then delivered the reporter construct along with several miRNAs predicted to target the APP and BACE1 3'-UTR into human astroglial U373 cells. Several "hits" (e.g. miR20b and miR-298) resulted in reduced reporter expression. We further validated the reporter expression data for miR-298 (and miR-339-5p) by Western analysis of native BACE1 levels, which were significantly reduced following their transient delivery, with a potential to lower toxic soluble Aβ levels. Moreover, miR-20b or miR-298 delivery significantly reduced native APP levels in these human cells. Thus, miRNA-298 targets both APP and BACE1 expression. Our results reveal a novel regulatory interaction between two important AD-related genes (APP and BACE1) and specific endogenously expressed miRNA species, represented by miR-298. Our ongoing studies evaluating the expression of miR-298 in brain tissue specimens from two patient cohorts may further unveil its role in AD. Additional experiments suggest that miR-20b has another target, specifically voltage-gated calcium channels, within AD pathology. Summarizing, we show that two miRNAs, namely miR-298 and miR-20b, are able to affect AD pathology by targeting more than one gene. These regulatory interactions likely serve as novel therapeutic targets and may enable the development of treatment strategies beneficial in the fight against AD. This work is supported by grants from the Alzheimer's Association and NIH.

Title: Aβ-induced synaptic loss requires glutamate binding to NMDA receptors but not ion-flux

Authors: *C. TACKENBERG, J. BIRNBAUM, R. M. NITSCH;
Univ. of Zurich, Schlieren, Switzerland

Abstract: Aggregates of beta-amyloid (Aβ) and tau represent the major histopathological hallmarks of Alzheimer's disease (AD). AD patients suffer from cognitive impairments which are caused by massive neuronal brain atrophy and synaptic loss. The reduction in synapse numbers is the best neuropathological correlate to the degree of dementia in AD. N-methyl-D-aspartate receptors (NMDARs) have been shown to mediate downstream effects of Aβ. NMDARs can trigger intracellular cascades via calcium entry, however also calcium-independent (metabotropic) functions of NMDARs have been described. We found that endogenous Aβ as well as exogenously added synthetic Aβ oligomers induced dendritic spine loss and reductions in pre- and postsynaptic protein levels in slice cultures. Synaptic alterations were mitigated by blocking glutamate-binding to NMDARs using NMDAR-antagonist APV but not by preventing ion-flux with calcium-chelator BAPTA or open channel blocker MK-801 or memantine. Synapse loss involved activation of p38 MAPK, which has been implicated in metabotropic NMDAR functions. Our data suggest that Aβ-induced synaptic loss depends on metabotropic-like mechanisms caused by glutamate binding to NMDARs but does not require calcium-influx.

Title: beta-Amyloid acutely changes astrocytic energy metabolism and glucose utilisation

Authors: *M. Y. ZILBERTER[1], R. VALDEBENITO[3], A. FISAHN[2], F. BARROS[3]; [2]Alzheimer's Dis. Res. Ctr., [1]Karolinska Institutet, Stockholm, Sweden; [3]Ctr. de Estudios Científicos, Valdivia, Chile

Abstract: Alzheimer's disease (AD) disrupts brain glucose utilization as its earliest clinical manifestation, preceding any cognitive impairment. We have previously reported that AD's hallmark toxic peptide amyloid beta (Aβ(1-42)) induces an imbalance in neuronal energy metabolism with downstream disruption of basic neuronal electrogenic properties, leading to network hyperactivity. Here we report that Aβ also perturbs astrocytic cytosolic glucolysis as well as mitochondrial respiration, evident as modified astrocytic NAD(P)H and FAD autofluorescence transients during hippocampal network activation. This disruption is underlain by Aβ's acute effect onto astrocytic glucose metabolism, seen as changes in both glucose uptake and glucolysis in cultured astrocytes. As astrocytes are crucial for ensuring proper energy supply to neurons, such a fundamental disruption is potentially a key part of AD effect on overall energy homeostasis and would explain our earlier finding that the AD model mice display up to 50% reduction in brain glycogen levels. Our results highlight the early, multi-faceted effect of AD pathology on brain energy metabolism across cell types.

Title: Loss of choline acetyltransferase activity caused by oxidative damage: Mechanisms and possible implications for Alzheimer's disease

Authors: *L. E. SANTOS[1], C. FIGUEIREDO-FREITAS[2], N. NUNES-TAVARES[1], S. T. FERREIRA[1], F. G. DE MELLO[1];
[1]Inst. de Biofísica Carlos Chagas Filho, [2]Inst. de Bioquímica Médica Leopoldo De Meis, UFRJ, Rio De Janeiro, Brazil

Abstract: Acetylcholine is a major neurotransmitter in both central and peripheral nervous systems, normally synthesized near pre-synaptic terminals in a reaction involving the transfer of an acetyl group from acetyl-coenzyme A to choline. This reaction is carried out by an enzyme known as choline acetyltransferase (ChAT, EC 2.3.1.6) [J. Neurophysiol. 1943; 6, 7], which is also regarded as a marker of cholinergic neurons. Disturbances of cholinergic neurotransmission have long been implicated in the development of several central nervous system (CNS) pathologies. Among them, Alzheimer's disease (AD) - an alarmingly prevalent form of dementia - stands out for having one of the most well established cholinergic hypothesis, first presented formally in the early 1980s [Science 1982; 217:408-414]. In 2001, using chick retina as a CNS model, our group showed that ChAT activity in cultured or *ex vivo* neurons can be markedly and quite specifically down-regulated by excitotoxic stimuli, such as excitatory amino-acid (EAA) treatments, long before any significant changes in cell viability or enzyme levels occur. This effect was shown to be dependent on calcium influx and at least partially on nitric oxide (NO) production [J Neurochem. 2001; 77:1136-1144]. More recently, we extended these results to a more specific context, and observed a similar loss of ChAT activity after treating cultured cholinergic neurons with oligomeric forms of the amyloid-β peptide (AβOs). These small oligomers are diffusible toxins found in AD brains and are currently regarded as possible culprits of the disease [JBC 2012; 287:19377-19385]. In the current work, we address whether nitrative or nitrosative stress-induced modifications are involved in this loss of ChAT activity. Several free-radical donors and thiol reagents are shown to directly inactivate the enzyme with efficiency dependent on the type of reaction or reactive species produced. Moreover, using S-nitrosothiol resin-assisted capture (SNO-RAC), 4-acetamido-4'-maleimidylstilbene-2,2'- disulfonic acid (AMS) labeling of reduced thiols and immunodetection with nitrotyrosine antibodies we find that treatments with EAAs, AβOs or NO donors change the oxidation pattern of ChAT molecules in cysteine and tyrosine residues. We also observe that such modifications correlate well with the loss of enzyme activity. These results suggest a novel mechanism for cholinergic deficit that precedes neuronal death and may be relevant in early-stage AD pathology.

Title: Centella asiatica protects against oxidative damage and mitochondrial dysfunction

Authors: *N. E. GRAY[1], C. J. HARRIS[2], A. SOUMYANATH[2], J. F. QUINN[2,3];
[1]Oregon Hlth. and Sci. Univ., Portland, OR; [2]Neurol., Oregon Hlth. & Sci. Univ., Portland, OR; [3]Dept. of Neurol. and Parkinson's Dis. Res. Educ. and Clin. Care Ctr. (PADRECC, Portland Veteran's Affairs Med. Ctr., Portland, OR

Abstract: Background: The plant *Centella asiatica* is used in traditional Chinese and Ayurvedic medicine to enhance cognition. We have previously shown that treatment with a water extract of *Centella asiatica* (CAW) attenuates learning and memory deficits in a mouse model of Aβ accumulation, and prevents cell death in *in vitro* models of Aβ toxicity. Yet the mechanism by which CAW exerts its neuroprotective effects has yet to be elucidated. In these studies we evaluated the effects of CAW on antioxidant response and mitochondrial function in response to Aβ *in vitro,* and the *in vivo* effects of CAW in healthy, aged animals. **Mechanism:** Using two neuroblastoma models of Aβ toxicity (MC65 and SH-SY5Y cells) we determined intracellular levels of reactive oxygen species (ROS) and the expression of the antioxidant response element (ARE) containing gene NRF2 and its target genes. We also measured expression of a several genes encoding protein components of the electron transport chain and intracellular ATP as well as mitochondrial respiratory flux, using the Seahorse XF Analyzer. Because mitochondrial dysfunction is also observed during normal aging, we investigated the effects of CAW on 20 month old wild type (WT) mice. Following two weeks of treatment with CAW, we analyzed learning and memory using the Morris Water Maze and measured the expression of ARE and mitochondrial genes in the brain. **Results:** CAW reduced intracellular ROS generated in response to Aβ and induced the expression of the ARE genes in both cell types. CAW also prevented the decrease in ATP in response to Aβ and induced the expression mitochondrial genes. Additionally CAW increased both basal and maximal mitochondrial respiration and attenuated the decrease in respiration observed in response to Aβ but had no effect on the spare respiratory capacity of mitochondria in those cells. CAW treatment significantly improved memory in aged WT mice an effect that persisted several days beyond the final trial. There was also a robust increase in the expression of mitochondrial and ARE genes in

both the hippocampus and cortex of CAW-treated animals. **Discussion:** Our data demonstrate that CAW can prevent Aβ-induced alterations ROS levels and ATP production. The data also show that CAW increases mitochondrial respiration but not the overall spare capacity of mitochondria *in vitro*. These data, together with the increase in mitochondrial gene expression in response to CAW, suggest that CAW may be inducing mitochondrial biogenesis. The experiments in WT mice support this hypothesis and show that the beneficial effects of CAW are not limited to Aβ toxicity but rather may be very broadly relevant in other contexts of mitochondrial dysfunction.

Title: Different segments of Amyloid-β drive distinct steps of toxicity

Authors: *A. K. DAS, R. PANDIT, B. CHANDRA, B. SARKAR, M. CHANDRAKESAN, S. MAITI;
Tata Inst. Fundamental Res., Mumbai, India

Abstract: Oligomers of the Amyloid-β (Aβ) peptide, but not the monomers or the mature fibrils, are thought to be the key toxic species in Alzheimer's disease. We have earlier shown that small Aβ oligomers (n-mers with n<10) display much higher membrane affinity than the monomers [1], and this is correlated with the emergence of a fibril-like tertiary fold in the structure [2]. Our recent structural study shows that the conformation of Aβ40 oligomers differs from the fibrils specifically at the turn (residues 22-29) and the N terminus (residues 1-10) regions [3]. Here we ask if these specific segments drive distinct steps leading to toxicity. We know that the core part of Aβ (Aβ18-35, which contains the turn region) folds similar to the full length peptide [4], so its properties can be studied independently. We find that the enhancement of membrane affinity is driven by this core region, but it lacks toxicity. Even a much longer fragment (Aβ10-40) shows similar properties. Interestingly, the N terminal fragment (Aβ1-9) by itself cannot initiate toxicity and neither can it bind to neuronal membranes. We create a minimal sandwich peptide comprising of just the core and the N-terminus (Aβ1-9/18-35) and find that while it has high

membrane affinity, it is still non-toxic. Thus interaction of Aβ1-9 with the rest of the peptide, or with another cellular component, enabled in turn by the right length of Aβ, is necessary for toxicity. Next, we find that a D enantiomer variant of Aβ1-9, attached to Aβ10-40, is also toxic. This suggests that N terminus is not involved in any stereospecific interactions (e.g. with receptors). It is likely that the N terminus non-stereo-specifically controls a critical post-attachment event, such as assembly formation on the membrane, internalization or vesicle dynamics. We are utilizing membrane diffusion measurements and fast quantitative multiphoton imaging of serotonergic vesicles [5] to probe these events. References [1] Sarkar, B. et al., Front. Abstract: Alzheimer's disease (AD) is a neurodegenerative disease, characterized pathologically by extracellular amyloid-beta (Aβ) plaques and intracellular neurofibrillary tangles. The "amyloid cascade hypothesis" proposes that aggregation of Aβ42 peptides into oligomers and plaques triggers a cascade of pathological events, leading to widespread neurodegeneration. There is increased interest in the role of inflammation in this process. Chronic inflammation may affect mechanisms of amyloid deposition and/or clearance, but many findings are contradictory. Such investigations may be particularly relevant in white matter, where local effects of toxic Aβ peptides have been proposed as a potential mechanism of primary white matter damage. Previously, we showed that soluble forms of Aβ40 and Aβ42 are higher in hemispheric white matter tissue of patients with AD. The current study explored cytokine levels in white matter tissue of AD patients and non-AD controls, and examined their association with soluble Aβ40 and Aβ42 measured in the same regions. We also examined white matter microglial activation and its association with myelin integrity. Fresh frozen post-mortem tissue was sampled from white matter in the prefrontal center semi-ovale and the parieto-occipital lobe at the level of the atrium from brains of AD patients (n=12) and non-AD controls (n=10). ELISA was used to measure soluble Aβ40 and Aβ42 levels. To measure quantitatively the levels of 40 cytokines, tissue from the same regions was analyzed with a Quantibody® array (Ray Biotech). To investigate microglial activation, we took mirror image samples from the contralateral formalin fixed hemisphere of each subject and rated the tissue on a four-point scale on CD68 stained slides. Myelin pathology was quantified from slides stained with Luxol fast blue. Microglial activation did not differ between AD patients and controls, but microglial activation was associated with loss of myelin integrity. Cytokine levels were similar in AD patients and controls, except for Intercellular Adhesion Molecule 1 (ICAM-1), which was higher in the AD group. Stratified by diagnosis, ICAM-1 levels correlated negatively with Aβ42 levels in anterior and posterior regions among AD patients, but not among controls. Previous work suggests that ICAM-1 induces expression of the amyloid-degrading enzyme neprilysin in microglia, which could account for the observed relationship between ICAM-1 and Aβ42. Taken together, these exploratory analyses highlight the complexity of the inflammatory response in white matter tissue in AD, which could have critical importance for the development of novel treatments for the disease.

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative disease and the leading cause of dementia. In recent years, in addition to grey matter pathology, white matter changes have come to be recognized as an important pathological feature in the emergence of the disease. Multiple studies suggest that there is axonal damage and loss, demyelination, death of oligodendrocytes, gliosis and other pathological white matter changes in the brains of AD patients. Despite the growing recognition of the potential importance of white matter abnormalities in the pathogenesis of AD, the pathological basis of white matter degradation remains to be elucidated. While multiple studies have attributed this white matter degeneration to concomitant small vessel disease or Wallerian-like degeneration, others suggest that primary white matter pathology may be due, at least in part, to other mechanisms, including local effects of toxic Aβ peptides. The current study investigated levels of soluble amyloid-beta (Aβ) in white matter of AD patients. Fresh frozen tissue was sampled from anterior and posterior regions of cerebral white matter from post-mortem brains of AD patients (n= 12) and non-AD controls (n=10). ELISA was used to examine levels of both Aβ40 and Aβ42. Compared with controls, AD white matter samples had higher levels of both Aβ40 and Aβ42. While no regional white matter differences were found in Aβ40 levels, Aβ42 levels were higher in anterior regions than in posterior regions across both groups. After statistically controlling for total cortical plaque

load in the analysis, differences in soluble Aβ40 and Aβ42 between the groups remained, suggesting that white matter Aβ peptides accumulate independent of overall grey matter fibrillar amyloid pathology. Taken together, the results of the current study suggest potential pathological mechanisms that may contribute to white matter degeneration in AD. Given that white matter degeneration may be an early marker of disease, preceding grey matter atrophy, understanding the mechanisms and risk factors that may lead to white matter loss could help to identify those at high risk and to intervene earlier in the pathogenic process.

Title: LRP1 activates ERK1/2 in lipid rafts in neuron-like cells

Authors: *E. MANTUANO[1,2], V. MATTEI[3], V. TASCIOTTI[3], V. MANGANELLI[2], S. MARTELLUCCI[3], F. SANTILLI[3], T. GAROFALO[2], M. SORICE[2], S. L. GONIAS[1], R. MISASI[2];

Abstract: The cellular form of prion protein (PrPc) is a highly conserved cell surface GPI-anchored glycoprotein that was identified in cholesterol-enriched, detergent-resistant microdomains ('rafts') in neural and non-neural cells. Several physiological functions have been described for PrPC, including oxidative stress defense, metal ion homeostasis in the brain, and neuroprotection. Aβ oligomers, but not monomers or fibrils, bind tightly to PrPc (Kd ~ 0.4 nM) and, in hippocampal slices, PrPc PrPc is required for Aβ oligomer-mediated inhibition of long-term potentiation. Our results suggest that the activity of PrPc-Aβ requires lipid rafts and the transmembrane receptor, low-density lipoprotein receptor-related protein (LRP1). LRP1 functions as an endocytic receptor for a broad range of structurally and functionally diverse

ligands. LRP1 also functions in cell signaling, directly, in response to ligand-binding, and indirectly, by regulating levels of other signaling receptors. In neurons and neurite-generating cell lines, ligands control the signaling activity of LRP1 by directing the co-receptors that are recruited into a functional signaling complex with LRP1. LRP1 is also known to control surface and biosynthetic trafficking of PrPc in neurons. Our results show that PrPc is strictly associated with gangliosides in lipid rafts in neuroblastoma cells. Scanning confocal microscopy analysis revealed co-localization of PrPc with GM1, as well as TrkA with GM1, indicating the existence of a glycosphingolipid-enriched molecular complex. In order to analyze the mechanism by which recombinant PrPc initiates cell signaling in SK-N-BE2 and PC12 neuron-like cells, we examined ERK1/2 phosphorylation. ERK1/2 was robustly phosphorylated in cells that were treated with recombinant PrPc. ERK1/2 activation required LRP1 and was strictly dependent on the integrity of rafts. ERK1/2 activation was blocked by altering sphingolipid metabolism with fumonisin B1 or by disruption of lipid microdomains with methyl-β-cyclodextrin. These findings support a model in which LRP1 initiates signal transduction specifically in lipid rafts, where it forms multimolecular complexes that may include PrPc, TrkA and gangliosides. Although association of LRP1 with lipid rafts has been reported before, this is the first study to demonstrate a potentially significant LRP1 activity that depends on its distribution between rafts, clathrin-coated pits and other membrane domains.

Title: Aβ plaque formation and impaired protein quality control interact via γ secretase and result in a behavioural phenotype consistent with Alzheimer’s disease

Authors: ***F. VAN LEEUWEN**[1], R. J. G. GENTIER[1], M. L. M. VERHEIJEN[1], H. W. M. STEINBUSCH[1], M. O. GRIMM[2], V. J. HAUPENTHAL[2], T. HARTMANN[2];

Abstract: Aβ plaque formation is a prominent cellular hallmark of Alzheimer's disease (AD). To date, immunization trials in AD patients have not been effective in terms of curing or ameliorating dementia. In studies with transgenic animals (line #85; APP Swe PSEN1Δexon 9) it was shown that there is limited clearance of pre-existing amyloid plaques. Therefore, more knowledge about the mechanism and relevance of Aβ plaque formation is required before reconsidering trials. We discovered that misframed ubiquitin (UBB+1) is unable to ubiquitinate degradable targets and cannot be deubiquitinated, thereby dose dependently inhibiting the ubiquitin proteasome system (UPS). Thus results in ERAD dysfunction, stress of mitochondria, their neuritic clogging and a phenotype of impaired contextual behaviour (Dennissen et al., Prog. Neurobiol., 96, 190-207, 2012). Recently, pooled GWAS studies, pathway analysis and proteomics identified protein ubiquitination as one of the key modulators of AD and support our hypothesis of a dysfunctional UPS as a causative factor in AD (Manavalan et al., Exp. Mol. Med., 45, E39, 2013). For more than a decade a relation between a dysfunctional UPS and Aβ plaque formation has been surmised but never proven in detail. It is now possible to address this issue by crossbreeding 2 transgenic lines in a pure C57Bl6 genetic background (e.g., lines #3413 with postnatal UBB+1 over expression, proteasomal inhibition and a proteome partly compatible with AD, line #85 with Aβ plaque formation starting at 4 months of age) and their crossbreed (e.g., lines #3413 x #85, van Tijn et al., Neurochemistry International, 61, 739-748, 2012). The results revealed that in line 85 with the Swedish double mutation, γ secretase activity was specifically decreased significantly at 3, 6 and 9 months of age, whereas α and β secretase activities were unaffected. However, in the crossbreed with a dysfunctional UPS the γ secretase activity (and not those of α and β) was enhanced at the age of 6 months; a critical period where Aβ plaque generation is attenuated. In the crossbreed, nest building and contextual memory, as determined in the Morris water maze, are impaired. Our new data implicate that there is strong interaction between a failing protein quality control by the UPS and Aβ plaque formation being mediated specifically via γ secretase. Currently the multimeric γ secretase complex (e.g., nicastrin, PSEN1) is analysed. These results show a striking inverse correlation between γ secretase activities and Aβ plaque load and will contribute to a better understanding of strategies to ameliorate or cure AD, via γ secretase modulation.

Title: Preservation of hippocampal mTOR/p62 autophagy signaling pathways in AD

Authors: *E. J. MUFSON[1], B. HE[1], M. D. IKONOMOVIC[2], M. NADEEM[1], J. WUU[3], S. E. PEREZ[1];
[1]Neurol Sci., Rush Univ. Med. Ctr., CHICAGO, IL; [2]Depts. Neurol. and Psychiatry, Univ. of Pittsburgh and Geriatric Res. and Educ. Clin. Ctr., Pittsburgh, PA; [3]Dept. Neurol., Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: The mammalian target of rapamycin (mTOR) and p62 play a role in the cascade of cellular events associated with tau phosphorylation, and endosomal-lysosomal (E-L) autophagy processes early in the onset of Alzheimer's disease (AD). Previously, we have shown a down-regulation of the early endosome Rab5 and an up-regulation of the late lysosomal hydrolase cathepsin D (Cat D) in the hippocampus of people who died with a premortem clinical diagnosis of mild cognitive impairment (MCI) compared to no cognitive impairment (NCI). However, whether levels of mTOR and p62 are dysregulated and their relation with Aβ and tau pathology during the progression of AD is unknown. Here, we quantified changes in hippocampal mTOR phosphorylated at serine 2448 (pmTORs2448) and serine 2481 (pmTORs2481), total mTOR, p62 and the novel human Aβ receptor leukocyte immunoglobulin-like receptor B2 (LilrB2) in tissue harvested from subjects with a premortem clinical diagnosis of NCI, MCI and mild/moderate AD within 12 months prior to death. All groups were matched by age and postmortem interval and underwent detailed postmortem neuropathologic evaluations. Western blot analysis of tissue homogenates revealed stable levels of phosphorylated mTOR proteins, total mTOR and p62 as well as LilrB2 across the three clinical groups examined. pmTORs2448, pmTORs2481 and total mTOR were positively correlated with each other, but not with p62. pmTORs2448 levels showed a weak negative association with increased levels of Cat D, but not Rab5. Conversely, p62 showed a strong positive association with total (soluble and insoluble) $A\beta_{1-42}$ and $A\beta_{1-40}$ levels, whereas LilrB2 was weakly correlated with both, $A\beta_{1-42}$ and $A\beta_{1-40}$. Surprisingly, only pmTORs2481 and total mTOR values were weakly correlated with global cognitive z-score, but not with MMSE or episodic memory z-score, or with the neurofibrillary tangle Braak staging. Collectively, our findings demonstrate that the downstream levels of

mTOR/p62 autophagy signaling molecules and LilrB2 amyloid receptor remain relatively unchanged in these cases, suggesting that these E-L signaling factors as well as the Aβ receptor LilrB2 may not play a key role in the initiation of hippocampal neuronal degeneration during the onset of AD.

Title: N-acetylglucosamine polymers impede synaptic plasticity, are neurotoxic and accumulate in sporadic alzheimer's disease Brains

Authors: *G. BUSETTO, M. FAVERO, E. TURANO, B. BONETTI;
Neurolog. and Movement Sci., Dep. of Neurosci, Univ. of Verona, Verona, Italy

Abstract: For familial Alzheimer's disease (AD), a large body of evidence supports a causative role of β-amyloid (Aβ). Unfortunately this hypothesis does not fully explain the pathogenesis of sporadic AD, which accounts for the majority of AD cases. In fact, recent pharmacological treatments aimed at reducing the Aβ burden failed to obtain clinical benefits. It is known that, besides Aβ, other molecules are present in amyloid plaques of sporadic AD brains, including insoluble polymers of N-acetylglucosamine (GlcNAc, possible result of a metabolic shift of glucose utilization from glycolysis to the hexosamine pathway) of whom the potential role in the pathogenesis of AD remains to be elucidated. We found that the acute application of precursors of GlcNAc polymers (5 mM N-acetylglucosamine and 150 μM UDP- N-acetylglucosamine) to murine hippocampal slices does not affect basal synaptic transmission (measured as excitatory post synaptic field potentials [fEPSPs] and paired-pulse ratio), but reduces the expression of long term potentiation (LTP) of CA1 glutamatergic synapses, similarly to Aβ 25-35 (0.5 μM) (fEPSPs slope relative to baseline: control 165 ± 6%, n=11; experimental 131 ± 10%, n=10, p=0.01; Aβ 135 ±3%, n=6). This effect is mainly postsynaptic (no modification of paired-pulse ratio after LTP induction). We also found that cultured neurons (SH-SY5Y cell line and primary hippocampal neurons) and microglia (N9 cell line and primary microglia) synthesize polymers of GlcNAc if treated with polymers' precursors. Moreover, polymers' precursors have a specific

neurotoxic effect, reducing to 40% the survival of hippocampal cultured neurons after 48hrs, while leaving fibroblasts unperturbed. We further tested the effect of polymers' precursors on hippocampal slice cultures (up to 7 days) and found evidence of synaptic damage (reduction of synaptophysin and syntaxin with immunoblotting). Finally, polymers' precursors activate microglia to a same extent as Aβ (assessed with MTT assay). These data support the hypothesis that, in case of sporadic AD, polymers of GlcNAc and high doses of their precursors may cause both neuronal damage and microglia activation, thus contributing to the Aβ-derived neurotoxicity.

Title: Time-dependent alterations of MMP9 and ANG-2 in hippocampus of rat with chronic bilateral common carotid artery occlusion

Authors: M.-S. KIM[1], *C. CHUNG[1], W. JEON[2], J.-S. HAN[1];
[1]Dept. of Biol. Sci., Konkuk Univ., Seoul, Korea, Republic of; [2]Korea Inst. of Oriental Med., Daejeon, Korea, Republic of

Abstract: Chronic cerebral hypoperfusion causes neurological dysfunction including cognitive impairment. Chronic decreased cerebral blood flow is associated with neuropathological changes of vascular dementia and Alzheimer's disease (AD). An experimental animal model of chronic cerebral hypoperfusion is the bilateral common carotid artery occlusion (BCCAo) using the rat. In the BCCAo model, it has demonstrated that not only neural damage and memory deficits are occurred, but also angiogenesis is promoted. Angiogenesis may help in neuronal reorganization following initial occlusion, and also associate with reduced neurological deficits in rats with chronic BCCAo. The present experiment was conducted to examine the time-dependent alterations in angiogenesis-related proteins and factors. We examined an alteration of angiogenesis-related proteins in the hippocampus of rats with chronic BCCAo. Male Wistar rats (12 weeks-old) were randomly divided into sham-operated group, BCCAo-group with1 week,

BCCAo-group with 4 weeks, and BCCAo-group with 8 weeks by the time elapsed after the BCCAo. We found out time-dependent alterations of the expression levels of angiogenesis-related proteins using western blotting. The proteins associated with angiogenesis, such as angiopoietin-2, were altered as time progresses after the BCCAo. In addition, we confirmed the cellular location of the angiogenesis-related proteins, which are located in neurons and astrocytes, using double-immunofluorescence staining. Altered microvascular density depended on the time elapsed after the BCCAo. Overall, our findings would provide a better understanding of angiogenic factors on cerebral angiogenesis and could serve as effective therapeutic strategies for chronic cerebral hypoperfusion-associated neurological disorders such vascular dementia and AD.

Title: Selective progranulin deficiency in neurons produces frontotemporal dementia-like deficits

Authors: ***A. E. ARRANT**[1,2], A. J. FILIANO[2], A. H. YOUNG[2], E. D. ROBERSON[2,3];
[2]Neurol., [3]Neurobio., [1]Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Frontotemporal dementia (FTD) is a progressive, fatal neurodegenerative disorder that is the second most common cause of dementia after Alzheimer's disease. Loss-of–function mutations in progranulin (*GRN*) that result in progranulin deficiency are a major genetic cause of FTD, producing 5-10% of all cases. Progranulin-deficient mice ($Grn^{+/-}$ and $Grn^{-/-}$) have been generated to model progranulin deficiency, and develop an FTD-like phenotype including abnormal social and emotional behavior and amygdala dysfunction by 6 months of age. $Grn^{-/-}$, but not $Grn^{+/-}$, mice also develop inflammation, gliosis and lipofuscinosis that increases with age. A key question for FTD with *GRN* mutations is how progranulin deficiency causes disease. Progranulin is a secreted glycoprotein that is expressed by both neurons and microglia in the brain, so loss of progranulin from either or both cell types could cause of FTD. We investigated

whether loss of progranulin from neurons is sufficient to cause FTD-like behavior by generating neuron-specific progranulin knockout (N-KO) mice by crossing CaMKIIa:Cre mice with $Grn^{fl/fl}$ mice. N-KO mice had 32% lower progranulin protein levels in the cortex than Cre-negative mice, showing that a substantial fraction of brain progranulin is neuron-derived. We then tested 9-month-old N-KO mice and Cre-negative littermates for social and emotional behaviors. Similarly to our previous observations of global progranulin-deficient mice (Filiano et al, 2013 J. Neurosci.), N-KO mice exhibited increased social dominance and a trend for reduced sociability. N-KO mice also had reduced c-Fos expression in the amygdala after exposure to a novel, social environment. These data show that neuronal progranulin deficiency is sufficient to produce similar social behavioral and amygdala deficits as those seen in global progranulin-deficient mice. Markers of inflammation, gliosis, and lipofuscinosis were not significantly elevated in N-KO mice, showing that neuronal progranulin deficiency is not sufficient to reproduce the gliosis and lipofuscinosis of $Grn^{-/-}$ mice.

Title: Concordance between inclusions, microglia activation and disease phenotype in primary progressive aphasia with progranulin mutations and TDP-43 pathology

Authors: M. PETERSON, S. S. AHMADIAN, S. WEINTRAUB, *E. J. ROGALSKI, E. BIGIO, M.-M. MESULAM, C. GEULA;

1.Cognitive Neurol. and Alzheimer's Dis. Center, CNADC, Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Aggregation of misfolded proteins in abnormal inclusions is a common feature of most neurodegenerative diseases. The exact relationship of these inclusions to the disease phenotype and patterns of atrophy is incompletely understood, particularly in frontotemporal lobar degeneration (FTLD) and its variants. While there have been dazzling advances in the genetics and cellular biology of FTLD-TDP, quantitative information on the regional distribution of TDP-43 inclusions, other pathology such as microglial activation and their relationship with disease phenotype are glaringly absent from the literature. The major goal of this study was to clarify the relationship between transactivation response element DNA binding protein-43 (TDP-43) inclusions, microglial activation and disease phenotype in primary progressive aphasia (PPA-TDP), a variant of FTLD-TDP in which aphasia is the salient clinical feature and is accompanied by atrophy in perisylvian language network in the dominant hemisphere (usually on the left). We used brains from three cases of PPA-TDP with progranulin mutations for this study. Inclusions were visualized immunohistochemically using an antibody to human phosphorylated TDP-43 and activated microglia were identified using an antibody to HLA-DR. Modified stereological techniques were used to quantify TDP-43 inclusions and activated microglia in inferior frontal gyrus (IFG), inferior parietal lobule (IPL), and superior temporal gyrus (STG), cortical areas involved in the processing of language, and in entorhinal cortex / hippocampus (ERC / Hip), areas involved in the processing of memory. When counts from all areas were combined across cases, significantly higher density of TDP-43 inclusions and activated microglia were observed in the left hemisphere when compared with the right ($p<0.02$). The lowest density of TDP-43 inclusions occurred in the memory related ERC / Hip. Two cases were classified as the logopenic subtype of PPA, in which greatest cortical atrophy has been observed in IPL; in these cases, substantially higher densities of TDP-43 inclusions were detected in the left IPL. A third case was classified at the agrammatic subtype and displayed the highest density of TDP-43 inclusions in IFG / prefrontal cortex, the area known to show the greatest atrophy in this subtype. The distribution of microglia displayed a similar pattern. These observations suggest concordance between TDP-43 inclusions, microglial activation, disease phenotype and putative sites of greatest atrophy in PPA-TDP with progranulin mutations. It remains to be seen if similar concordance exists in sporadic PPA-TDP cases.

Title: Role of S100B in defining pathological changes in Alzheimer's disease

Authors: *H. WU[1], R. NAGELE[2], V. VENKATARAMAN[1];
[1]Dept of Cell Biology, GSBS, Rowan University-SOM, Stratford, NJ; [2]New Jersey Inst. for Successful Aging Rowan-SOM, Stratford, NJ

Abstract: Alzheimer's disease (AD) is a devastating neurodegenerative disease for which no cure (other than palliative) exists. The search for a cure demands knowledge of the early pathological changes - critical necessity both for diagnostic as well as treatment purposes - which has remained elusive. Several biomarkers for AD are reported. S100B is one of them, although there is conflicting evidence. Our laboratory is investigating the role of S100B, if any, in AD. In order to explain the onset and progression of AD, this laboratory has been proposed a "multi-hit hypothesis", with a breach in the blood brain barrier, elevation of serum abeta42 peptide interaction with serum auto antibodies and change in cellular calcium as the critical determinants. An animal model system was designed based on these "hits" and the results were compared between wild-type and S100B KO mice. The results demonstrate that the pathological changes in the S100B KO mice are more advanced than that observed in the wild-type. Furthermore, we have identified at least one site of action for S100B: establishment and/or maintenance of an intact blood brain barrier. Further investigation is in progress.

Title: The role of a splice variant of carboxypeptidase E in neurodegeneration with links to Alzheimer's disease

Authors: N. X. CAWLEY[1], Y. CHENG[1], T. YANIK[2], C. LIU[3], S. R. K. MURTHY[1], *Y. LOH[1];
[1]NICHD, NIH, Bethesda, MD; [2]Dept. of Biol. Sci., Middle East Tech. Univ., Ankara, Turkey; [3]Univ. of Sydney, Sydney, Australia

Abstract: Recent work has demonstrated a functional role of carboxypeptidase E (CPE) in neuroprotection and cancer cell survival. A non-redundant nucleotide sequence database search with human CPE, against the GeneBank EST database, identified an EST sequence entry from Alzheimer cortex tissue representing a splice variant of CPE. The three adenosine insertion mutations results in a CPE protein with 9 new amino acids within the first beta-pleated sheet after the pro-domain. We have named this mutant, QQ CPE, due to the presence of two glutamine residues in the new sequence. Transfection and expression of QQ CPE in Neuro2a cells demonstrated that it was poorly made and failed to be secreted into the culture medium, in contrast to WT CPE that was efficiently made and secreted. Western blot analysis showed the presence of the pro-form of QQ CPE indicative of accumulation in the ER. QQ CPE levels were increased after treatment of the cells with MG132, a proteosomal inhibitor, indicating that the mutant CPE was degraded by the proteosome. Further inhibitor studies with E64d, a cell permeable thiol protease inhibitor, also increased the levels of QQ CPE, indicating that a portion of the mutant was targeted for degradation by the lysosome. Expression of the mutant in Neuro2a cells resulted in the initiation of ER stress induced cell death signaling as evidenced by the expression of CHOP, a transcription factor induced under conditions of ER stress. Overexpression of QQ CPE in rat hippocampal and cortical neurons also resulted in increased levels of CHOP in these neurons, in addition to increased cytotoxicity and neuronal cell death as measured by LDH and MTT assays. Co-expression of WT and QQ CPE resulted in the degradation of both forms of the protein and reduction in the secretion of WT CPE, indicating that the mutant was acting in a dominant recessive manner. Preliminary behavioral experiments on ~8 month old QQ CPE transgenic mice have demonstrated a reduced learning and memory capacity compared to their WT littermates as measured by the Morris water maze protocol. We speculate that aged neurons expressing WT and QQ CPE may result in 1) a reduction in overall levels of CPE due to degradation initiated by the mutant and 2) may become more susceptible to ER stress-induced cell death leading to neuronal loss. This would result in the loss of the neuroprotective functions of CPE and possibly lead to neurodegenerative diseases including Alzheimer’s disease.

Title: Calcineurin proteolysis is associated with astrocyte and small vessel pathology

Authors: *M. PLEISS[1], H. MOHMMAD ABDUL[2], J. L. FURMAN[5], R. P. GUTTMANN[3], E. PATEL[2], D. M. WILCOCK[4], P. T. NELSON[2], C. M. NORRIS[2];

Abstract: The Ca2+ dependent protein phosphatase calcineurin (CN) has been implicated as a causative factor in multiple neuropathological features of Alzheimer's disease (AD) including synapse dysfunction, neuroinflammation, and amyloidosis. Dysregulation of CN activity during AD appears to arise, in part, from the disruption or complete removal of the CN autoinhibitory domain located near the C terminus of the CN catalytic subunit. Commercially available antibodies that target the N terminus of the CN catalytic subunit reveal the presence of an approximately 48 kDa fragment in human brain tissue during early stages of cognitive decline and also in a variety of experimental models of neurodegeneration. While useful for determining the extent of CN proteolysis in Western blot applications, N terminus antibodies do not reveal the cellular location of the proteolysis. Knowing where CN is proteolyzed in nervous tissue seems critical to understanding the mechanistic basis of its many deleterious actions, particularly because CN is found at high levels in both neurons and glial cells where it is involved in different cellular functions. To address this gap in our understanding of CN regulation, we generated custom rabbit polyclonal antibodies to CN A based on previously identified calpain (CP)-dependent cleavage sites. One of these antibodies (referred to here as "ΔCN48") detects a 48 kDa fragment in Western blot assays, but does not detect full-length CN. The ΔCN48 antibody was then used for immunohistochemical labeling of human brain sections characterized by both AD and mixed AD/vascular pathologies. The anatomical features labeled by the ΔCN48 antibody included astrocyte clusters and vascular associated elements and/or processes. We also observed numerous ΔCN48-positive astrocytes associated with microinfarcts. Surprisingly, we

have seen very little neuronal labeling with this antibody. The results suggest that astrocytes and, perhaps astrocyte end-feet, are a primary locus for CP-dependent CN proteolysis in injured or diseased nervous tissue. This work may provide new mechanistic insights into the impact of Ca2+ dysregulation on neurodegenerative diseases.

Title: Identification of novel calcineurin/NFAT transcriptional targets mediating Alzheimer's disease synaptic dysfunction

Authors: *E. HUDRY[1], J. CORRADI[2], A. CACACE[3], B. HYMAN[4];
[1]Dept. of Neurol. Alzheimer Res. Unit, MGH, Charlestown, MA; [2]Exploratory Biol. and Genomics, [3]Bristol-Myers Squibb, Wallingford, CT; [4]MGH - Harvard Med. Sch., Charlestown, MA

Abstract: Previous studies in Alzheimer's disease (AD) patients and in AD transgenic animals have suggested that the presence of soluble amyloid ß peptides and/or tau potentially leads to chronic activation of the neuronal calcium dependent phosphatase calcineurin (CaN, also termed protein phosphatase 2B). Upon activation, CaN is responsible for at least two broad types of effects biologically relevant to AD pathophysiology. First, CaN leads to a rapid post-translational modulation of post-synaptic proteins such as cofilin and AKAP79, a process associated with long-term depression. Second, CaN dephosphorylates the nuclear factor of activated T cells (NFAT), which leads to its translocation to the nucleus and to the expression of target genes encoding important proteins implicated in neuronal survival. Importantly, our previous work has shown that targeted inhibition of CaN/NFAT alleviates Aß-mediated neurotoxic events,

suggesting that the transcriptional impact of this particular cascade may be of relevance in the disease. In order to characterize the expression profile changes dependent upon CaN/NFAT-activation in neurons, intrahippocampal injections of adeno-associated vectors coding for wild-type CaN (wtCaN), constitutively activated CaN (CACaN) and GFP (control vector) were performed in wild-type mice. After laser capture microdissection of the transduced neuronal cells, a whole genome micro-array assay identified 6 genes differentially modulated by CACaN (as compared with wtCaN and GFP): Neuronatin (NNAT), Nurr1 (Nr4a2), VGF nerve growth factor (VGF), Hippocalcin (HPCA), Heat shock protein 5 (Hspa5) and corticotropin-releasing hormone (CRH). Further validation by qRT-PCR in human hippocampal tissue confirmed the significant increased expression of VGF and CRH in AD compared with aged-matched controls. By using *in vivo* gene transfer, we demonstrate that CaN activation impacts the expression level of a set of genes in neurons. In particular, our findings highlight for the first time a possible link between a chronic induction of calcineurin and CRH, a peptide hormone and neurotransmitter potentially involved in the stress response in Alzheimer's disease. Further studies will decipher if interfering with the CRH cascade, may alleviate amyloid induced, CaN-dependent, neurotoxic effects. Title: Hippocampal Cathepsin D and APP/Aβ processing in Alzheimer's disease

Authors: *S. E. PEREZ[1], B. KOVACS[1], S. W. SCHEFF[2], E. J. MUFSON[1];
[1]Dept Neurolog Sci., Rush Univ. Med. Ctr., CHICAGO, IL; [2]Sanders-Brown Ctr. on Aging, Univ. Kentucky, Lexington, KY

Abstract: Endosomal-lysosomal (E-L) dysfunction occurs prior to β-amyloid (Aβ) and tau-containing neurofibrillary (NFT) pathology and may underlie neuronal selective vulnerability during the progression of Alzheimer's disease (AD). Western-blot data have demonstrated an up-regulation of the lysosomal hydrolase Cathepsin D (Cat D) in the hippocampus of people who died with a clinical diagnosis of mild cognitive impairment (MCI) compared to no cognitive impairment (NCI). The hippocampus is involved early in the onset of AD as evidenced by the mediation of cognition and, NFT and Aβ pathology. Since E-L pathways are major routes of amyloid precursor protein (APP) processing and tau dysregulation, we examined whether hippocampal intraneuronal Cat D was associated with Aβ and/or NFT pathology early in AD. Hippocampal neuronal Cat D, NFT density and intraneuronal APP/Aβ levels were quantified using immunohistochemistry and densitometry in paraffin sections from subjects with a premortem clinical diagnosis of NCI, MCI or mild to moderate AD. Adjacent hippocampal sections were immunolabeled with antibodies against oligomeric tau TOC1 and TNT, phosphorylated AT8 and truncation Tau C3 as well as with 6E10 an APP/Aβ marker. Optical density (OD) analysis revealed a significant increase in Cat D-immunoreactive (-ir) levels within CA4 hippocampal neurons in AD compared to NCI, but not in CA2/3 or CA1 perikarya. The density of the CA1 hippocampal AT8 and TOC 1-ir neurons was significantly increased in AD compared to NCI, whereas intraneuronal APP/Aβ-ir OD levels were unchanged in the different hippocampal subfields examined across groups. Hippocampal neuronal Cat D OD values did not correlate with NFT density, Braak staging or mini-mental state examination (MMSE) during AD progression. Conversely, AT8 and oligomeric TOC1-ir neuronal density showed the strongest association within all hippocampal subfields across groups, but only AT8 and TOC1 NFT density within CA1 showed a strong association with Braak staging and MMSE scores. Remarkably, there was a positive association between intraneuronal OD measurements of APP/Aβ and Cat D-ir values in CA2/3 across groups and a trend in the CA1 pyramidal cell layer. These data suggest that Cat D alterations in hippocampal neurons occur late in AD and may be associated to APP/Aβ processing rather than tau pathology.

Title: Abnormity of myelination in Alzheimer's Disease mouse models

Authors: *Y. WU[1], Y. ZHANG[2];
[1]Sch. of Life Science,Peking Univ., Beijing, China; [2]Sch. of Life Sciences,Peking Univ., Beijing, China

Abstract: Abnormity of myelination in AD mouse models Yu Wu, Yan Zhang The abnormity of myelination has been reported in Alzheimer's disease (AD) patients. We now report a pathway involved in regulating myelination, which acts abnormally in APP/PS1 transgenic mouse (AD mouse models). Ankyrin G, DR6, caspase6 and neuregulin1 are four important factors in the pathway. We found that the expression of Ankyrin G is decreased in APP/PS1 transgenic mouse, which finally regulate the activation of neuregulin1 to affect myelination by DR6 and caspase6. Schwann cells and DRG neurons *in vitro* co-culture systems were used to observe the myelination. So far, our data suggested that the abnormity of myelination might play important role in AD pathology, which may affect the spread of action potential.

Title: The Ca2+ sensor S100A1 modulates neuroinflammation, histopathology and Akt activity in the PSAPP Alzheimer's disease mouse model

Authors: *L. AFANADOR[1], D. A. KEELING[1], Y. ZHANG[1], T. PRICE[1], A. X. ZARATE[1], I.-H. LIN[1], K. B. DUFFY[1], E. A. ROLTSCH[2], D. B. ZIMMER[1];
[1]Univ. of Maryland Sch. of Med., Baltimore, MD; [2]LSU Hlth. Sci. Ctr. Sch. of Med., New Orleans, LA

Abstract: The contribution of the Ca^{2+} sensor S100A1 to *in vivo* Alzheimer's disease (AD) pathobiology has not been elucidated although S100A1 regulates numerous cellular processes linked to AD. This study uses genetic ablation to ascertain the effects of S100A1 on neuroinflammation, beta-amyloid (Aβ), plaque deposition and Akt activity in the PSAPP AD mouse model. PSAPP/S100A1$^{-/-}$ mice exhibited decreases in astrocytosis (GFAP burden), microgliosis (Iba1 burden) and plaque load/number when compared to PSAPP/S100A1$^{+/+}$ mice at six and twelve months of age. The presence of detectable S100A1 staining in human AD specimens is consistent with a detrimental gain of S100A1 function in AD. Plaque associated PO_4-Akt and PO_4-GSK3β staining was also reduced while non-plaque associated staining was increased. S100A1·Akt complexes were undetectable in PC12 cells and AD brain tissue suggesting that S100A1 indirectly modulates Akt activity. In contrast, S100A1·RyR (ryanodine receptor) complexes were present in human/mouse AD brain and exhibited Ca^{2+}-dependent formation in neuronal cells. This is the first direct demonstration of an S100A1 target protein complex in tissue/cells and identifies the RyR as a primary S100A1 target protein in the brain. However, over 20 *in vitro* target proteins have been reported for S100A1 and it is unlikely that the RyR is the only intracellular S100A1 target protein in the AD brain. Studies are underway to determine if Hsp70/Hsp90 multichaperone complex, protein phosphatase 5, L-type Ca2+ channel, SERCA pump, tau, tubulin and synapsin are *in vivo* S100A1 target proteins.These data suggest that S100A1 inhibition may be a novel strategy for normalizing aberrant Ca^{2+} signaling in AD.

Title: The role of ATM in Alzheimer’s disease pathogenesis

Authors: *X. SHEN[1], J. CHEN[2], K. HERRUP[1], K. HERRUP[2];
[1]Life science, HKUST, Hong Kong, CHINA, Hong Kong; [2]Cell Biol. and Neurosci., Rutgers Univ., Piscataway, NJ

Abstract: Neuronal cell loss is one of the hallmarks of Alzheimer's disease (AD). Although its mechanism is elusive, unscheduled cell cycle reentry has been proposed to be an important part of the process. ATM (ataxia telangiectasia [A-T], mutated) is involved in cell cycle checkpoint control and DNA damage repair. ATM also plays a role in epigenetic histone modification through its regulation of the subcellular localization of the histone deacetylase, HDAC4. We believe that this epigenetic function raises the possibility that although A-T is a disease of childhood, ATM may play a role in AD. We hypothesized that reductions in ATM activity may be one of factors leading to cell cycle related neuronal cell loss in AD. We performed immunohistochemistry on postmortem brain tissue from human AD patients and age-matched control individuals using several ATM-related antibodies and cell cycle markers. Using the translocation of HDAC4 to the nucleus as a marker for the loss of ATM activity, we found that a significant decrease in ATM function in hippocampus of individuals with AD compared with controls. Curiously, the CA2 sub-region was the region with the most levels of HDAC. Correspondingly, S1981-phosphosphorylated ATM (an activating phosphorylation) was found localized in cytoplasmic granules in hippocampal pyramidal cells. We hypothesize that the neurons under the stress of lower ATM activity initiate a protective response by activating ATM. We are currently analyzing brain stem, frontal cortex and cerebellum of these cases, and will correlate the levels of ATM activity with the presence of cell cycle events and other markers. Thus, the decrease in ATM activity was confirmed in AD, yet its mechanism and downstream effects are not fully revealed.

Title: VILIP-1 protein in Alzheimer disease and frontotemporal lobar dementia postmortem brain tissue

Authors: *C. M. KIRKWOOD[1,2], M. L. MACDONALD[2,3], T. A. SCHEMPF[2], P. A. MURRAY[2], M. D. IKONOMOVIC[7,4], M. SUN[5], Y. DING[5,3], N. A. YATES[5,3], J. K. KOFLER[6], O. L. LOPEZ[4], R. A. SWEET[2,7];
[1]Univ. of Pittsburgh, Carnegie, PA; [2]Psychiatry, [3]Biomed. Mass Spectometry Ctr., [4]Neurol., [5]Cell Biol., [6]Neuropathology, Univ. of Pittsburgh, Pittsburgh, PA; [7]Mental Illness Research, Education, and Clin. Ctr., VA Pittsburgh Healthcare Syst., Pittsburgh, PA

Abstract: Visinin-like protein 1 (VILIP-1) is a neuronal calcium sensor in a subfamily of closely related EF-hand Ca2+-binding proteins that mediate receptor trafficking and are required for induction of long term depression. VILIP-1 has recently been reported to be increased in cerebrospinal fluid and plasma of Alzheimer disease (AD) subjects relative to normal controls, and to individuals with other dementias, suggesting a potential role as an AD biomarker. Higher cerebrospinal fluid VILIP-1 levels were also predictive of more rapid cognitive decline. However, how VILIP-1 expression levels are altered in the brain tissue of AD and other dementia subjects remains largely unknown. Using a targeted mass spectrometry approach, we measured VILIP-1 protein levels in superior frontal gyrus gray matter from a set of Braak Stage 3 - 5 AD (n=59) subjects, along with both frontemporal lobar dementia (FTLD) (n=11) and normal control (n=12) subjects. A trend towards reduced VILIP-1 levels in AD subjects compared to controls was observed. Within AD subjects, VILIP-1 levels were unaffected by a number of indicators of more rapid progression or disease severity: presence of psychosis, Braak stage, MMSE score, and the presence of Lewy bodies. Similarly, measures of soluble tau, phosphotau, and amyloid-β did not correlate with VILIP-1 levels. FTLD subjects had significantly lower levels of VILIP-1 compared to controls, which could indicate that loss of VILIP-1 is due to neuronal loss rather than being due to a neuropathologic process specific for AD. An expanded evaluation of VILIP-1 levels in mesial temporal gray matter, a region highly compromised in early stages of AD, and the parietal cortex, a region largely unaffected in FTLD, from a subset set of AD and FTLD subjects will also be presented to further test this hypothesis.

Title: In the hippocampal region of Alzheimer's disease, IRS-1 pS616, a candidate biomarker of brain insulin resistance, rises first in CA1 and later in the subiculum and perirhinal cortex

Authors: *A. SAMOYEDNY[1], M. P. BALDASSARI[2], H. KAZI[2], L.-Y. HAN[2], S. E. ARNOLD[2], J. Q. TROJANOWSKI[2], D. A. BENNETT[3], K. TALBOT[1];
[1]Neurosurg., Cedars-Sinai Med. Ctr., Los Angeles, CA; [2]Psychiatry, Univ. of Pennsylvania, Philadelphia, PA; [3]Neurol., Rush Univ., Chicago, IL

Abstract: BACKGROUND: *Ex vivo* tests of insulin responsiveness in AD brain tissue show that it is profoundly insulin resistant compared to that of normal, age- and sex-matched controls (Talbot et al., JCI 122: 1316-1338, 2012; Wang et al. J. Neurosci. 32: 9773-9784, 2012). Among the most consistent correlates of such brain insulin resistance is elevation in basal levels of insulin receptor substrate-1 phosphorylated at serine 616 (IRS-1 pS616). Viewed immunohistochemically, this phenomenon reflects accumulation of the phosphospecific antigen in neuronal cytoplasm and neuropil (Talbot et al., 2012). In normal cases, IRS-1 pS616 is restricted to neuronal nuclei. As we reported earlier, this candidate biomarker of brain insulin resistance is elevated in hippocampal field CA1 in AD dementia cases and to a lesser degree in mild cognitive impairment (MCI) cases. Here we studied the same phenomenon throughout the hippocampal region (HR = CA1-3 + dentate gyrus [DG] + subiculum + combined pre- and para-subiculum + entorhinal cortex [ERC]) + perirhinal cortex). METHODS: We studied the two cohorts analyzed in our earlier report (Talbot et al., 2012), namely 24 pairs of cognitively normal and AD dementia cases matched for age and sex in the University of Pennsylvania brain bank and a set of 30 cognitively normal, 29 MCI, and 31 AD dementia not significantly different in age or male/female ratio from the Religious Orders Study (ROS) at Rush University. Immunohistochemistry was performed on coronal sections of the HR using an Invitrogen anti-IRS-1 pS616 antibody (44-550) at 1:500 as specified in Talbot et al. (2012). The density of neurons with extra-nuclear IRS-1 pS616 in each anatomical area was quantified using ImagePro Plus. RESULTS: Elevated extra-nuclear IRS-1 pS616 in MCI or AD dementia cases was seen only in neurons, specifically glutamatergic (i.e., pyramidal) cells in the HR. This antigen was found in clustered microdomains around cell nuclei, as well as in primary dendrites, neuritic

processes, neuropil threads, and perhaps axons. In MCI cases, the density of HR neurons with extra-nuclear IRS-1 pS616 was significantly ($p < 0.05$) increased only in CA1, but in AD dementia cases, the density of such cells was significantly increased in CA1, the subiculum, and the perirhinal cortex. The density of these pathological neurons was not elevated in CA2, CA3, DG, pre- and para-subiculum, or the ERC of MCI or AD dementia cases. CONCLUSION: These findings suggest that a candidate biomarker of brain insulin resistance (IRS-1 pS616) in the HR is limited to glutamatergic neurons and appears first in CA1 as seen in MCI cases and only later in the subiculum and perirhinal cortex as seen in AD dementia cases.

Title: Cerebrocortical IRS-1 pS616, a candidate biomarker of brain insulin resistance, may be an AD biomarker

Authors: *K. TALBOT[1], B. M. SAGGU[2], S. A. RIZVI[3], M. A. KAHN[4], A. J. SAMOYEDNY[1], J. Q. TROJANOWSKI[5];
[1]Cedars-Sinai Med. Ctr., Los Angeles, CA; [2]Nassau Univ. Med. Ctr., East Meadow, NY; [3]Neurolog. Inst. of the Cleveland Clin., Cleveland, OH; [4]State Univ. of New York, Buffalo, NY; [5]Univ. of Pennsylvania, Philadelphia, PA

Abstract: BACKGROUND: Among the most consistent correlates of brain insulin resistance in AD is an elevation in basal levels of insulin receptor substrate-1 phosphorylated at serine 616 (IRS-1 pS616) (Talbot et al., JCI 122: 1316-1338, 2012). Since this elevation can be produced by beta amyloid (Bomfim et al., JCI 122: 1339-1353), IRS-1 pS616 may be a biomarker of AD and other neurodegenerative disorders (NDD) with abnormally high beta amyloid levels (e.g., dementia with Lewy bodies, DLB). To test this, we quantified IRS-1 pS616 in cerebrocortical neuronal cell bodies and neuropil in AD, DLB and NDDs with typically low beta amyloid levels: corticobasal degeneration (CBD, a tauopathy) and a TDP-43 positive, tau-negative form of

frontotemporal lobar degeneration (FTLD/TDP-43). METHODS: Seventeen quintuplets of normal, AD, DLB, CBD, and FTLD/TDP-43 cases matched for age (within 5 y), sex, and postmortem interval (within 4 h) were selected in the brain bank of the Center for Neurodegenerative Disease Research at the University of Pennsylvania. In each case, sections were cut from fixed blocks of neocortical areas (motor, prefrontal, and temporal) and hippocampus. These were reacted immunohistochemically for IRS-1 pS616 using Invitrogen antibody 44-550 (1:500). In all brain areas, we calculated the density of neurons (cells per unit area) with extra-nuclear IRS-1 pS616 (usually restricted to cell nuclei in normal cases) and the optical density of IRS-1 pS616 immunoreactivity in neuropil. RESULTS: A one-way ANOVA showed highly significant ($p < 0.002$) differences among the case groups in the density of neurons with extra-nuclear IRS-1 pS616 in all brain areas studied and in IRS-1 pS616 neuropil in all those areas except motor cortex. Post-hoc tests showed that this was due to higher levels of both IRS-1 pS616 measures in AD cases compared to all the other groups with one exception, namely higher than normal neuropil IRS-1 pS616 in CA1 of DLB cases. CONCLUSIONS: These results support the hypothesis that IRS-1 pS616 in the neocortex and/or CA1 is associated with NDDs often characterized by elevated beta amyloid. The consistent increase in IRS-1 pS616 across cortical areas in AD and its consistent absence in a tauopathy and a TDP-43 proteinopathy suggests that elevated cerebrocortical IRS-1 pS616 may be a reliable and relatively selective biomarker of AD.

Abstract: Neuronal accumulation of UBB+1, a frameshift variant of ubiquitin B, is a hallmark of Alzheimer disease (AD). How UBB+1 contributes to neuronal dysfunction remains poorly understood. Here we show that, in hippocampal brain regions of AD patients with neurofibrillary tau tangles, UBB+1 co-exists with VMS1, the mitochondrion-specific component of the ubiquitin-proteasome system (UPS). Expression of human UBB+1 in yeast disturbs the UPS, leading to mitochondrial stress and cytotoxicity. Inhibition of UPS activity exacerbates UBB+1-triggered cytotoxicity, while UPS stimulation by the transcription activator Rpn4 reduces UBB+1 cytotoxicity. High levels of the Rpn4 target protein Cdc48 and its conserved cofactor Vms1 are sufficient to relieve UBB+1-triggered cytotoxicity. The fact that AD-induced cellular dysfunctions can be avoided by UPS activity at mitochondria has far-reaching pathophysiological implications.

Title: Aggregation properties of the small nuclear ribonucleoprotein U1-70K in Alzheimer Disease

Authors: I. DINER[1], C. M. HALES[2], L. RABENOLD[1], I. BISHOF[1], D. DUONG[1], H. YI[1], O. LAUR[1], G. MARLA[3], L. J. JAMES[2], A. LEVEY[2], *N. T. SEYFRIED[4];

Abstract: Recent evidence indicates that U1-70K and other U1-specific small nuclear ribonucleoproteins (snRNPs) are sarkosyl-insoluble and associate with tau neurofibrillary tangles (NFTs) selectively in Alzheimer disease (AD). Currently, the mechanisms underlying the conversion of highly soluble nuclear U1 snRNPs into insoluble cytoplasmic aggregates remain elusive. In this study, immunogold electron microscopy was used to demonstrate that U1-70K associates with filamentous structures in the cytoplasm that resembled twisted-ribbon NFTs. Following biochemical fractionation nearly all U1-70K was sarkosyl-insoluble in AD brain tissue, but not in control brain. Herein we demonstrate that total homogenate fractions from AD brains function as seeds for aggregation of soluble U1-70K from control brain homogenate or recombinant U1-70K to become sarkosyl-insoluble. This indicates that biomolecules harbored within AD brain sequester normal U1-70K into an insoluble form. This effect was not dependent on RNA, and did not correlate with tau levels as AD homogenates with reduced levels of these components were still capable of seeding U1-70K. By contrast, proteinase K-treated AD homogenates and sarkosyl-soluble fractions were unable to seed soluble U1-70K, suggesting that aggregate-prone proteins in AD brain are responsible for seeding U1-70K. Finally, by expressing recombinant N- and C-terminal truncations of U1-70K, we determined that the highly disordered low complexity C-terminus is necessary and sufficient for U1-70K aggregation. These results support that AD homogenate can induce the aggregation of soluble U1-70K in a protein dependent manner.

Title: Differential regulation of cortical Munc18-1 splice variants in Alzheimer's disease: Correlations with the severity of cognitive decline and neuropathology in a community-based aging study

Authors: A. RAMOS-MIGUEL[1], C. HERCHER[1], C. L. BEASLEY[1], A. M. BARR[2], J. A. SCHNEIDER[3], D. A. BENNETT[3], *W. G. HONER[4,1];

Abstract: Loss of synaptic connections stands among the earliest events in the pathophysiology of Alzheimer's disease (AD). The mechanisms involving synaptic damage are unclear. We previously showed that weak interactions of the soluble NSF attachment protein receptor (SNARE), the molecular engine of neurosecretion, were associated with cognitive decline and AD pathology, without a significant loss of syntaxin-1 and SNAP-25 monomers. Munc18-1 (M18) is a critical molecule for SNARE assembly. We hypothesized that the age-related SNARE decline could be caused by abnormal M18 expression. Cortical samples from the middle-frontal gyrus were collected from deceased participants enrolled in the Memory and Aging Project, a community-based aging study. Cognitive abilities of the participants were evaluated annually, and neuropathological assessments met Reagan criteria. Participants were grouped into non- ($n = 56$) or mild ($n = 50$) cognitive impairment (NCI/MCI), or AD ($n = 70$). Selective antibodies targeting M18a and M18b splice variants were used for quantitative Western blotting, immunohistochemistry, and co-immunoprecipitation. Cortical levels of M18a were dramatically downregulated in AD (64%, $p < 0.001$) compared with NCI or MCI. Only a marginal reduction of M18b (9%, $p = 0.033$) was found in the same samples. Other presynaptic proteins (synaptophysin, syntaxin-1, SNAP-25) were not significantly altered, indicating that the M18 deficit may precede synaptic loss. M18a density was strongly related to global cognitive score ($r = 0.323$, $p < 0.001$) and neuropathology ($r = -0.266$, $p < 0.001$), whereas these correlations were weaker for M1b ($r = 0.179$, $p = 0.018$; $r = -0.216$, $p = 0.004$, respectively). Comparative analyses of human cortical sections revealed substantial differences in the distribution of M18 variants. While M18b was ubiquitously expressed across all layers, M18a showed perinuclear localization, mainly in layer IV-VI neurons. M18b, but not M18a, co-localized with synaptophysin in presynaptic terminals. Tau-positive cells (AT8 and Alz-50) barely expressed M1a, whereas M1b was intact regardless the presence of these pathological tau forms. Moreover, the amount of syntaxin-1 co-immunoprecipited with M18b was 5-fold larger than observed with M18a. The results suggest that loss of M18a in cortical neurons is an important event in the pathogenesis of AD. M1a deficiency may be linked to early neuronal damage, since weak to null expression of this variant was observed in tau positive cells. The cytosolic localization and its low affinity for syntaxin-1 suggest that M1a activity is unrelated to neurosecretion.

Title: Amyloid peptides associated with human dementias, Aβ42, ABri and ADan cause differential neurotoxicity in *Drosophila* brain

Authors: *M. S. MARCORA[1], A. C. FERNANDEZ-GAMBA[2], R. VIDAL[3], L. MORELLI[2], M. F. CERIANI[2], E. M. CASTAÑO[2];

Abstract: Several neurodegenerative diseases share common features such as their clinical progression with age, synaptic abnormalities followed by neuronal loss and the presence of amyloid deposit in the brain. Alzheimer's disease (AD), the most common cause of dementia, is characterized by the aged-associated dysfunction of cholinergic neurons and the progressive accumulation of amyloid β (Aβ) and hyperphosphorylated tau, major components of senile plaques and neurofibrillary tangles (NFT), respectively. Familial British and Danish dementias (FBD and FDD) are autosomal dominant neurodegenerative disorders associated to the accumulation of amyloids ABri and ADan, respectively. Internal proteolysis of the precursor protein BRI2 carrying different mutations leads to the release of ABri and ADan, which are highly amyloidogenic *in vitro* as compared to Aβ. *Drosophila* melanogaster is a suitable animal model to study the relationship between different amyloids and their specific neurodegenerative and behavioral phenotype. We generated transgenic *Drosophila* lines that over-express human amyloids Aβ42, ABri and ADan, respectively, or a control peptide Bri2-23 (the non-amyloidogenic product of the internal proteolysis of wild type BRI2) using the Gal4/UAS binary system. Pan-neuronal expression revealed an age-dependent toxicity of amyloids as determined by the ability of flies to climb in a geotaxis paradigm when compared to Bri2-23. ADan-

expressing flies displayed a significant impairment in climbing ability at 7 days post eclosion (p.e) ($p< 0.001$), while ABri and Aβ42 showed a significant toxicity at 15 and 21 days respectively ($p<0.01$). Histological analysis of paraffin brain sections showed thioflavine-S-negative accumulation of amyloids peptides along with mild vacuolization. In addition, we analyzed the levels of Bruchpilot (Brp), a protein involved in clustering and vesicle release at the presynaptic active zones. Western blots from fly heads showed an age-dependant reduction of Brp in amyloid-expressing as compared to controls. At 7 days p.e. no differences were found while at 21 days Brp levels in amyloid-expressing flies were reduced (approximately a 20%) as compared to Bri2-23 control flies. Our results indicate that different amyloids display differential neurotoxicity in the CNS. However, all of them appear to affect synaptic transmission in an aged-dependent manner. These *Drosophila* models will allow a systematic and unambiguous assessment of differences and similarities in the mechanisms of toxicity of diverse amyloid peptides associated with dementia.

Abstract: INTRODUCTION Alzheimer's disease (AD) is a progressive, neurodegenerative and incurable disorder. Many studies have attributed iron-related oxidative stress as a factor promoting neuronal damage. Free iron in the neurons leads to the formation of reactive oxygen species that are neurotoxic, hence neuronal damage. Immunohistochemistry studies have shown co-localization of iron with amyloid plaques (Aβ) and hyper-phosphorylated Tau proteins (HP-tau) which are the hallmark histopathological changes seen in AD. In fact, we hypothesize that Aβ and HP-tau sequester the excess iron that overwhelms the ferritin protein, the primary iron storage protein. Such co-localizations are also seen with the Magnetic Resonance Imaging (MRI). However, we do not know the pathophysiological mechanism or related stages of disease with regard to Aβ and HP-tau iron sequestration. Nuclear Magnetic Resonance (NMR) is based on the principal that a ferromagnetic substance would have different Longitudinal (T1) and Transverse (T2) relaxation based on their environment they are in. We titrated NMR relaxation values for iron-bound AD-associated protein complexes. METHODS Hydrogen atoms are ferromagnetic; hence, they align so that their axis is parallel to in the applied magnetic field of NMR. A radiofrequency pulse was delivered to tip these atoms from their position. The atoms again try to align according to magnetic field. These atoms, based on their environment, relax back to their original position giving the longitudinal relaxation (T1). Atoms also have their spin and when they are tipped off their position, they precess back giving the transverse relaxation (T2). Phosphate NMR is based on phosphorous atoms. RESULTS We conducted NMR (proton and phosphate) on different iron-bound AD-associated protein complexes at varying concentration levels. Phosphate saline buffer in deuterium was used as a control. The T1 relaxation ranges from 65.3 ± 0.2 ms to 10.96 ± 0.5 s. T2 values ranges from 20 ± 2 ms to 24.3 ± 13.5 s and T2* ranges from 13 ms to 774 ms. CONCLUSIONS We have been able to determine T1, T2 and T2* values for varying concentrations of iron-bound proteins and appropriate controls. These values were not only different for individual iron-protein complexes but also different for varying concentrations of same iron-protein complexes. We also conducted the phosphate based NMR: the result showed different relaxation properties for iron phosphate complexes at different concentrations. These relaxation properties can be used to inform MRI for generating contrast images. Our ultimate goal is to develop a diagnostic imaging technique for AD in murine and human brains.

Abstract: Alzheimer's disease (AD) causes tissue loss and neuronal death, which drastically affect cognitive functions. The most remarkable signs of brain damage in AD include shrinkage of the brain volume and white matter disruption. Patients with mild cognitive impairments (MCI) also display similar but less prominent change in the brain. Although previous research has reported poor neurocognitive performance of these patients, the relationship between brain damage and cognitive impairments remains unclear. The present study employed volumetric measurement, voxel-based morphometry (VBM) and tract-based spatial statistics (TBSS) to compare the group differences. The correlations of performance in the attention, memory and language domains and indices of grey and white matter integrity were also examined. We observed significant difference in the total hippocampus volume among the three groups. The VBM analysis showed significant difference in the hippocampus, thalamus, the PFC, visual and motor cortices between the AD and control groups, but only the hippocampus, thalamus, and the visual cortex between the control and MCI groups ($p<0.001$). In terms of cortical thickness, the control group had significantly greater thicknesses in bilateral middle temporal gyrus and left parahippocampus than the AD and MCI groups. Significant difference in the right parahippocampus thickness was only seen between the MCI and control groups. The TBSS analysis only revealed significant difference in FA and MD between controls and ADs. The regions displaying significant difference included inter-commissural and association tracts. Pearson correlation analysis showed significant correlations in multiple grey and white matter ROIs with Delayed recall of Logical Memory and Semantic Verbal Fluency. The study has suggested that atrophy and cortical thinning in temporal and occipital regions are closely related with memory and verbal deficits in patients.

Title: MicroRNAs in human cerebrospinal fluid as diagnostic biomarkers for Alzheimers Disease

Authors: *J. A. SAUGSTAD[1], T. A. LUSARDI[5], C. A. HARRINGTON[2], J. I. PHILLIPS[1], B. LIND[3], J. A. LAPIDUS[4], J. F. QUINN[3];
[1]Anesthesiol. & Perioperative Med., [2]Integrated Genomics Lab., [3]Neurol., [4]Publ. Hlth. & Preventive Med., Oregon Hlth. & Sci. Univ., PORTLAND, OR; [5]RS Dow Neurobio. Labs, Legacy Res. Inst., Portland, OR

Abstract: Alzheimer's disease (AD) is the most common form of dementia and the greatest known risk factor for AD is increasing age. Although AD is progressive, AD treatments can temporarily slow disease progression. Thus a preclinical tool that could diagnose AD earlier in stage and allow treatments to be initiated earlier in the disease would be of great clinical value. However, there are currently no biomarkers that can reliably predict the onset of AD, nor are there any that can distinguish early AD from other age-related dementias. The existence of extracellular RNAs in biofluids provides a fertile molecular landscape from which diagnostic and prognostic biomarkers may be isolated and exploited. Hence, the identification of RNAs present in cerebrospinal fluid (CSF) provides an opportunity to define important biomarkers for clinical use in neurodegenerative diseases. We examined microRNA (miRNA) expression in human CSF to evaluate their clinical utility as diagnostic biomarkers for AD. We isolated total RNA from existing, banked CSF samples isolated from healthy subjects and AD patients obtained from the Oregon Alzheimer’s Disease Center (OADC) and analyzed miRNA expression using TaqMan® Array Human MicroRNA Card Set v3.0 (Life Technologies) arrays. Initial studies included CSF samples representing 16 healthy and 16 AD subjects, with male and female equally represented. In this proof-of-principle analysis, subjects were segregated into “Group 1” and “Group 2” by disease status, and only miRNA presence/absence was considered, without regard to abundance. Analysis was restricted to 208 miRNAs, each of which was variably present in as few as 5, and as many as 25, of the 32 subjects. Results from these studies revealed that ~8% of the miRNAs

were significant at the 0.05 level by Fisher's Exact test. Five miRNAs met the 25% false discovery rate (FDR) threshold, while 2 met the 10% FDR threshold. Of the 5 with FDR 10%, 1 miRNA was preferentially expressed in Group 1, and 4 in Group 2. A classification rule combining 2 miRNAs preferentially expressed in Group 2 yielded correct classification percentages of 87% and 94% for Groups 1 and 2, respectively. These studies highlight the potential utility of miRNAs in human CSF as clinical biomarkers for AD. The presence/absence analysis used here did not rely on any form of normalization, and thus may be a robust means to identify clinical biomarkers. Further analyses will investigate the use of multiple miRNA targets, incorporating relative abundance levels, to improve the sensitivity and specificity of disease identification. Additional healthy and AD CSF samples are being processed to confirm the specificity of these results.

Title: Phage display: the search for blood-base biomarkers in Alzheimer's disease

Authors: *C. CARROLL[1], E. H. KOO[3], Z. AN[4], Y. LI[2];
[2]Mol. Pharmacol. & Chem. Program, [1]Mem. Sloan Kettering Cancer Ctr., New York, NY;
[3]Neurosciences, Univ. of California at San Diego, San Diego, CA; [4]Brown Fndn. Inst. of Mol. Med., Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX

Abstract: Alzheimer's disease (AD) is the sixth leading cause of death in the US, and there is currently no effective treatment or cure. Pathology in AD is thought to develop decades before symptoms present, so we set out to find a biomarker for the disease that can be used to track the progression. Current biomarkers are either invasive (cerebral spinal fluid) or expensive (brain imaging), making a blood-based biomarker an attractive alternative. We used two phage-display libraries, which display random peptide sequences on its coat, to pan antibody populations in either AD or age-matched control blood serum. We found approximately eighteen sequences that

were enriched in AD samples, of which 5 were validated. Validation studies were done on the original twenty samples using an enzyme-linked immunosorbent assay (ELISA), where higher absorbance values for AD patient samples over control samples corresponded to a positive hit. We are now testing a blinded set of serum samples to see if our panel can effectively sort AD from normal controls. This panel has the potential to serve as an effective diagnostic tool. If the disease is diagnosed earlier, therapeutics that failed earlier clinical trials could be retested for increased efficacy in this pre-symptomatic cohort.

Title: Transferrin receptor mediated transcytosis of an antibody based radioligand for quantification of intrabrain levels of soluble amyloid-beta aggregates

Authors: *D. SEHLIN[1], X. T. FANG[1], L. M. CATO[1], J. FÄLTING[3], G. ANTONI[2,4], L. LANNFELT[1], S. SYVÄNEN[1];
[1]Dept. of Publ. Health/Geriatrics, [2]Dept. of Medicinal Chemistry, Preclinical PET Platform, Uppsala Univ., Uppsala, Sweden; [3]BioArctic Neurosci. AB, Stockholm, Sweden; [4]PET Ctr., Uppsala Univ. Hosp., Uppsala, Sweden

Abstract: Positron emission tomography (PET) [11C]PIB imaging detects amyloid plaques formed early in the course of Alzheimer’s disease (AD) pathogenesis. The introduction of

[11C]PIB was a game changer for diagnosis of AD as amyloid plaque imaging detects AD pathogenesis early in the course of disease and helps distinguishing AD from other types of dementia. However, the plaque pathology does not correlate well with disease progression or outcome of therapeutic interventions, limiting the usefulness of amyloid PET tracers for such applications. The aim of the present project was to develop a PET radioligand based on an antibody (mAb158) that binds selectively to soluble amyloid β (Aβ) protofibrils, which may correlate better with disease severity than amyloid plaques. Antibodies are large molecules which do not readily pass over the blood-brain barrier (BBB). To reduce the size of the molecule and to decrease the systemic half-life, a F(ab')2 fragment of the antibody was generated. F(ab')2-158, lacking Fc related effector functions, showed a pronounced reduction in half-life in mice (2 hours for F(ab')2-158 compared to 11 days for mAb158) which is advantageous for imaging as high PET radioligand concentrations in the blood of the brain would give rise to a large confounding unspecific signal. To further improve F(ab')2-158 as a PET ligand it was chemically linked to a transferrin receptor (TfR) antibody, enabling TfR mediated transcytosis to actively transport F(ab')2-158 over the BBB and bind to its target in the brain. After radiolabelling with 125I, the bispecific fusion protein was analysed with ELISA to confirm retained binding to both Aβ protofibrils and TfR. Next, APP-transgenic (tg-ArcSwe) and non-transgenic mice of different ages received a single injection of radioiodinated fusion protein or F(ab')2-158. After saline perfusion, brains were collected 2 h to 3 days post injection and the brain uptake was measured *ex vivo* and compared to brain levels of soluble Aβ protofibrils and total Aβ. The fusion protein displayed a ten-fold higher brain uptake compared to F(ab')2-158 and its brain retention increased with age, correlating closely with brain levels of soluble Aβ protofibrils. After labelling with a PET radionuclide, this fusion protein has the potential to become useful for PET-imaging of soluble Aβ aggregates in AD patients.

Title: Distribution of autoradiography signal of [18F]T807 and [3H]T807 matches with that of tau antibody AT100 in post-mortem brain tissue of Alzheimer's patients

Authors: *F. GOMEZ[1], Y.-G. LIN[2], Q. LIANG[2], J. RYDER[3], H. WANG[3], G. ATTARDO[2], M. MINTUN[2], D. SKOVRONSKY[2];

Abstract: The autoradiography of the PET biomarker [18F]T807 in postmortem brain tissue of one Alzheimer's (AD) patient has been reported to overlap with that of the anti PHF-tau antibody AT100. The present study is designed to extend these finding by using brain tissue from 10 AD patients that present different degrees of tau accumulation. In order to establish the correlation between tau aggregation and [18F]T807 autoradiography signal, the distribution of [18F]T807 was examined in the same cortical section of AD (n=10) or normal controls (n=2) subject using either autoradiography of the radioligand or AT100 immunohistochemistry. In a second set of slices a similar protocol was conducted using [3H]T807 in order to increase the resolution of the ARG signal and show cellular colocalization of the radioligand and the PHF-Tau antibody. We found that the pattern of both [18F]T807 and [3H]T807 signal distribution match closely with that of the PHF-Tau antibody. We are currently conducting the quantification of these results and the colocalization studies using [3H]T807 and AT100.

Title: Methodology for computing white matter nerve fiber orientation in human histological slices

Authors: *J. J. WISCO[1], A. NAZARAN[2], H. V. VINTERS[3], N. K. BANGERTER[2]; [1]Physiol. and Developmental Biol., [2]Electrical and Computer Engineering, and Neurosci. Ctr., Brigham Young Univ., Provo, UT; [3]Pathology and Lab. Med., David Geffen Sch. of Med. at UCLA, Los Angeles, CA

Abstract: INTRODUCTION We endeavor to validate Diffusion Tensor Imaging (DTI) tractography algorithms in histologically processed and stained white matter fibers of brain tissue specimens that have matching DTI data. Our initial manual segmentations attempts have been labor intensive, time consuming, and subjective. In this work, we present an algorithm for calculating the average directionality of nerve fibers across a given Region of Interest (ROI) in the white matter of Luxol Fast Blue stained sections through the medial temporal lobe. The presented method is rapid and computationally efficient, and is based on a threshold of the histological slices and 2D Fourier domain (FD) analysis. The calculation provides a central tendency of the nerve fibers (CTNF) in sample images in an ROI along with the confidence over the estimation (CE) of the orientation. METHODS We obtained one high-resolution scanned image of a histological section from 8 different subjects. In each image, we defined over 800 ROIs at various isotropic sizes ranging from 0.4x0.4 mm up to 0.8x0.8 mm for analysis. Reconstructing fiber directionality involved a multi-step, semi-automated process of 1) threshold segmentation on LAB color space, 2) transformation of segmented image into the FD, 3) high pass filtering and calculating the energy of the image in "angular window size" of the FD at each angle, and 4) calculating of CTNF based on an angular orientation histogram (AOH) of image energy in FD. To calculate CTNF, we compute the average orientation in the 180 degrees range in AOH where the standard deviation (SD) is minimum. We calculate CTNF in 180 degrees range due to conjugate symmetry in FD. We also use the minimum SD to calculate CE. An expert anatomist evaluated the determined fiber directionalities in comparison with visually inspected fiber directionality from the same ROI's. RESULTS Our semi-automated method agrees with that of the expert visualization, but also recognizes nuances of microstructure that contribute to the calculated fiber orientation in each ROI. The method is extraordinarily fast. The same region of analysis for one tissue slice takes several months to achieve using visual judgment. Our algorithm can calculate better results in hours. In addition, with increasing resolution of the ROIs, accuracy of the orientation estimates increases, particularly in the white and gray matter interface. CONCLUSION Our research team will now be able to efficiently compare anatomical fiber directionality from histological sections with matched DTI of the same post-mortem specimens. In future, we will apply the algorithm to small biopsies and to whole-brain axial, coronal, and sagittal sections.

Title: The effects of physical exercise on hippocampal microvasculature in a mouse model of Alzheimer's disease

Authors: *E. MALISZEWSKA-CYNA[1,3], J. J. OORE[1], M. THEODORE[1], L. A. M. THOMASON[2], A. DORR[2], M. M. KOLETAR[2], J. STEINMAN[5,4], J. G. SLED[5,4], B. STEFANOVIC[4,2], I. AUBERT[1,3];

Abstract: Alzheimer's disease (AD) is associated with cerebrovascular impairments including decreased vascular density, increased tortuosity, and capillary fragmentation. Moreover, global hypoperfusion has been found to correlate with amyloid-β accumulation and exacerbated cognitive decline. Current treatment strategies for AD patients focus primarily on managing symptoms but fail to address the persistent neurovascular impairment that leads to cognitive deficits. Targeting the neurovascular unit is gaining recognition as an important therapeutic strategy for AD. The difficulty in devising such treatment lies in part in the complexity and multitude of factors involved in AD pathology. Physical exercise has the potential for broad beneficial effects to prevent or delay some pathologies associated with AD, including vascular compromise. Physical fitness triggers several protective mechanisms: it can increase perfusion and neovascularization mediated by angiogenesis and it can increase the bioavailability of growth factors stimulating formation of new vessels. We hypothesize that physical exercise has beneficial effects on brain microvasculature in an animal model of amyloidosis. After developing plaque deposits and cognitive deficits, mice with amyloid pathology and their non-transgenic

littermates entered the study. Half of these mice had access to a spinning disk on which they could run freely and the other half were housed in a standard cage with no spinning disk. After 3 months, the animals were deeply anaesthetized and perfused with Nile red enriched Mercox resin to visualize the microvasculature. The brains were then isolated, dehydrated and placed in a clearing solution for 3 days. The complete microvasculature of the hippocampus was imaged by 2-photon fluorescence microscopy at 512 x 512 nominal in-plane resolution, every 2.5 um, over 0.5 x 0.5 cm x 0.1 mm region using 780 nm excitation. The microvascular network was identified using multi-scale, semi-automated tracking algorithm. Vessel diameter, length, tortuosity, and density were quantified. Pilot data suggest a 14% increase in mean length and a 22% increase in mean diameter of the hippocampal microvasculature with running resulting in restoration of vessel density in transgenic animals with running. The importance of neurovascular health for cognitive function and for combating AD is receiving increasing interest. This research has the potential to provide new treatment options, including promotion of an active lifestyle so as to prevent or delay AD pathology, ultimately providing a better quality of life in the elderly population and in AD patients.

Title: The spatial relationship between iron, tangles, and plaques in the subiculum

Authors: *B. J. HERRINGTON[1], B. BARZEE[1], S. BARLOW[1], S. ROBISON[1], M. HANSEN[1], A. SALIN[1], M. STONE[2], J. BRIDGEWATER[2], T. KAVAFYAN[2], K. STEED[1,2], M. E. STARK[2], H. DONG[3], A. W. TOGA[3], H. V. VINTERS[2], J. J. WISCO[1,2,4];

Abstract: INTRODUCTION: Alzheimer's disease (AD) appears to show its effects at a particularly early stage within the hippocampus. More specifically, the subiculum of the hippocampus has been noted as a region that is subjected to more severe pathological changes due to the disease. Hyper-phosphorylated Tau proteins (HP-tau) and amyloid-beta plaques (Abeta) are known to be associated with AD pathology, and Abeta has been shown to spatially correlate with non-heme iron (Fe). Iron induces a signal dropout in susceptibility-weighted Magnetic Resonance Imaging (MRI). This signal dropout indicates that MRI could potentially be used to detect HP-tau and Abeta *in vivo*. Our objective is to determine the spatial correlation between Abeta, HP-tau, and Fe within the subiculum. Our hypothesis is that both proteins should exhibit spatial correlation with Fe. METHODS: Hippocampi were sectioned (6 microns thick) and serially stained using immunohistochemistry for tau, Abeta, and Fe. Each slide was digitally scanned and viewed using Leica Digital Image Hub. Images of the subiculum from each section were exported to Adobe Photoshop CS6 and pseudocolored according to each stain. Each image was then aligned together using a manual affine registration and elastic warp. We compared the spatial overlap of each stain. Our data set consisted of 5 hippocampi from deceased subjects: a 76-year-old (yo) F with cerebrovascular disease (CVD), AD Braak Stage VI and diffuse Lewy Body Disease; a 96 yo F with CVD and Braak VI; one 70 yo M with Braak VI only; an 86 yo M with Braak IV-V; and our control, an 81 yo F who suffered from scleroderma and severe pulmonary hypertension. RESULTS: A spatial correlation was observed between Abeta and Fe in the subiculum of all four of our disease subjects. HP-tau, although showing an overlap with Fe, was much more widespread throughout the subiculum in these four subjects. Our 81 yo F control did not show co-localization between Fe, Abeta, or HP-tau. CONCLUSION: Our lab previously demonstrated that in individuals with Braak VI, there exists a spatial correlation between only Abeta and Fe in the hippocampus, but in the entorhinal cortex, a co-localization between HP-tau and Fe only. This new data indicates that in the Braak VI subiculum, Abeta spatially correlates with only Fe. This has sensitivity and specificity implications for diagnostic susceptibility weighted MR imaging. Our observation of widespread HP-tau in the subiculum is consistent with the widespread HP-tau usually observed in later Braak stages (V and VI). In future studies, there should be an attempt to explore the co-localization of HP-tau with Fe in earlier Braak stages.

Title: Detection of soluble amyloid beta and Tau proteins in the interstitial fluid of non-human primates by *in vivo* microdialysis

Authors: *A. RASSOULPOUR[1], M. HEINS[1,2], G. FLIK[1], I. VEINBERGS[1], J. FOLGERING[2], J. SUTCLIFFE[2], C. SCHLUMBOHM[2], T. CREMERS[2];
[1]Brains On-Line, LLC, South San Francisco, CA; [2]Encepharm GmbH, Gottingen, Germany

Abstract: Alzheimer's disease (AD) is the most common cause of age-related cognitive decline, affecting more than 35 million people worldwide. Amyloid plaques of which amyloid is the main component and neurofibrillary tangles consisting of fibrillar tau aggregates are both hallmarks of Alzheimer's disease. In recent years, much attention has focused on the soluble forms of amyloid and tau proteins that are released by cells and can be found in the interstitial fluid (ISF) surrounding cells. These soluble forms of the proteins are hypothesized to have a biological role on their own, and, in addition, contribute to the pathophysiology of AD and other neurodegenerative diseases. Previous work using *in vivo* microdialysis of the rodent brain has demonstrated the ability to detect the soluble forms of these proteins by microdialysis in mouse ISF as well as to modulate their levels in the CNS, therapeutically (Cirrito el al, 2003; Yamada et al., 2011; Rassoulpour et al., 2010). In the current study we utilized push-pull microdialysis in the hippocampus and prefrontal cortex of 4-5 year old cynomologous monkeys to measure $A\beta_{42}$ and total-Tau protein in the ISF. In addition, $A\beta_{42}$ and total-Tau proteins were measured in the CSF and plasma of the same animals. We found that both $A\beta_{42}$ and total-Tau protein can be detected in the ISF from the cynomologous monkey. Analysis of tissue from the hippocampus and prefrontal cortex, CSF and plasma revealed differential expression across areas. Current studies are underway to further examine the levels of these proteins in response to pharmacological manipulation and to compare with the effects seen in rodents. Taken together with future pharmacological data in multiple species and compartments, this data may provide

greater insight into the utility of *in vivo* microdialysis evaluation of pathogenic proteins as an impactful translational method in neurological disease drug discovery.

Title: Spatial correlation between iron, plaques, and tangles in the entorhinal cortex may present iron to be a potential biomarker for alzheimer's disease using MRI

Authors: ***S. H. BARLOW**[1], M. HANSEN[1], A. SALIN[1], B. BARZEE[1], K. STEED[1,2], J. J. WISCO[1,2,3], M. STONE[2], J. BRIDGEWATER[2], T. KAVAFYAN[2], E. STARK[2], H. V. VINTERS[2], H. DONG[4], A. W. TOGA[4], B. J. HERRINGTON[1];
[1]Brigham Young Univ., Provo, UT; [2]Dept. of Pathology and Lab. Med., David Geffen Sch. of Med., Los Angeles, CA; [3]Dept. of Neurobio. and Anat., Univ. of Utah, Salt Lake City, UT; [4]Lab. of Neuro Imaging, UCLA, Los Angeles, CA

Abstract: INTRODUCTION: Although Alzheimer's Disease (AD) is one of the highest causes of death in the United States, there are still very few effective treatments and many of these treatments focus on slowing down the effects of the disease, not curing it. The effects of AD are usually not seen until AD has progressed for a long time. Finding a way to diagnose AD early is an important step in curing the disease. The entorhinal cortex is one of the first regions of the brain to exhibit AD pathology - the buildup of Amyloid-beta plaques (Abeta) and hyper-phosphorylated Tau protein tangles (HP-tau). Non-heme iron (Fe) has been shown to spatially correlate with Abeta. Since Fe causes a signal dropout in susceptibility-weighted Magnetic Resonance Imaging (MRI), this imaging modality could possibly be used as a way to detect

Abeta in the brain. The purpose of our research was to confirm that iron correlated spatially to Abeta in the entorhinal cortex. Also, we wanted to see if HP-tau also correlated to iron in the entorhinal cortex. METHODS: We stained entorhinal cortex regions that were sectioned 6 microns thick for Abeta, HP-tau, and Fe. Each section was scanned and viewed with Leica Digital Image Hub. We then exported images of the entorhinal cortex from different sections to Adobe Photoshop CS6, pseudo-colored images of the different stains, and aligned the images of the different stains on top of each other with a manual affine registration and elastic warp. We then qualitatively analyzed the spatial overlap of the three stains. We obtained our data from entorhinal cortex regions of five deceased subjects: a 76-year-old (yo) F with cerebrovascular disease (CVD), AD Braak Stage VI and diffuse Lewy Body Disease; a 96 yo F with CVD and Braak VI; one 70 yo M with Braak VI only; a 86 yo M with Braak IV-V; and our control, an 81 yo F who had scleroderma and pulmonary hypertension. RESULTS: We confirmed that Fe spatially correlates with Abeta, but much less so with HP-tau in the entorhinal cortex in the Braak IV-V subject. The 81 yo F control did not show spatial correlation between Fe, Abeta, or HP-tau as expected. However, in the Braak VI subject, this trend was reversed: we saw more correlation between Fe and HP-tau than between Fe and Abeta. CONCLUSION: A signal dropout in the entorhinal cortex due to Abeta using MRI may be a method to diagnose AD in its earlier stages. A signal dropout in the entorhinal cortex due to HP-tau could be a potential diagnosis for AD in its later stages. In the future, we want to look at the correlation of iron to Abeta and HP-tau in earlier stages of AD.

Title: *In vivo* investigation of brain glucose utilization in APP-PS1 mice: [18F]FDG micro-pet vs [14C]2-DG autoradiography

Authors: C. WINTMOLDERS[1], A.-M. WALDRON[2], A. BOTTELEBERGS[1], J. KELLEY[1], S. STAELENS[2], *X. LANGLOIS[1];
[1]Janssen Res. and Develop., Beerse, Belgium; [2]Mol. Imaging Ctr. Antwerp, Univ. of Antwerp, Antwerp, Belgium

Abstract: BACKGROUND: Brain glucose utilization imaging, such as FDG-PET, is proving to be a powerful tool for the detection and monitoring of neurodegenerative diseases such as Alzheimer's Disease (AD). The reduction of brain glucose utilization in patients is most likely related to AD-associated neuropathology; however the exact causality still needs to be established. Studying brain glucose metabolism in transgenic AD mouse models may help to further characterize this causality. Our previous studies in TASTPM mice showed a negative correlation between amyloid plaque load and brain glucose uptake using [18F]FDG micro-PET and [14C]2-DG autoradiography. The present study was conducted to confirm this finding in another transgenic model, the APP-PS1 mice, and to compare the sensitivity and reliability of [18F]FDG micro-PET and [14C]2-DG autoradiography by comparing the measurements of brain glucose uptake within the same animal. METHODS: Brain glucose uptake was measured in 12-month-old female APP-PS1 mice which overexpress human mutated APPswe (KM670/671NL) and PS1 (L166P). First, static µPET scans were acquired after intravenous injections of [18F]-FDG and a conscious uptake period of 45 minutes. In addition, mice were scanned with [18F]-Florbetapir to assess amyloid burden. Six weeks after the µPET scans, [14C]2-DG was administered by intraperitoneal injections. The animals were sacrificed after an uptake period of 45 minutes and brain tissue was processed for autoradiography and immunohistochemistry. RESULTS: The results demonstrated that 12-month-old APP-PS1 mice display a global hypo-metabolism compared to wild type control mice. The outcome for both of the brain glucose utilization detection methods was similar. Also, high amyloid burden could be detected with amyloid PET and immunohistochemistry. CONCLUSION: The *in vivo* [18F]FDG/[18F]-Florbetapir PET results were confirmed by the *ex vivo* [14C]2-DG autoradiography /immunohistochemistry experiments, thus demonstrating the translatability of these findings. All animal studies were ethically reviewed and carried out in accordance with European Directive 86/609/EEC Welfare and Treatment of Animals.

Title: Toward specific Aβ oligomer aptamers

Authors: *K. M. NELSON[1], S. SREEVATSAN[2], K. H. ASHE[3], M. A. WALTERS[1];
[1]Inst. for Therapeut. Discovery and Develop., [2]Vet. Population Med., [3]N. Bud Grossman CMRC, Univ. of Minnesota, Minneapolis, MN

Abstract: Alzheimer’s disease (AD) is the most common neurodegenerative disease in the United States. While the exact cause of AD remains undefined, compelling genetic evidence suggests the accumulation of neurotoxic oligomers and fibrils of the amyloid-β peptide (Aβ) trigger disease onset. It is generally accepted that oligomers are more neurotoxic than fibrils, and several oligomers have been isolated from brain tissue and characterized to varying degrees. There is no consensus, however, on which of these oligomers are the most important in disease pathogenesis. The methods used to characterize oligomers vary between laboratories, making it difficult to compare results. Recent biophysical studies of a variety of Aβ amyloid fibrils have yielded atomic-resolution structures that differ in detail but are substantially similar in specific quaternary structural motifs, which serve as an organizing principle around which fibrils may be classified. The structure of Aβ oligomers however, remains elusive. New evidence indicates that different oligomers may affect neurons through separate pathways. We hypothesize that specific neurotoxic oligomers must have distinct quaternary structures that dictate their various biological functions. We propose to decipher the distinctive structural motifs of specific Aβ oligomers using single-stranded DNA aptamers. We are building a toolkit of aptamers that bind selectively to different classes of Aβ assemblies. We will establish their basis of binding using NMR and use this information to infer the structure of specific Aβ oligomers in humans with AD and transgenic mice that model AD. Quaternary structure-specific aptamers may provide mechanistic insights into the neurotoxicity of Aβ oligomers, and aid the development of diagnostic tools and therapeutic reagents.

Title: The differential effect of exercise on motor cortex vasculature in a model of Alzheimer's disease

Authors: L. A. M. THOMASON[1], E. MALISZEWSKA-CYNA[2], J. STEINMAN[3], *I. AUBERT[2], J. G. SLED[3], B. STEFANOVIC[1];
[1]Physical Sci., [2]Brain Sci. Res. Program, Sunnybrook Res. Inst., Toronto, ON, Canada; [3]Mouse Imaging Ctr., Toronto, ON, Canada

Abstract: Alzheimer’s disease (AD) is a neurodegenerative disorder that is the leading cause of dementia world-wide. While the primary pathological hallmarks of AD remain amyloid-beta plaques and neurofibrillary tangles, there is growing interest in the role of the brain vasculature in the disease etiology and progression. Exercise is known to increase angiogenesis and has been shown reduce amyloid-beta load and improve cognitive function in mouse models of AD. We were thus interested in assessing the effect of exercise on the vasculature in the motor cortex of a transgenic mouse model of AD (TgCRND8). Male and female TgCRND8 and their non-transgenic littermates were given access to a running wheel from 3-months of age until 6-months of age. At 6 -months of age, TgCRND8 mice were injected (IP) with Methoxy XO4 to label amyloid-beta and sacrificed 24 hours later. TgCRND8 and non-transgenic littermate mice were perfused with a mercox-BABB (Benzyl Alcohol-Benzyl Benzoate) solution containing Nile red to visualize the microvasculature. After fixation in 4% paraformaldehyde, the brain was dehydrated progressively with methanol and cleared by BABB. Four 0.5x0.5x1mm3, partially overlapped (by ~25%), regions in the primary motor cortex (M1) were imaged on a two photon fluorescence microscope, using 780nm excitation. Acquired volumes were deconvolved and stitched together. A multi-scale automated segmentation algorithm was used to track the

vasculature. Our preliminary results suggest that vessel density is decreased by ~20% in the motor cortex of the TgCRND8 mice compared to their non-transgenic littermates and the 3-month exercise regimen partially resolves this effect. These data support further investigation into the functional consequences of exercise as a potential regimen attenuating the progressive decrease in vascular density in AD.

Title: Functional connectivity changes associated with financial capacity impairment in prodromal and clinical Alzheimer's disease

Authors: *T. A. BARTEL[1], D. L. KERR[1], D. G. MCLAREN[2], D. C. MARSON[1]; [1]Neurol., Univ. of Alabama At Birmingham, Birmingham, AL; [2]Neurol., Massachusetts Gen. Hosp. and Harvard Med. Sch., Charlestown, MA

Abstract: INTRODUCTION: The key IADL of financial capacity (FC) clinically shows declines early in prodromal and clinical Alzheimer's disease (AD). Prior structural MRI studies have shown relationships between cortical atrophy and FC decline in patients with mild cognitive impairment due to AD (MCI) and mild dementia due to AD (AD). Here we build on this work by examining the relationship of DMN resting state functional connectivity to FC in cognitively normal older adults (CN), patients with MCI, and patients with AD. METHODS: Participants consisted of 51 CN, 27 MCI, and 31 AD patients diagnosed by study consensus conference. Participants completed the Financial Capacity Instrument (FCI) and a resting state fMRI scan. Time series data was extracted from four seed regions: (1) the posterior cingulate cortex (PCC), (2) medial prefrontal cortex (mPFC), and (3/4) left/right inferior parietal lobules (lIPL, rIPL). Seed region time courses were correlated with the whole brain. Correlations were

then converted to Z-scores using Fisher's z-transform. Two-sample t-tests assessed connectivity differences between groups. The relationship between connectivity and FCI score was assessed using multiple regression models including age and education as covariates. Results were thresholded at $p<0.01$ in at least 10 voxels. RESULTS: Significant differences in FCI score existed across groups ($p<0.001$). Consistent with prior fMRI studies, we also found DMN connectivity decreases in the MCI and AD groups relative to CN. For CN, we found positive relationships between FCI score and DMN connectivity with the right middle frontal gyrus (all seed regions). For MCI patients, we found positive relationships in the superior frontal gyrus (lILP, rIPL, mPFC) and superior parietal lobule/precuneus (lIPL, mPFC). For AD patients, we found positive relationships with insular cortex (lIPL, rIPL), superior temporal lobe (lIPL, mPFC, PCC), and posterior cingulate/precuneus (rIPL, PCC). CONCLUSIONS: This study suggests that intrinsic connectivity changes in prodromal and clinical AD are linked to impaired FC. Using cortical DMN nodes as seed regions, we found that FC, as represented by the FCI, is linked to connectivity within and between multiple brain networks in AD. The results provide initial evidence that functional connectivity metrics can augment neuroanatomical and cognitive models of FC decline, and provide insights into how network dysfunction impairs FC in AD.

Title: MR relaxometry of short-T2 tissues using 3D ultra-short echo time MRI in *ex vivo* brain with known Braak VI taopathy

Abstract: INTRODUCTION: The location and amount of proteins in the brain can be used to discriminate between different neurological diseases. However, it is very difficult to directly image proteins in the brain with MRI due to a very weak and rapidly decaying (short T2*) MR signal that is overwhelmed by the much stronger and longer-lasting (longer T2*) signal from other water components in the brain. Normal MRI techniques are not suitable for probing the signal of very short T2* tissues, since the signal from these tissues has typically decayed before it is sampled. Here, we explored the use of a custom 3D ultra-short TE (UTE) technique to detect signal from very short T2* tissue in an *ex vivo* brain with known Braak VI taopathy. With the technique, we were able to detect the MR signal from tissues with T2* values of less than 1ms. We were further able to quantify both the T1 and T2* of the short-T2* tissues detected. METHODS: We implemented a 3D UTE MRI sequence with a 3D cones k-space trajectory, and conducted *ex vivo* scans on a 3 Tesla scanner of a formalin fixed human temporal lobe from a subject with known Braak VI taopathy, heaviest in the hippocampus and para hippocampal gyrus. We chose an area of the brain for our study that we expect to have high volume of beta amyloid and tau proteins. We then acquired the UTE images at TEs of 0.4, 0.6, 0.8, 1, 1.2, 1.5, 2, 2.5, 3, and 3.5ms and TR of 16ms. Resolution was 1mm isotropic and the FOV was 15 cm in all directions. Each of these scans was repeated at flip angles ranging from 5 to 60 degrees. Difference images were then formed by subtracting the TE=3.5ms images from the TE=0.4ms images, effectively suppressing longer T2* tissues. We defined four regions of interest (ROIs) in areas with visible short T2* signal in the hippocampus and then calculated an average T2* for each ROI by fitting the signal from each echo to a simple monoexponential curve. T1 was then estimated for each ROI by ascertaining which flip angle yielded the largest signal for the corresponding ROI, and applying the Ernst angle formula relating maximum signal to flip angle and T1. RESULTS: We measured T2* values in the short T2* tissues at approximately 1.5 - 2.6ms for the ROIs having about 5-12 pixels. We hypothesize that these regions yielding short T2* MR signal correlate with areas with heavy Tau protein deposits. The T1 estimated in these regions was approximately 300ms. Short T2* signal is detected both in areas around the hippocampus as well as around blood vessels. CONCLUSION: A novel 3D UTE MRI sequence with a 3D cones k-space trajectory was used to image short T2* tissues in the hippocampus. Future work will seek to determine if the short T2* signal observed is water bound to protein deposits as hypothesized.

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disease that affects one in nine people over age 65. Discovering biomarkers that allow efficient monitoring of the disease will help identify individuals at risk for AD and may serve as therapeutic outcome measures. Since 2010, the Alzheimer's Disease Neuroimaging Initiative (ADNI) has included diffusion tensor imaging (DTI) in the MR protocol to better understand how white matter integrity and connectivity change as AD progresses. In this longitudinal study, we monitored patients and cognitively healthy elderly people to evaluate changes in measures of white matter fiber integrity after one year. Baseline and one-year follow-up structural T1-weighted brain MRI and diffusion-weighted images (5 b0s and 41 DWI) were obtained from 35 cognitively normal subjects (age: 74.5 +/- 6.5 y; 18M/16F), 81 people with MCI (age: 73.3 +/- 7.3 y; 53M/28F), and 28 AD patients (age: 77.1 +/- 8.2 y; 21M/7F). Average white matter fiber integrity measures of fractional anisotropy (FA) and mean diffusivity (MD) were calculated from 16 tract-wise regions of interest and across the entire white matter at both time points. The percent differences in these DTI measures relative to baseline were obtained. We used a random effects linear regression model (to account for the various acquisition sites) and tested for statistical one-year differences between AD patients and healthy elderly, covarying for age and sex. We also related changes in white matter microstructure to changes in clinical dementia rating (CDR). We used the false discovery rate (FDR) to correct for multiple comparisons. AD patients had significantly greater

reductions in integrity (as determined by lower FA and higher MD) within the entirety of the white matter (WM). These effects were noted regionally in the superior longitudinal fasciculus, the inferior fronto-occipital fasciculus (IFO), and the corpus callosum (CC) for FA, as well as the corona radiata and the CC for MD. We also found a negative association between changes in CDR score (where higher values denote worse performance) and the average FA across the full white matter. This association was positive with respect to diffusivity (a greater increase in CDR corresponds to increased diffusivity and reduced white matter coherence). To a large extent, these significant associations were also localized to the same WM regions, including the IFO and the CC.

Title: *In vivo* PET imaging of Aβ plaques using 89Zr labeled Bapineuzumab in the 5xFAD mouse model

Authors: ***J. STEVENS**[1], P. MARTINEZ[1], A. FRANSSEN[1], L. DUBOIS[3], C. URBACH[4], B. BRANS[4], P.-J. VISSER[2], D. VUGTS[5], G. VAN DONGEN[5], M. LOSEN[1];

Ctr., Amsterdam, Netherlands

Abstract: Background: Alzheimer's Disease (AD) is the most common neurodegenerative disorder amongst the elderly. Recently, a number of large Phase III clinical trials using passive immunotherapy have met with disappointing results. It is currently thought that treatment in these patients started too late and therefore early diagnosis of AD is becoming increasingly important. Recent advances in PET imaging tracers have provided means to detect amyloid

deposition in the brain. Our results show that it might also be feasible to use antibodies as a diagnostic tool to visualize brain pathology *in vivo*. Methods: Recombinantly produced bapineuzumab (hu-IgG1) or isotype controls were labeled with 89Zr. 100 µg antibody (3.7 MBq) was injected intraperitoneally into 6 and 9 months old female 5xFAD or wild type (WT) littermate controls. Mice were subsequently scanned for 1 hour using a Siemens Focus 120 microPET every second day over a period of up to 10 days. Activity in dissected brain regions was measured using a gammacounter, and autoradiography of brain slices was performed for validation of the PET imaging data. Results: 1 day after injection a specific binding could already be detected in 5xFAD mice injected with bapineuzumab compared to WT control animals. The signals remained stable over a period of 10 days. No difference between 5xFAD and WT animals was found in the isotype control group. While difference between 5xFAD and WT animals could readily be detected at 6 months of age, this difference increased at 9 months of age. Conclusion: This study shows the first proof of principle that anti-Aβ antibodies accumulate in the brain *in vivo*, and this within one day after injection using PET. The longer half-life of 89Zr compared to other isotopes also allows this method to be used in more clinics around the world for diagnosis of AD and also allows for the study of antibody dynamics in the brain. Furthermore, this new technique holds great promise for the further study of AD, by using for instance antibodies directed against different forms of Aβ.

Title: Blood-brain barrier breakdown as the starting point of cerebrovascular diseases: A dynamic contrast-enhanced magnetic resonance imaging study

Authors: *A. MONTAGNE[1], S. BARNES[2], M. HALLIDAY[1], M. SWEENEY[1], A. SAGARE[1], A. AHUJA[1], M. LAW[3], H. CHUI[4], R. JACOBS[2], B. ZLOKOVIC[1];

Abstract: There is increasing evidence showing blood-brain barrier (BBB) compromise in individuals with vascular cognitive impairment including those with mild cognitive impairment (MCI) stage and Alzheimer's Disease (AD). Furthermore, apolipoprotein E4 (apoE4), known as the most prevalent genetic risk factor for AD, has direct toxic effect on the cerebrovascular system and has been associated with an increased susceptibility of the BBB to injury. To explore these relationships, we assessed the BBB permeability (Ktrans, blood-to-brain transfer) in different brain regions using dynamic contrast-enhanced magnetic resonance images (DCE-MRI). The DCE images were analyzed using various mathematical models including the commonly used Patlak analysis. In total, we performed neurological testing, BBB permeability measurements with DCE-MRI, and lumbar puncture to measure vascular injury biomarkers and determine the effects of apoE genotype in a cohort of 28 patients. Patients were separated clinically into young normal controls (n=6; age range 23-47), age-matched to MCI normal controls (n=11; age range 55-90) and MCI (n=11; age range 55-84). We found an age-dependent BBB leakage in the cohort of cognitively normal individuals (n=17; age range 23-90), especially within the hippocampus CA1 region and Dentate Gyrus (DG). We also found that the BBB integrity is more affected in MCI patients compared to age-matched controls, which is most pronounced in the hippocampus CA1 region ($p<0.001$). Preliminary data also suggest that apoE4 carriers (n=5) have an increased BBB permeability compared to non-carriers (n=9), once more in the above-mentioned brain regions. Our imaging data were corroborated by increased values of albumin quotient and increased cerebrospinal fluid (CSF) levels of sPDGFRβ (soluble Platelet-Derived Growth Factor Receptor-Beta), a marker of mural cells pericytes. These results show that changes to the cerebrovasculature occur in the hippocampus in an age-dependent manner and worsen in MCI patients and apoE4 carriers. The different DCE models that were used to get Ktrans gave different absolute values but nearly identical results between group comparisons, suggesting the results are robust to the specific pharmacokinetic model used and not an artifact of the modeling. This paradigm should bring further understanding regarding the mechanism of the BBB disruption and recovery, help establish the relationship between subtle BBB disruption and cognitive decline, and possibly serve as an early indicator of neurovascular dysfucntion associated with cognitive impairment.

Title: Altered task-evoked fMRI activity in preclinical Alzheimer's disease

Authors: *B. A. GORDON[1], T. BLAZEY[2], T. L. S. BENZINGER[3], J. C. MORRIS[4], A. M. FAGAN[5], D. M. HOLTZMAN[5], J. ZACKS[6], D. A. BALOT[6];

Abstract: Background: There is a growing emphasis on examining the preclinical stages of Alzheimer's disease (AD). Such states can be defined in non-demented control individuals according to levels of AD pathology measured using amyloid imaging or cerebrospinal fluid levels of Aβ42, tau, and p-tau. Rising levels of such pathology precedes the onset of cognitive dysfunction. It is critical to understand how functional networks in the brain respond in such preclinical phases in the absence of significant cognitive impairment. In a population of cognitively normal adults we examined whether levels of pathology correlated with altered blood oxygenation levels in two tasks requiring sustained attention. Methods: Participants consisted of 66 cognitively normal individuals (mean age=63.9, females=42), with no evidence of clinical dementia as reflected by a Clinical Dementia Rating of 0. Participants performed two mixed-design fMRI tasks. Each task alternated between short rest blocks and longer task blocks, with randomly jittered inter-trial intervals within a test block. The first task required participants to make a living/nonliving judgment to presented words. The second task was a Stroop task, where participants responded to the color of words where the color information was congruent, incongruent, or had no overlap with the word information. AD biomarkers were quantified using mean cortical binding potential (MCBP) from an amyloid PET session, and levels of tau, ptau, and Aβ42 were obtained from cerebrospinal fluid. Analyses controlled for the age, gender, and education level of the participants. Results: When examining block-level effects, each task elicited robust activations in visual, dorsal attentional, and salience networks and deactivations in the default-mode network (DMN). For both tasks, higher levels of CSF tau and ptau were associated with greater block level activations distributed across dorsal attention and salience networks. There were no significant associations with measures of amyloid. In the first task, animate trials deactivated the DMN less and inanimate trials evoked more activity in motor

regions. In the Stroop task, incongruent trials elicited more activity in the anterior cingulate cortex, left lateral parietal regions, and bilaterally in the dorsolateral prefrontal cortex. There were no significant associations between trial-level effects and any AD biomarkers. Conclusions: This study demonstrates altered functional activity related to CSF markers of neurodegeneration in the presence of no behavioral impairment. The observed effects were most prominent in functional networks thought to support attentional control.

Title: Regiospecific loss of essential sphingolipids in the early stages of alzheimer's disease

Authors: ***N. KAIN**[1], T. COUTTAS[1], A. DON[1], B. GARNER[2];
[1]UNSW, Univ. of New South Wales, Sydney, Australia; [2]Univ. of Wollongong, Sydney, Australia

Abstract: Background: The greatest genetic risk factor for Alzheimer's disease (AD) is the ε4 allele of the brain lipid transporter Apolipoprotein E, which directly regulates secretion of the

potent neuroprotective signaling lipid Sphingosine 1-Phosphate (S1P) from astrocytes in the brain1. S1P synthesis is catalysed by sphingosine kinases 1 and 2 (SphK1 and 2)2. In this study, we investigated whether alterations to S1P metabolism occur early in AD pathogenesis and if the activity and protein levels of enzymes responsible for S1P formation and degradation may provide an explanation for any changes in S1P levels observed. Methods: By liquid chromatography-tandem mass spectrometry we quantified S1P levels in six brain regions that are differentially affected by AD pathology, in a cohort of 34 post-mortem brains, divided into four groups based on Braak Neurofibrillary Tangle (NFT) staging. Results: S1P levels were significantly positively correlated with SphK1 activity in the hippocampus ($P = 0.012$), providing the enzymatic basis for declining S1P with increasing NFT pathology. Hippocampal S1P levels were 2.5-fold higher in ApoE2 carriers compared to ApoE4 carriers, and multivariate regression analysis indicated that hippocampal S1P levels are significantly influenced by both Braak stage and ApoE genotype. Conclusions: This is the first report describing loss of S1P and sphingosine kinase activity in pre-clinical AD pathogenesis. Furthermore, SphK1 has been reported to positively regulate glutamate secretion, long-term potentiation, and synaptic strength in hippocampal neurons3, establishing a rationale for further exploration of S1P and its receptors as possible targets of interest in AD therapy. 1.Soliven, B., Miron, V., & Chun, J. Title: Classification of Alzheimer's disease using nonlinear independent component analysis

Authors: *D. DUNCAN, T. STROHMER;
Mathematics, Univ. of California, Davis, Davis, CA

Abstract: Objective: Alzheimer's Disease (AD) is the most common type of dementia and affects over 5 million people in the United States and over 35 million people worldwide; these numbers are expected to grow significantly. Therapeutic intervention is most likely to be

beneficial in the early stages of the disease, so it is important to identify the disease as early as possible in order to administer medication that will effectively stop the disease. The goal of this study is to classify magnetic resonance imaging (MRI) data of brains of patients with AD and those without AD and then to identify changes in brain MRI in early stages of AD. Methods: A novel approach based on the diffusion map framework, a leading manifold learning methods, is used for this classification. Diffusion mapping provides dimensionality reduction of the data and pattern recognition that can be used to distinguish brains of patients with AD from the controls. Since diffusion mapping may detect abnormal behavior in the data, it can be used to determine differences in brains of patients with AD. Diffusion mapping assumes access to the underlying process that it aims to reveal, but in MRI data, the relationship between the images and the underlying brain activity may be stochastic, and the data are assumed to be noisy due to calibration. Thus diffusion mapping is not the most suitable approach to use with the MRI data. An extension of diffusion maps that uses local principal components analysis (PCA) constructs coordinates that generate efficient geometric representations of the complex structures in the MRI. A data-driven adapted distance is used between blocks of MRI data to approximate the Euclidean distance between the features from the data that are considered noisy due to calibration differences. Results: Neuroimaging has been shown to be a powerful tool for studying changes in the progression of AD. MRI scans are useful for identifying features that can help predict which patients will develop AD. The data used are from the Alzheimer's Disease Neuroimaging Initiative (ADNI), a worldwide project in which subjects who have mild cognitive decline and memory loss problems are recruited to clinical trials for MRI scans. The algorithm is tested on MRI data from patients who developed AD and cognitively normal subjects (controls). Conclusions: The important difference in our method and other methods that have been used to classify and detect early onset of AD in patients is the nonlinear and local network approach, which is necessary to eliminate the calibration differences of MRI data of patients with different shapes and sizes of brains as well as to account for the various types of scanners and centers collecting data.

Abstract: HIV/AIDS is associated with cognitive impairment and in some cases with dementia, but the profile of atrophy differs from that seen in Alzheimer's disease (AD). Over 50% of HIV+ individuals show significant neurocognitive impairment. HIV preferentially affects white matter and several subcortical structures even in patients on combination antiretroviral therapy. The differential profiles of atrophy may be functionally relevant in these populations. Here, we compared the morphometry of several subcortical structures in AD and HIV+ participants using shape-based and volumetric analyses. We studied 210 HIV+ participants (48.6 ± 8.4 years; 175 men and 35 women) scanned by the HIV Neuroimaging Consortium and 144 AD subjects (76.4 ±7.3 years; 77 men and 67 women) from the ADNI dataset. FreeSurfer was used to segment the accumbens, amygdala, caudate, cerebellum, hippocampus, pallidum, putamen and thalamus. We studied the global intrinsic geometry and local surface topology of the structures' surfaces using the Laplace-Beltrami spectrum of eigenvalues (EVs) and eigenfunctions (EFs), respectively, using Shape-DNA. The first 20 EFs and 200 corresponding level sets were computed for each structure. Level set lengths were used as a metric of local shape variation. To test for the effect of diagnosis on local shape, a regression of level set length on diagnosis, age, sex and acquisition location was used. As expected, subcortical volumes are generally smaller in AD than in HIV. In the shape domain, the left amygdala (EVs 1 and 3), left thalamus (EVs 2 and 5), right amygdala (EV 2), right thalamus (EVs 2, 3 and 5) and left accumbens (EVs 3, 5, 10, 11, 17 and 18) were significantly different. Only the lengths of level sets 104 – 131 along the second EF of the left thalamus were significant after FDR (Figure 1). We report differential patterns of atrophy in AD and HIV which may add to our understanding of these diseases. Future work will determine whether these shape differences can determine the functional relevance of these differences and predict longitudinal outcomes in HIV and AD.

Title: Distinct patterns of structural brain network in mild cognitive impairment with high and low amyloid-beta burden: Graph-theoretical analysis of diffusion tensor imaging

Authors: ***D. LEE**[1], E. SEO[2], J. PARK[3], J. HAN[1], D. YI[1], B. SOHN[4], Y. CHOE[1], M. BYUN[1]; [1]Jongno-gu, Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of; [2]Chosun Univ., Kwangju, Korea, Republic of; [3]Hanyang Univ., Seoul, Korea, Republic of; [4]Boramae Med. Ctr., Seoul, Korea, Republic of

Abstract: *Background:* Amnestic mild cognitive impairment (aMCI) has been considered as a prodromal state of Alzheimer disease (AD). Approximately 40% of aMCI individuals, however, show very low beta-amyloid protein (Aβ) deposition, not sufficient for being regarded as AD. Very little is known about the differences of brain alterations between aMCI individuals with very low Aβ burden and those with high Aβ burden.*Objectives:* This study aimed to compare the characteristics of structural brain networks between aMCI with high and low Aβ burden using graph theoretical analysis of diffusion tensor imaging (DTI). *Methods:* We included 25 aMCI and 23 cognitively normal (CN) elderly. They underwent clinical evaluation, carbon-11-labelled Pittsburgh compound B (^{11}C-PiB) positron emission tomography (PET), DTI, and neuropsychological tests. Based on ^{11}C-PiB uptake values, aMCI group was divided into low Aß burden group, so called PiB-negative aMCI (aMCI_PiB-, n=11) and high Aß burden group, so called PiB-positive aMCI (aMCI_pib+, n=14). All CN elderly had very low Aß burden. Brain regions except cerebellum were parcellated into 90 regions of interest (ROIs) which served as nodes. Edges were determined by DTI tractography with a threshold of four fibers. WM networks were constructed for each subject and analyzed using graph theoretical approaches. *Results:* The overall MCI group showed reduced small-world index compared with CN elderly group (p=0.049). Subgroup analysis revealed that aMCI_PiB+ showed no significant change compared with CN. In contrast, aMCI_PiB- showed reduced local clustering compared with CN (p=0.049) and aMCI_PiB+ (p=0.019). In terms of neural substrates of cognitive deficits, animal fluency was associated with path length (r=-0.655, p=0.040) and local clustering (r=-0.694, p=0.026), respectively, in aMCI_PiB+, while no relation was found in a MCI_PiB-. *Conclusions:* Our results suggest that, in spite of clinical similarity, aMCI_pib+ and aMCI_pib- have distinct patterns of brain network alteration and their relation to cognitive impairments.

Title: Investigating white matter alterations in people with Down syndrome

Authors: *L. R. WILSON[1], T. ANNUS[1], G. WILLIAMS[2], Y. T. HONG[2], T. FRYER[2], P. J. NESTOR[3], S. H. ZAMAN[1], A. J. HOLLAND[1];
[1]CIDDRG, Dept. of Psychiatry, [2]Wolfson Brain Imaging Centre, Dept. of Clin. Neurosciences, Univ. of Cambridge, Cambridge, United Kingdom; [3]German Ctr. for Neurodegenerative Dis., Magdeburg, Germany

Abstract: Down syndrome (DS) is caused by a third copy of chromosome 21, and is the most commonly identified cause of intellectual disability. Furthermore, chromosome 21 contains the amyloid precursor protein gene and people with DS, who consequently have three copies of this gene, typically develop Alzheimer's disease (AD) in middle age. It is important to understand how amyloid accumulation leads to neurodegeneration in order to prevent dementia in DS, but also because it may inform our understanding of sporadic AD. Gaining a detailed understanding of how the structure of the DS brain differs from typical development before the accumulation of amyloid is vital, so that changes due to neurodegeneration in the presence of amyloid can be accurately mapped. Thus, the aim of this study was to determine how white matter tracts in DS may differ from the typically developing population, prior to the development of amyloid pathology. Seventeen adults with DS (7 male) and 15 typically developing controls (6 male) matched for age underwent diffusion weighted 3Tesla MRI (2mm isotropic resolution; 63 non-colinear directions). Participants with DS also underwent positron emission tomography (PET) using [11C]-Pittsburgh compound-B (PiB) to rule out the presence of fibrillar Aβ. Fractional anisotropy (FA) was compared between the two groups using tract based spatial statistics. FA in the DS group was reduced across the brain ($p < 0.001$), most extensively in tracts of the frontal and superior temporal lobes. Significant alterations were also seen in the anterior thalamic radiation; the anterior corpus callosum; the posterior cingulum; and the cerebellum, with smaller clusters in the corticospinal tracts. These results may suggest altered connectivity in frontal regions in people with DS prior to Aβ pathology. This is interesting because unlike sporadic AD, the dementia that arises in DS often manifests with changes in behaviour and personality, which are suggestive of a frontal lobe disturbance. The present results suggest that a possible explanation for this may be that developmental alterations in frontal connections in DS make these regions selectively vulnerable to accumulation of amyloid later in life.

Abstract: OBJECTIVE: To investigate whether TBI severity is associated with AD like metabolic decline independent of age in a cohort of mid-life veterans **BACKGROUND**: There is increasing evidence suggesting that a history of TBI is increasing the risk for dementia and may fasten its onset. However, it is unclear to what extent there is a specific link between TBI and AD. **DESIGN/METHODS**: A convenience sample of mid-life veterans was selected from our study center. Diagnosis of TBI severity and Post-traumatic stress disorder (PTSD) was established using research criteria. All patients underwent FDG imaging within 1 week of the examination. FDG scans were spatially normalized to the MNI FDG template in SPM8 and smoothed with at 6mm kernel. The scans were next entered into a multiple regression analysis with TBI severity as variable of interest and Age, CAPS scores, and presence of memory complaints as nuisance variables. Whole brain T-maps exploring negative correlations between TBI severity and metabolic decline were performed using family wise error (FWE) at $p < 0.05$. **RESULTS**: Our sample consisted of 50 Veterans seen at the CA WRIISC. 6 Cases were excluded due to no available CAPS scores despite positive PTSD diagnosis, and 1 subject was excluded due to extensive brain changes related to history of MS. Whole brain multiple regression analysis controlling for Age, PTSD, and Memory complaints demonstrated Glucose metabolism decreased significantly with increasing TBI severity in the right precuneus and left angular gyrus. **Conclusions:** TBI severity is associated with AD like metabolic decline independent of age.

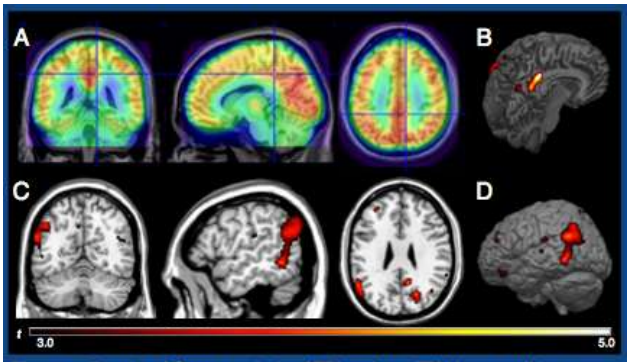

Figure Results of Group analysis of TBI and non TBI Veterans (Mean age 47) evaluated at the CA War Related Illness and Injury Study Center (CA WRIISC). (A) Average FDG-PET images for group demonstrating no clear areas of hypometabolism at the individual subject level. Cross hairs indicate area of right precuneus, with no clear hypometabolism. (B, C, D) Multiple regression analysis controlling for age, PTSD level (using CAPS score) and presence of memory complaints in same cohort of patients, demonstrating areas of hypometabolism in the right precuneus and left angular gyrus. Data is thresholded at $t > 3$ for illustration purposes (peak in the precuneus, $t = 5.45$). Results are presented in neurological orientation. The observed hypometabolic pattern is noted to be similar to that seen in Alzheimer's Disease.

Title: Brain and plasma neuronal pentraxin receptor levels in a transgenic APP/PS1 rat model of cerebral amyloidosis

Authors: E. TENG[1], T. BILOUSOVA[2], K. TAYLOR[2], R. GYLYS[2], *S. A. FRAUTSCHY[3], J. M. RINGMAN[2], G. M. COLE[1];
[1]Greater Los Angeles VA/UCLA, Los Angeles, CA; [2]UCLA, Los Angeles, CA; [3]Res. (GRECC) Neurol. (UCLA), Veteran's Greater Los Angeles Healthcare Syst., Los Angeles, CA

Abstract: Neuronal pentraxin receptor (NPR) is a synaptic protein that is almost exclusively produced in the brain and has been implicated in AMPA receptor trafficking and long-term depression. Proteomic studies indicate that NPR can be detected in cerebrospinal fluid and plasma, and suggest that it may serve as a biomarker for Alzheimer's disease (AD). However, the mechanistic association between AD pathology and brain and plasma NPR levels remains uncertain. We examined age-associated NPR expression in brain and plasma in a transgenic APP/PS1 rat model of AD in which Aβ plaque deposition begins at 9 months of age and becomes widespread by 18-20 months of age. Western blotting revealed similar levels of full-length (55 kD and 65 kD) NPR species in wild-type (Wt) and APP/PS1 rats in cortical homogenate at 3 months of age (prior to Aβ plaque deposition), but significantly increased levels of both species in APP/PS1 rats at 9 and 18-20 months of age (p's<0.02). Subsequent analyses indicated that these age-dependent differences were driven by relative increases in NPR in membrane-associated fractions, and relative decreases in NPR in soluble fractions. Genotype-related differences in NPR expression in membrane-associated fractions were also seen in the hippocampus, which exhibits significant Aβ pathology, but not in the cerebellum, where Aβ pathology is not evident. Western blotting conducted on plasma samples showed relative elevations of a 26 kD NPR fragment in APP/PS1 rats relative to Wt rats at 9 and 18-20 months of age (p's<0.02), but not at 3 months of age. In 18-20 month-old animals, plasma levels of the 26 kD NPR fragment correlated with cortical [$r(11)=0.66$, $p=0.03$] and hippocampal [$r(14)=0.67$, $p=0.01$] levels of the 65 kD full-length NPR species. We subsequently examined human plasma samples obtained from presymptomatic *PSEN1* mutation (A431E) carriers or related at-risk controls. Levels of the 26 kD NPR fragment were significantly higher with increased age ($p=0.007$) and in mutation carriers ($p=0.012$). Taken together, our findings from APP/PS1 rat brain suggest that NPR and Aβ accumulate in similar temporal and regional patterns. Aβ pathology may increase membrane-associated NPR levels via TACE inactivation. Furthermore, age- and genotype-related differences were seen in rat and human plasma levels of a 26 kD NPR fragment, which raise the possibility that this fragment may represent a peripheral biomarker of cerebral NPR levels and Aβ accumulation that may be particularly sensitive to early stages of disease progression.

Title: Magnetic resonance spectroscopy (MRS) in CNS disease models

Authors: K. LEHTIMÄKI, *L. TAHTIVAARA, T. LAITINEN, T. AHTONIEMI, A. NURMI; Charles River Discovery Res. Services Finland Ltd, Kuopio, Finland

Abstract: Magnetic resonance imaging (MRI) is used routinely in clinical studies and imaging is becoming the only truly translatable, non-invasive biomarker to human central nervous system (CNS) diseases. MRI is applied, for example, in clinical Alzheimer's and Huntington's disease for diagnosis, and in clinical trials to assess therapeutic effects. Same imaging tools can be used as translational markers for preclinical CNS research. In addition to anatomical MRI, magnetic resonance spectroscopy (MRS) can be used to study metabolic changes in the brain to determine the relative concentrations of key brain metabolites in disease and during therapeutic interventions. In order to study brain metabolite changes in CNS disease indications and to find common nominators, various rodent CNS disease models were analyzed with *in vivo* 1H-MRS to detect changes in the following metabolites: creatine (Cr), phosphocreatine (PCr), GABA, glutamate (Glu), glutamine (Gln), myo-inositol (INS), N-acetyl-aspartate (NAA), N-Acetyl-aspartyl-glutamic acid (NAAG), taurine (Tau), and choline (Cho). CVN mouse model (APPSweDI/NOS2-/-) for Alzheimer's disease and aged rats for cognitive decline were analyzed for hippocampal metabolites, G93A-SOD1 model for ALS was analyzed for brainstem metabolites, and R6/2 and Q175 models for Huntington's disease were analyzed for striatal metabolites. In the CVN model for Alzheimer's disease and aged rat model for cognitive decline, 1H-MRS analysis of *in vivo* metabolites showed significant changes associated to aging: INS had increased whereas NAA had decreased in hippocampus. SOD1 model for ALS showed decrease in markers related to neuronal health and neurotransmission, including derecrease in NAA and GABA in brainstem. The Huntington's disease models showed typically increased glutamine and creatine, and decreased NAA in striatum. Relevant changes in brain metabolites associated to neuronal health, neurotransmission and energy metabolism can be detected with MR spectroscopy. As similar findings have also been reported in clinical studies, the results obtained highlight the importance of non-invasive *in vivo* 1H-MR spectroscopy as a translational marker to study CNS diseases.

Title: Lymphocytes from sporadic Alzheimer's disease patients display alterations in apoptosis associated with increased p21 levels

Authors: ***U. WOJDA**[1,2], J. WOJSIAT[2], K. LASKOWSKA-KASZUB[2], J. KUZNICKI[1]; [1]IIMCB, Warsaw, Poland; [2]Nencki Inst. of Exptl. Biol., Warsaw, Poland

Abstract: Despite intensive research, the pathogenesis of Alzheimer's disease (AD) is poorly understood so that an effective cure and reliable early markers are missing. There are data showing that in AD alterations in cellular processes occur not only in neurons, but also in peripheral cells such as lymphocytes. Recently, we have demonstrated in sporadic AD (SAD) lymphocytes G1 phase arrest and increased levels of p21 protein, the key regulator of G1/S cell cycle checkpoint and apoptosis, and the p53 target (1). Our current work aimed at comparing apoptotic response to oxidative stress evoked by 2-deoxy-D-ribose (2dRib) treatment in EBV-immortalized B-lymphocytes from healthy individuals, 8 patients with familial AD (FAD) bearing 8 different mutations in PS1: P117R, M139V, L153V, H163R, S170F, F177L, I213F, E318G, and 16 patients with sporadic form of AD. Using MTT assay, we found that 24h after 40 mM 2-deoxy-D-ribose (2dRib) treatment, the percentage of surviving SAD lymphocytes was significantly decreased comparing to the age-matched controls and FAD cells. In agreement with these data, early apoptosis measured by AnnexinV staining was higher in SAD lymphocytes than in control and FAD cells. Also measurements of mitochondrial membrane potential (MMP) using cationic dye JC-1 showed differences in the response to 2dRib between SAD and FAD cells: MMP of SAD lymphocytes was significantly decreased comparing to control and FAD cells. Accordingly, SAD lymphocytes showed increased percentage of cells with fragmented DNA in SubG1-phase, when compared to control and FAD lymphocytes. Comparing the

response in two control groups age-matching SAD and FAD, we found that the differences between SAD and FAD cells are not due to aging. Moreover, higher apoptotic response in SAD lymphocytes was correlated with increased levels of p21 protein. Altogether, our results showed that SAD lymphocytes are more vulnerable to 2dRib than age-matched control and FAD cells and that mechanism of apoptosis in SAD differs from FAD. Our data indicate that lymphocytes may be useful for further studies on the molecular aspects of AD pathology and for the development of new diagnostic methodologies targeting apoptotic proteins such as p21. 1. Abstract: Recent advances in Magnetic Resonance Imaging (MRI) have greatly enhanced the ability of researchers and clinicians to assess the structural and functional integrity of the aging brain. An important source of age-related cognitive dysfunction is cerebrovascular disease.

However, while high field-strength magnets and advanced neuroimaging protocols (e.g. T2* and Susceptibility Weighted Imaging (SWI)) have increased the sensitivity of diagnostic imaging, they simultaneously highlight the relative paucity of information on the precise nature of vascular-related abnormalities. Attempts to refine the interpretation of MRI anomalies have relied on immediate histological analysis of tissue samples imaged postmortem, which may not fully reflect the signal from the living brain, or on the necessarily delayed analysis of tissue samples from patients who had been imaged during life, often months or years previously. The current investigation examined the correspondence between *in vivo* MRI, *ex vivo* MRI, and post-mortem histology in a nonhuman primate model of cerebral β-amyloid (Aβ) angiopathy (CAA). Four aged squirrel monkeys (*Saimiri sciureus*), which naturally develop CAA in old age, and a younger control subject were imaged *in vivo* in a Siemens 3T MRI. Following euthanasia, the brains were fixed and then re-scanned at 3T and in a Bruker 7T MRI. Histological analysis indicated that no major lesions were missed by T2, T2* and/or SWI, i.e., no unexpected lesions were revealed microscopically in tissue sections. T2*/SWI scans consistently detected hemosiderin deposition both *in vivo* and *ex vivo*. Despite significant, widespread Aβ deposition in the brains of the aged animals, the deposits were not associated consistently with MRI signal anomalies. However, in the occipital lobe of one aged animal, a large, parenchymal, T2-TSE hyperintensity was detected *in vivo* that also included focal hypointensities revealed by T2*/SWI sequences. Histologically, this region was marked by inflammation and reactive gliosis associated with large-vessel CAA, hemosiderin, and vascular cuffing. While overall there was reasonably good correspondence between the *in vivo* and *ex vivo* images, there were occasional discrepancies. Establishing the histological basis of signal irregularities in MRI scans will be critical to the accurate interpretation of vascular-related brain changes in the elderly.

Title: Viral vector mediated expression of mutant huntingtin in the dorsal raphe produces neuropathology but does not induce depressive-like behaviors in wildtype mice

Authors: *M. R. PITZER[1,2], A. WARDEN[1], J. LUERAS[1], S. WEBER[1], J. MCBRIDE[2];
[1]Univ. of Portland, Portland, OR; [2]Oregon Natl. Primate Res. Cntr, Beaverton, OR

Abstract: Huntington's disease (HD) is a neurodegenerative disorder caused by the mutation in the huntingtin gene(HTT). An expansion in the gene's repeat length for the glutamine codon (CAG) renders a misfolded, dysfunctional protein that often incorporates into inclusion bodies. HD is characterized by motor and cognitive decline as well as mood disorders, with depressive symptoms being particularly common. Approximately 50% of the HD population suffers from depressive symptoms. Because these symptoms often manifest a decade or more prior to the knowledge that the person is at risk for the disease, we hypothesize that some portion of the early depression in HD is a consequence of the pathology arising from the mutant gene. While not wholly effective, depression in HD is often treated with drugs that increase serotonin availability. With this in mind, the current mouse study was designed to investigate whether the over-expression of mutant HTT in the serotonin-producing neurons of the dorsal raphe of wildtype mice can produce depressive-like behaviors. Consequently, we stereotaxically injected adeno-associated virus (AAV) encoding mutant HTT containing either a toxic (AAV-82Q) or control (AAV-16Q) CAG repeat length into the dorsal raphe of wildtype mice. Depressive-like behaviors and motor behaviors were assessed for 12 weeks following surgery. Post-necropsy, quantitative PCR and immunohistochemistry (IHC) verified AAV transduction in the dorsal raphe nucleus. IHC also demonstrated microgliosis and mutant huntingtin-positive inclusions in serotonergic neurons in animals injected with AAV-82Q but not controls. Importantly, AAV-82Q mice showed a 75% reduction in the cells stained positively for the serotonin synthesis enzyme, tryptophan hydroxylase-2 compared to controls ($p<0.05$). Despite mutant HTT-mediated pathology in the midbrain dorsal raphe neurons, no significant changes in motor or depressive-like behavior were detected. Consequently, we conclude that 11 weeks of mutant HTT expression in the dorsal raphe of wildtype mice is sufficient to reduce serotonin enzyme staining but is not sufficient to elicit depressive-like behaviors. Ongoing studies are investigating if a longer timecourse of mutant HTT expression might be necessary to elicit depressive-like behaviors or if mutant HTT expression in other regions of the brain, such as the hippocampal dentate gyrus, may play a role in HD depression. Together, these results may be helpful in addressing which therapeutic and/or pharmacological strategies could have the highest impact when treating depressive symptomology in patients suffering from HD.

Abstract: Results from genetic studies and from experiments with animal models have suggested the involvement of adenosine A_{2A} receptor ($A_{2A}R$) in the pathogenesis of Huntington Disease (HD). An $A_{2A}R$ gene polymorphism has been found to be significantly associated with a decrease in the age at onset in HD, and some controversial abnormalities of $A_{2A}R$ expression or function have been found in transgenic mouse HD models. We recently reported a complete insensitivity of the $A_{2A}R$ antagonist, KW-6002, at inducing locomotor activity in a transgenic HD rat model[5]. When trying to discover a possible $A_{2A}R$ abnormality, we found no evidence for differences in the striatal density of $A_{2A}R$ (with saturation experiments with the $A_{2A}R$ antagonist [^{3}H]ZM-241385), or in the ability of the $A_{2A}R$ agonist CGS 21680 to produce locomotor depression. Significantly, transgenic rats did not respond to the locomotor activating effects of the adenosine A_1 receptor (A_1R) antagonist CPT either. Again no evidence for differences were seen in the striatal density of A_1R (with saturation experiments with the $A_{2A}R$ antagonist [^{3}H]DPCPX) or in the ability of the A_1R agonist CPA to produce locomotor depression. The results therefore indicate the existence of a decreased striatal adenosinergic tone, which was confirmed with *in vivo* microdialysis experiments, with a significantly lower extracellular concentration of adenosine in transgenic HD rats compared to controls. These results support a switch in the focus of research in the pathogenesis of HD from the receptor ($A_{2A}R$) to the neurotransmitter (adenosine) and from the neuron to the astrocyte.

Abstract: Learning and memory deficits are common clinical features of Huntington's disease (HD) and the most distressing symptoms at early disease stages. These cognitive impairments have been mainly associated to fronto-striatal HD pathology. However, accumulating evidence point to an important role of the hippocampus in cognitive and synaptic dysfunction in HD. The negative role of the p75NTR neurotrophin receptor in spine density, learning and memory prompted us to explore whether disturbed p75NTR function could contribute to hippocampal-dependent cognitive decline in HD. In this study, we show that the levels of p75NTR are

significantly increased in the hippocampus of two distinct HD mouse models and HD patients. Genetic normalization of hippocampal p75NTR levels in novel HD mutant mice heterozygous for p75NTR (KI:p75+/-) prevented cognitive and synaptic plasticity deficits and ameliorated dendritic spines abnormalities likely by normalization of the GTPase RhoA activity. We also demonstrate that viral-mediated over-expression of p75NTR in the wild-type hippocampus reproduced HD learning and memory deficits while knockdown of p75NTR in the hippocampus of HD mice prevented cognitive decline. Moreover normalization of p75NTR levels in KI;p75+/- mice do not recover striatal function and strongly underscore the hippocampus as the specific brain region involved in recognition, spatial and associative memory deficits in KI;p75+/- mice and agree with our hypothesis that aberrant p75NTR expression in the hippocampus of KI mice underlie HD hippocampal-memory deficits. Together, these findings provide new evidence for hippocampal-dependent cognitive deficits in HD and reveal a novel mechanism for p75NTR on mediating synaptic, learning and memory dysfunction in HD suggesting the possibility of treating synaptic and memory impairments in HD by pharmacological or genetic modulation of p75NTR function.

Title: Neonatally transplanted human glial progenitors improves motor skills and survival of R6/2 mouse model of Huntington’s disease

Authors: ***A. BENRAISS**, J. MAUCERI, T. J. MICHAEL, H. B. BURM, D. CHANDLER-MILITELLO, S. WANG, S. A. GOLDMAN;
Univ. of Rochester Med. Ctr., ROCHESTER, NY

Abstract: Huntington's disease (HD) is caused by an expansion of the CAG tri-nucleotide repeat of the first exon of the gene encoding huntingtin (Htt). Although striatal neuronal death is a hallmark of HD, the extent to which neuronal death is cell-autonomous or instead dependent upon interactions with glia has been unclear. To address the specific role of both glial progenitor cells (GPCs) and their derived astrocytes in the pathogenesis of HD, we investigated the effect of chimerizing the striata of newborn immunodeficient rag1-/- mice with GPCs generated from HD patient-derived embryonic stem cells. In this model, the striatally-injected hGPCs expand over time, either remaining as progenitors or differentiating into astrocytes. By 12 weeks of age, the brains of these mice reveal extensive chimerization, with predominantly human striatal glia. We found that mice engrafted with HD hESC GPCs (48 CAGs) manifested poor motor coordination relative to controls engrafted with normal hESC GPCs (18 CAG), as assessed by rotarod testing. On that basis, we then performed the converse experiment, and asked whether normal glia might rescue aspects of the Huntington Disease phenotype; we did so by engrafting normal human GPCs into the striata of R6/2 (120Q) HD mice. For this experiment, GPCs were isolated from 18-22 week g.a. fetal human brain using CD44-based magnetic activated cell sorting (MACS), then transplanted into the striata of the newborn R6/2 mice. We found that the engrafted mice displayed slower motor deterioration than did their untreated controls, as assessed by rotarod. Linear regression revealed that the rate of motor deterioration was significantly slowed in the human GPC engrafted mice, relative to untreated controls ($F = 4.8$ [2, 124 df]; $P<0.001$). In addition, the normal human glial chimeric R6/2 (120Q) x rag1-/- mice survived longer than untreated mice, with a mean increase in lifespan of 12 days (hGPC-engrafted, n=29; untreated, n=28; $P<0.01$ by ANOVA). Together, these data suggest that glial pathology may contribute significantly to the motor decrements and neurodegeneration associated with HD, and that targeting glial pathology in HD may provide significant therapeutic benefit.

Title: Expression and colocalization of somatostatin and NMDA receptor subtypes in huntington transgenic mice brain

Authors: S. PAIK, *R. K. SOMVANSHI, C. SINGH, S. ZOU, U. KUMAR;
Fac. of Pharmaceut. Sci., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: In Huntington's disease (HD), medium sized aspiny neurons expressing somatostatin (SST) are selectively preserved whereas projection neuron positive to N-methyl-D-aspartate receptors (NMDARs) are significantly lost. Our recent studies also revealed that SSTR1/5 double knockout mice exhibit neurochemical and biochemical changes comparable to HD transgenic (tg) mice brain. However, the distributional pattern of SSTR and NMDAR subtypes at the levels of mRNA and protein as well as their colocalization in HD tg mice brain is not known. Accordingly in the present study, we determined the expression and colocalization of SSTR and NMDAR subtypes in wt and HD tg mice brain. Experimental Procedure: Receptor expression in mice brain was accomplished by using qRT-PCR and colocalization by double labeled immunofluorescence immunocytochemistry in brain sections from wt and HD tg mice. Results: Our results showed significant changes in receptor expression in cortical and striatal brain regions of wt and HD tg mice. mRNA expression of SST in striatum was lower in comparison to cortex of wt mice whereas in HD tg mice SST mRNA levels decreased significantly in both cortex and striatum. SSTRs mRNA expression in striatum was in the order of SSTR1>SSTR2>SSTR3>SSTR4>SSTR5. In contrast, receptors mRNA expression in cortex was in the order of SSTR1>SSTR3/SSTR4>SSTR2>SSTR5. HD tg mice exhibited significant changes in receptor specific manner in cortex and striatum. SSTR1 mRNA was increased whereas SSTR2, SSTR4 and SSTR5 mRNA levels were decreased with no significant changes in SSTR3 mRNA levels in cortex. In case of striatum, mRNA expression of SSTR1 and SSTR2 was decreased with no significant changes in SSTR3, SSTR4 and SSTR5. NMDARs mRNA expression in cortex and striatum was relatively higher for NR2B followed by NR1 and NR2A in wt mice brain and decreased significantly in HD tg mice. Also, the protein expression of receptors in striatum and cortex was comparable to mRNA levels. The sub-cellular colocalization of SSTR with NMDAR subtypes was receptor and region specific in wt and HD tg mice. Conclusions: Our results suggest that significant loss of SST and SSTR subtypes in cortex might be responsible for the activation of striatal NMDARs due to the withdrawal of inhibitory effect of corticostriatal glutamatergic input to the striatum. Receptor specific colocalization of SSTR with NMDAR subtypes in projection neurons may account for selective survival of these neurons in excitotoxicity.

Title: Role of palmitoylation in synaptic and extra-synaptic NMDAR localization in striatal neurons: Implications for Huntington disease

Authors: R. KANG[1], *L. A. RAYMOND[2];
[1]Univ. of British Columbia, vancouver, BC, Canada; [2]Dept Psychiatry and Brain Res. Ctr., UBC, Vancouver, BC, Canada

Abstract: Previous studies have shown NMDA receptor (NMDAR) activity is altered in YAC transgenic mouse models of Huntington disease (HD), prior to onset of motor deficits. In YAC72 early postnatal striatal neuron cultures, the NMDAR subunit GluN2B was shifted from internal pools to the plasma membrane and showed a significantly faster rate of NMDAR insertion to the surface (Fan, et al., 2007). In acute cortical-striatal brain slices from 1 month-old YAC128 mice, elevated striatal NMDAR current and GluN2B surface expression was found localized to extrasynaptic sites (Milnerwood, et al, 2010**)**. Here, we investigated a potential mechanism for the increased NMDAR extra-synaptic localization in YAC HD mice. Palmitoylation is a post-translational protein modification increasingly recognized as an important regulator of neuronal development, synaptic function and plasticity. Recently, NMDARs have been reported to be palmitoylated, and palmitoylatoin on different clusters of cysteine residues results in distinct effects on NMDAR surface expression in cultured cortical neurons (Hayashi, et al., 2009). We found that palmitoylation of GluN2B was reduced in striatum of YAC128 mice starting at one month of age. Furthermore, NMDARs containing the cluster II palmitoylation-resistant mutant GluN2B (GluN2B(5CS)) showed significantly enhanced surface expression in striatal neurons from FVB/N mice in striatal-cortical embryonic co-cultures, mimicking the increase observed for wild-type GluN2B in YAC128 co-cultures. Notably, the enhanced surface expression of GluN2B(5CS) in FVB/N SPNs was not observed at synaptic sites, but instead was restricted to extra-synaptic surface membrane. Interestingly, the palmitoylation of GluN2B was reduced by 4h treatment with 100μM 2-bromopalmitate in cultured cortical neurons, and synaptic activity-dependent palmitoylation of GluN2B was regulated differentially in FVB/N vs. YAC128 striatal neurons. These results suggest that reduced palmitoylation on cluster II of GluN2B contributes to the enhanced extra-synaptic surface expression of GluN2B in YAC128 striatal neurons, and that

the palmitoylation of GluN2B plays a critical role in the pathological mechanism of Huntington disease. 5 *Funded by the Canadian Institutes of Health Research.*

Title: Aberrant tracer coupling between striatal medium spiny neurons in a mouse model of Huntington's disease

Authors: B. KADRIU, C. ROZAS, M. A. CHACON, *S. S. DELLAL, D. S. FABER; Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Electrical transmission between neurons via gap junctions is present throughout the brain and is necessary for synchronizing neural circuits. Furthermore, gap junctions permit the diffusion of small signaling molecules and metabolites between connected cells. There is also evidence that, like their chemical counterparts, electrical synapses can undergo plasticity. Specifically, the neurotransmitter dopamine has been demonstrated to both weaken and enhance coupling between cells in the retina through its actions at D1 and D2 receptors, respectively. Huntington's disease (HD) is a hereditary neurodegenerative disease characterized by severe motor impairment that involves the loss of striatal medium spiny neurons (MSNs) and cortical projection neurons. Dopamine (DA) is a critical factor for the normal operation of the basal ganglia, and during the early stages of HD in humans, DA levels are increased and DA receptor expression is decreased. We were interested in whether this dopaminergic dysfunction in the striatum in HD leads to aberrant electrical connectivity between MSNs. To begin to address this question, we performed whole-cell patch-clamp recordings on MSNs with the diffusible morphological tracer neurobiotin (NB), which is small enough to cross-gap junctions. We then performed immunohistochemistry (IHC) on these brain slices using a fluorophore-tagged streptavidin, collected z-stacks via confocal laser-scanning microscopy, and then counted the number of tracer coupled cells. We found that on average, the number of coupled cells was threefold greater for MSNs from R6/2 mice (a rapidly progressing HD model), as compared to

their wild type (WT) littermates. This difference was observed at both the early and late time points of the disease (5 and 12 weeks). We also found that when brain slices were treated with the gap junction blocker meclofenamic acid (100 μM), there was significantly less tracer coupling and there was no longer a difference in tracer coupling between WT and HD, indicating that the tracer coupling was due primarily to passage of the NB from the recorded cell across gap junctions. In agreement with this observation, we found that there was increased expression of connexin 36 in HD striatum (R6/2, 5 weeks), but not in cortex, as assessed by Western blot analysis. These results complement prior findings that HD pathology is characterized by significant changes in both chemical and electrical transmission in the striatum. Future work will aim to determine whether the increases in cell coupling in striatum result from a dysregulated dopaminergic system and whether it contributes to the motor symptoms of HD.

Abstract: Histone deacetylase (HDAC) inhibition is proposed as a therapeutic strategy for Huntington's disease (HD)[1-2] . Genetic knockdown of HDAC4 in the R6/2 HD mouse model, a transgenic overexpresser of exon 1 *HTT* with an expanded CAG repeat, ameliorates behavioural as well as cortico-striatal neurophysiological deficits and improves survival. Aggregation of huntingtin protein (HTT) in CNS tissue is also reduced on HDAC4 knockdown in the R6/2 model, and also in HdhQ150 knock-in mice, which carries the full length mutant CAG expanded *HTT* allele[3]. These data suggest that an HDAC4-selective inhibitor has therapeutic potential in

HD. Previously we have reported on highly selective compounds for HDAC class IIa enzyme inhibition over class I, IIb and III enzymes with potent cellular activity[4], however, these compounds demonstrated limited phenotypic improvements in an HD mouse model, R6/2, which was attributed to a relatively low predicted free fraction in brain. Here we describe the profiles of a novel compound series of catalytic-site small-molecule inhibitors of the class IIa HDACs, as well as attempts to develop an associated biomarker strategy for the assessment of target engagement in the brain. The improved brain exposure and free fraction in brain of these compound gives us greater confidence for their assessment of efficacy in rodent models of HD. *1. Sadri-Vakili G and Cha JH., Curr. Title: Potential mechanisms of altered excitability in the striatum of a mouse model of Huntington's disease

Authors: *M. A. CHACON, C. ROZAS, D. BARTOLOME-MARTIN, Y. CAO, D. S. FABER; Albert Einstein Col. of Med., Bronx, NY

Abstract: We are interested in biophysical mechanisms underlying altered excitability of medium spiny neurons (MSNs) in dorsal striatum of mouse models of Huntington’s Disease (HD). Here we describe two potential complementary mechanisms. First, we recently demonstrated a build up of accommodation of spike firing rate in MSNs called fast-activity

dependent homeostasis (fADH). fADH is induced by repetitive impulse activity and is manifest by a progressive attenuation in the induced firing rate. Interestingly, fADH is impaired in the R6/2 mouse model of Huntington's disease at pre-or early-symptomatic stages. Here we asked if this phenomenon occurs in the BACHD transgenic models of HD and if it is displayed selectively by MSNs of the direct (D1) and/or indirect (D2) pathways. Using whole-cell recordings we found that at 2 and 3 months of age fADH is decreased in BACHD MSNs, as compared with wild type (WT) littermates, while there is no difference at 1 and 6 months. The impaired fADH can be rescued by activators of the voltage-gated potassium channel Kv7.2/3, which is involved in the regulation of excitability and spike frequency accommodation. Analysis of D1- and D2-expressing MSNs did not show any significant difference in fADH, although we found differences in intrinsic properties of both D1 and D2, as reported previously. In agreement with the observed fADH, WT D1-MSNs exhibit an increased M-current activation in resting conditions, as compared with BACHD D1-MSNs which did not exhibit any enhanced activation current. Surprisingly, no differences were found in D2-MSNs. Second, an increased input resistance (Rin), which could also contribute to hyperexcitability, was found in 2 and 3 month old BACHD mice, as observed in other HD mouse models. This increased resistance is most not likely due to a change in rectification, since the slopes of I-V curves were increased in both the depolarizing and hyperpolarizing directions in BACHD MSNs. To study this in more detail we use BaCl2, a blocker of Kir channels. Membrane voltage responses to hyperpolarizing and depolarizing current injections in the presence of BaCl2 show a significant loss of rectification. However, after BaCl2 superfusion, the difference in slope between WT and BACHD mice was maintained, again suggesting that a loss of rectification does not account for the increased Rin in BACHD mice. These results demonstrate an age-dependent appearance of fast-activity dependent homeostasis in striatal MSNs of WT mice, which is not present in BACHD mice at the same age, and suggest that reduced activation of both Kv7.2/7.3 channels and a leak conductance can underlie the hyperactivity of MSNs in BACHD mice.

Title: Characterization of a potential novel therapeutical tool to reverse histone hypoacetylation in neuropathologies

Authors: *D. M. GUIRETTI, L. M. VALOR, A. BARCO;
Inst. de Neurociencias (UMH-CSIC), Sant Joan d´Alacant, Spain

Abstract: It has been proposed that alteration in the level of neuronal histone acetylation in the brain may underlie cognitive decline and other neurological symptoms associated with aging, neurodegenerative diseases (e.g., Huntington's and Alzheimer's diseases) and congenital intellectual disability disorders (e.g., Rubinstein-Taybi syndrome). Consistent with this view, inhibitors of histone deacetylases (HDACi) ameliorate neuropathological traits in animal and cellular disease models for these conditions. However, the chronic treatment with compounds may cause significant side effects because the indiscriminate promotion of acetylation can interfere with cell division and have other deleterious consequences. To minimize the adverse effects of HDACi and overcome the highly transient impact of HDACi administration, we have generated a recombinant lentivirus that overexpresses the KAT domain of the CREB-binding protein (CBP) selectively in neurons. This strategy for the genetic enhancement of neuronal histone acetylation in neurons may represent a novel therapeutic approach in the neuropathologies referred above. We believe that the comparison of the consequences of the infection with this lentivirus and HDACi treatments will contribute to a better understanding of the pleiotropic effects associated with HDACi-induced hyperacetylation and the refinement of related therapeutic strategies by improving targeted delivery to affected brain regions. We first demonstrate the effectiveness of the viral vector to increase the acetylation level of the four-nucleosome histones in primary hippocampal cultures. In addition, we also observed the hyperacetylation of several non-histone substrates. Moreover, these biochemical changes correlated with an increase in the number of dendritic spines in infected hippocampal neurons. Importantly, unlike the chronic pharmacological treatment, the genetic manipulation did not compromise neuronal survival. Additional experiments to investigate the impact on gene expression of this chronic increase of KAT activity are in progress, as well as the evaluation of this genetic tool in cellular and animals models of neuropathology.

Genet., Ctr. for Mol. Med. and Therapeutics, Child and Family Res. Institute, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Mammalian sirtuins are a conserved family of class III NAD^+-dependent deacetylases, which have been postulated to be beneficial for targeting mitochondrial abnormalities. Being a neurodegenerative disease that selectively affects the striatum and the cortex, Huntington's disease (HD) has been commonly linked to mitochondrial dysfunction as one of the main pathological mechanisms. Therefore, we hypothesized that modulation of sirtuins might be beneficial in HD. In this study we tested the influence of resveratrol (RESV) *versus* nicotinamide (NAM, a Sirt inhibitor) in counteracting mitochondrial dysfunction in HD cells expressing full-length human mutant huntingtin, namely striatal and cortical neurons isolated from YAC128 transgenic mice embryos and HD human lymphoblasts. Moreover, we analyzed the effect of RESV and NAM in an *in vivo* HD model. We observed a slight decrease in histone acetylation with RESV and increased histone acetylation with NAM in HD cell models. Moreover, HD lymphoblasts exhibited a decrease in PGC-1alpha and Tfam protein levels, linked to a small reduction in the number of mitochondrial DNA copies. Functionally, both HD models displayed

a deregulation in mitochondrial respiration and mitochondrial membrane potential, implicating a decline in mitochondrial function. Interestingly, both RESV and NAM completely restored most of the evaluated parameters, providing a positive add on mitochondrial function in HD. In the *in vivo* study 1 mg/kg/day RESV and 250 mg/kg/day NAM were administered to 9 month-old YAC128 *versus* wild-type (WT) mice during 28 days. We found that RESV increased the latency to fall off in the rotarod test; moreover, RESV and NAM greatly increased histone acetylation in both YAC128 and WT striatal and cortical samples. Additionally, NAM completely restored the levels of mitochondrial-encoded complex IV subunit in YAC128 striatal samples. These data suggest that RESV and NAM are able to modulate protein acetylation and ameliorate mitochondrial function in HD, which may partially control HD-related motor disturbances.

Title: Transplantation of genetically altered mesenchymal stem cells over expressing human and mouse brain derived neurotrophic factor in the R6/2 transgenic mouse model of Huntington’s disease

Authors: *A. C. MOORE[1,2], A. CRANE[1,2], M. LU[1,2,3], G. DUNBAR[1,2,3,5], J. ROSSIGNOL[1,2,4]; [2]Program in Neurosci., [3]Dept. of Psychology, [4]Col. of Med., [1]Central Michigan Univ., Mount Pleasant, MI; [5]Field Neurosciences Inst., Saginaw, MI

Abstract: Huntington’s disease (HD) is an incurable, progressive neurodegenerative disorder caused by an expanded CAG trinucleotide repeat on chromosome four. In HD, degeneration of

medium spiny neurons begins in the putamen and caudate nucleus and progresses to the cerebral cortex, as its severity increases. Symptoms include cognitive dysfunction and chorea. After its onset, life expectancy of victims of HD is about 20 years. Although there is currently no known cure for HD, stem cell therapies offer viable potential for replacing or protecting affected cells in animal models of HD. Recent research suggests that bone marrow derived mesenchymal stem cells (MSCs) exert neuroprotective effects through expression of brain derived neurotrophic factor (BDNF), a protein that supports survival of existing neurons and differentiation of developing stem cells, which is diminished in those afflicted with HD. To counter its depletion, the goal of this study was to genetically modify MSCs with a permanently integrative lentivirus to over-express either human or mouse BDNF. Lentiviral vectors containing green fluorescent protein (GFP) and human and mouse BDNF were constructed from E. coli plasmids and verified with PCR and restriction assay. Following verification, the vectors were then introduced in a culture medium of packaging cells for virus purification and collection. After purification, bone-marrow-derived MSCs from the R6/2 transgenic mouse model of HD were separately transfected with the human BDNF lentivirus and the mouse BDNF lentivirus. Fluorescent microscopy imaging indicated that MSCs express GFP, which suggests BDNF expression. Enzyme linked immunosorbent assay (ELISA) was used to quantify BDNF levels in cells and in the cell culture media of both BDNF-transfected MSCs and MSCs with an empty vector. Western blotting was used to confirm the presence or absence of BDNF in all groups (MSCs transfected with human BDNF, MSCs transfected with mouse BDNF, and empty vector). Cells from each of these groups were transplanted into the striatum of R6/2 mice and motor performance was measured using the rotarod apparatus. Results suggest that genetically altered BDNF-secreting MSCs have the potential to promote behavioral sparing. Support for this project was provided by funding from the Ronald E. McNair Scholars Program (to AM), the college of Medicine (to JR), and the John G. Kulhavi Professorship and Field Neurosciences Institute (to GLD).

Title: The influence of gaze on static postural control in individuals with Huntington’s disease

Authors: *L. COOKE[1], L. MURATORI[2], K. BEERS[1], C. FISCHER[1], E. RABIN[1];
[1]NYIT Col. of Osteo, Old Westbury, NY; [2]Physical Therapy, Stony Brook Univ., Stony Brook, NY

Abstract: It is possible that increased postural sway in Huntington's disease (HD) is related to poor ocular control. Posture is controlled with visual feedback, among other modalities. In order to interpret retinal feedback, corresponding feedback about eye position is required to distinguish eye movement from external movement. One of the first presenting symptoms of HD is abnormal ocular motor control including impairments in voluntary eye movements (saccades) and the vestibulo-ocular reflex (VOR) used to stabilize gaze during head movement. HD patients show impairment of fixation, difficulty suppressing saccades toward novel visual stimuli, and an inability in making saccades without head movement. Inability to suppress reflexive glances to novel stimuli and delayed voluntary saccades may be due to damage of the frontal lobes and basal ganglia in the earliest stages of the disease. The purpose of this study was to determine whether impaired ocular control in individuals with HD contributes to increased postural sway. Seven individuals with HD and seven healthy controls participated in all conditions. To determine if changing gaze is disruptive to postural control, participants were initially asked to stand as still as possible with feet side-by-side for 25 seconds while watching several different conditions of stationary and moving targets on a screen. Head and trunk position were captured using a Vicon camera system and eye position was recorded via Iscan video-based eye tracking system. Results: (1) Participants with HD swayed with greater amplitude in all conditions; (2) Individuals with HD had greater sway power at frequencies related to visual stimuli changes; (3) Participants with HD moved their head and eyes in phase of one another. These findings support the notion that postural sway in people with HD is indeed influenced by changes in gaze, and that some of those postural movements may be related to gaze control.

Title: Thioltransferases TXN1 and TXNDC10 protect against neuronal atrophy in a lentiviral mouse model of Huntington's disease

Authors: *Z. LU[1,2], L. BARROWS[1], J. CHEN[1,2], J. MOLINE[1], J. FOX[1,2];
[1]Dept. of Vet. Sci., [2]Interdepartmental Grad. Neurosci. Program, Univ. of Wyoming, Laramie, WY

Abstract: Huntington's disease (HD) is a progressive neurologic disorder caused by polyglutamine-expanded mutant huntingtin protein (mhtt). Mutant hungtingtin protein forms oxidative and thiol-dependent oligomers whose rate of degradation is slower than monomeric mhtt. We have hypothesized that a thiol transferase exists that converts oxidized mhtt oligomers to monomeric protein and may thereby decrease mhtt levels. We screened a number of thiol transferase enzymes by co-transfection with plasmids encoding N171-40Q huntingtin and thioltransferases into COS1 cells and measured mhtt levels 48 hours later by Western blot analysis. The primary screen revealed that the thioltransferases thioredoxin 1 (TXN1) and thioredoxin domain-containing protein 10 (TXNDC10) decreased total soluble mhtt. In a secondary screen we expressed enzymatically active / inactive versions of TXN1 and TXNDC10 with N171-40Q huntingtin. We were able to confirm that TXN1 and TXNDC10 decreased N171-40Q huntingtin levels in COS1 cells. We subcloned these two genes separately into a lentiviral vector that uses the phosphoglycerate kinase promoter. We tested their potential protective effects in mouse HD by co-injection of lentiviruses expressing the following combinations of genes: WT control (N171-18Q + inactive TXN1 or TXNDC10), HD control (N171-82Q + inactive TXN1 or TXNDC10) and HD treated (N171-82Q + active TXN1 or TXNDC10). Lentivirus was delivered by unilateral intra-striatal injection at 8 weeks of age in B6/C3H F1 female mice; mice were sacrificed at 16 weeks of age. There was no effect of the treatments on behavioral outcomes. However, the HD control group had significantly smaller striatal neuronal cell bodies than the WT control group as determined by confocal stereology; this effect was reversed in the HD treated groups by both TXN1 and TXNDC10. Therefore, TXN1 and TXNDC10 provide therapeutic benefit in this lentiviral model of HD.

Title: Xyloketals protect polyQ-induced toxicity in *C. elegans*

Authors: *Z. PEI, Y. ZENG;
Dept. of Neurol., The First Affiliated Hospital, Sun Yat-Sen Univ., Guangzhou, Guangdong, China

Abstract: Huntington's disease (HD) is an autosomal dominant inherited neurodegenerative disorder characterized by progressive motor dysfunction, including chorea and dystonia, emotionl disturbances, memory, and weight loss. Unfortunately, no treatment is available to prevent the progression of the disease.The protein aggregation is the pathological hallmark of HD, while inhibition of protein aggregation has shown beneficial effects against HD. Model organisms, such as *C. elegans* are powerful tools in drug development. Marine environments are rich sources of novel and unusual secondary metabolites, many of which show considerable promise as therapeutic agents. Xyloketals are a series of novel natural compounds from marine mangrove fungi. We previously demonstrated that xyloketal B has neuroprotective effects in different cell models via its antioxidant properties. In the present study, we generated HD elegans model by expressing different repeats (Q16, Q60 and Q150) in muscle cells under the control of the unc-54 myosin heavy-chain promoter. We found that expression of HD repeats-dependently induced protein aggregation. The expression of Q 16 was diffuse while the expression of Q60 or Q150 was focal distribution corresponding to protein aggregates. Moreover, the formation of protein aggregates was associated with the dysfuntion of mobility. Q60 or Q150 but no Q16 severely impaired the mobility of animals. Xyloketals significantly reduced polyQ aggregation and alleviated the associated dysfunction of mobility. Thus, xyloketals may represent an attractive candidate for treatment of HD.

Abstract: Huntington's disease (HD) is a devastating, neurodegenerative disease that typically strikes in mid-life and is caused by a CAG repeat expansion within the coding region of the HD gene. HD primarily induces degeneration of medium spiny neurons within the striatum and atrophy of the cortex, but emerging data suggests that the neurovascular unit (NVU) and blood-brain barrier (BBB) also contribute to disease pathogenesis. Vascular abnormalities and aberrant gene regulation of the BBB in HD patients and animal models warrant further investigation of this system in HD. Two critical pathways implicated in HD, Shh and Wnt signaling, are utilized by astrocytes and brain endothelial cells (BEC) in the NVU to control BBB development and maintenance. We therefore hypothesize that abnormal signaling exists in and between BECs, astrocytes and neurons, which causes abnormal expression of BBB proteins and contributes to neuronal dysfunction and pathogenesis in HD. To test this hypothesis, we have used a panel of induced pluripotent stem cell (iPSCs) with varying numbers of CAG repeat units to generate *in vitro* models of HD neurons and other cells of the NVU, including BECs and astrocytes. Preliminary data shows functional and transcriptional changes in these cells. RNA-Seq and qPCR reveal a number of BBB/NVU genes that are differentially expressed in HD and these HD BECs exhibit disruption of tight junction organization, reduced TEER, and decreased resistance to puromycin treatment. Furthermore, iPSC-derived NSCs and BECs recapitulate BBB pathology seen in HD animal models, such as abnormal WNT/SHH signaling. Ongoing studies will determine if aberrant signaling from astrocytes or cell autonomous defects lead to BBB disruption and if alterations in signaling and transcription exist between the cellular subunits of the NVU, affecting BBB maintenance and subsequent neuronal damage. Understanding these changes in signaling and the effects on the BBB in HD will allow us to better understand the contributions of BBB breakdown to the progression of HD and other CNS diseases where the BBB is disrupted. These studies will provide a resource for therapeutic assay development applicable to a broad spectrum of neurodegenerative diseases.

Title: Investigating effects of extracts of human adipose-derived stem cell in Huntington's disease

Authors: *M. LEE[1], W. IM[2];
[1]neurology, Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of; [2]Seoul national university hospital, seoul, Korea, Republic of

Abstract: Stem cell therapy is a perspective remedy for permanent terminal disorders including Huntington's disease (HD). Adipose-derived stem cell (ASC) is as an abundant and easily available source of stem cells with multipotent characters suitable for regenerative medical applications. Stem cells secrete various factors which can modulate a hostile microenvironment of diseases. ASCs also express multiple growth factors and could be used to treat disease via secretion factors, called paracrine mechanism. We have previously showed that extracts isolated from human ASCs (hASC-extracts) slow the progression of Huntington's disease (HD). Here, we investigated the mechanism of effects of hASCs-extracts and found that small vesicles isolated in hASCs-extracts show the similar effects *in vitro* HD model.

Title: The treatment benefit of the Group 2 metabotropic glutamate receptor agonist LY379268 in R6/2 mice stems from a neuroprotective rather than a symptomatic effect

Authors: *A. J. REINER, Y. DENG, N. DEL MAR, H. REN, J. T. ROGERS;
Anat. & Neurobio., The Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: We have found that daily subcutaneous injection with a maximum tolerated dose of the mGluR2/3 agonist LY379268 (20mg/kg sc) beginning at 4 weeks of age dramatically improves the phenotype in R6/2 mice, especially in males, who we found show a slightly more aggressive R6/2 phenotype than females. For example, we found that daily 20mg/kg LY379268 in male R6/2 mice prevents a 20% striatal neuron loss at 10 weeks, and significantly improves motor parameters such as rotarod performance and distance traveled in open field. In the present study, we examined if the LY379268 benefit is due to an acute palliative effect of the drug on behavior, or if it is due to a cumulative neuroprotective effect from the daily delivery of the drug. To test the acute effects, we examined rotarod and open field performance in 10 week old male R6/2 mice before and 6, 12 and 24 hours after a single sc administration of 20mg/kg LY379268. We found that the mice showed substantial and significant deficits at 6 and 12 hours after drug on both rotarod (40% reduction) and open field distance traveled (50-75% reduction), but recovered by 24 hours. No such treatment-related deficits were seen when these same mice were injected with vehicle on a subsequent day. In a second line of study, we determined if chronic treatment with 20mg/kg LY379268 beginning at 4 weeks of age would still produce a benefit, even if drug injections were curtailed (and replaced by vehicle injections) for the last three days prior to testing at 10 weeks of age. We found that both those chronically treated male R6/2 mice receiving the 3-day LY379268 holiday prior to behavioral testing, and those receiving drug through to the test day, performed significantly better on rotarod and open field than did R6/2 males not receiving LY379268 (2-fold improvement). As R6/2 males receiving drug and then vehicle during the 3-day drug holiday performed somewhat better than did R6/2 males receiving drug throughout, the results suggest that despite the benefit of chronic treatment, the drug retains an acute depressive effect. Our overall results are consistent with a neuroprotective effect of daily LY379268 for treating R6/2 HD mice, which our evidence suggests is in large part mediated by a cortical and thalamic BDNF boosting effect of the drug (Reiner et al., Brain Res., 2012). Modifying dose and treatment frequency may make it possible to achieve the neuroprotective effect without the acute suppressive effect of LY379268.

Title: The protective effect of metformin on the mutant huntingtin induced toxicity

Authors: ***J. JIN**[1], M. TAO[2], Q. PENG[1], M. JIANG[1], W. DUAN[1,3,4];
[1]Dept. of Psychiatry and Behavioral Sci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Dept. of Psychological and brain science, Johns Hopkins Univ., Baltimore, MD; [3]Departments of Neurosci., Baltimore, MD; [4]Program in Cell. and Mol. Med., Baltimore, MD

Abstract: Huntington's disease (HD) is a devastating neurodegenerative disease caused by the pathological elongation of the CAG repeats in the huntingtin gene. Caloric restriction (CR) has been a most reproducible environmental intervention to improve health and prolong lifespan. We have demonstrated that CR delayed onset and slow disease progression in a mouse model of HD. Metformin, an anti-diabetic drug, mimics CR acting on cell metabolism at multiple levels. A recent study has shown that long-term administration of metformin improved health span and lifespan in mice. In addition, administration of metformin in drinking water improved motor function and extended survival in an HD mouse model. These studies provided compelling evidence that metformin may be an ideal repositioning drug for HD treatment. To determine whether metformin directly modulates mutant huntingtin-induced neurotoxicity, striatal cells expressing mutant huntingtin were treated with metformin, we found that metformin rescued cell toxicity induced by mutant huntingtin, indicated by reduced LDH release and increased ATP levels. Furthermore, metformin activated AMPK in normal striatal cells and attenuated the inactivation of AMPK in mutant huntingtin expressing striatal cells, pharmacological blocking AMPK activation partially abolished the protective effects of metformin on mutant huntingtin, indicating that AMPK and other signaling pathways are involved in the protective effect. We are

investigating molecular mechanisms underlying the protective effect of metformin in HD. Our ultimate goal is to develop a fast track therapeutic strategy for HD.

Title: Toward developing a panel of antisense oligonucleotide drugs targeted to single nucleotide polymorphisms enriched within mutant huntingtin genes to provide an allele-specific gene silencing treatment option for the majority of the Huntington disease population

Authors: *N. S. CARON, A. L. SOUTHWELL, N. H. SKOTTE, C. KAY, Y. XIE, E. B. VILLANUEVA, E. PETOUKHOV, C. N. DOTY, M. R. HAYDEN;
Med. Genet., Ctr. for Mol. Med. and Therapeut., Vancouver, BC, Canada

Abstract: Huntington disease (HD) is a devastating neurodegenerative disorder for which there is no effective treatment. HD is caused by a CAG trinucleotide repeat expansion in the HTT gene (>35 repeats), resulting in an elongated polyglutamine tract within the huntingtin protein. The expansion of the polyglutamine tract in mutant huntingtin results in gain of toxic cellular functions leading to the pleiotropic symptoms of HD. Therefore, reducing levels of mutant huntingtin in patients is an attractive therapeutic strategy for the treatment of HD. Others have demonstrated that non-selective reduction of huntingtin levels through a variety of gene-silencing modalities improves behavioural and neuropathological phenotypes in rodent models of HD. However, the wild type protein is essential for neuronal health, and the reduction of both wild type and mutant huntingtin may not be well tolerated over the long treatment duration required in humans. Thus, selectively reducing levels of mutant huntingtin represents a more favourable therapy for the treatment of HD. One strategy for the selective reduction of mutant huntingtin is the use of RNase-H activating antisense oligonucleotides (ASOs) targeted to single nucleotide polymorphisms (SNPs) within HTT that are in linkage disequilibrium with the CAG

expansion. Our lab has previously evaluated ASOs targeted to one such HD-associated SNP and identified potent, selective, and well tolerated candidates currently undergoing pre-clinical validation. However, targeting a single HD-associated SNP can maximally provide a treatment option for ~50% of the HD population. Therefore, we are pursuing a combinatorial approach by developing a panel of ASOs targeting 3-5 HD-associated SNPs heterozygous in minimally overlapping patient populations to increase population coverage for the majority of those with HD.

Title: Age-dependence of chloride and potassium channel dysfunction in Huntington’s disease skeletal muscle

Authors: *D. R. MIRANDA, M. WONG, C. M. MCKEE, M. MENDIZABAL, R. J. TALMADGE, A. A. VOSS;
California State Polytechnic Univ., Pomona, CA

Abstract: Huntington’s disease (HD) is a genetic disorder that causes a gradual impairment of movement, a progressive decline in cognition and increasingly severe behavioral irregularities. Although typically considered a primary neuropathy, we recently found skeletal muscle defects in HD that may contribute to the motor defects. In the R6/2 mouse model of HD, currents through the skeletal muscle chloride channels (ClC-1) and inward rectifying potassium channels (Kir) are significantly reduced compared to wild type at the end-stage of the disease (10 to 12 weeks of age). This reduction is correlated with aberrant splicing of *Clcn-1* (ClC-1 gene) mRNA

and decreased total *Clcn-1* and *Kcnj2* (Kir2.1 gene) mRNA in HD skeletal muscle. Because ClC-1 and Kir channel currents help maintain the resting membrane potential, their reduction causes the muscle to become hyperexcitable and may help explain the chorea, dystonia, and muscle rigidity that characterize HD. In this study, we determined the time course over which these channel defects develop. We measured ClC-1 and Kir currents in individual *flexor digitorum brevis* and *intraosseous* muscle fibers from male and female R6/2 mice using two-electrode voltage clamp. We also examined *Clcn-1* mRNA processing and total amounts of *Clcn-1* and *Kcnj2* mRNA. Measurements were taken from both HD and wild type muscle obtained from mice ranging from 20 to 76 days of age. Our results show an early and progressive dysfunction in ClC-1 channels in HD muscle that parallels the developing muscle defects. For example, at 5 weeks of age, the earliest time point that motor symptoms are observed in R6/2 mice, we found a significant decrease in the ClC-1 conductance in HD (1.62 ± 0.14 mS/uF, n=11) compared to wild type (2.27 ± 0.16 mS/uF, n=8) muscle fibers (values shown as mean ± SEM with a P=0.01). These functional defects were associated with changes in *Clcn-1* and *Kcnj2* mRNA. The results show muscle defects that can help explain the motor symptoms observed throughout the lifetime of the HD mice.

Abstract: Olfactory dysfunction and altered neurogenesis are observed in several neurodegenerative disorders including Huntington disease (HD). These deficits are an early symptom and correlate with decline in global cognitive performance, depression and degeneration of olfactory regions in the brain. The olfactory dysfunction observed in neurodegenerative diseases is often accompanied by structural abnormalities of the olfactory epithelium, the olfactory bulb (OB) and the olfactory cortices in human brain. Despite evidence demonstrating early olfactory dysfunction in HD patients, only limited details are available in murine models. Preliminary data demonstrate a decrease in OB weight (YAC128, p=0.027; BACHD, p=0.023) and the volume of the piriform cortex (YAC128, p=0.004; BACHD, p=0.013) is observed in HD vs. WT mice. Furthermore, a decrease in piriform neuronal counts (p=0.003) and enhanced immunostaining of EM48 is observed in the olfactory regions of YAC128 vs. WT brain. We also examined odor investigation behaviors in the mice using the habituation/dishabituation test. YAC128 mice investigate trial 1 odors longer than WT littermates (p=0.04).In order to determine whether apoptotic events are associated with the olfactory dysfunction and altered neurogenesis in HD we are assessing caspase activation and TUNEL. Preliminary data demonstrate that a significant decrease in the proform of caspase-6, suggesting activation, and an increase in levels of the proform of caspase-8 are observed in pre-symptomatic YAC128 OB vs. WT. No change in caspase-3 or -9 was detected. At the present time there is a serious lack of biomarkers for either HD or Alzheimer disease. Identification of early markers of the disease will help inform therapeutic approaches for these diseases and will clarify the utility of olfactory function tests in patients with these disorders and in the aging population.

Title: Acute exposure to Chlorpyrifos generates oxidative stress and mitochondrial dysfunction in a striatal cell model of Huntington's disease

Authors: G. A. DOMINAH, *G. F. KWAKYE;
Oberlin Col., Oberlin, OH

Abstract: In spite of the genetic cause of Huntington's disease (HD), emerging evidence strongly suggests environmental influence on the age of onset, progression, and severity of the disease. However, the identity of the environmental risk factor is currently unknown. Recognizing the similarities in the pathophysiological mechanisms between HD and pesticide neurotoxicity, we hypothesized that the common agricultural pesticide chlorpyrifos (CPF) would exhibit disease-toxicant interaction and reveal the influence of CPF in HD neuropathophysiology. We investigated the effects of acute CPF toxicity and its principal metabolites chlorpyrifos oxon (CPO) and 3,5,6-trichloropyridinol (TCP) in an established murine striatal ST*Hdh* cell model of HD by assessing cell viability, reactive species production, mitochondrial membrane potential, antioxidant buffering capacity, and energy homeostasis, as well as antioxidant mediated neuroprotection. Following a 48-hour exposure to the metabolites CPO and TCP, we observed no significant dose and genotypic differences in cell survival. Interestingly, expression of mutant HD resulted in increased dose-dependent susceptibility to CPF exposure and production of reactive species compared to wild-type cells. Furthermore, we report that the mutant HD induced vulnerability to CPF exposure is mediated through diminished antioxidant buffering capacity, enhanced production of free radicals, decreased mitochondrial function and energy production. To further investigate the possible neuroprotection of HD cells against CPF neurotoxicity, we treated ST*Hdh* cells with N-acetylcysteine (NAC) and observed that the CPF induced toxicity was significantly ameliorated in mutant HD cells. These results strongly suggest that mutant HD and CPF exhibit a disease-toxicant interaction to cause enhanced striatal neurotoxicity via oxidative stress and mitochondrial dysfunction that could exacerbate the neurodegenerative processes in HD.

Title: Polyamine modulates mutant huntingtin toxicity

Authors: M. JIANG[1], J. ZHENG[1], S. ABADALI[1], Q. PENG[1], J. JIN[1], *W. DUAN[1,2,3]; [1]Dept Psychiatry, Johns Hopkins Univ., BALTIMORE, MD; [2]Dept. of Neurosci., [3]Program in Cell. and Mol. Med., Johns Hopkins Univ., Baltimore, MD

Abstract: Polyamines such as putrescine, spermidine, and spermine are small organic polycationic molecules that are present in almost all-living organisms. The regulation of these polyamines is required for cells to grow and function in an optimal manner. Dysregulation of cellular polyamines is associated with aging and various pathological conditions, including Huntington's disease (HD) (Vivo et al., Neurosci Lett 2001). In addition, cellular polyamine levels decreased along with aging. Consequently, dietary supplement of spermidine efficiently induced autophagy and ameliorated age-induced memory impairment, increased life span in low organisms, and reduced age-associated protein oxidation in mice. These data imply the important role of polyamines in aging and age-associated neurodegenerative diseases. In this study, we tested the effects of spermidine on mutant huntingtin-induced toxicity in a cell model of HD. Striatal cells expressing mutant huntingtin were treated with spermidine for 24 hrs. We found that spermidine induced autophagy, and dose-dependently attenuated mutant huntingtin toxicity, indicated by reduction of lactate dehydrogenase release and maintainence of ATP levels in striatal cells expressing mutant huntingtin under serum withdrawal condition. The molecular mechanisms by which spermidine protects cells against mutant huntingtin toxicity and the contribution of polyamine pathways to HD pathogenesis are under investigation. We expect that our results will provide a new understanding of the polyamine pathway in HD pathogenesis and a potential novel therapeutic strategy for HD. Title: Epigenetic and transcriptional dysregulation in prodromal Huntington's disease

Authors: *F. YILDIRIM, C. W. NG, Z. R. CROOK, D. E. HOUSMAN, E. FRAENKEL; MIT, Cambridge, MA

Abstract: Transcriptional dysregulation is an early and pivotal feature of Huntington's disease that is strongly reflected in mouse models of this disorder. We have recently demonstrated in *in vitro* and mouse models genome-wide changes in DNA methylation and histone H3K4 trimethylation patterns that may underlie transcriptional dysregulation in HD (1, 2). In the study reported here, centering on the prodromal disease stage, we discovered that the pathogenic transcriptional and epigenetic alterations in the brain in mouse models in fact precede the overt onset of disease symptoms. Genome-wide analysis of transcription by RNA sequencing (RNA-Seq) revealed many key neuronal genes such as Drd1a and Drd2, Penk and Adora2a whose disruption are significant in HD pathogenesis to be down-regulated in the R6/1 mouse striatum as early as 8 weeks of age. RNA-Seq in a second mouse model that is the full length Huntingtin model of CHL2 [Hdh(CAG)150] heterozygous knock-in mice validated the ongoing transcriptional dysfunction in the striatum during prodromal HD and confirmed a highly significant overlap of differentially-expressed genes between the R6/1 and CHL2 models even at this early disease stage (142 overlapping genes, $p < 3e\text{-}128$). Comparison with a human HD study (3) showed that gene expression changes in our mouse models were consistent in the caudate nucleus of postmortem brains from HD patients (162 genes in R6/1 ($p < 3e\text{-}54$) and 51 genes in CHL2 ($p < 1.3e\text{-}10$)). This provides strong evidence that these mice models faithfully recapitulate the transcriptional dysfunction in human HD and that a significant portion of the early transcriptional changes persist throughout the later disease stages. Extension of our studies to genome-wide analysis of histone H3K27 acetylation, an active transcription and enhancer mark, by chromatin immunoprecipitation followed by sequencing (ChIP-Seq) revealed highly coordinated ($p< 1.7e\text{-}10$) histone acetylation changes along with the detected transcriptional changes in the striatum of R6/1 mice at 8 weeks of age. By studying the DNA sequences that lie within the altered H3K27 acetylation regions, we identified transcriptional regulators whose activity may be most proximally-disrupted by mutant Huntingtin consequently leading to the earliest transcriptional changes that we detected by RNA-Seq. The potential therapeutic value of targeting these predicted transcriptional regulators is currently under evaluation by functional experiments in mouse models of HD. 1.M. Abstract: Huntington’s disease (HD) is an autosomal dominant neurodegenerative disorder caused by an abnormal expansion of CAG repeats encoding a polyglutamine sequence in the N-terminal region of the HD gene. It has been suggested that postnatal reduction of mutant huntingtin through protein interference or conditional gene knockout could prove to be an effective therapy for patients suffering from HD. The current study explored novel methods to reduce or silence expression of the mutant Huntingtin allele using transcription activator-like effectors (TALE) in primary human HD fibroblasts. In this study, human HD and control fibroblasts with varying CAG repeat lengths were characterized by the ratio of mutant to healthy huntingtin protein using homogeneous time-resolved fluorescence, levels of reactive oxygen species (ROS) via immunocytochemistry, the amount of poly-ubiquitinated proteins using

Western blots, and size of the CAG repeats through polymerase chain reaction. For allele-specific targeting, three TALE designed to target single-nucleotide polymorphisms (SNP) in the mutant allele were packaged into a vector backbone containing a Krüppel associated box (KRAB) domain to promote transcriptional repression of the disease-associated allele. Each SNP site was carefully selected based on proximity to the promoter region, global minor allele frequency (MAF) score, and specificity of the TALE to its target region. Three additional TALE used in unique combinations with each other and designed to target specific sites in the expanded CAG regions were packaged into a vector backbone containing the nuclease FokI to create double stranded breaks in the mutant allele. This strategy was implemented to shorten the expanded CAG repeats by gene collapse and non-homologous end-joining repair. The efficacy of each gene targeting strategy was quantified by transfecting primary human HD or control fibroblasts with either a TALE designed for gene suppression or correction. The rate of change pre- and post-treatment of the mutant protein ratio, ROS, poly-ubiquitinated proteins, and expression of the expanded CAG repeats was then quantified. This study demonstrates the potential of gene modification using TALE and provides a foundation for personalized treatment for individuals suffering from Huntington's disease. *Support for this project was provided by the NIH (Nolta), and philanthropic donors from the HD community, including the Roberson family and TeamKJ.*

Title: Insulin-like growth factor 1 signalling in huntington disease

Authors: *N. H. SKOTTE[1], M. A. POULADI[2], K. HUYNH[1], T. T. NIELSEN[3], R. GRAHAM[4], A. NØRREMØLLE[3], M. R. HAYDEN[1];

Abstract: Huntington disease (HD) is a hereditary, fatal neurodegenerative disorder caused by a CAG repeat expansion in the huntingtin gene, which results in an elongated polyglutamine stretch causing a toxic gain of function in the mutant huntingtin (mHTT) protein. At this time, there is no way to stop or reverse the course of the disease. The pathogenesis of HD is complicated and multiple pathways are compromised. Cleavage of mHTT at the caspase-6 cleavage site (aa586), which generates toxic N-terminal cleavage fragments containing the expanded polyglutamine repeat, is a crucial step in the pathogenesis of HD. The mechanisms causing the excessive activation of caspase-6 in HD are not completely clear, but recent evidence suggests that regulation happens at both transcriptional and posttranslational steps. It has be shown that insulin-like growth factor 1 (IGF-1) signaling can induce caspase-6 phosphorylation and prevent its activation. This finding coupled with several studies showing reduced plasma and tissue IGF-1 levels in HD patients as well as in cellular and animal models of HD, makes the IGF-1 pathway an interesting target for HD therapy. In this study, we examined if there is a relationship between reduced IGF-1 levels and aberrant caspase-6 activation in HD. Using striatal cell lines derived from knock-in mice containing HTT with 7 or 111 glutamines (Q7/Q111 cells), we confirm that Q111 cells expressing mHTT secrete reduced levels of IGF-1 compared to wtHTT expressing Q7 cells. We show that the decrease in secreted IGF-1 levels in Q111 cells is associated with enhanced activation of caspase-6 and increased cell death after serum deprivation. IGF-1 supplementation of Q111 cells reduces serum deprivation-induced caspase-6 activation, prevents the generation of the toxic mHTT 586 fragment, and ameliorates cell death compared to non-supplemented Q111 cells. Lastly, transcriptional analysis demonstrate that the HD mutation may impair the IGF system at multiple levels by affecting the expression of IGF receptors and binding proteins. Our findings suggest that dysregulated IGF-1 signalling may contribute to the excessive activation of caspase-6 in HD and that modulation of the IGF system may be an alternative approach to reduce mHTT cleavage.

Title: Regulation of mitochondrial autophagy by mutant huntingtin

Authors: *J. MARGULIS[1,2], D. M. ANDO[1,2], S. M. FINKBEINER[1,2];
[1]Gladstone Inst. of Neurolog. Dis., San Francisco, CA; [2]Univ. of California, San Francisco, San Francisco, CA

Abstract: Huntington's disease is an inherited and incurable neurodegenerative disorder caused by an abnormal polyglutamine (polyQ) expansion in huntingtin. The mechanisms of mutant huntingtin-mediated neurotoxicity remain unclear; however, dysregulation of protein quality control is known to be a key event in Huntington's disease pathogenesis. Here, we tested whether mutant huntingtin also affects mitochondrial quality control via dysregulation of mitochondrial autophagy, or mitophagy. In order to monitor autophagy-mediated flux of mitochondria in live neurons, we developed a sensitive and quantitative image-based technique utilizing automated microscopy and photoswitchable fluorescent proteins. The rate of mitochondrial degradation measured using this technique is sensitive to pharmacological inducers and inhibitors of mitophagy in primary neurons as well as neuronal cell lines. We found that expression of mutant huntingtin in both primary neurons and human induced pluripotent stem cell (iPSC)-derived neurons reduces mitochondrial half-life, and that this effect is dependent on the presence of the first 17 amino acids of huntingtin. The presence or absence of mutant huntingtin inclusions also affects mitochondrial function and half-life. Thus, mutant huntingtin-mediated regulation of mitophagy may represent a novel target for therapeutic intervention in Huntington's disease.

Title: Differences in synaptic scaling in striatal-cortical co-cultures from wild-type and YAC128 mice

Authors: *A. I. SMITH-DIJAK[1,2], J. B. MAU[1], L. A. RAYMOND[1];
[1]Psychiatry, [2]Grad. Program in Neurosci., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Huntington disease (HD) is a neurodegenerative disorder caused by a polyglutamine expansion in the huntingtin protein, producing mutant huntingtin (mHtt). Many pre- and postsynaptic proteins interact with mHtt, and the function of at least some of these proteins is affected by the disease-causing mutation. One of the consequences of these changes in protein function is alterations in synaptic signaling and plasticity. For example, there are changes in the localization of the NMDA receptor subunit GluN2B, which have consequences for cell signaling and survival. Particularly affected are the cortico-striatal synapses, especially those between cortical neurons and striatal spiny projection neurons (SPNs). We set out to examine changes in synaptic scaling, a form of homeostatic plasticity in which the strength of synapses in a network is increased or decreased in response to the overall level of activity in the network, in excitatory synapses onto striatal SPNs from the YAC128 HD mouse model. We used immunocytochemical analyses and electrophysiological measurements to determine the effect of 48 hours of treatment with either tetrodotoxin (TTX), bicuculline (BIC) or vehicle (water) on synaptic strength and organization in striatal-cortical co-cultures from embryonic wild-type (WT) and YAC128 mice; experiments were done after 3 weeks in culture. We found that both the degree and direction of scaling was changed in YAC128 compared to WT cultures. Specifically, we assessed: co-localization of the (postsynaptic) GluA2 AMPA receptor subunit and the (presynaptic) VGLUT1 glutamate transporter; the density of dendritic spiny protrusions; and the amplitude and frequency of miniature excitatory postsynaptic currents (mEPSCs). Of the changes observed in these metrics in response to treatment with TTX or BIC versus the vehicle control, some were conserved between the two genotypes, while others differed in size and/or direction of change. These findings suggest that homeostatic plasticity, in particular synaptic scaling, is impaired in HD in ways which could contribute to the neuronal dysfunction and eventual neurodegeneration which take place during the HD disease process.

Title: Elevated oxidative stress exacerbates neuronal atrophy via activation of AMPK-α1 in Huntington's disease

Authors: *Y. CHERN[1], T.-C. JU[2], H.-M. CHEN[2];
[1]Inst. Biomed Sci., Taipei, Taiwan; [2]Inst. of Biomed. Science, Academia Sinica, Taipei, Taiwan

Abstract: Huntington's disease (HD) is an autosomal dominant neurological disorder induced by a CAG trinucleotide expansion in the exon 1 of Huntingtin (HTT) gene. We previously reported that the abnormal activation of AMPK-α1 contributes to neuronal degeneration in HD. We showed here that the elevated oxidative stress evoked by mutant HTT (mHTT) caused the abnormal activation of AMPK-α1 and resulted in neurotoxicity in a striatal progenitor cell line (STHdhQ109) and in the striatum of a transgenic mouse model of HD (R6/2). Administration of an antioxidant (N-acetyl-cysteine, NAC) to R6/2 mice normalized the activation of AMPK-α1, reduced neuronal toxicity, ameliorated ventricle enlargement, and improved motor dysfunction. Given that NAC also reduced the oxidative stress-induced AMPK-α1 activation and the death of STHdhQ109 cells, the beneficial effect of NAC *in vivo* is likely to be direct. Interestingly, the activation of AMPK elevated the level of oxidative stress in STHdhQ109 cells and in the striatum of R6/2 mice, whereas the suppression of AMPK lowered the level of oxidative stress. In summary, we present evidence to show a detrimental, positive feedback regulation between the elevated oxidative stress and the activation of AMPK-α1 in HD.

Title: Effects of post-translational modifications sites mutations of full-length huntingtin on neuronal toxicity

Authors: *N. ARBEZ, T. RATOVITSKI, L. NUCIFORA, J. STEWART, A. CHAUDHARY, C. ROSS;
Div. of Neurobio., Johns Hopkins Univ., Baltimore, MD

Abstract: Huntington's disease (HD) is a fatal progressive neurodegenerative disorder involving movement, cognitive and emotional symptoms. Post-translational modifications (PTMs) of expanded huntingtin (Htt) are likely to be important mediators or modulators of HD pathogenesis. Phosphorylation has been shown to have a significant impact on expanded Htt-mediated cellular toxicity. While these studies established the involvement of some N terminal phosphorylation sites, they were carried out using the N terminal fragments of Htt. In this study, aimed to functionally validate PTMs of Htt, we established cellular and biochemical assays using full length Htt. We investigated the effects of alterations of PTM sites of Htt on itsneuronal toxicity. In parallel, we studied some biochemical and structural properties ofHtt with PTM alterations. A series of constructs expressing full length Htt with PTM alterations were created. Sites were selected from previously established important phosphorylation sites (like S13 and S16) as well as potential new sites previously identified in the laboratory. We established nuclear condensation cell toxicity assay for full-Length-Htt expressed in primary neurons. Over the time of the experiment, full length Htt can strongly induce cell death. The levels of toxicity achieved with full length Htt are however lower than toxicity observed with Htt fragments (N586-82Q Htt or Exon1-82Q). Using our PTM mutants, we have confirmed the protective effects of T3D and S13/16D alterations. We have also confirmed the protective effect of S421D alteration, and also observed protection with S421A and K444R mutations within full-length Htt. Since the nuclear localization of Htt or its fragment is important in the pathology of HD, we developed an assay for quantitative analysis of nuclear/cytoplasmic localization of FL-Htt expressed in primary neurons by using confocal analysis. We found no difference between the FL-Htt constructs tested so far. Since the aggregation and the structure of Htt are important for its toxicity, we established a limited proteinase K digestion assay using our FL Htt mutants. We also established an *in vitro* aggregation assay using purified Htt-N586 proteins.Using these two assays, .we demonstrated differences between full-length normal, expanded Htt and PTM mutants. These new and

confirmed PTMs sites of Htt that modulate the cellular toxicity represent potential new therapeutical targets for the treatment of HD.

Title: Differential effect of HDAC3 on cytoplasmic and nuclear polyglutamine aggregates

Authors: T. MANO[1], T. SUZUKI[2], *A. IWATA[3];
[1]Neurol., Univ. Tokyo Hosp., Tokyo, Japan; [2]Kyoto Pref Univ. Med., Kyoto, Japan; [3]Neurol., Univ. Tokyo Medicne Neurol., Tokyo, Japan

Abstract: Histone deacetylases (HDACs) are one of the therapeutic targets of polyglutamine (pQ) diseases possibly through fixing aberrant translational deactivation caused by mutant polyglutamine proteins. Among various HDACs, HDAC3 is a unique class 1 HDAC that localizes in both cytoplasm and in the nucleus. However, precise functions of HDAC3 in those two compartments are vaguely known so far. HDAC3 directly binds to short pQ and the interaction is important in suppressing HDAC3's neurotoxicity, which is broken with long pQ chain and supposedly promotes neuronal death (Bardai, 2013). Therefore, HDAC3 can be a good therapeutic target for pQ diseases. However, other study using heterozygote knockout mouse did not show any efficacy on Huntington's disease pQ model mouse (Moumn**é**, 2012). Thus, the role of HDAC3 in the pathogenesis in pQ diseases is yet to be fully understood. We tried to resolve this issue by focusing on different role of HDAC3 on cytoplasmic and nuclear pQ aggregates. In addition to previous findings, we found that HDAC3 preferably binds to nuclear pQs compared to cytoplasmic ones. Specific HDAC3 inhibitors increased the amount of total pQ aggregates by increasing the amount of nuclear aggregates, whereas decreasing the amount of cytoplasmic aggregates. Selective HDAC3 inhibitors impaired nuclear proteasome activity, but quite interestingly promoted cytoplasmic proteasome activity. Our findings suggest that HDAC3 has

differential functional role in the cytoplasm and in the nucleus in terms of pQ aggregate degradation.

Title: The role of complement-microglia interactions in driving synaptic loss and disease progression in Huntington's disease

Authors: D. K. WILTON[1], A. FROUIN[1], A. DAGGETT[2], W. YANG[2], *B. A. STEVENS[1]; [1]F. M Kirby Neurobilogy Ctr., Childrens Hosp. Boston, Boston, MA; [2]UCLA, Los Angeles, CA

Abstract: Huntington's disease (HD) is an inherited neurodegenerative disorder, characterized by motor, cognitive, behavioral and psychological dysfunction. In common with many neurodegenerative disorders one of the earliest events in HD pathology is dysfunction and loss of synapses (Graveland et al., 1995; Ferrante et al., 1991). Our laboratory recently identified components of the classical complement cascade as mediators of synapse elimination during developmental synaptic refinement (Schafer et al., 2012). Our data suggests a model in which less active synapses are selectively labeled with complement and then engulfed by microglia that express complement receptors (Ie CR3/Cd11b). In this study we have investigated whether aberrant reactivation of this pruning mechanism occurs in HD and whether it is responsible for the synaptic dysfunction observed. We find that in two mouse models of HD (BACHD and the knock-in model zQ175) levels of complement cascade components are elevated in disease affected regions and increase in line with disease progression. Using high resolution microscopy we show that at early time points complement localizes specifically to vulnerable cortico-striatal synapses prior to their loss from the striatum. Interestingly microglia in these regions adopt a more phagocytic phenotype at this time point suggesting they may be acting to engulf these synapses in a similar manner to that seen in the developing visual system. These results suggest that aberrant interactions between the complement system and microglia may drive early loss of

cortico-striatal synapses and contribute to behavioral deficits and neurodegenerative pathology in HD.

Abstract: Despite the identification of the pathogenic poly-CAG expansion to the huntingtin (*Htt*) gene as the cause of Huntington's Disease (HD) over 20 years ago, there remains no effective treatment for the disease. Numerous studies have been performed to identify molecules or genes which modulate the toxic effects or expression of mutant HTT (mutHTT). These studies have often been based around a single hypothesis (e.g. reducing aggregation or preventing caspase cleavage). Often, an exogenous promoter driving expression of a HTT fragment with a polyQ length well beyond a clinically relevant range is required to generate a sufficient assay signal suitable for reliable screening. This may have contributed to the lack of translatability of hit genes or molecules from one screen to another, and to higher *in vivo* models of HD. Recent advances in HTT protein detection by HTRF and MSD assays have allowed us to develop an HTRF assay detecting the expression of native mutHTT and total HTT proteins in immortalized HD patient lymphoblasts, chosen due to their clinical relevance. Cells are plated into 384-well plates and exposed to compounds for 48 h before being lysed, after which mutHTT and total HTT levels are quantified by specific antibody combinations. Toxicity is monitored by ATP determination as a surrogate for cell number. As these assays are able to measure changes in

HTT protein levels, they are not biased to identify molecules which only affect one hypothetical method of HTT toxicity (*e.g.* aggregation). As the *Htt* gene is expressed in an endogenous genomic context and with an HD-patient relevant Q-length, the assay may pick up a wide range of molecules affecting transcription, translation, and/or changes to protein fate within the cells. A pilot screen of 7000 compounds (tested n=2) from the CHDI collection comprising of both hypothesis-based and diverse compounds has revealed that the assay is suitable for HTS (Z' >0.3; S:B>2), and hit matter can be reliably detected and efficiently translated from single point to IC_{50} curves. Molecules with validated activity against the PI3K and mTOR family were identified and show good translation into a rat neuronal co-culture assay, where they both promote survival and lower HTT at similar concentrations as those identified in the primary assay. Further validation of these and other hit compounds to establish an extended screening cascade, including validation in alternative cell lines (e.g. stem cell derived neuronal precursors or fibroblasts) and determination of mechanism of action of hit compounds (i.e. do hits work via transcription, translation, autophagy pathways etc.) will be described.

Title: Mutant Huntingtin mediated repression of antioxidant gene expression is rescued by a novel Nrf2 activating agent

Authors: L. TINDALE, *R. C. CUMMING;
Dept. of Biol., Univ. of Western Ontario, London, ON, Canada

Abstract: Mitochondrial dysfunction and elevated reactive oxygen species (ROS) levels are strongly implicated in various neurodegenerative disorders, including Huntington's disease (HD). Expression of the mutant Huntingtin protein (mHtt) containing an expanded polyglutamine repeat is associated with oxidative stress and toxicity in striatal neurons. We previously demonstrated that overexpression of mHtt in PC12 cells leads to elevated ROS production and a concomitant decrease in expression of the antioxidant protein peroxiredoxin1 (Prx1). Interestingly, treatment with the compound dimercaptopropanol (DMP) prevents mHtt-mediated inhibition of antioxidant gene expression and neurotoxicity. Nuclear factor erythroid 2-related factor 2 (Nrf2) is a transcription factor responsible for regulating expression of a diverse array of antioxidant genes under the control of cis-acting antioxidant response elements (AREs), including Prx1. Nrf2 is maintained at very low levels by its negative regulator Kelch-Like ECH-associated Protein 1 (Keap1), which facilitates the ubiquitination and subsequent degradation of Nrf2 by the proteasome. Post-translational modification of Keap1 and/or Nrf2 by electrophiles and oxidants disrupts the Keap1-Nrf2 interaction, resulting in the stabilization and nuclear translocation of Nrf2. There is currently great interest in identifying Nrf2 activating compounds for the treatment of neurodegenerative diseases. Here we demonstrate that mHtt prevents Nrf2 nuclear translocation and activation of antioxidant enzyme expression in PC12 cells and in an immortalized striatal cell line (STHdhQ111). In contrast, DMP exposure decreases the levels of Keap1, thereby allowing activation of Nrf2 even in the presence of mHtt. Preliminary findings indicate that DMP promotes the degradation of Keap1, possibly via an autophagic/lysosomal process. The identification of DMP as a neuroprotective agent that facilitates the degradation of Keap1 and promotes Nrf2 activation is highly novel and suggests that alternative modes of Nrf2 activation exist. In addition, DMP, also known as British anti-Lewisite (BAL), was shown to attenuate disease progression in a long term study of two HD patients conducted in 1955. The current study highlights previously unknown intracellular targets of DMP and indicates that this FDA approved compound may have relevance for the treatment of HD and other neurodegenerative disorders.

Title: Mutant huntingtin alters Tau phosphorylation and subcellular distribution

Authors: *D. BLUM[1], F. HERRERA[2], T. MENDES[2], L. FRANCELLE[3], M. BASQUIN[1], H. OBRIOT[1], D. DEMEYER[1], N. SERGEANT[1], E. GERHARDT[4], E. BROUILLET[3], L. BUEE[1], T. OUTEIRO[4,2];

Abstract: Tau abnormalities play a central role in several neurodegenerative diseases, collectively known as tauopathies. In the present study, we examined whether mutant huntingtin, which causes Huntington's disease (HD), modifies Tau phosphorylation and subcellular localization using cell and mouse HD models. Initially, we used novel bimolecular fluorescence complementation (BiFC) assays in live cells to evaluate Tau interactions with either wild type (25QHtt) or mutant huntingtin (103QHtt). While 25QHtt and Tau interacted at the level of the microtubule network, 103QHtt and Tau interacted and formed "knot-like" inclusions localized in the vicinity of the microtubular organizing center (MTOC). Fluorescence recovery after photobleaching experiments also indicated that, whereas homomeric 103QHtt/103QHtt pairs rapidly re-entered into inclusions, heteromeric 103QHtt/Tau pairs remained excluded from the "knot-like" inclusions. Interestingly, *in vitro* Tau relocalization was associated to Tau hyperphosphorylation. Consistent with this observation, we found strong Tau hyperphosphorylation in brain samples from two different mouse models of HD, R6/2 and 140CAG knock-in. This was associated with a significant reduction in the levels of Tau phosphatases (PP1, PP2A and PP2B), with no apparent involvement of major Tau kinases. Thus, the present study strongly suggests that expression of mutant huntingtin leads to Tau hyperphosphorylation, relocalization, and sequestration through direct protein-protein interactions in inclusion-like compartments in the vicinity of the MTOC. Likewise, our data also suggests that Tau alterations may also contribute to HD pathogenesis.

Title: Elevated neonatal iron intake potentiates progression in the R6/2 mouse model of Huntington's disease

Authors: ***K. L. BERGGREN**[1,2], J. CHEN[1,2], J. MILLER[1], J. H. FOX[1,2];
[1]Vet. Sci., [2]Interdepartmental Grad. Neurosci. Program, Univ. of Wyoming, Laramie, WY

Abstract: Huntington's disease (HD) is an autosomal dominant neurodegenerative disorder resulting from expression of polyglutamine-expanded huntingtin protein. Brain iron accumulation is implicated in potentiating the neurodegeneration in HD, Parkinson's disease, amyotrophic lateral sclerosis and Alzheimer's disease. Iron levels are also elevated in the brains of HD mice. The purpose of this study was to test the hypothesis that elevated dietary iron intake potentiates HD in the R6/2 mouse model. We tested the effect of nutritionally relevant levels of elevated iron intake during the neonatal period (post-natal days 10-17) and in adult life (5-12 weeks of age). In study 1, neonatal wild-type (WT) and R6/2 HD mouse pups were dosed with vehicle or 120μg/g body weight carbonyl iron/day. HD mice demonstrated poorer performance in spontaneous in-cage wheel running with disease progression. Neuronal cell body size in the striata and cortices of R6/2 mice at 12 weeks were significantly decreased compared to WT controls; there were further decreases in both regions of HD mice with iron supplementation. Levels of oxidized glutathione and lactate, markers of oxidative stress and energetic dysfunction, were increased in the cortices and striata of iron-treated HD mice compared to HD-control mice. In study 2, HD and WT adult mice were fed diets containing 50, 150 or 500 ppm iron from 5-12 weeks. In contrast to the neonatal study we have not found any effect of these different dietary iron levels on HD outcomes. Taken together, our findings show that the neonatal mouse HD brain is vulnerable to elevated iron intake. Early-life iron nutrition may influence onset and progression of human HD.

Title: Optogenetic control of parvalbumin-expressing interneurons in the R6/2 and Q175 mouse models of Huntington's disease

Authors: *L. GALVAN, C. CEPEDA, M. LEVINE;
IDDRC, Semel Inst. For Neurosci. and Human Behavior, BRI, UCLA, Los Angeles, CA

Abstract: Huntington's disease (HD), a neurodegenerative disorder caused by a mutation in the IT15 gene, is characterized by dysfunction and ultimate degeneration of striatal medium-sized spiny neurons (MSNs) and cortical pyramidal neurons (CPNs). Although it was thought that interneurons were relatively spared in HD, recent studies have shown a significant loss of parvalbumin (PV)-expressing interneurons that increases with severity of the disease. PV-expressing interneurons display fast-firing properties and mediate feed-forward inhibition in the striatum as well as limit CPN excitability. MSNs display an increase in GABAergic activity whereas CPNs show an increase in glutamatergic activity in several HD mouse models as the phenotype progresses. We hypothesized that PV-expressing interneurons may contribute to MSN and CPN dysfunction in HD. Previously we demonstrated significant changes in PV-expressing interneuron-evoked inhibitory responses in MSNs in symptomatic R6/2 mice using optogenetics. Here, using a similar optogenetic paradigm, we further examined alterations in PV-expressing interneuron inputs to MSNs and to CPNs in the R6/2 model. Additionally, we examined PV-expressing interneuron evoked responses in another HD mouse model, the Q175 knock-in, which has a more protracted course of phenotype progression. R6/2 and Q175 mice were crossed with PV-Cre mice and subsequently injected with a Cre-dependent channelrhodopsin-2 (ChR2) construct using viral delivery. MSNs or layer II/III CPNs were recorded in slices in voltage clamp mode. In symptomatic R6/2 mice, MSN recordings showed that activation of striatal PV-expressing interneurons induced significantly larger evoked GABAergic responses with faster

kinetics than responses from wildtype controls (WTs). GABAergic responses in CPNs from R6/2 mice exhibited a significant increase in charge and different kinetics compared to those from WTs. In presymptomatic Q175 mice activation of PV-expressing interneurons in the striatum showed a trend to evoke larger MSN GABAergic responses with faster rise times than occurred in WTs, an effect similar to observations in R6/2 MSNs. Preliminary results from CPNs in Q175 mice suggested a different trend than that observed in R6/2 CPNs and findings from symptomatic Q175 mice indicated that these dysfunctions may not be maintained in the late stage of the disease in this model. Taken together these findings indicate that PV-expressing inhibitory interneurons uniquely affect MSNs and CPNs in each mouse model and can contribute to neuronal microcircuit alterations in HD.

Title: Comparison of phosphodiesterase 10A, dopamine receptors D1 and D2 and dopamine transporter ligand binding in the striatum of the R6/2 and BACHD mouse models of Huntington's disease

Authors: *S. MILLER[1], G. HILL DELLA PUPPA[1], J. REIDLING[2], L. M. THOMPSON[3], J. TREANOR[1];
[1]Neurosci., Amgen Inc., Thousand Oaks, CA; [2]Memory Impairments and Neurolog. Disorders Inst., [3]Memory Impairments and Neurolog. Disorders Inst. and Neurobio. and Behavior, Univ. of California at Irvine, Irvine, CA

Abstract: Huntington's disease is an autosomal-dominant inherited neurodegenerative disorder characterized by motor dysfunction, cognitive decline and emotional and psychiatric disturbance. The genetic mutation is characterized by a CAG expansion resulting in formation of a mutant huntingtin protein with an expanded poly-glutamine repeat region. The medium spiny neurons of the striatum are particularly vulnerable to the toxicity of this protein and striatal degeneration is believed to underlie many of the motor symptoms that are typical of the disease. Phosphodiesterase (PDE) 10A is expressed at high levels in the medium spiny neurons of the striatum and may therefore represent a biomarker for disease progression. Our study investigated

changes in PDE10A binding using the selective PDE10A tracer ^{3}H-7980 at representative stages of Huntington's disease in two different mouse models, R6/2 and BACHD. R6/2 mice carry a transgene encoding an amino terminal fragment of the HD gene and show robust transcriptional and behavioral changes. BACHD mice express a full length transgene and display later behavioral dysfunction, aggregation and selected transcriptional abnormalities. Changes in PDE10A binding were compared to binding of radioligands for dopaminergic markers expressed by medium spiny neurons, e.g. dopamine transporter (DAT) labelled with ^{3}H-WIN 35,428 and dopamine receptors D2 and D1 labelled with ^{3}H-raclopride and ^{3}H-SCH23390, respectively. We show that in the R6/2 model binding of all ligands is significantly decreased at 8 and 12, but not 6 weeks of age. In contrast, no changes were detectable in the BACHD model at 8, 10 or 12 month of age. These findings suggest that radioligands can successfully detect neurodegeneration of the striatum of R6/2. Since decreases in D2 and PDE10A binding have been demonstrated in patients, our data suggests that this approach using the R6/2 mouse model is well suited for translational biomarker studies in Huntington's disease that may be applicable to human clinical trials of PDE10A targeted treatments.

Title: Oligodendrocyte dysfunction in Huntington's disease

Authors: *W. WEI[1,2], B. HUANG[1], X.-J. LI[1], S. LI[1];
[1]Human Genet., Emory Univ., Atlanta, GA; [2]Neurol., Tongji Hospital, Huazhong Univ. of Sci. and Technol., Wuhan, China

Abstract: Huntington's disease (HD) is a fetal, progressive neurodegenerative disorder caused by an abnormal expansion of the CAG repeat that encodes an expanded polyglutamine tract in the N-terminal region of mutant huntingtin (htt) protein. Despite the ubiquitous expression of mutant htt, HD shows selective neurodegeneration. Numerous studies have focused on neurons for pathogenesis studies, but growing evidence also indicates non-neuronal cell toxicity of htt, such as glial htt toxicity that is evidenced by white matter abnormalities in HD. However, how and why mutant htt affects oligodendrocyte is not investigated yet. To address this issue, we generated PLP-150Q and PLP-23Q-htt transgenic mice, which express mutant and wild type htt, respectively, in oligodendrocytes. PLP-150Q mice displayed progressive neurological symptoms and demyelination. To further investigate the pathogenic role of mutant htt in oligodendrocytes at endogenous level, full length mutant htt knock-in mice that express GFP exclusively in oligodendrocytes were generated. By sorting GFP-positive cells, we were able to enrich oligodendrocytes that express full-length mutant htt at the endogenous level. RNA-Seq was performed on these cells to obtain the transcriptome profiling. Our study will provide insights into the pathogenesis and therapeutic targets associated with oligodendrocytes in HD.

Title: Differential and region-specific contributions of GABAergic interneurons in mouse models of Huntington's disease

Authors: *S. M. HOLLEY, K. N. RUDBERG, C. CEPEDA, M. S. LEVINE;
IDDRC, Semel Inst. for Neurosci. and Human Behavior, BRI, UCLA, Los Angeles, CA

Abstract: Throughout the course of Huntington's disease (HD), patients experience a loss in motor coordination and disturbances in mood, partly as a dysfunction of the corticostriatal pathway. In the R6/2 model of HD, we previously have shown alterations in inhibition in both cortex and striatum when compared to WT mice (Cepeda et al., 2013, Cummings et al., 2009). Here, we used optogenetics to investigate the specific contribution of GABAergic somatostatin (SOM) and neuropeptide Y (NPY) interneurons in striatum and cortex of HD mouse models. In striatal medium-sized spiny neurons (MSNs) from symptomatic R6/2 mice, optically activating SOM interneurons expressing channelrhodopsin produced inhibitory postsynaptic currents (IPSCs) that did not differ in amplitude but displayed faster kinetics compared to responses evoked in MSNs from wildtypes (WTs). Similar results were obtained when optically evoking IPSCs in symptomatic Q175 mice (12-14 month old). To further examine the contribution of striatal SOM interneurons, we optically silenced these interneurons with halorhodopsin and observed decreased frequencies of spontaneous (s)IPSCs in a subset of R6/2 MSNs with more R6/2 MSNs exhibiting such frequency reduction compared to WTs. This finding suggests that SOM-expressing interneurons may contribute to the increased inhibition observed in striatal MSNs of R6/2 mice. Activating NPY interneurons in the striatum resulted in very large IPSCs in both WT and R6/2 MSNs that displayed similar amplitudes and kinetics. Interestingly, average MSN IPSC responses from NPY interneurons were 10x larger in amplitude than SOM activated IPSCs suggesting a larger inhibitory contribution from these interneurons in the striatum. In the cortex of R6/2 mice, optically evoked IPSCs in pyramidal neurons, via SOM interneuron activation, were smaller in amplitude compared to WT responses but displayed no significant differences in kinetics. Thus, the reduced inhibition from SOM interneurons in the cortex may contribute to hyperexcitability of pyramidal neurons. Furthermore, average striatal IPSC responses through SOM interneuron activation in R6/2 and Q175 MSNs were smaller in magnitude than responses observed in cortical pyramidal neurons indicating a difference in the inhibitory contribution of SOM interneurons in the cortex and striatum. Taken together, the findings show differential inhibitory contributions from SOM and NPY interneurons in cortex and striatum in mouse models of HD.

Title: Altered spontaneous synaptic currents in external globus pallidus neurons in the R6/2 mouse model of Huntington's disease

Authors: *J. BARRY, G. AKOPIAN, C. CEPEDA, M. S. LEVINE;
IDDRC, Semel Inst. For Neurosci. and Human Behavior, BRI, UCLA, Los Angeles, CA

Abstract: Huntington's disease (HD) is a hereditary neurological disorder characterized by chorea, cognitive deficits and psychiatric symptoms. In HD there is a loss of striatal medium-sized spiny neurons (MSNs). In particular, MSNs of the indirect output pathway, which project primarily to the external segment of the globus pallidus (GPe), are believed to be affected earlier in the progression of HD. Electrophysiological changes in GPe and other striatal output regions have not been characterized in detail. In the present study we examined spontaneous inhibitory (sIPSC) and excitatory (sEPSC) postsynaptic currents in the GPe of symptomatic R6/2 mice and their wildtype (WT) littermates *in vitro*. sIPSC recordings were made from 29 neurons in WTs and 26 in R6/2 mice. There were no significant differences in average sIPSC amplitude, frequency or interevent intervals. However, GPe neurons from both R6/2 and WT mice could be subdivided in two groups with respect to event amplitude-frequency histograms. One population of cells (Type 1) displayed amplitude-frequency histograms with one peak and relatively small average amplitudes of events (48±6.6 pA, n=21 in WT and 49±6.4 pA, n=17 in R6/2), while the second population (Type 2) exhibited two peaks and had higher average amplitudes of events (124±18.3 pA, n=8 in WT and 105±16.6, n=9 in R6/2). For Type 1 neurons average sIPSC frequency was significantly higher for cells from R6/2 compared to WTs (25.8±2.1 for R6/2 vs 19.1±1.3 for WT; p=0.01) while for Type 2 neurons the average frequency was lower for cells from R6/2 compared to WTs (19.4±2.0 for R6/2 vs. 27.2±2.5 for WT; p=0.03). Average sIPSC amplitudes for Type 1 or Type 2 GPe neurons were similar for R6/2s and WTs. sEPSC recordings were made in 18 GPe neurons in WTs and 16 neurons in R6/2s. There was a significantly lower amplitude of sEPSCs in R6/2 mice (8.9±2.5 pA in R6/2 vs. 14.1±5.8 pA in WTs; p=0.0022). Overall the frequency of sEPSCs in both groups was low compared to sIPSCs and differences in frequency were not observed between R6/2 and WT mice. Assuming that large sIPSCs are associated with action potential-dependent inputs to GPe neurons, the change in sIPSC frequency of Type 1 and Type 2 cells may reflect altered properties of different synaptic connections in symptomatic R6/2 mice. We have now begun to use optogenetics to more specifically examine inhibitory inputs from the striatum to the GPe. Taken together these findings indicate that an imbalance in inhibition in conjunction with reduced amplitude of

excitatory events underlies alterations in firing patterns and function of GPe neurons in R6/2 mice.

Title: Role of p75 neurotrophin receptor signaling in pathogenesis of Huntington's Disease

Authors: ***A. WEHNER**[1], R. L. ALBIN[2], B. A. PIERCHALA[1];
[1]Biol. and Materials Sci., [2]Neurol., Univ. of Michigan-Ann Arbor, Ann Arbor, MI

Abstract: Huntington's disease (HD) is a dominantly-inherited neurodegenerative disorder characterized by a constellation of motor, cognitive, and psychiatric symptoms. HD is caused by a CAG expansion in the *huntingtin (HTT)* gene. While the mutant protein is ubiquitously expressed, the striatum is affected earlier than most other brain regions. Striatal neurons are dependent on brain-derived neurotrophic factor (BDNF) from the cortex for proper function and survival. Non-mutant Htt has been shown to enhance BDNF expression by binding to the BDNF promoter and is also important for transport of BDNF to the striatum. In HD post-mortem tissue, there is a decrease in BDNF levels in the striatum, which has also been observed in animal models of HD. BDNF functions through its high affinity receptor, TrkB, to promote survival and maintain normal neuronal function. BDNF, however, can also bind to a lower affinity neurotrophin receptor, p75. Recent studies suggest both TrkB and p75 are improperly regulated in the striatum of HD patients and mouse models of HD. While BDNF-TrkB signaling almost exclusively promotes survival and metabolic function, p75 signaling is able to induce survival or apoptosis depending on its available ligand and associated co-receptor. In this study, we investigated the role of p75 in the Q175 knock-in mouse model by examining the level and activation of various downstream signaling molecules, as well as receptor components and effectors that associate with p75. Additionally, we examined these same signaling pathways in $Q175^{+/+};p75^{+/+}$, $Q175^{+/-};p75^{+/+}$, $Q175^{+/-};p75^{-/-}$, and $Q175^{+/+};p75^{-/-}$ mice. Electrophysiological and pathological differences were also investigated. We observed increased p75 levels in the

striatum of $Q175^{+/-}$ mice compared to WT littermates at 6 weeks of age, but not at 5 or 10 months of age. We also discovered an interaction between p75 and TrkB in the striatum at all three ages, but this interaction was reduced in the $Q175^{+/-}$ mice at 6 weeks and 5 months of age. Interestingly, the association between p75 and its apoptotic receptor components increases in $Q175^{+/-}$ mice at 10 months of age. Several downstream pathways are also dysregulated. These data suggest that p75 may play an early role in augmenting pro-survival signaling through TrkB during striatal development, and disruption of this signaling complex may be a pathological feature of HD. Conversely, at later stages of disease, p75 may play an opposing pro-apoptotic role in the striatum. This potential dual role of p75 in the pathogenesis of HD is intriguing and suggests further studies are necessary to determine the extent to which p75 and TrkB are useful therapeutic targets.

Title: Electrophysiological alterations of striatal cholinergic interneurons in the R6/2 mouse model of Huntington's disease

Authors: A. PARIEVSKY, S. M. HOLLEY, P. R. JOSHI, J. Y. CHEN, *C. CEPEDA, M. S. LEVINE;
IDDRC, Semel Inst. for Neurosci. and Human Behavior, BRI, UCLA, Los Angeles, CA

Abstract: Huntington's disease (HD) is a neurodegenerative disorder characterized by striatal, cortical, and thalamic degeneration. Medium-sized spiny neurons (MSNs), the projection neurons of the striatum, make up ~90-95% of the striatal population, and show significant degeneration in HD. Large cholinergic interneurons (LCI), which constitute only ~2% of the striatal neuronal population, are relatively spared but show functional deficits such as decreased acetylcholine release. We examined electrophysiological properties of LCIs to elucidate the role of these neurons in the progression of HD. Experiments were conducted in the R6/2 HD fragment mouse model, which expresses exon 1 of the human huntingtin gene and shows a

severe and rapidly progressing phenotype. Striatal LCIs were identified by somatic size, spontaneous action potential firing, and membrane properties. Previous findings have shown that the majority of excitatory glutamatergic inputs to LCIs arise from the centromedian-parafascicular (CmPf) nuclear complex of the thalamus and less so from the cerebral cortex. Evoked excitatory currents in LCIs were examined by expressing channel rhodopsin (ChR2) in the CmPf or cortex. Evoked inhibitory currents were examined by expressing ChR2 in striatal somatostatin (SOM)-containing interneurons. Spontaneous excitatory and inhibitory postsynaptic currents were also compared. LCIs from symptomatic R6/2 mice (~65 days) displayed reduced membrane capacitance and higher input resistance, consistent with reduced somatic size, as well as more irregular firing patterns and bursts of actions potentials. Due to minimal innervation of LCIs by corticostriatal projections, cortical stimulation rarely resulted in postsynaptic evoked responses, and when responses were evoked, they were very small. Both thalamostriatal evoked amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and N-methyl-D-aspartate (NMDA) receptor-mediated currents were minimally affected in the R6/2s. Spontaneous excitatory currents, mediated by AMPA receptors, were unchanged in frequency. GABAergic inhibitory currents evoked by stimulation of SOM-expressing interneurons were increased in amplitude and spontaneous GABAergic inhibitory currents were increased in frequency. As cell death of MSNs has been explained by increased excitatory inputs to these neurons, unaltered excitatory inputs to LCIs is in marked contrast to changes seen in MSNs and may explain the selective sparing of LCIs. Increased inhibitory currents displayed by LCIs provide a potential mechanism to explain the impaired ability of these neurons to fire regularly and release acetylcholine.

Title: Altered calcium dynamics of cortical microcircuits in the R6/2 mouse model for Huntington's disease

Authors: *A. M. ESTRADA SANCHEZ[1], T. INDERSMITTEN[1], M. HAIEM[2], C. CEPEDA[1], P. GOLSHANI[2], M. S. LEVINE[1];
[1]IDDRC, Semel Inst. For Neurosci. and Human Behavior, BRI, UCLA, [2]Dept. of Neurology, David Geffen Sch. of Med., UCLA, Los Angeles, CA

Abstract: Huntington's disease (HD) is an inherited neurodegenerative disorder, characterized by dysfunctional neuronal processing along the corticostriatal pathway, which is believed to set the stage for components of its behavioral phenotype. Although changes in electrophysiological properties of cortical pyramidal neurons have been described, little is known about changes in cortical microcircuits that will impact striatal activity. Here, we used two-photon microscopy to evaluate calcium dynamics in cortical neuronal microcircuits in the R6/2 transgenic mouse model of HD. When mice were 4 weeks of age adeno-associated virus-1 (AAV1), containing the genetically-encoded calcium indicator GCaMP6, was injected into motor cortex. Two weeks after the injection, a craniotomy was performed and a glass window was implanted over the cortical injection area. Cortical calcium dynamics in layers 2/3 were then evaluated using two-photon laser microscopy in mice freely running on a spherical treadmill. Cortical calcium activity was assessed during resting and running epochs. The results showed that, based on the amplitude of change in calcium transients ($\Delta F/F$), cortical neurons in both wildtype (WT) and R6/2 mice fell into two categories: neurons showing either low or high amplitude average calcium transients. Relative to WT, a larger proportion of neurons in the R6/2 mice displayed reduced amplitude calcium transients. There was a corresponding increase in the proportion of neurons with high average amplitude calcium transients in WT mice. Interestingly, the increased proportion of neurons with reduced amplitude calcium transients observed in R6/2 mice occurred during both running and resting. We also analyzed the proportion of cell pairs with significantly correlated calcium signals as a function of distance between pairs. There was an increase in the proportion of cell pairs with significantly correlated calcium transients in R6/2 mice compared to WT mice. This increase was more evident when animals were running on the treadmill. Together, these findings indicate that neuronal activity patterns in cortical circuits in HD become altered. Future studies will shed light on the effect of these changes on striatal activity and its role in triggering the HD phenotype.

Title: Investigation of symptoms of Huntington's Disease transgenic mice reveals prevalence of a high anxiety phenotype possibly due to abnormal serotonergic and noradrenergic neurotransmission

Authors: *S. K. ALSELEHDAR, E. D. ABERCROMBIE;
Ctr. for Mol. and Behavioral Neurosci., Rutgers, The State Univ. of NJ, Newark, NJ

Abstract: Mouse models of Huntington's Disease (HD) are useful in translational studies of HD because the models well encapsulate the progressive nature of HD at both behavioral and neuropathological levels. To further address the face validity of these models, we characterized the progression of the motor phenotype of two full-length transgenic HD models (YAC128 and BACHD) using multiple tests. In our approach we monitored the mice's general activity levels weekly in a photobeam cage rack system using clear Plexiglas activity chambers and testing motor coordination on a fixed-speed rotarod task monthly. As expected, HD mice were more active in the activity chambers than wildtype (WT) mice at young ages (6 weeks through 12 weeks). Previously, this has been correlated to the early choreic phase of the human disease. However, the behavior exhibited by both WT and HD mice in the activity chamber was highly variable, which masked the differences between genotypes. To determine if this variability was due to test environment, we measured general locomotion of a second cohort of WT and HD mice in a familiar home cage environment. Post hoc tests revealed that the YAC and BAC models expressed hyperkinesis in both test environments but this effect was more robust in the familiar home cage as evident by less within-group variability in activity levels. We propose that these findings reveal an underlying anxiety profile in these mice that was enhanced by exposure to a novel environment. Heightened levels of anxiety and depression are prevalent characteristics of HD in humans and many studies have observed this in several HD mouse models as well. It is important to investigate these symptoms since they are highly expressed by individuals with HD long before any of the hallmark motor deficits. Abnormal serotonergic and noradrenergic function is thought to underlie several of the psychiatric symptoms of HD. To show the prevalence of these behaviors, we will first characterize the anxiety and depressive phenotype of BACHD mice using multiple tests. We selected BACHD mice because they showed more robust anxiety compared to YAC128 mice. Next, we will use *in vivo* microdialysis to investigate if serotonergic and noradrenergic neurotransmission are affected in HD, particularly in hippocampus. The hippocampus receives dense projections from both serotonergic raphe nuclei

and noradrenergic locus coeruleus. Furthermore, changes in hippocampal neurotransmission are thought to underlie certain abnormal behaviors such as depression in a non-disease state. We propose that a similar pathology may be occurring in HD, ultimately driving the same behavioral abnormalities. This work is in progress.

Abstract: Huntington's disease (HD) is a progressive and fatal neurodegenerative disorder caused by a mutation in the HTT gene producing an expansion of glutamine repeats. The principal neuropathology of HD is a loss of striatal and cortical projection neurons, leading to a progressive disconnection between the cortex and striatum. Dopamine (DA) modulation of glutamatergic inputs also is disrupted in HD mouse models. Previous studies using the YAC128 mouse model of HD have provided evidence that excess DA may be present early in disease progression (2 months of age) whereas DA is depleted in the late stages (11 months). The present study used channelrhodopsin (ChR2) to selectively activate DA inputs to identified striatal medium-sized spiny neurons (MSNs) in triple transgenic YAC128 mice and control littermates (WT) expressing Cre recombinase under the tyrosine hydroxylase promoter and DsRed fluorescence under the DA D1 receptor promoter, which identifies direct-pathway MSNs. ChR2 was stereotaxically injected into the substantia nigra pars compacta of mice at 2 and 11 months

of age. Fast-scan cyclic voltammetry demonstrated no significant differences in amplitude of DA release between WT and YAC128 mice at 2 months of age. However, the decay time of DA release was significantly increased in slices from YAC128 mice, suggesting that alterations in the DA transporter occur. Addition of quinpirole, a D2 agonist, had smaller effects on DA release in YAC128 mice indicating a possible reduction of autoreceptor function. Furthermore, inhibiting DA reuptake with GBR 12935 produced smaller effects on release and decay time in 2 month-old YAC128 mice. In 11 month-old mice, the alterations in kinetics of DA release in YAC128 were less evident. Whole-cell patch clamp electrophysiological recordings in 2 month-old mice showed that ChR2-evoked release of DA had differential effects on synaptic transmission of D1 and D2 receptor-expressing MSNs. Release of DA increased the frequency of spontaneous excitatory postsynaptic currents (sEPSC) of D1-MSNs from WT mice but had no effect on sEPSC frequency of D1-MSNs from YAC128 mice. In contrast, DA release decreased EPSC frequency of D2-MSNs from both WT and YAC128 mice. Together, these data demonstrate that DA neurotransmission, particularly DA transporter and modulatory function, are altered early in disease progression. Slower decay times of DA release may contribute to increases in stereotypies observed in HD mice. Furthermore, treatments aimed at reducing the presence of DA at the synaptic cleft might help normalize behavioral alterations.

Abstract: Huntington disease (HD) is an inherited neurodegenerative disease with no disease-modifying therapy currently available. In addition to characteristic motor deficits and atrophy of the caudate nucleus, signature hallmarks of HD include behavioral abnormalities, immune activation, and cortical and white matter loss. The identification and validation of novel therapeutic targets that contribute to these degenerative cellular processes may lead to new interventions that slow or even halt the course of this insidious disease. Semaphorin 4D (SEMA4D) is a transmembrane signaling molecule that modulates a variety of processes central to neuroinflammation and neurodegeneration including glial cell activation, neuronal growth cone collapse and apoptosis of neural precursors, as well as inhibition of oligodendrocyte migration, differentiation and process formation. Therefore, inhibition of SEMA4D signaling could reduce CNS inflammation, increase neuronal outgrowth and enhance oligodendrocyte maturation, which may be of therapeutic benefit in the treatment of neurodegenerative diseases. A high affinity neutralizing antibody to SEMA4D has been described that prevents the interaction between SEMA4D and all of its known receptors, PlexinB1, PlexinB2 and CD72. Anti-SEMA4D treatment inhibits development of experimental autoimmune encephalomyelitis in multiple rodent models and promotes remyelination following chemically-induced demyelination. Considering the convergent pathogenic pathways of neuroinflammatory and neurodegenerative diseases, anti-SEMA4D treatment may have benefits in other indications, including HD. We have evaluated the preclinical therapeutic efficacy of anti-SEMA4D treatment in the YAC128 transgenic HD mouse model. Anti-SEMA4D treatment ameliorated neuropathological signatures, including striatal, cortical, and corpus callosum atrophy and prevented testicular degeneration in YAC128 mice. In parallel, a subset of behavioral symptoms were improved in anti-SEMA4D treated YAC128 mice, including reduced anxiety-like behavior and rescue of cognitive deficits. There was, however, no discernible effect on motor deficits. The preservation of brain grey and white matter and improvement in behavioral measures in YAC128 mice treated with anti-SEMA4D suggest that this approach could represent a viable therapeutic strategy for the treatment of HD. Importantly, this work provides *in vivo* demonstration that inhibition of pathways initiated by SEMA4D constitutes a novel approach to moderation of neurodegeneration.

Title: A theoretical model for the pathogenesis of adult onset dystonia due to GNAL mutations

Authors: *D. A. PETERSON, T. J. SEJNOWSKI;
Salk Inst., La Jolla, CA

Abstract: The pathogenesis of adult onset dystonia has been elusive. Recent genetic studies have implicated mutations in GNAL, which codes for the alpha subunit of the guanine nucleotide-binding protein G(olf). G(olf) is the dominantly expressed stimulatory G protein in the striatum andit mediates intracellular signaling pathways downstream from the D1-type dopamine receptors (D1Rs). Heterozygous knockouts (GNAL +/-) exhibit reduced locomotion during a 5-day period of sensitization to D-amph or cocaine. However, after a 9-day withdrawal, the locomotor behavior in response to a D-amph or cocaine challenge is normalized to that of control animals (GNAL +/+)(Corvol et al. 2007 Neuropsychopharmacology). Although this gross measure of motor function normalizes in the GNAL +/- mice, we hypothesize that other aspects of their motor functions would be pathological. Specifically, we predict that the heterozygous mice would be impaired in instrumental learning tasks, given the putative roles of the basal ganglia in learned action selection and phasic striatal dopamine release in feedback-based learning. At the mechanistic level, we hypothesize that the impaired D1R-G(olf)-AC-PKA

signaling pathway in the GNAL +/- mice leads to altered patterns of synaptic plasticity. Through a cascade of homeostatic processes downstream from PKA with increasingly longer time constants, short-time constant acute behavior and learning are relatively intact, while long time constant feedback-based learning is subtly altered. In conjunction with repeated patterns of context-specific motor selection, synaptic tagging, remodeling, and synaptogenesis and pruning lead to pathological action selection circuits in the striatum. This model sets the stage for new experimental tests of the GNAL mouse model and a rational basis for future therapeutics development in adult onset dystonias.

Title: Cerebellar encoding of neck input primes cortical plasticity of hand representation: The case of cervical dystonia

Authors: *S. O. MEUNIER[1], A. KISHORE[2], C. HUBSCH[3], T. POPA[4], A. RICHARD[5], E. ROZE[3], M. VIDAILHET[3];
[1]CRICM, INSERM, Paris, France; [2]Movement Disorders unit, SCTIMST, Trivandrum, India; [3]Neurol., APHP, Salpetriere hospital Paris, France; [4]ANR-10-IAIHU-06, CENIR Salpetriere hospital, France; [5]UPMC, CR ICM Paris, France

Abstract: We have previously shown, in healthy subjects, that the responsiveness to plasticity induction of the cortical hand representation in the primary motor cortex can be primed by changing the excitability of the cerebellar cortex (Popa et al 2013). Such a priming effect was lost in patients with writer's cramp (Hubsch et al 2013). We reasoned that if this abnormal encoding plays a direct role in generating dystonic manifestations, patients with cervical dystonia and no hand impairment, should have a preserved cerebellar priming of hand cortical plasticity. We compared 22 patients with a cervical dystonia and 22 healthy subjects. We assessed how sham, excitatory and inhibitory stimulations of the cerebellum (obtained by means of sham, intermittent and continuous thetaburst stimulations to cerebellum respectively) influenced an externally evoked plasticity (using a 5Hz paired associative stimulation protocol) in the cortical hand area. After sham cerebellar stimulation PAS-induced plasticity was similar in healthy controls and patients. Cerebellar excitation decreased the ensuing PAS-induced plasticity and cerebellar inhibition enhanced it in the healthy controls. At contrast cerebellar inhibition decreased the PAS-induced plasticity and cerebellar excitation let it unchanged in patients (INTERVENTION*GROUP $P<0.0003$). In control experiments we explored 8 healthy subjects while they maintained a head rotation to the right. In this condition cerebellar inhibition decreased the PAS-induced plasticity and cerebellar excitation increased it. These results show that the directional changes of cerebellar priming in cervical dystonia patients were linked to the involuntary head tilt that they maintained during the recordings. Provided that head positions were matched cerebellar inhibition induced similar decrease of PAS-induced plasticity in patients and healthy controls yet cerebellar excitation was efficient only in the less affected patients and lost in the more affected (linear regression $R2 = 0.4$, $P < 0.004$). Cerebellar priming of cortical plasticity is preserved in not severely affected cervical dystonia patients stressing the role of this priming in dystonic manifestations patients. Part of this priming is most in severely affected patients suggesting a spread of the pathological process from the cortical hand representation to other body part representations receiving the abnormally encoded cerebellar input.

Title: Selective alteration of striatal cholinergic function in a symptomatic mouse model of DYT1 dystonia

Authors: *S. S. PAPPAS, W. T. DAUER;
Dept Neurol., Univ. of Michigan, Ann Arbor, MI

Abstract: Dystonia is a movement disorder characterized by prolonged involuntary twisting movements that reflect selective dysfunction of CNS motor circuits. Abnormal basal ganglia function is implicated as a key cause of dystonic movements, but the cellular basis for neuronal dysfunction remains undefined. DYT1 dystonia, the most common inherited form of primary dystonia, is caused by a dominantly inherited loss of function mutation in the TOR1A gene (encoding the protein torsinA). To model dystonia-related neuronal dysfunction in forebrain motor circuits, we deleted torsinA selectively from forebrain GABAergic and cholinergic neurons. These mice are born at normal Mendelian frequencies, are indistinguishable from littermate controls, and perform normally in neonatal motor tests. However, by two to four weeks of age they develop clear motor dysfunction, including abnormal prolonged limb clasping and truncal twisting, reduced ability to hang from a wire grid, and hyperactivity. These mice show no gross brain neuropathological changes as assessed by Nissl, hematoxylin and eosin or GFAP immunostaining. However, they exhibit a selective loss of striatal cholinergic interneurons that begins between 1 and 4 weeks postnatally. No changes in cell number are seen in GABAergic medium spiny neurons or several classes of GABAergic interneurons. Significant reduction of striatal acetylcholinesterase activity provides further evidence of cholinergic dysfunction in this model. These findings demonstrate that among striatal cell types, maturing cholinergic interneurons have a unique requirement for torsinA function. These mice model several key features of DYT1 dystonia, including a developmental onset of striatal dysfunction and temporally related motor dysfunction, paralleling the late childhood/early adolescence onset of the human illness. This behaviorally symptomatic mouse model of dystonia therefore provides a powerful platform for identifying specific circuits and cell types that drive abnormal motor function in DYT1 dystonia.

Title: M1 muscarinic receptor subtype as a therapeutic target for the rescue of striatal synaptic plasticity alterations in basal ganglia disorders

Authors: M. MALTESE[1,2], G. MADEO[1,3], G. MARTELLA[1,2], T. SCHIRINZI[3], G. SCIAMANNA[1], G. PONTERIO[1], A. TASSONE[1], P. BONSI[1], P. J. CONN[4], *A. PISANI[3,1]; [1]Neurophysiol. and Plasticity Lab., Fondazione Santa Lucia IRCCS, Rome, Italy; [2]Systems Med., Univ. of Rome "Tor Vergata", Rome, Italy; [3]Clinica Neurologica Univ. Tor Vergata, Rome 00133, Italy; [4]Vanderbilt Ctr. for Neurosci. Drug Discovery, Nashville, TN

Abstract: Competitive antagonists of muscarinic receptors (mAChRs) are currently used in the pharmacological treatment of movement disorders such as Parkinson's disease and dystonia, although the existing drugs for clinical use are non-selective mAChR antagonists, associated with a broad array of undesirable central and peripheral side effects. Despite the clinical utility of this class of drugs, the mechanism of action still remains poorly understood. Furthermore, these anticholinergic drugs are not selective for specific mAChR subtypes and they display a wide range of negative side effects. In the present study we tested the effect of different mAChR antagonists on corticostriatal synaptic plasticity alterations recorded from medium spiny neurons (MSNs) in DYT1 dystonia heterozygous knock-in mice (Tor1a+/Δgag mice) and control mice (Tor1a+/+ mice). Tor1a+/Δgag mice exhibited a significant impairment of bidirectional corticostriatal synaptic plasticity, consisting in a loss of long term depression (LTD) and synaptic depotentiation (SD), as compared to controls. A complete rescue of physiological LTD and SD in knock-in mice was obtained by applying the M1-preferring antagonists pirenzepine (100 nM) and trihexyphenidyl (3 μM) as well as the novel selective M1 mAChR antagonist, VU0255035 (100 nM). Conversely, the non-selective mAChR antagonists orphenadrine (100 nM) produced only a partial rescue of synaptic plasticity deficits, whereas biperiden (20 μM) failed to restore synaptic plasticity. Our study demonstrate that M1 mAChR antagonism offsets synaptic plasticity deficits in the striatum of Tor1a+/Δgag mice, providing a potential mechanistic

rationale for the development of improved antimuscarinic therapies for movement disorders characterized by corticostriatal plasticity alterations, such as DYT1 dystonia and Parkinson's disease.

Title: Electrophysiological characterization of DYT1 dystonia mouse models

Authors: *F. YOKOI[1], H. CHEN[1], C. C. CHEETHAM[2], S. L. CAMPBELL[3], J. D. SWEATT[3], Y. LI[1];
[1]Neurol., Univ. of Florida, Gainesville, FL; [2]Neurology, Neurobio., [3]Neurobio., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: DYT1 early-onset generalized torsion dystonia is an inherited movement disorder caused by mutations in one allele of *DYT1* (*TOR1A*), coding for torsinA. The most common mutation is a trinucleotide deletion (ΔGAG), which causes a deletion of a glutamic acid residue (ΔE) in the C-terminal region of torsinA (torsin$A^{\Delta E}$). Other *DYT1* mutations, such as an 18-base

pair in frame deletion and a 4-base pair frame-shift mutation, have also been reported. Electrophysiological recording in CA1 regions of hippocampal slices is one of the established experimental models to examine long-term and short-term synaptic plasticity in the brain. Hippocampal CA3 pyramidal cells project to CA1 pyramidal cells through Schaffer collaterals. We and another group previously reported that theta-burst-induced long-term potentiation (LTP) in the CA1 region is not altered in *Dyt1* ΔGAG heterozygous knock-in (KI) mice. Here, we examined short-term synaptic plasticity and synaptic transmission in the hippocampal slices. Field recordings in the hippocampal Schaffer collaterals pathway revealed significantly enhanced paired pulse ratios (PPRs) in *Dyt1* KI mice, suggesting an impaired synaptic vesicle release. Whole-cell recordings from the CA1 neurons showed that *Dyt1* KI mice exhibited normal miniature excitatory post-synaptic currents (mEPSC), suggesting that action-potential independent spontaneous pre-synaptic release was normal. On the other hand, there was a significant decrease in the frequency, but not amplitude or kinetics, of spontaneous excitatory post-synaptic currents (sEPSC) in *Dyt1* KI mice, suggesting that the action-potential dependent pre-synaptic release was impaired. Although hippocampal torsinA was reduced in *Dyt1* KI mice, it was not clear whether decreased hippocampal torsinA level itself affects the synaptic plasticity or torsin$A^{\Delta E}$ does it. To analyze effect of torsinA loss to the synaptic plasticity, *Dyt1* heterozygous knock-out (KO) mice were further examined as a model with a frame-shift mutation. *Dyt1* heterozygous KO mice showed more reduced hippocampal torsinA than *Dyt1* KI mice. Contrast to *Dyt1* KI mice, *Dyt1* heterozygous KO showed enhanced hippocampal LTP and normal PPRs in the acute brain slices. These results suggest that the extreme reduction of torsinA causes enhanced hippocampal long-term synaptic plasticity. On the other hand, the short-term plasticity deficits found in *Dyt1* KI mice may be caused by torsin$A^{\Delta E}$-specific toxic-gain of function. Torsin$A^{\Delta E}$ and decreased torsinA levels seem to affect short-term and long-term synaptic plasticity, respectively. Different mutations in *DYT1* may differently affect synaptic plasticity and symptoms.

Title: Motor phenotypes associated with Ciz1 deficiency

Authors: *M. S. LEDOUX[1], K. KURUVILLA[1], H. HONDA[2], J. XIAO[1];
[1]Univ. of Tennessee Hlth. Sci. Ctr., MEMPHIS, TN; [2]Hiroshima Univ., Hiroshima, Japan

Abstract: Missense mutations in Cip1-interacting zinc finger protein 1 (CIZ1) have been associated with adult-onset primary cervical dystonia. CIZ1 is a p21(Cip1/Waf1)-interacting zinc finger protein expressed in brain and involved in DNA synthesis and cell-cycle control. To date, neither nonsense nor large deletion mutations leading to haploinsufficiency have been identified in subjects with dystonia. Therefore, the relative contributions of gain- or loss-of-function to the pathogenesis of CIZ1-associated dystonia remain indefinite. To provide a platform for mechanistic studies of CIZ1 biology, we have begun to characterize *Ciz1* gene-trap knockout (KO) and *Ciz1*-floxed mice. Using relative quantitative RT-PCR, we confirmed that *Ciz1* transcripts were reduced by 50% in heterozygous gene-trap mice and absent from homozygotes. In *Ciz1*-floxed mice, there were no apparent effects of loxP sites on transcription in spinal cord, cerebellum, striatum, midbrain, thalamus or frontal cortex. In adult wild-type littermates, cerebellum showed the highest expression levels of *Ciz1*, about two fold higher than liver, whereas expression levels in cerebral cortex, midbrain, and thalamus were approximately 50% higher than liver. Adult wild-type, heterozygous and homozygous mice were weighed and subjected to a battery of motor tests including open-field activity, rotarod, vertical rope climbing, a raised-beam task, grip strength, and gait analysis (DigiGait). Initial testing showed an overall effect of genotype on weight, activity, grip strength and the raised-beam task. Ongoing experiments are assessing interactions among age, gender and genotype given that cervical dystonia is more common in females with mean age-of-onset after 45 years.

Title: Effects of nicotinic receptors on striatal dopamine efflux in a cholinergic-specific dyt1 knock-out mouse model of dystonia

Authors: *C. THOMPSON, K. ESKOW JAUNARAJS, D. STANDAERT;
Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Early onset torsion dystonia (DYT1) is characterized by sustained muscle contractions causing twisting and repetitive movements or abnormal postures due to a mutation in the gene TOR1A, encoding the protein torsinA. Recent evidence in several mouse models of DYT1 dystonia, including cholinergic neuron-specific knockout of the DYT1 gene (ChAT-KO), shows abnormal striatal dopamine release compared to wild-type mice. This suggests that dopamine receptor signaling is particularly altered in striatal cholinergic neurons. In ChAT-KO mice, muscarinic acetylcholine receptors have reduced sensitivity to muscarinic antagonists; however, nicotinic acetylcholine receptors (nAchR) have not been examined. Because of our interest in the interplay between dopaminergic and cholinergic signaling in dystonia, we have used ChAT-KO mice as a mouse model of DYT1 dystonia in order to characterize the effects of nicotine on striatal dopamine release (DA). In a between-subject design, male ChAT-KO or control mice were implanted with a striatal microdialysis cannula and treated with either vehicle or nicotine (10mM, infused). Mice were then sacrificed and sectioned in order to verify probe placement. Results showed that ChAT-KO mice had a significantly greater DA efflux than control mice when nicotine was administered. This shows that striatal neuron nAChRs in ChAT-KO mice are more sensitive to nicotine than the control mice. Ongoing studies are looking into nicotinic involvement in other mouse models of DYT1 dystonia. Further investigation into the dopamine-acetylcholine relationship in several models of dystonia is needed to understand the mechanism between nAchRs and motor dysfunction induced by mutation in the TOR1A gene.

Abstract: Spasmodic dysphonia (SD) is a primary task-specific focal dystonia of unknown pathophysiology, which is characterized by involuntary spasms in the laryngeal muscles leading to uncontrolled voice breaks during speaking. In this study, we investigated differences in spontaneous fluctuations of brain activity during the rest in sporadic SD patients (ADductor and ABductor types) compared to healthy volunteers (HV) and assessed SD phenotype-specific organization of resting-state networks (RSNs) in both clinical phenotypes. Resting-state fMRI images were acquired in 27 ADSD, 21 ABSD and 28 HV on a 3T Philips scanner. Independent component analysis (ICA) identified 27 RSNs across all subjects (MELODIC-ICA, FSL). We a priori selected 2 RSNs with the sensory-motor (SMC) and the language (LC) components. Dual-regression analysis was performed to identify subject-specific temporal dynamics and associated spatial maps. Statistical inference was performed using a two-sample t-test (all patients vs. HV, and ABSD vs. ADSD) at a corrected $p \leq 0.05$. Compared to HV, patients showed decreased SMC functional connectivity in the left laryngeal/orofacial primary sensorimotor cortex, inferior frontal gyrus (Broca's area), operculum, auditory cortex, and right premotor cortex. Conversely, patients showed increased LC connectivity in the left premotor cortex, which did not overlap with the region of decreased SMC connectivity. Direct comparisons between the patient groups showed that ABSD had increased SMC connectivity in the left supramarginal gyrus and superior parietal lobule, bilateral operculum, and right supplementary motor area. In addition, ABSD patients compared to ADSD showed increased LC connectivity in the left somatosensory cortex, inferior parietal lobule and right inferior/middle temporal gyri. Our findings demonstrated abnormal organization of resting-state networks related to speech sensorimotor control in SD patients, which may underlie abnormal functional connectivity during dystonic task production. Phenotype-specific differences in SMC and LC functional network organization between ADSD and ABSD may be associated with different genetic variants.

Title: Alterations of the functional interplay between striatal dopamine D2 receptor and RGS9-2 in movement disorders

Authors: *P. BONSI[1], G. PONTERIO[1], G. SCIAMANNA[1,3], A. TASSONE[1], G. MANDOLESI[1,3], V. VANNI[1,3], V. ZACHARIOU[4], E. BEZARD[5], A. PISANI[2,3];

Abstract: Striatal dopamine and acetylcholine regulate voluntary movement and their imbalance is critically involved in motor dysfunction in Parkinson's disease (PD) and dystonia. RGS9-2, striatal R7 family member regulating dopamine D2 receptor (DRD2) localization and signalling, negatively modulates levodopa-induced dyskinesia (LIDs) in experimental PD. Indeed, RGS9-2 overexpression achieved by viral vector injection into the striatum diminishes the intensity of involuntary movement caused by levodopa treatment in both rat and monkey models of PD and dyskinesia. Given previous evidence of a significant dysfunction of striatal DRD2 in DYT1 dystonia, we investigated whether viral-mediated RGS9-2 overexpression might restore DRD2 function in DYT1 mice. As previously observed, electrophysiological recordings from cholinergic interneurons (ChIs) of both hMT1 and *Tor1a*$^{+/\Delta E}$ striatal slices showed an abnormal increase of firing activity, instead of the reduction observed in wild-type neurons, in response to DRD2 activation by quinpirole. Conversely, the inhibitory effect on ChI firing activity of mu-opioid receptor, whose function is also regulated by RGS9-2, was unaltered. hMT1 mice overexpress the human protein with the DYT1 dystonia mutation, ΔE-torsinA. However, the levels of endogenous torsinA are developmentally regulated in wild-type mice, reaching a peak at P7 in the striatum. We therefore characterized the developmental expression of endogenous torsinA in knock-in *Tor1a*$^{+/\Delta E}$ striata, and found significantly reduced (~50%) torsinA levels throughout the postnatal development (P7-P60). Immunoblotting experiments demonstrated a significant reduction of DRD2 protein level at P60 in DYT1 striatal homogenates. The reduction of DRD2 level seems due to an increased rate of degradation by lysosomal proteases, since it was abolished by the protease inhibitor leupeptin. Of note, also the level of RGS9-2 was reduced at P60 in DYT1 mice. Conversely, the levels of an RGS9-2 interacting protein, Gβ5, and of the closely related RGS7 protein were unchanged in *Tor1a*$^{+/\Delta E}$ striata. *In vivo* viral-mediated delivery of RGS9-2 in DYT1 striata restored RGS9-2, but not torsinA, levels to normal values, with respect to the contralateral vehicle-injected striata. Electrophysiological recordings from ChIs in acute slices from the RGS9-2-injected striatum demonstrated a rescue of D2 receptor

inhibitory response to quinpirole. These observations demonstrate a key role of RGS9-2 in DYT1 dystonia pathophysiology, as described in LIDs in experimental PD, suggesting that the DRD2-RGS9-2 interplay may represent a common target in movement disorders.

Abstract: DYT1 dystonia is a severe movement disorder, caused by a 3-bp deletion in the C-terminal coding region of the protein torsinA (TorA). It is still unclear whether TorA mutation is responsible for the failure of cellular processes encoding motor learning and memory, and whether this impairment occurs in specific species or in selective brain regions. The present work confirms our previous findings obtained in distinct mouse models of DYT1 dystonia, specifically transgenic mouse model overexpressing human mutant torsinA (TorA) and mice with selective TorA deletion in cholinergic interneurons (ChI) (Martella et al, 2009; Sciamanna et al 2012). Electrophysiological recordings were performed from both striatal and hippocampal

acute slices in knock-in (Tor1aΔGAG+/-) mice and transgenic overexpressing human torsinA (hMT) rats and their respective wild-type littermates. The aberrant electrophysiological responses to D2 dopamine receptor (D2R) activation from ChI has been detected in the two rodent DYT1 models, Tor1aΔGAG+/- mice and hMT rats, consisting in an excitatory response to the D2R agonist quinpirole, rather than the expected inhibition occurring in wild-type animals. Moreover, alterations of corticostriatal long-term synaptic plasticity were observed in Tor1aΔGAG+/- mice. Indeed, in MSNs recorded long-term depression (LTD) could not be elicited, as compared to wild-type mice. Additionally, long-term potentiation (LTP) in mutant torsinA mice exhibited increased amplitude, and low-frequency stimulation (LFS), which induces a synaptic depotentiation (SD) in controls, failed to depotentiate corticostriatal synapses in Tor1aΔGAG+/- mice. These synaptic plasticity abnormalities exhibit a regional specificity, since a theta-burst stimulation protocol induced a LTP of normal amplitude at CA1-hippocampal synapses in Tor1aΔGAG+/- mice. These findings validate our previous results and endorse the existence of a specific electrophysiological phenotype linked to DYT1 mutation, irrespective of the species analyzed.

Title: Novel approaches for diagnosis and therapeutics for DOPA responsive dystonia

Authors: *L. JONES[1], L. GOOD[1], N. SHARMA[2], P. BHIDE[1], I. A. ARMATA[1];
[1]Florida State Univ., Tallahassee, FL; [2]Mass Gen. Hosp., Boston, MA

Abstract: The *GCH1* gene encodes the GTP cyclohydrolase 1, which is an enzyme involved in dopamine biosynthesis. Mutations in the *GCH1* gene are associated with dopa-responsive dystonia (DRD), a debilitating movement disorder affecting adults as well as children. Over 114 *GCH1* mutations are linked to DRD with only three single nucleotide polymorphisms (SNPs)

detected within its 5'untranslated region (5'UTR). We have previously reported that among these three 5 UTR SNPs, only the +142C>T is of biological significance because it reduces GCH1 protein levels. In support of this finding, genetic studies show that individuals with a +142T manifest DRD while individuals with a +142C are unaffected. Here we show that the presence of a +142T introduces an upstream translational codon (uAUG) leading to production of two GCH1 protein products; the normal GCH1 enzyme from the normal ATG and a second truncated abnormal protein from the uATG. The latter abnormal protein competes with the normal protein (unpublished data). We are currently developing an antibody specific for the mutant uATG-initiated peptide which can be used as a diagnostic tool for this type of DRD, as well as a tool for screening therapeutic potential of novel compounds that can tilt the balance towards the normal ATG. Accurate DRD diagnosis is critical so that the patient can benefit from L-DOPA treatment at the earliest stages of the disease. Finding novel therapy is also critical because treatment of the symptoms using L-DOPA leads to side effects such as dopa-induced dyskinesias. Our findings open new avenues for novel diagnostic and therapeutic approaches.

Title: Kinematic motion sensors objectively characterize neck movements in cervical dystonia

Authors: *O. SAMOTUS[1], H. VAFADAR[1], F. RAHIMI[1], J. LEE[1], M. JACKMAN[2], M. JOG[2,1];

Abstract: Cervical dystonia (CD) is characterized by varying abnormal neck posturing with superimposed hyperkinetic movement such as tremor. Visual assessments are highly subjective and often incorrectly characterize an individual's neck movements. Kinematic technology using motion sensors can quantitate the static and dynamic movements of the neck. This study aims to develop a sensor-based method for kinematic assessment of cervical dystonia. 11 CD patients

underwent a kinematic assessment in a seated position involving surface attachment of 1 electrogoniometer at spinal segments C2 and T2, an accelerometer and inclinometer on the right temple and an inclinometer on each shoulder. Neutral head position was recorded for each patient for kinematic calibration. Recordings captured CD in a seated eyes open and closed scenario. Natural position of the neck and head were marked once patient's eyes were closed for 1 minute. Additional range of motion kinematics were recorded at 90° left/right rotation of head, tilt up/down to chest, and lateral left/right tilt. Deviation from calibrated neutral position revealed the severity of a patient's fixed posturing in lateral, vertical and rotational degrees of freedom (DOF). At patient's natural position, angular tremor amplitudes for each DOF were plotted. Interpretation of these results led to grouping the 11 patients into two categories based on their prevalent neck movements. 5 patients commonly had mild to severe asymmetrical fixed posturing, accompanied by mild corrective hyperkinetic movements. 6 patients commonly had mild to severe head tremors with mild fixed posturing. As involuntary twisting of the neck and superimposed head tremors contribute to abnormal neck movements, kinematics can objectively measure the biomechanics of the neck. Kinematics can aid clinicians to better tailor focal treatments for cervical dystonia, such as botulinum neurotoxin type A injections.

Title: Focal dystonia in torsin A +/- mice after transient nerve injury

Authors: *J. VOLKMANN, I. U. ISAIAS, B. TEKIN, A. ALTTOA, D. KLEIN, T. HIGUCHI, A. REIF, C. W. IP;
Dept. of Neurol., Julius-Maximilians-University, Wuerzburg, Germany

Abstract: Objective: To date no satisfying rodent model of idiopathic dystonia with typical clinical features exists. DYT1 dystonia is the most common genetic form of primary torsion dystonia in humans caused by an autosomal-dominant "loss of function" mutation in the torsin A gene. Interestingly, the penetrance of DYT1 dystonia is markedly reduced with only 30 % of carriers manifesting the typical limb-onset generalized dystonia in childhood. Here, we pursue

the hypothesis, that dystonia manifests in genetically predisposed individuals only after a "second hit" (e.g. abnormal sensory input) causing maladaptive plasticity of the basal ganglia-cortex network. To this end, we observed the motor recovery of torsin A +/- and wildtype mice after a transient nerve injury and examined dopaminergic metabolic changes in the basal ganglia in response to the trauma. Methods: Development of dystonia after a sciatic nerve crush was assessed by blinded clinical scoring of hindlimb movements and by using a gait analysis system for rodents (CatWalk XT). Immunohistochemical stainings of the peripheral nerve for myelin basic protein and neurofilament as well as electroneurographic measurements were used to exclude permanent injury of the peripheral nerve. Western blot analysis was performed for dopamine transporter (DAT), D1 and D2 receptors (striatum) as well as quantitative RT-PCR analysis for DAT (midbrain). Ex-vivo autoradiography (AR) after intravenous DAT radioligand I-123 ioflupane administration was used to assess the DAT binding potential in the striatum. Results: 8 weeks after the sciatic crush a higher dystonia score of the hindlimb and a decreased step sequence regularity index were found in torsin A +/- compared to wt mice. Histology and electroneurography excluded a different degree of peripheral nerve injury in the two groups. Instead, we found several indicators of an altered dopaminergic neurotransmission in the striatum in response to the trauma: torsin A +/- compared to wt mice showed decreased baseline mRNA and protein levels of presynaptic DAT, which increased after peripheral nerve injury in the mutant mice only. In parallel, postsynaptic D1 and D2 receptor protein levels decreased after trauma. AR exhibited a reduced DAT binding capacity in Torsin A +/- mice after peripheral nerve injury. Conclusion: Our data indicate that peripheral nerve injury triggers the clinical manifestation of focal dystonia in susceptible mice. Dopaminergic neurotransmission is altered in torsin A +/- mice and could play an important role in the central network changes leading to a dystonic phenotype after the injury.

Title: Acetylcholine-induced calcium transients are sensitized in central neurons associated with DYT1 dystonia

Authors: *S. IWABUCHI, J.-Y. KOH, N. C. HARATA;
Dept. of Mol. Physiol. & Biophysics, Univ. of Iowa, Iowa City, IA

Abstract: Enhanced activity of the cholinergic system in the brain has been associated with a movement disorder dystonia. This notion is based on the clinical findings that anti-cholinergic agents are effective in alleviating symptoms in some patients. These agents are typically antagonists of M1 muscarinic acetylcholine receptors, which are coupled to G proteins and the mobilization of intracellular calcium. However, the cellular basis for the hyper-cholinergic state is not understood well. We have tested the hypothesis that the susceptible neurons are more sensitive than wild-type neurons to acetylcholine. To this end, we have used a mouse model of DYT1 dystonia, the most common inherited form of this disorder. DYT1 dystonia is caused by the deletion of a single glutamic acid residue in torsinA (ΔE-torsinA), a protein expressed widely throughout the brain. Heterozygous ΔE-torsinA knock-in mice reproduce the genetic status of patients. We used live-cell fluorescence imaging of the intracellular calcium concentration to evaluate the responses to acetylcholine in cultured striatal and hippocampal neurons, which normally express both torsinA and M1 muscarinic receptors. A high concentration of acetylcholine (10 μM) induced calcium transients in most neurons of both heterozygous and wild-type mice. These calcium transients often oscillated in amplitude, both during and after the 20-sec application of acetylcholine. They were observed in dendrites, somata and axons, and were completely blocked by pretreatment with the broad-spectrum muscarinic antagonist atropine (0.1 μM). An intermediate concentration of acetylcholine (1 μM), however, more effectively induced calcium transients in heterozygous vs. wild-type neurons. A low concentration (0.1 μM) induced detectable calcium transients only in heterozygous neurons. Interestingly, the calcium transients in the neurons treated with low acetylcholine were observed mainly in axons. These results suggest that the mutant neurons are sensitized to acetylcholine. Since intracellular calcium is an important regulator of neuronal excitability, the observed changes in cholinergic sensitivity in different subcellular regions could underlie the hyper-cholinergic state in DYT1 dystonia.

Title: Neurochemical and behavioral dysfunction in a new mouse model of dopa-responsive dystonia

Authors: *S. ROSE, X. YU, H. A. JINNAH, E. J. HESS;
Emory Univ., Atlanta, GA

Abstract: Dystonia is characterized by involuntary muscle contractions that cause debilitating twisting movements and postures. Although the pathogenesis of dystonia is not understood, reduced dopamine neurotransmission is observed across many different forms of dystonia, including dopa-responsive dystonia (DRD). DRD is cause by mutations in genes integral to dopamine synthesis, including tyrosine hydroxylase (TH), the rate-limiting enzyme in dopamine synthesis. Therefore, to better understand the role of dopamine in dystonia, we have created a knockin mouse bearing the DRD-causing TH mutation c.1160C>A; p.381Q>K (DRD knockin mice). TH activity is reduced by ~90% *in vivo* in these mice, causing a dramatic reduction in dopamine concentration. Behaviorally, DRD knockin mice exhibit abnormal movements reminiscent of human dystonia. These movements are exacerbated by dopamine receptor antagonists, illustrating the role for reduced dopamine tone in the expression of dystonia. DRD knockin mice also exhibit abnormal circadian regulation of locomotor activity, with hyperactivity at the start of the dark cycle and hypoactivity by the end of the dark cycle. These studies establish DRD knockin mice as a useful model for examining dopaminergic mechanisms underlying dystonia.

Title: Paretic and paratonic dystonia alleviated by pallidal stimulation

Authors: *Y. MIYAGI[1,2], T. OHMURA[1], T. SHIRAISHI[3], K. YAMASHIRO[4];
[1]Dpt.Stereotactic and Functional Neurosurg., Kaizuka Hosp., Fukuoka, Japan; [2]Grad. Sch. of Med. Sci., Kyushu Univ., Fukuoka, Japan; [3]Dpt. Neurol., Ikeda Hosp., Kanoya, Japan; [4]Dpt. Neurosurg., Okinawa Nanbu Med. Ctr., Haebaru, Japan

Abstract: A 22-year-old woman presented with a quadriplegia after symptoms of common cold at 17 years old. Based on the tentative diagnosis as abnormal autoimmune response, she was treated by the steroid pulse therapy but the quadriplegia did not respond to steroid at all in a short term. After repeating the exacerbation and remission, the muscle weakness of her limbs resolved spontaneously and gradually over the next three years. At 20 years old, the muscle power of her limbs recovered enough so that she could work as a caregiver in the facility for the disabled. At the age of 22, she felt uneasiness in all limbs and she began to lose the muscle power of all limbs, finally presenting with a quadriplegia in the following two days. Although her limb muscles were flaccid during voluntary movement (paretic), muscle tone turned rigid immediately in response to passive movement of limb joints (paratonic). There were neither involuntary movement nor abnormal posture of the limbs. All the other neurological findings other than the muscle tone of extremities, such as cranial nerve, cognitive, autonomic and sensory systems were totally normal. The paretic/paratonic symptoms were not alleviated by any pharmacotherapy. Deep brain stimulation of the internal globus pallidus diminished both paretic and paratonic symptoms and she recovered the voluntary motor control of extremities immediately after the implantation. Dystonia is typically defined as a syndrome of involuntary movement and abnormal postures caused by abnormal co-contractions of agonist and antagonist muscles and paretic loss of voluntary motor control is very rare. Paratonia, another form of abnormally increased muscle tone with an involuntary variable resistance during passive movement, has been thought to result from frontal lobe dysfunction such as late stage of dementia. Paretic and paratonic form of dystonia has never been reported as yet. The present case suggested that some atypical features of dystonia (coexistence of paresis and paratonia) could result from pathological output of the basal ganglia.

Title: Pathophysiology of spasmodic dysphonia: A combined transcranial magnetic stimulation and functional magnetic resonant imaging study

Authors: *T. J. KIMBERLEY[1], M. CHEN[2], R. SCHMIDT[2];
[1]Program in Physical Therapy, Univ. of MN, Minneapolis, MN; [2]Physical Med. and Rehabil., Univ. of Minnesota, Minneapolis, MN

Abstract: Introduction Adductor spasmodic dysphonia (AdSD) is a primary task specific focal dystonia affecting the laryngeal muscles during speech. The pathophysiology of AdSD is unclear. Transcranial magnetic stimulation (TMS) studies on non-affected muscles (e.g. first dorsal interosseous) have demonstrated that there was significantly greater activation in M1 cortex. However, the excitability of the laryngeal motor cortex evaluated by the affected muscle (thyroarytenoid, TA), has not been investigated. In this work we developed a method to determine cortical excitability using the TA muscle EMG responses to TMS over laryngeal motor cortex and compared the results between the AdSD and healthy individuals. Method Cortical stimulation responses were acquired by two pairs of fine-wire hooked electrodes that were inserted into the right and left TA muscles. Peripheral nerve responses to stimulation were also collected to confirm the cortical response and latency. The cortical stimulation responses were measured by cortical silent period (CSP). Peripheral response was delivered to the mastoid. Latency of response to both cortical and peripheral stimulation were quantified. The CSP values were compared between healthy (H, n=2) and AdSD (S, n=1) individuals were compared. Result Preliminary results are presented. Ipsilateral responses with no silent period were observed from mastoid stimulation; bilateral responses were observed from the cortical stimulation, verifying cortical stimulation. The average CSP values for each subject: H1: 62.97 ms (contralateral, L) and 63.28 ms (ipsilateral, R); H2: 35.90 ms (contralateral, L) and 34.50 ms (ipsilateral, R); and S1: 59.50 ms (contralateral, L) and 49.38 ms (ipsilateral, R). Discussion The differences in the response pattern between mastoid and cortical stimulation confirmed that the CSP were elicited cortically. The CSP values indicated that it was possible to assess the cortical excitability by the

proposed method. CSP values from L and R TA were similar in healthy controls, but were different in AdSD subject. This finding needs further confirmation with more data. Conclusion We have developed a valid method to evaluate the excitability of the laryngeal motor cortex. The preliminary results confirmed that the CSP responses can be cortically evoked. Future work will use the comparison of the cortical excitability between AdSD and healthy individuals. These results will help to gain a better understanding of the mechanism of the inhibition networks of the brain of AdSD.

Title: Diffusion tensor image analysis of a novel mouse model of dystonia

Authors: *A. BADEA[1], Y. QI[1], S. QIU[3], S. BHAGAT[4], N. CALAKOS[2];
[1]Radiology, [2]Neurol., Duke Univ. Med. Ctr., DURHAM, NC; [3]Sch. of Med., Duke Univ., Durham, NC; [4]Neurol., Duke Univ. Med. Sch., Durham, NC

Abstract: **Introduction**. Dystonia is a neurological syndrome characterized by twisting movements or sustained abnormal postures. A novel, rare *TOR1A* variant (p. F205I) identified in an individual with late-onset, focal dystonia raised the possibility that this *TOR1A* variant may contribute to the expression of dystonia (Calakos, 2010). A mouse model with a knockin mutation was created to test the functional significance of this variant. In prior studies, DTI MRI changes have been described in DYT1 patients and asymptomatic carriers as well as asymptomatic DYT1 knockin mice (Argyelan, 2009; Ulug, 2011). We examined whether similar abnormalities were present in this novel model using high field, high resolution magnetic resonance histology. **Methods.** Twelve animals (6 of each genotype; littermate controls) were perfusion-fixed and actively stained with Gadolinium prior to MR imaging at 9.4T. A diffusion tensor imaging (DTI) protocol with 6 directions was used to reconstruct tensors and derived DTI

parametric maps (Jiang et al, 2011). ANTS (Avants et al 2011) was used for registration. SurfStat (Chung et al, 2010) was used for voxel-wise statistics for log Jacobian and DTI parametric maps. A novel atlas of the mouse brain was used for a regional quantitative characterization of volume and DTI parametric changes. **Results.** Atlas-based segmentation enabled regional analysis of DTI parametric changes for 100 brain regions. FA in the inferior cerebellar peduncle was different at $p<0.05$ between the dystonia animal models and age-matched controls. Other white matter tracts showed a trend towards reduced FA at $p<=0.1$. These include the brachium of the superior colliculus (bsc), the posterior commissure (pc), and the spino-cerebellar tract (dsc+vsc). FA was reduced between 5-10 % in these white matter structures (approx. 5% reduction in FA for bsc, 8% for icp and pc, and 11% in spinocerebellar tract). Also showing a trend, towards larger FA however, was the area occupied by the gigantocellular reticular nuclei (9% larger FA than in controls). **Conclusion.** Our results confirm and extend findings in the field. We see changes in regions that have been implicated in prior studies (cerebellar tracts). In addition, there are a number of new areas implicated. Notably, unlike prior mouse models studied with this imaging modality, F205I mice have motor impairments. Efforts are underway to determine whether correlations between imaging data and behavior exist, as data from human studies have indicated.

Title: Distinct oscillatory pallido-cortical networks revealed by simultaneous pallidal iEEG and MEG in patients with dystonia

Authors: W.-J. NEUMANN[1], A. JHA[2], A. BOCK[1], J. HUEBL[1], G.-H. SCHNEIDER[3], T. SANDER[4], V. LITVAK[2], *A. A. KUEHN[1];
[1]Dept Neurology, Charité, Berlin, Germany; [2]The Wellcome Trust Ctr. for Neuroimaging, Univ. Col. London, London, United Kingdom; [3]Dept Neurosurgery, Charité, Berlin, Germany; [4]Physikalisch Technische Bundesanstalt, Berlin, Germany

Abstract: Question: Little is known about the organisation of oscillatory network activity in pallidocortical circuits that are being modulated by deep brain stimulation (DBS) as a treatment for dystonia. In Parkinson's Disease, simultaneous subthalamic intracranial EEG (iEEG) and magnetoencephalographic (MEG) recordings have revealed distinct sources for alpha (7-13 Hz) and beta (13-35 Hz) networks. To characterize the oscillatory pallido-cortical network in dystonia we performed simultaneous MEG and iEEG recordings from the GPi in 8 patients (age: 47.8 ± 3.7 years; 6f/2m) with dystonia. Methods: Simultaneous MEG-iEEG recordings were conducted with the patients lying at rest with eyes open. Bipolar iEEG recordings were acquired from adjacent contact pairs of the DBS electrodes. To visualize peaks of frequency specific cortico-pallidal coherence the Dynamic imaging of coherent sources (DICS) beamforming method was utilized. Standard Statistical Parametric Mapping (SPM) methods were used to identify significant clusters of coherence in 3D source space. Source activity from these clusters was extracted using the Linearly-Constrained Minimum Variance beamformer method and directionality of information flow was analysed using granger causality based methods. Results: Group level analysis of the 3D DICS images revealed significant clusters of coherence in the theta (4-8 Hz), alpha (7-13 Hz) and beta (13-30 Hz) band in distinct anatomical locations. In the theta band, a cluster spanning from subcortical areas to the temporal cortex, with the coherence maximum in the mid temporal lobe, was identified ($p < 0.01$). A cluster restricted to the cerebellum was significant in the alpha band ($p < 0.01$). Pallido-cortical coherence in the beta band (13-30 Hz) was significant in the sensorimotor areas ($p < 0.01$). Directionality analysis revealed bidirectional coupling in all networks with predominant driving of the cortical signal by the GPi in the theta and alpha band, as opposed to a predominant cortical driving of the GPi signal in the beta band. Conclusions: We have demonstrated that the human internal pallidum is interconnected with the cerebral cortex in spatially and spectrally distinct functional oscillatory networks in patients with dystonia. Pallido-cortical coherence in the beta band was localized to motor areas, supporting previous findings in patients with Parkinson's disease. More interesting, pallido-cortical coherence in the alpha band was focussed to a central cerebellar source that may hint at cerebellar involvement in patients with dystonia as has been recently discussed for results from imaging studies.

Title: An investigation of gene expression changes in motor neurons in a mouse model of spinal muscular atrophy

Authors: *C. C. PHILLIPS[1], A. W. HARRIS[3], M. MAEDA[4], M. E. R. BUTCHBACH[4], M. A. HARRINGTON[2];

Abstract: Spinal Muscular Atrophy (SMA) is a genetic motor neuron disease resulting from the loss of mutation of the *survival motor neuron 1* (*SMN1*) gene. SMA is characterized by the degeneration and death of motor neurons leading to neuromuscular dysfunction and ultimately mortality in those affected. Work with mouse models for spinal muscular atrophy has shown that SMN-deficient motor neurons are impaired in central circuitry and synaptic function including loss of afferent synapses associated with proprioceptive inputs. Recent work from our lab has shown that motor neurons from mouse models are increasingly less able to fire action potentials as the disease progresses. SMN plays a crucial role in processing of mRNA, so disruption of this protein could lead to defects in expression for other proteins needed for motor neuron function. Consideration of additional gene-expression mediated dysfunction is essential to further characterize the pathophysiology of the disease. In motor neurons, the axon initial segment (AIS) functions as the spike initiation zone. We are investigating changes in the expression of genes important in the function of the AIS, including ankyrin 3 (*Ank3*), and the sodium channels NaV1.1 *(Scna1)* and NaV1.6 *(Scna8)* in motor neurons from a mouse model of SMA. In severe SMA mouse motor neurons differentiated from embryonic stem cells, using whole transcriptome sequencing, we found significant reductions in the levels of *Scna8* and *Ank3* transcripts Scna1 mRNA levels were not affected by reduced SMN protein observed in SMA motor neurons. Changes in the expression of these proteins over the course of disease progression may be a key driver of motor neuron dysfunction.

Title: Survival motor neuron protein expression in motor neurons alters their intrinsic excitability in spinal muscular atrophy

Authors: *J. LOMBARDO[1], L. KONG[2], C. J. SUMNER[2], M. A. HARRINGTON[1]; [1]Delaware State Univ., Dover, DE; [2]The Johns Hopkins Univ., Baltimore, MD

Abstract: Spinal Muscular Atrophy (SMA) is an inherited autosomal recessive disorder caused by loss or mutation of the Survival Motor Neuron 1 (SMN1) gene, resulting in loss of lower motor neurons and atrophy of muscle. Current research with SMA mouse models has mainly focused on the synaptic properties of motor neurons, demonstrating that defects appear at the neuromuscular junction as well as at central sensorimotor synapses before motor neuron cell death. However, recent work in the SMA-Δ7 mouse model, the most commonly studied SMA model, has shown that rescuing SMN protein expression specifically in motor neurons can prevent synaptic dysfunctions at the neuromuscular junction and restore central synapses. This suggested that lack of SMN protein expression in motor neurons, and motor neurons themselves might be the origin of the main features of SMA pathology. To characterize the alterations of motor neuron properties and understand their contribution to SMA, we used the recently developed mouse model in which SMN protein expression is rescued in SMA-Δ7 motor neurons under the control of the Choline Acetyl-transferase (ChAT) gene promoter. Early alterations of motor neuron intrinsic electrophysiological properties were studied with the whole-cell patch clamp technique in spinal cord slices obtained from the lumbar enlargement of SMA-Δ7 mutant mice, SMA-Δ7 mutant mice with SMN protein re-expressed in motor neurons, and control mice. In addition, confirmation of motor neuron identity of the electrophysiologically recorded cells

was achieved through morphological characterization and ChAT expression of the recorded cells.

Title: Therapeutic potential of heat shock protein 27 on Guillain-Barré syndrome

Authors: ***P. ASTHANA**[1], G. ZHANG[2], K. A. SHEIKH[2], C. H. E. MA[1];
[1]Dept. of Biomed. Sci., City Univ. of Hong Kong, Tat Chee Avenue, Hong Kong; [2]Dept. of Neurol., Univ. of Texas Med. Sch., Houston, TX

Abstract: Guillain-Barré syndrome (GBS) is an autoimmune disease affecting the peripheral nervous system in which a person's own immune system damages their peripheral nerves, causing muscle weakness, paralysis, and loss of sensation in lower limbs. GBS patients suffer from muscle weakness in the lower limbs progressing rapidly in the ascending fashion resulting flaccid neuromuscular paralysis. Several clinical studies indicated that antibodies against ganglioside (anti-GD1a) in the sera of GBS patients are the most commonly recognized autoimmune markers in all forms of GBS targeting the neuromuscular junction (NMJ). Clinical studies have already reported the failure of target reinnervation and nerve repair in patients. Recent studies showed that Hsp27 accelerates axonal growth in peripheral neuron and functional recovery in animal model of peripheral nerve injury. The objective of present study is to determine the protective effect of Hsp27 on GBS. Anti-gangliosides GD1a/GT1b-2b (IB7) was administered intraperitoneally after peripheral nerve crush in Hsp27 transgenic and littermate mice. Series of behaviour experiments were performed such as pinprick assay (sensory), and grip strength (motor). Animals were perfused and tissues (gastrocnemius muscle, plantar muscle, brain, sciatic nerve and dorsal root ganglion) were harvested for histological analysis. The protective effect of Hsp27 was observed in grip strength test during initial days of recovery as

compared to IB7 treated littermates. These findings were consistent with pinprick test as initial response was observed 9 days earlier in Hsp27 transgenic group. The number of innervated NMJ increase significantly in Hsp27 transgenic mice as compared to IB7 treated littermate. Further analysis on axon number will be performed. Our pilot study indicates that Hsp27 as a potential therapeutic target for GBS.

Abstract: Mutations in glycyl-tRNA synthetase (GARS) can lead to the axonal form of Charcot-Marie-Tooth disease (CMT) or CMT2D. CMT is the most common inherited disorder of the peripheral nervous system. Due to progressive length-dependent degeneration of both motor and sensory axons, patients suffer from distal muscle weakness and atrophy in combination with sensory deficits. An endogenous ENU-induced mutation in Gars results in the development of motor and sensory deficits in mice, reminiscent to CMT2D in patients. In these mice, the amplitudes of the compound muscle action potentials (CMAPs) and the sensory nerve action potentials (SNAPs) are severely reduced, indicating axonal degeneration of both motor and sensory axons. This leads to reduced motor performance and reduced grip strength of the paws

together with sensory loss. Moreover, the mitochondrial axonal ransport is reduced in cultured DRG neurons from mutant Gars mice hich could be restored by the pharmacological inhibition of histone deacetylase 6 (HDAC6). Therefore, we investigated if HDAC6 could serve as a therapeutic target in this mutant Gars-induced CMT2 mouse model. Pharmacological HDAC6 inhibition in these mice led to improved neuromuscular innervation increased motor and sensory nerve conduction resulting in improved motor performance. Interestingly, we discovered a direct interaction between GARS and HDAC6. The interaction is strengthened by the CMT-causing mutation, which enhances the HDAC6 activity. These results explain the beneficial effect of inhibiting HDAC6 and suggest that HDAC6 may be involved in the etiology of CMT2D. Regardless of the mechanism, our results show that HDAC6 is a promising therapeutic target for peripheral neuropathies like CMT for which currently no pharmacological therapy exists.

Title: Generation of experimental model of myasthenia gravis with antibodies against LRP4

Authors: *S. MORI, R. TAKASHIMA, K. SHIGEMOTO;
Tokyo Metropolitan Inst. of Gerontology, Tokyo, Japan

Abstract: Myasthenia gravis (MG) is an autoimmune disease characterized by ptosis, fatigue, and muscle weakness. It is caused by autoantibodies associating with postsynaptic membrane proteins at neuromuscular junctions (NMJs). Several recent studies identified autoantibodies against low-density lipoprotein receptor-related protein (LRP4), an agrin receptor that is critical for NMJ development, in patients with double-seronegative MG-that is, patients without immunoreactivity toward acetylcholine receptors (AChRs) or muscle-specific kinase (MuSK). A variety of autoantibodies have been observed in MG patients. However, generally, such antibodies have not been associated clearly with MG pathogenesis. Elucidating the potential pathogenic role of anti-LRP4 autoantibodies in MG will require the establishment of an experimental autoimmune MG (EAMG) model. In the present study, we prepared the

recombinant protein of an extracellular region of human LRP4 and injected it into female A/J mice. After two or three injections, LRP4-injected mice exhibited weight loss and reduced strength, relative to controls. Electromyography with 3-Hz repetitive stimulation showed a decremental pattern of compound muscle action potentials (CMAPs) in LRP4-injected animals that was similar to that observed in MG patients, indicating that the animals had impaired neuromuscular transmission. The LRP4-injected mice also had marked reductions in pre- and post-synaptic labeling. Furthermore, sera from LRP4-injected mice blocked agrin-induced AChR clustering while inhibiting MuSK activation in cultured myotubes. These results demonstrate that an EAMG model was established in mice via active immunization, and further provide evidence suggesting that anti-LRP4 autoantibodies may play a role in the onset of double-seronegative MG. Given that A/J mice carry mutations that result in complement (C5) deficiency, our EAMG model suggests that complement activation is dispensable in MG pathogenesis caused by anti-LRP4 antibodies.

Abstract: Skeletal muscles fibers from *mdx* (Duchenne Muscular Dystrophy disease model) and dysferlin-null (Dysferlinopathy disease model) mice show elevated intracellular Ca^{2+} levels and sarcolemmal permeability to dyes (i.e., Evans blue, EB^{4-}), as well as extensive inflammation and cell death. However, the molecular mechanisms underlying such pathological changes remain unknown. Here, we evaluated the possible involvement of connexins-based hemichannels (Cx HC) as the mechanism involved in the increased sarcolemmal permeability to molecules observed in the aforementioned animal models. Protein levels of Cx39, Cx43 and Cx45 were elevated in *mdx Tibialis Anterior* muscles of 3 months old mice, and they were located mainly in the sarcolemma. In addition, we analyzed muscle biopsies (Quadriceps or Deltoids muscles) from 4 patients that bear dysferlin mutations, all of which exhibited Cx43 in the sarcolemmal membrane, whereas in biopsies from control individuals this protein was absent. Sarcolemma permeability, as evaluated with EB^{4-} (*in vivo*) uptake, was increased in *mdx* myofibers, and absent in myofibers from *mdx* mice treated with carbenoxolone, a hemichannels blocker. We also demonstrated in HeLa-cells that EB^{4-} passes the membrane through Cx HC. A similar mechanism might explain the EB^{-4} uptake observed by others in animal models of dysferlinopathy. Further, the annexin V (A5) reactivity was analyzed in myofibers from control and *mdx* mice, only *mdx* myofibers positive for A5 were also positive for EB^{4-}, suggesting that Cx HC are involved in apoptosis processes. Thus, inhibition of Cx HC would protect myofibers from damage induced by the absence of dystrophin (*mdx* condition), and a similar phenomenon could also be operating in dysferlinopathies. We propose that the presence of Cx HC could be a common pathway that facilitates skeletal muscle damage in muscular dystrophies.

Title: The spectrum of deletions and duplications in the Dystrophin (dmd) gene in a cohort of patients with Duchenne Muscular Dystrophy in Sri Lanka

Authors: *N. THAKUR[1,2], A. ABEYSEKERA[2], J. WANIGASINGHE[3], V. H. W. DISSANAYAKE[2];
[1]Med. Genet. Unit, Dept. of Med., Natl. Acad. of Med. Sciences, Bir Hosp., Kathmandu, Nepal; [2]Human Genet. Unit, Fac. of Med., [3]Dept. of Paediatrics, Fac. of Med., Univ. of Colombo, Colombo, Sri Lanka

Abstract: Background: Duchenne muscular dystrophy (DMD), which affects 1 in 3500 newborn male, is one of the most common fatal neurodegenerative disorders in children. It is an X-Linked recessive disorder and the most severe form of dystrophopathies affecting newborn males. It is the most common muscular dystrophy in all parts of world. Deletions and duplications are thought to be the major mutation underlying this disease accounting for approximately 65% and 6% of mutations respectively. Approximately 30% of DMD patients have unidentified mutations or point mutations in the dystrophin gene. Method: 50 clinically diagnosed children with DMD were screened after taking a written informed consent with the parents. We applied Multiple Ligation Probe Amplification (MLPA) to analyze the spectrum of deletions and duplications involving the dmd gene in Sri Lankan population. Results: Detection rate of the DNA rearrangements was 88% in 50 patients including 40 (80%) deletions and 4 (8%) duplications. Among 50 patients, 40 (80%) had deletions, 4 (8%) had duplications and 6 (12%) had no deletions and duplications. Single exon involvement was seen in 8 (16%) children. Two exons involvement was seen in 3 (6%) children, three exons involvement was seen in 6 (12%), four exons involvement was seen in 1 (2%) child and more than four exons involvement was seen in 26 (52%) children. The most common deletion was the deletion spanning from exon 45 to exon 52 which was seen in 6 (12%). The next common exon deletion was single exon 45 deletion which was seen in 4 (8.0%) children. The most frequent mutant region fell within exons 45 to 55 (52%) in dmd gene, followed by exons from 21 to 44 (26%) and exons from 1 to 20 (26%) and the least common region fell within exons 56 to 79 (4%). Conclusion: This study is the first to report the deletions/duplications pattern in patients with DMD in Sri Lanka. MLPA technique can be used effectively to diagnose clinically suspected DMD patients. The deletion/duplication pattern seen in the Sri Lankan population was similar to that of the other global populations.

Abstract: Mutations in acetylcholine receptor (AChR) subunits, expressed as pentamers in neuromuscular junctions (NMJ), cause various types of congenital myasthenic syndromes. In AChR pentamers, the adult ε subunit gradually replaces the embryonic γ subunit as the animal develops. Due to this switch in subunit composition, mutations in specific subunits result in synaptic phenotypes that change with developmental age. However, a mutation in any AChR subunit is considered to affect the neuromuscular junctions of all muscle fibers equally. Here, we report a zebrafish mutant of the AChR δ subunit that exhibits two distinct NMJ phenotypes specific to two muscle fiber types: slow or fast. Homozygous fish harboring a point mutation in the δ subunit form functional AChRs in slow muscles, while receptors in fast muscles are non-functional. To test the hypothesis that different subunit compositions in slow and fast muscles underlie distinct phenotypes, we stained larvae with an antibody specific for γ/ε subunits. Both wild type and the mutant larvae lacked γ/ε subunits in slow muscle synapses. These findings in zebrafish suggest that some mutations in human congenital myasthenic syndromes may affect slow and fast muscle fibers differently.

Title: Astrocytes in Amyotrophic Lateral Sclerosis (ALS): A fundamental rearrangement of vascular and synaptic organization

Authors: *I. LORENZINI[1], J. PREMINGER[2], S. NATH[3], J. D. ROTHSTEIN[2]; [2]Neurol., [1]Johns Hopkins Univ. Sch. of Med., BALTIMORE, MD; [3]Neurol., johns Hopkins Univ. Sch. of Med., BALTIMORE, MD

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a neurodegenerative disease characterized by the loss of cortical and spinal motor neurons. Although motor neurons are vulnerable in ALS, other cells are also affected. Glial cells are known to be major contributors of disease onset and disease progression. Astrocytes in particular, become reactive displaying changes in structure and function. We examined in detail the astrocyte structure during normal and chronic motor neuron degeneration using highly specific inducible transgenic astroglial reporter mice. Confocal imaging analysis and three-dimensional (3D) reconstruction of protoplasmic astrocytes from motor cortex and spinal cord revealed significant differences in the surface area and volume. A major astrocyte role in the CNS is to give metabolic support to neurons through the interactions with blood vessels. In order to know if this interaction is affected during disease conditions, we created a 3D imaging assessment to show astrocytes' contact with blood vessels. Mutant astrocytes from the spinal cord lose contact with the vasculature at late stages of ALS disease and significantly extend long processes over the limit of their domain. Astrocytes also form spherical-like structures during symptomatic and end-stages of the disease suggesting a potential phagocytic role. Further studies showed that a subset of astrocytes from the ventral regions of the lumbar spinal cord have a phagocytic role during disease conditions. Overall, these changes suggest that astrocytes rearrange their structure during ALS disease affecting multiple synapses as well as the metabolic and vascular support. Results from this investigation provide a deeper understanding of the astroglial biology and pathology in the setting of neurological disease.

Title: Brain computer interface for communication in completely locked-in patient using near infrared spectroscopy

Authors: *U. CHAUDHARY[1], B. XIA[1], S. VESSER[1], G. GALLEGOS-AYALA[1], N. BIRBAUMER[1,2];
[1]Inst. of Med. Psychology and Neurobio., Univ. of Tubingen, Tubingen, Germany; [2]Irccs, Ospedale San Camillo, Venezia, Italy

Abstract: Amyotrophic lateral sclerosis (ALS) is a progressive motor disease of unknown etiology resulting eventually in a complete destruction of the peripheral and central motor system but only affecting sensory or cognitive functions to a minor degree. Almost all people with ALS experience a motor speech disorder as the disease progresses. At some point in the disease progression, 80 to 95% of patients with ALS are unable to meet their daily communication needs using natural speech. Later, most become unable to speak at all. Brain computer-interface (BCI) technology has generated considerable research interest for the "locked-in" patients such as those in the late stages of ALS. Several EEG-based BCI are currently in use namely slow cortical potential (SCP)-BCI, sensorimotor rhythm (SMR)-BCI and P300-BCI but none of them have been successful for communication in ALS patients in completely locked in state (CLIS). Hence there is a need to find an alternative neuroimaging technique to design a more effective BCI to help ALS patient in CLIS with communication. Near infrared spectroscopy (NIRS) is an emerging neuro-imaging modality which employs near-infrared light to non-invasively or invasively investigate cerebral oxygenation changes in healthy and neurologically challenged adults and children. Previous researches have shown that NIRS can be successfully used to design BCI; hence NIRS was used to design BCI to help ALS patient in CLIS with communication. Recently NIRS was used successfully to investigate the functional activations in the motor cortex of 67 year old female CLIS patient in response to auditorily presented stimuli containing correct or incorrect statements and open questions. The hemodynamic change in the motor cortex of the CLIS patient was recorded across many sessions spread over more than a year and was used to train a classifier to predict the "yes" and "no" answering pattern of the CLIS patient who was previously trained to use an EEG-BCI without success. The trained classifier was able to provide online feedback ("your answer was classified as (in) correct") to the patient with performance rate of 71.76%. This is the first carefully documented case of communication in a CLIS patient with BMI, which holds promise and raises the hope for communication in CLIS. Hence, to further validate the preliminary findings of our lab and refine the technology of NIRS-based BCI for communication in CLIS-patients extensive studies are presently carried out on CLIS patients using combined NIRS-EEG based BCIs.

Abstract: Mitochondrial myopathies belong to a larger group of systemic diseases caused by morphological or biochemical abnormalities of mitochondria. Mitochondrial disorders can be caused by mutations in either the mitochondrial or the nuclear genome. Only 5% of all mitochondrial disorders are autosomal dominant. We analyzed DNA from members of a previously reported Hispanic kindred with an autosomal dominant mitochondrial myopathy (Tahmoush et al. 1997). Linkage analysis suggested a putative locus on the pericentric region of the long arm of chromosome 22 (22q11). Using the tools of integrative genomics, we established C22orf16 (later designated as CHCHD10) as the only high scoring mitochondrial candidate gene in our minimal candidate region. Sequence analysis revealed a double missense mutation (R15S; G58R) in cis in CHCHD10 which encodes a coiled-coil helix coiled-coil helix protein of unknown function. These two mutations completely co-segregated with the disease phenotype and were absent in 1481 Caucasian and 80 Hispanic controls. Expression profiling showed that CHCHD10 is enriched in skeletal muscle. Mitochondrial localization of the CHCHD10 protein

was confirmed using immunofluorescence in cells expressing either wild-type or mutant CHCHD10. We found that expression of the G58R, but not the R15S, mutation induced mitochondrial fragmentation. Our findings identify a novel gene causing mitochondrial myopathy, thereby expanding the spectrum of mitochondrial myopathies caused by nuclear genes. Our findings also suggest a role for CHCHD10 in the morphologic remodeling of the mitochondria.

Title: Morphological changes to the structure of the neuromuscular junction in a canine model of duchenne muscular dystrophy

Authors: ***S. HADDIX**[1], Y. LEE[2], I. SMITH[2,3], J. N. KORNEGAY[4,3], W. THOMPSON[2,3]; [1]Texas A&M Univ., College, TX; [2]Biol., [3]Inst. for Neurosci., [4]Col. of Vet. Med. and Biomed. Res., Texas A&M Univ., College Station, TX

Abstract: Duchenne muscular dystrophy (DMD) is an X-linked genetic disease in which mutations of the dystrophin gene lead to skeletal and cardiac muscle abnormalities. It affects 1 in 5000 boys and has no known cure or effective treatment. Previous observations have suggested that not only are muscle fibers in these patients and animal models sensitive to damage, but their neuromuscular junctions (NMJs), the cholinergic synapse between motor neurons and muscle fibers, are also dramatically affected. The similarity of the junctional alterations observed in muscles treated with myotoxic drugs suggests that a process of degeneration and regeneration in fibers produces the synaptic changes. To further assess mechanisms underlying morphological alterations, we have examined NMJs in dogs that have dystrophin mutations leading to a severe

dystrophy (Golden Retriever muscular dystrophy, GRMD), a model much more akin to human DMD than the commonly used mdx mice (to date 10 dogs analyzed, 4 in depth). Using fluorochorome-conjugated α-bungarotoxin, a snake toxin that binds specifically to muscle acetylcholine receptor (AChR), postsynaptic alterations at NMJs of GRMD extensor hallucis longus muscles were examined. We found changes to AChR aggregates that mirror those in the canonical mdx mouse. The majority of GRMD AChR aggregates were large and dispersed into fragments as compared to pretzel-shaped, continuous aggregates in controls. Moreover, there were a number of "ghost" junctions in which nerve, Schwann cells and cholinesterase were no different than other GRMD junctions, but these sites seemed, in several cases, to be dimly stained for AChR and to lack postsynaptic sarcomeric structures in the associated muscle fiber. Ghost junctions and AChR fragmentation resemble similar structures seen in normal mice after postsynaptic muscle fiber ablation and upon muscle fiber regeneration, respectively, suggesting that altered NMJs results from necrosis/regeneration of muscle fiber at the synaptic region. In addition to fragmentation of AChR aggregates, there was a distinct population of minute and compact AChR aggregates in dystrophic muscle, more prevalent in later stages of disease. There was also a change in the innervation pattern of the GRMD muscles: adjacent muscle fibers were often innervated by the same axon, apparently due to preterminal sprouting. This suggests a loss of some motor innervation to the muscles and an enlargement of motor units. Our observations suggest morphological changes at NMJs in the GRMD model accumulate with time and act as a compounding factor in the progression of the disease.

Title: Astrocytes isolated from transgenic Δ7 SMA mice have altered protein secretion

Authors: ***E. FORAN**[1], T. NGUYEN[1], P. R. LEE[2], C. GRUNSEICH[1], J. NOFZIGER[1], E. S. ARNOLD[1], B. BURNETT[3], K. FISCHBECK[1];

Abstract: Spinal muscular atrophy (SMA) is the most common inherited cause of death in infants and young children. It is caused by the deletion or mutation in the survival of motor neuron 1 (SMN1) gene, leading to a deficiency of the ubiquitously expressed SMN protein. SMA is characterized by slowly progressive weakness and atrophy of the limb muscles associated with motor neuron loss in the spinal cord. Currently, there is no disease specific effective treatment available. Loss of SMN leads to degeneration of motor neurons; however recent work has shown the importance of other cell types in CNS diseases. Astrocytes are the most numerous cell type in the CNS and are required for correct functioning of motor neurons in the spinal cord; however the characterization of the role of astrocytes in SMA is still at early stages. We present here evidence that spinal cord astrocytes from an SMA mouse model have abnormalities in the secretion of several factors that could affect motor neuron health. We used the SMN2+/+;SMNΔ7+/+;Smn-/- (SMAΔ7) mouse line to examine the effects of decreased levels of SMN on astrocytes and how they interact with motor neurons. To validate changes seen in the SMAΔ7 mouse model in a human model of SMN depletion, we have also differentiated patient and parental control-derived iPS cell lines (GM23240 and GM23241) into astrocytes and motor neurons. We found altered mRNA and protein expression, and protein secretion in astrocytes isolated from the SMAΔ7 mice in comparison to astrocytes isolated from littermate controls. In particular, the secretion profile of astrocytes isolated from the SMAΔ7 mice was abnormal. Such secretion alterations may lead to a decreased ability to support motor neurons *in vitro* and *in vivo*. We are using co-cultured motor neurons and astrocytes and motor neurons grown in astrocyte-conditioned media to determine how these alterations affect motor neuron survival, growth, and physiology. These astrocyte defects may contribute to motor neuron degeneration in SMA and thus could be a novel target for therapeutic intervention.

Title: Effects of suramin on stretch-activated calcium channel protein TRPC1 and calsequestrin in the diaphragm of old mdx mice

Authors: *D. O. MOREIRA, H. SANTO NETO, M. MARQUES;
Dept. of Structural and Functional Biol., Unicamp, Campinas, Brazil

Abstract: Duchenne muscular dystrophy (DMD) is a devastating inherited neuromuscular disorder with an incidence of 1 in 3500 live male births. DMD is characterized by a mutation in the X-chromosome that leads to a lack of dystrophin in skeletal and cardiac muscles. In DMD and in the mdx mice model of DMD, the absence of dystrophin leads to sarcolemma instability, increased calcium influx and consequent myonecrosis. Abnormal calcium entry and buffering seem to play important roles in dystrophy pathology and stretch activated calcium channels, such as the transient receptor potential canonical channel 1 (TRPC1), greatly contribute to calcium changes in dystrophic fibers. In this study we investigated the effects of suramin, an anti-fibrotic agent on TRPC1 levels in the diaphragm of mdx mice, at later stages of the disease (11 months). We also investigated the effects of suramin of the levels of calsequestrin, the main calcium-binding protein of the endoplasmic reticulum. Mdx mice (8 months old) received intraperitoneal injections of suramin (60 mg/kg body weight), twice a week for 3 months. Control mdx mice (8 months old) were injected with saline. Western blot analysis showed that suramin decreased the levels of TRPC1 (2.3±0.2 in control vs 1.3±0.3 in suramin-mdx, $p<0.05$) and improved the levels of calsequestrin (0.5±0.1 in control vs 0.9±0.2 in suramin-mdx, $p<0.05$). Suramin also decreased muscle fiber total calcium (29% decrease as observed with inductively coupled plasma-optical emission spectrometry). The present results suggest that suramin, in addition to its anti-fibrotic action can ameliorate dystrophy in the mdx diaphragm, at later stages of the disease, by acting on calcium entry (TRPC1) and calcium binding (calsequestrin) mechanisms.

Title: Effects of omega-3 therapy in the cardiomyopathy of the mdx mice, at later stages of the disease

Authors: *A. F. MAURICIO, J. A. PEREIRA, H. SANTO NETO, M. J. MARQUES;
Dept. of Structural and Functional Biol., UNICAMP, Campinas, Brazil

Abstract: Duchenne muscular dystrophy is the most common and severe dystrophynopathy in childhood characterized by absence of dystrophin, with progressive muscle wasting and cardiorespiratory failure. In the absence of dystrophin there is sarcolemma instability, increased calcium influx and myonecrosis. Cardiomyopathy is one of the most frequent causes of death in DMD. In the mdx mice model of DMD, signs of cardiomyopathy are first seen around 9 months of age. We investigated the effects of omega-3 therapy in the mdx cardiomyopathy, at later stages of disease (13 months of age). Mdx mice (8 months of age) received fish oil containing eicosapentaenoic acid and docosahexanoic acid (300mg/kg via gavage, 3 days a week), for 5 months. Control mdx received nujol in an equivalent dose and period. Control mdx showed elevated (3 times) serum levels of CK-MB, an indicator of heart necrosis, compared with normal C57BL/10. Omega-3 reduced CK-MB (119±20 UI in mdx-nujol vs. 86±20 UI in mdx-omega-3). In control mdx, electrocardiogram analysis indicated alterations in the amplitudes of some waves, a decrease in the R/S ratio and a significant increase in the cardiomyopathy index. Omega-3 ameliorated some of these heart functional parameters. No changes in heart fibrosis area were seen in omega-3-mdx, with higher levels of fibrosis in the right ventricule (16±3% in mdx-nujol vs. 13±3% in mdx-omega-3). The levels of TNF-a (proinflammatory cytokine), TGF-b (profibrotic factor) and metaloproteinases(MMP)-9 and MMP-2 were all increased in the heart of control mdx in comparison to normal C57BL/10. Omega-3 significantly reduced the levels of TNF-a (1.5±0.4 in mdx-nujol vs. 1.1±0.03 in mdx-omega-3) and MMP-9 (1.3±0.1 in mdx-nujol vs. 1.1±0.09 in mdx-omega-3), with a tendency to reduce TGF-b (1.9±0.3 in mdx-nujol vs. 1.7±0.4 in mdx-omega-3; $p > 0.05$, Anova). The present results demonstrate that omega-3 is effective against cardiomyopathy in the mdx mouse, at later stages of the disease, being able to improve functional parameters and to regulate molecular markers (TNF-a, TGF-b and MMPs) of dystrophy progression, therefore deserving future investigation in DMD clinical trials.

Title: Generation and characterization of C9ORF72 Amyotrophic Lateral Sclerosis (ALS) astrocytes derived from patient fibroblasts

Authors: *J. T. PHAM[1,2], E. L. DALEY[1], C. J. DONNELLY[1], T. GENDRON[4], L. PETRUCELLI[4], R. G. SATTLER[1], J. D. ROTHSTEIN[1,3];

Abstract: Amyotrophic lateral sclerosis (ALS) is one of the most common neurodegenerative diseases, characterized by progressive loss of upper and lower motor neurons as well as associated interneurons. An intronic GGGGCC hexanucleotide repeat expansion in the *C9ORF72* gene was recently identified as the most common genetic cause of ALS. Studies investigating *C9ORF72* pathogenesis have primarily focused on neurons. However, glial cells are also known to play an important role in ALS by modulating disease onset and progression. In particular, astrocytes often exhibit altered structure and functionality under disease conditions. We examined the role of astrocytes in *C9ORF72* ALS by generating astrocytes from patient fibroblasts and assessing mechanisms by which intronic repeat expansions can cause disease. First, patient fibroblasts were reprogrammed into induced pluripotent stem (iPS) cells, which were then differentiated into astrocytes (iPS-A). These iPS-A robustly immunostain for astrocyte markers, including glial fibrillary acidic protein (GFAP), CD44, S100β, and Vimentin. Co-culturing iPS-A with primary mouse cortical neurons increased mRNA expression of excitatory amino acid transporter 2 (EAAT2), an astrocyte-specific glutamate transporter tightly regulated by neurons *in vivo*. EAAT2 functionality was evaluated further with pending protein expression and functional sodium-dependent ^{3}H-glutamate transport assessments in *C9ORF72* ALS and control iPS-A. Next, we explored pathological consequences of the repeat expansion in the iPS-A. *C9ORF72* iPS astrocytes had decreased levels of total *C9ORF72* mRNA in comparison with control iPS-A as quantified by RT-PCR. Probing the iPS-A with RNA fluorescent *in situ*

hybridization showed accumulation of RNA foci containing the (GGGGCC)n repeat expansion, which were more abundant in *C9ORF72* iPS-A. We also investigated the localization of poly-glutamine-proline (poly-GP) repeat-associated non-ATG (RAN) protein product in *C9ORF72* iPS-A. Poly-GP RAN translation products were detectable by ELISA in supernatants taken from *C9ORF72* iPS-A cultures but not from control cultures. These findings show that iPS-A are a viable model, allowing us to more faithfully recapitulate processes occurring in patients and to thus gain a more thorough understanding of the disease. Results suggest that astrocytes are affected in *C9ORF72* ALS and could potentially contribute to disease pathogenesis.

Title: Inhibition of hematopoietic prostaglandin D synthase improves symptoms of muscular dystrophy in a mouse model of Duchenne muscular dystrophy

Authors: K. TANAKA[1], K. ARITAKE[3], M. TAYAMA[1], K. SHIGENO[1], *Y. HAYASHI[2], E. SASAKI[1], T. UTSUGI[1], T. SASAOKA[4], Y. URADE[3];

Abstract: Duchenne muscular dystrophy (DMD) is a genetic and lethal disease. No complete cure for the disease is still established. The fibers of skeletal muscle in DMD patients are highly susceptible to damage of the membrane and easily suffer necrotic change, because of the loss of dystrophin in the muscle. This pathological condition leads to progressive weakness of all skeletal muscles, including diaphragm. Then, the patients show weakened motor activity, such as dysbasia. In the past (SfN2013 etc.), we have reported that prostaglandin D_2 (PGD_2) synthesized by hematopoietic PGD synthase (HPGDS) may play an important role in the pathology of DMD and that the inhibition of HPGDS would be an effective therapy for DMD. Recently, a novel high-selective HPGDS inhibitor, TAS-205, was found in our laboratory. This compound is useful to validate our hypothesis. Therefore, the effect of TAS-205 was evaluated using

dystrophin-deficient (*mdx*) mice, which is an animal model of DMD. *In vitro* study, inhibitory effects of TAS-205 were evaluated on enzyme activity in cell-free assay and Ca^{2+}-ionophore stimulated PGD_2 production in a human basophilic leukemia (KU812). *In vivo* study, *mdx* mice (C57BL/6 back ground) were supplied the diet including 0.01% or 0.1% TAS-205 from 8 to 9 weeks of age in the pharmacokinetic evaluation, or from 5 to 9 weeks of age in the efficacy evaluations. To determine the plasma concentration of TAS-205, the blood was collected on day 7 after beginning of the treatment with TAS-205. At 9 weeks of age, we measured the urinary tetranor-PGDM level, a metabolite of PGD_2, and the locomotor activity during night-time. Also, the rate of necrotic fibers area was evaluated in cross sections of the diaphragm muscle. *In vitro* study, TAS-205 inhibited the enzyme activity of HPGDS (IC_{50}:56 nM) and reduced PGD_2 production in KU812 (IC_{50}:83 nM). When *mdx* mice were given the diet including 0.01% TAS-205 for 7 days, TAS-205 concentrations in plasma of *mdx* mice were 156-232 nM, which were enough to inhibit HPGDS. The urinary tetranor-PGDM concentration was significantly higher in *mdx* mice than that in wild-type mice. TAS-205 dose-dependently suppressed the urinary tetranor-PGDM amount in *mdx* mice. The locomotor activity during the night-time was significantly lower in *mdx* mice than that in wild-type mice. And, in histological study, many necrotic fibers were detected in diaphragm muscle of *mdx* mice, although it was hardly in wild-type mice. TAS-205 at high dose significantly reduced the necrotic muscle fibers and recovered the locomotor activity in *mdx* mice. These results support our hypothesis that a highly selective HPGDS inhibitor, such as TAS-205, would be an effective therapy for DMD.

Title: Mbnl1; Mbnl2 conditional double knockout mice as a model for the myotonic dystrophy brain

Authors: *K.-Y. LEE[1,2], F.-J. FERNANDEZ-GOMEZ[3,4], S. EDDARKAOUI[3,4], M. LI[2], J. THOMAS[2], D. FINN[2], N. HAMED[2], L. BUÉE[3,4], N. SERGEANT[3,4], M. SWANSON[2]; [1]Chang Gung Mem. Hospital, Keelung, Taipai, Taiwan; [2]Mol. Genet. and Microbiology, Ctr. for NeuroGenetics and the Genet. Inst., Univ. of Florida, Col. of Med., Gainesville, FL; [3]Inserm UMR837-1 and Univ. Lille Nord de France, Jean-Pierre Aubert Res. Center, Alzheimer & Tauopathies, F-59045, Lille, France; [4]Regional Univ. Hosp. of Lille, Lille, France

Abstract: Myotonic dystrophy (DM), the most common form of adult-onset muscular dystrophy, is a multi-systemic disorder that has severe effects on brain function. Neuropathological studies reveal neurofibrillary tangles in DM and mis-splicing of microtubule-associated protein Tau (MAPT). Muscleblind-like (MBNL) proteins are developmentally regulated alternative splicing factors and the MBNL gene family consists of three paralogs (MBNL1, MBNL2, MBNL3) with distinct spatial and temporal expression patterns. In the mouse, Mbnl3 is primarily expressed during embryogenesis while Mbnl1 and Mbnl2 promote adult isoform splicing patterns for specific target genes. Although Mbnl1 is predominantly expressed in adult skeletal muscle, Mbnl2 is highly expressed in the adult brain. In DM, abnormal expansions of CTG and CCTG microsatellites in the DMPK and CNBP genes, respectively, results in the expression of C(C)UGexp mutant RNAs that bind, and subsequently sequester, the MBNL proteins resulting in MBNL loss-of-function. This disease model is supported by Mbnl1 and Mbnl2 single knockout (KO) mouse models that recapitulate the major manifestations of DM in skeletal muscle (myotonia) and the brain (learning/memory deficits, REM sleep mis-regulation). To test the hypothesis that compound loss of MBNL activity would recapitulate additional CNS features of DM disease, we have generated neuron-specific Mbnl1; Mbnl2 double KO (DKO) mice (Mbnl1ΔE3/ΔE3; Mbnl2cond/cond; Nestin-Cre+/- (Nestin-Cre DKO). Mbnl DKOs are small, show impaired motor functions and are characterized by a nearly complete reversal to fetal brain splicing patterns, including Mapt exons 2, 3 and 10. Specific anti-Tau antibodies and two-dimensional electrophoresis (2DE) immunoblotting revealed that Tau protein expression was profoundly altered in the Mbnl1; Mbnl2 DKO brain with equivalent expression of the 0N4R (Tau isoform lacking exons 2 and 3 but including exon 10) and 0N3R (lacking exon 10) Tau isoforms. We conclude that Mbnl1; Mbnl2 DKO mice provide a novel animal model to characterize the molecular events leading to DM CNS disease.

Title: Evaluations of seizures and behavior in Slack-/- mice suggest separate pathways for epilepsy and developmental delay in patients with Slack-associated epileptic encephalopathies

Authors: *I. H. QURAISHI[1], R. L. COUTURE[2], M. L. SCHWARTZ[2], L. K. KACZMAREK[3]; [1]Dept. of Neurol., [2]Neurobio., [3]Pharmacol. and Cell. and Mol. Physiol., Yale Univ., New Haven, CT

Abstract: Slack (Kcnt1) is a Na^+-activated K^+ channel that has been implicated in several epilepsy syndromes including Malignant Migrating Partial Seizures of Infancy (MMPSI). Patients with mutations in Slack develop intractable epilepsy with neurodevelopmental or psychiatric comorbidities. We previously demonstrated that epilepsy-associated Slack mutations are paradoxically associated with gain of function in the channel conductance, and that Slack interacts with proteins necessary for normal neuronal development, particularly Fragile X Mental Retardation Protein (FMRP). To determine whether the epilepsy and behavioral phenotypes in patients with these mutations are functions of the increased current or of loss of FMRP binding, we performed tests of seizure thresholds and behavioral screening in adult male Slack-/- mice. Slack-/- mice did not have spontaneous seizures. Acute seizure thresholds were measured with maximum electroshock and pentylenetetrazole. Maximum electroshock seizure thresholds were slightly lower in Slack-/- than Slack+/+ mice. Measurement of severity of fixed high current electroshock seizures was confounded by decreased mortality in the Slack-/- mice. With pentylenetetrazole there was no difference in latency to Racine 5 seizures between groups. Behavioral screening was done with open field and rotorod tasks. In an open field test Slack-/- mice had less exploratory behavior than wild type animals. Rotorod testing suggests impaired motor learning. These results suggest that loss of Slack interactions, in the absence of increased the current seen in the human epilepsy mutations, may be sufficient to produce neurodevelopmental changes without spontaneous seizures or large changes in seizure thresholds.

Title: Chronic high intensity sound stimulation inhibits Schaffer-CA1 hippocampal long-term potentiation in Wistar rats but not in those of the Wistar Audiogenic Rat (WAR) strain

Authors: *A. O. CUNHA[1], J. A. C. OLIVEIRA[2], S. S. ALMEIDA[3], N. GARCIA-CAIRASCO[2], R. M. X. LEAO[2];
[1]Univ. of Sao Paulo, Ribeirao Preto, Brazil; [2]Physiol., [3]Psychology, Univ. of Sao Paulo, RIBEIRAO PRETO, Brazil

Abstract: High intensity sound stimulation can cause convulsive seizures in susceptible mice and rats. The repetition of these stimuli, in turn, will evoke a change in seizure behavioural repertoire together with the appearance of epileptic EEG activity in limbic structures. In the hippocampus, seizures lead to indiscriminate and widespread long-term potentiation (LTP) due to structural and biochemical alterations. Here, we investigated if LTP of hippocampal Schaffer-CA1 synapses is altered by chronic high intensity sound stimulation (HISS) in normal Wistar rats and in a strain of audiogenic seizure-prone rats (Wistar Audiogenic Rats - WAR). HISS consisted of two daily acoustic stimulations (120 dB) for ten days. Animals were observed before, during and after HISS and their seizures were analysed and scored for severity. Then, the rats were trained during 4 days (6 sessions) in a circular pool, divided in quadrants with a hidden platform and then tested for spatial navigation. One week after the end of the experiments, animals were killed and their brains were removed and sliced in order to perform hippocampal electrophysiology. Field potentials (fEPSPs) in the stratum radiatum of CA1, were elicited by stimulation of Schaffer collaterals. LTP was induced by three trains of stimulation at 50 or 100 Hz for 1 second. After chronic HISS all WARs exhibited mesencephalic seizures and 50% of these animals developed limbic recruitment, while only 26% of Wistar rats presented mesencephalic seizures. HISS did not alter spatial navigation in both strains, although WARs

presented impaired navigation in comparison to Wistar rats. Surprisingly, HISS strongly supressed LTP in slices of Wistar-naïve animals, and inhibited LTP in slices from Wistar rats which presented mesencephalic seizures, but had no effect in LTP of WARs. We also observed that LTP in slices from control WARs rats had slower onsets than in control Wistar rats. These findings indicate that homeostatic processes seem to act on the Schaffer-CA1 synapses, preventing their potentiation probably to compensate for hyperactive afferent circuits in response to HISS, preventing seizures and not affecting spatial navigation. In audiogenic seizure-prone WARs these mechanisms seem to be disrupted and could account for their seizure susceptibility.

Title: Impulse response of local field potential to spikes relates activity in distant regions of the human brain

Authors: *B. A. LOPOUR[1], I. FRIED[2], D. L. RINGACH[3];
[1]Biomed. Engin., Univ. of California, Irvine, CA; [2]Neurosurg., [3]Neurobio. and Psychology, Univ. of California, Los Angeles, CA

Abstract: Simultaneous analysis of single neuron spiking and the local field potential (LFP) can be used to study both local processing of groups of neurons as well as network-level properties of neuronal circuits (Einevoll 2013). The simplest example of this is the spike-triggered average of the LFP, which has been applied to thalamocortical connectivity (Swadlow 2002, Jin 2011) and the cortex-basal ganglia network (Goldberg 2004). An alternative approach is to calculate the impulse response, which accounts for spatiotemporal correlations within spike trains that may make the spike-triggered LFP difficult to interpret (Einevoll 2013). The impulse response has been used to analyze the accuracy of LFP estimates based on multi-unit activity (MUA) (Rasch 2009) and functional connectivity within cortical circuits (Nauhaus 2012). In both studies, data were recorded from a grid of electrodes implanted in the cortex of nonhuman

primates. Here we apply the impulse response technique to MUA and LFP measurements recorded simultaneously from multiple regions of the human brain, and we show that it can be used to uncover correlated activity between distant brain regions and even across hemispheres. Recordings were taken from bilateral depth electrodes implanted in patients undergoing clinical evaluation for epilepsy surgery. Electrode locations were based solely on clinical criteria and typically included both temporal and frontal lobe regions. Eight to twelve electrodes were implanted in each patient, and the data were recorded from eight microwires extending from the tip of each one. Using simultaneous measurements from each brain region, we calculated the impulse response of the LFP to MUA between all possible pairs of recordings. We applied this technique to both the raw LFP and the amplitude spectrum of the LFP at frequencies between 1-100Hz, as a means of testing whether or not the LFP activity was phase-locked to the timing of the MUA. In each patient, we found significant LFP impulse responses to MUA recorded in a different brain region. Further, analysis of the amplitude revealed that in some cases the LFP had frequency components that were correlated (but not phase-locked) to multi-unit activity. As expected, these significant impulse responses were not observed between all pairs of brain regions. However, preliminary data suggest that strong correlations between LFP and MUA may be related to each patient's individual epileptic network, rather than functioning as a general measure of anatomical connectivity. This may have implications for the identification of the epileptogenic zone and the surgical treatment of epilepsy.

Abstract: Epilepsy is a common neurological disorder that affects 1% of the general population worldwide. Drug resistance to available therapies occurs in the 30-40% of the cases and no biomarkers for the disease progression are currently available. Therefore, a deeper understanding of the cellular and molecular mechanisms underlying epilepsy and epileptogenesis is required. We have recently found that the mRNA and protein levels of collagen VI (CVI), a component of the extracellular matrix, are increased in the rat hippocampus 4 weeks after status epilepticus, a well-characterized model of epilepsy. In the present study, we explored basic mechanisms of CVI action in the naïve hippocampus as a prerequisite for elucidating its implications in epilepsy. Hippocampal slices from naïve rats were incubated in CVI for 2 or 6 h. Field recordings were performed in the CA1 region of the hippocampus, in order to determine how CVI could affect basal synaptic transmission and paired-pulse facilitation, a form of short-term plasticity dependent on presynaptic mechanisms. Our results suggest that CVI has diverse effects depending on for how long the tissue is exposed to its increased levels. In the short term (2h), CVI may decrease inhibitory synaptic transmission and increase excitatory synaptic transmission, effects that may worsen the condition of hyperexcitability generally associated with epilepsy. Conversely, in the long term (6h), CVI may reduce transmitter release probability in excitatory synapses, thus counteracting hyperexcitability. Next step will be to explore CVI effects on the single-cell level in order to better clarify its mechanisms of action.

Title: Frequency dependent axonal block by high frequency stimulation in hippocampal CA1 region of rats

Authors: *Y. YU, Z. FENG, J. CAO, N. HU, Z. WANG;
Zhejiang Univ., Zhe Jiang, China

Abstract: Recent studies have shown that the axonal block may be one of the important underlying mechanisms for the therapeutic effects of high frequency stimulation (HFS) on brain disorders. In addition, refractory periods could be the mechanism of axonal block. But if HFS with higher frequencies over 100 Hz could generate axonal block more rapidly is unknown yet. To address this issue, we applied 1 minute long pulse trains to alveus fiber tract of hippocampus in anesthetized rats, and recorded antidromically-evoked population spike (APS) in the pyramidal layer of CA1 region. The APS amplitude of the first 100 ms and the last 50 ms periods of the HFS trains were measured to determine the generation speed of axonal block and the suppression degree of axons respectively. Paired-pulse test stimuli with an inter-pulse interval of 2.5 ms were delivered to evoke two APSs (APS1 and APS2) before (i.e., baseline) and ~8 s following HFS. The results showed that even within the very first 100 ms period, the APS amplitude decreased to 4.27±4.43% by the 400 Hz HFS, much more suppression than 38.69±14.16% of 200 Hz HFS and 68.97±11.66% of 100 Hz HFS. The suppression differences among the three frequencies remained till the end of HFS with all of the APS amplitude decreasing to less than 11.86±4.56% (Figure 1a). Paired-pulse tests applied at ~8 s following HFS showed that the ratio of APS2/APS1 decreased to 6.03±6.89% by the 400 Hz HFS, indicating a change of the refractory period by HFS. In addition, the decrease of the ratios were also frequency dependent (Figure 1b). The evoked APS by the test pulses following HFS trains showed that the entire recovery periods were not significantly different among the HFS with different frequencies (Figure 1c). The present results indicated that the axonal blocks caused by HFS were frequency-dependent up to 400 Hz, a much higher frequency than the common used ~130 Hz frequency in clinical application. It is potential that the HFS could modulate the excitability or activity of the neurons in the downstream and upstream areas by affecting axonal fibers in a much larger frequency ranges.

Title: Approaches to understanding human ion channel genetic variation and disease - an example with a KCNT1 variant and infantile epilepsy disorder

Authors: K. M. PADILLA[1], B. M. ANTONIO[1], S. C. SANTOS[1], Z. LIN[1], J. W. THEILE[1], M. L. CHAPMAN[1], S. PETROU[2], D. B. GOLDSTEIN[3], *D. S. KRAFTE[4];

Abstract: Understanding the functional significance of ion channel genetic variation is essential to realize the potential of precision medicine and targeted therapies for human disease. We have approached this challenge by analyzing a *de novo* variant in the KCNT1 protein, P924L, which is linked to epilepsy of infancy with migrating focal seizures (EIMFS). A recent publication demonstrated gain-of-function for P924L when expressed in Xenopus oocytes (Milligan et al 2014 Annals of Neurology doi: 10.1002/ana.24128). We designed a strategy to analyze KCNT1 P924L gene expression in recombinant cell systems and in iPSC-derived cortical neuron engineering using TALENs. The latter approach was unsuccessful in 2 iPSC-derived cell lines. In the 1st case, KCNT1 wt mRNA expression was absent in differentiated neurons while in the 2nd case 28 nucleofections and analysis of >1300 clones failed to yield appropriate targeting. Heterologous recombinant expression in HEK-293 cells was more successful leading to robust expression of wt KCNT1 with 77% of clones expressing functional KCNT1 channels. KCNT1 P924L was more difficult to constitutively express with only 12% of clones resulting in stable expression. This suggests possible negative selection when expressing P924L which was unexpected. To investigate the underlying cause we created inducible expression systems for wt and P924L KCNT1 and analyzed function and cell viability from 0-24 hrs post-induction using a ^{86}Rb flux assay. Compared to wt, P924L demonstrated lower signals at 24 hrs than at earlier time points. Cell viability, however, was similar between wt and P924L indicating the flux differences are likely not due to a toxic effect of the variant. Blocking KCNT1 channels by using an inhibitor during the experiment for all steps except the assessment of function restored the KCNT1 P924L ^{86}Rb signal to levels similar to wt. This result is consistent with published data demonstrating dysregulation of P924L leading to gain-of-function. Our results were confirmed by

electrophysiological analysis with current densities of 211 ± 33 pA/pF for P924L vs 9 ± 3 pA/pF for wt (both at 0 mV, following establishment of whole cell recording mode). In summary, our results with inducible expression in mammalian cells are consistent with those reported for gain-of-function with P924L in the Xenopus oocyte system. Chronic upregulation of KCNT1 P924L may lead to indirect effects on cell properties and viability which could explain why constitutive expression systems are poorly suited for detailed variant analysis for this ion channel.

Title: IGF-1 promotes epileptogenesis after injury through activation of Akt-mTOR, but not MAPK(ERK), signaling

Authors: Y. SONG[1], K. J. STALEY[2], *Y. BERDICHEVSKY[1];
[1]Lehigh Univ., Bethlehem, PA; [2]Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA

Abstract: Insulin-Like Growth Factor-1 (IGF-1) levels are elevated in brain tissues following head injury, and there is a significant elevation in IGF-1 receptor (IGF-1R) phosphorylation after traumatic brain injury (TBI). Phosphorylation of IGF-1R may lead to activation of MAPK (ERK) and PI3K-Akt signaling cascades, and IGF-1 was found to promote growth cone motility and neurite outgrowth. IGF-1 is neuroprotective in animal models of hypoxic-ischemic and traumatic brain injury; however, its role in neural circuit re-organization and signaling pathway activation suggests that it may contribute to epileptogenesis after injury. We investigated the role of IGF-1 in epileptogenesis in organotypic hippocampal culture model of posttraumatic epilepsy. We applied IGF-1 during the latent period between trauma and appearance of spontaneous seizures, and measured lactate production (biomarker of increased seizure activity), lactate dehydrogenase (LDH, biomarker of increased cell death), electrical activity, and phosphorylation of Akt, MAPK, and S6 (marker of mTOR activation) proteins. We then applied IGF-1 together with

inhibitors of Akt and MAPK and measured lactate and LDH levels. We found that IGF-1 application increases lactate and LDH release and phosphorylation of Akt and S6, but not MAPK. We also found that chronic IGF-1 application during the latent period causes an increase in electrographic ictal activity. Proepileptogenic effect of IGF-1 was significantly reduced by inhibitors of Akt, but not MAPK. We conclude that IGF-1 is neuroprotective immediately after injury, but proepileptogenic during the latent period and beyond through activation of Akt-mTOR signaling.

Title: Increased risk of hypoxic depolarization of the brainstem autonomic circuit in a mouse SUDEP model

Authors: *I. AIBA, J. L. NOEBELS;
Dept. of Neurol., Baylor Col. of Med., Houston, TX

Abstract: A subpopulation of epilepsy patients experience a sudden reduction in cardiorespiratory function and die in the absence of resuscitation. The phenomenon is termed sudden unexpected death in epilepsy (SUDEP) and is the leading cause of epilepsy-related mortality, however the mechanisms are not well understood. Here we investigated a potential contribution of hypoxic depolarization of brainstem autonomic nuclei in an established Kv1.1 knockout (KO) mouse model. Susceptibility of the juvenile Kv1.1 KO mouse brainstem to hypoxic insult was first evaluated in an acute transverse slices. Acute exposure to an artificial CSF solution lacking oxygen and glucose (0% O2, 0 mM glucose) resulted in the generation of a slow propagating wave of depolarization (i.e. Anoxic Depolarization: AD) detected by intrinsic optical signal and extracellular DC potential shift. The spontaneous wave of depolarization invaded the dorsal vagal nucleus (X), the hypoglossal nucleus (XII) and the nucleus of the tractus

solitarius (NTS). Kv1.1 KO brainstem slices showed a higher susceptibility to AD as determined by a significantly faster AD onset than wild-type (WT). Increasing the glucose concentration of the hypoxic solution (i.e. 0% O2, 5 mM glucose) did not affect AD onset in Kv1.1 KO slices whereas AD was largely delayed or prevented in WT slices. These *in vitro* data indicate that Kv1.1 KO mice have an increased risk of deleterious brainstem depolarization under severe hypoxia. We next examined whether such brainstem depolarization could occur during a seizure *in vivo*. Recurrent seizures were evoked by topical application of 4AP (100 mM, ~10 μl) in anesthetized mice and DC field potentials in the dorsal medulla were recorded with a glass microelectrode (~0.3 mm depth, 0.5 mm rostral to the obex). Cortical activity, heart and breathing rates were simultaneously monitored. WT mice showed relatively stable cardiorespiratory tone during seizures and none died. In contrast, the Kv1.1 KO mice showed severe apnea following seizure onset, and 83% (5/6) of mice died following a period of bradycardia and intermittent asystoles. In the dying Kv1.1 KO mice, a slow negative DC potential shift was detected in the brainstem coincident with the onset of the terminal cardiac arrhythmias. Together these data demonstrate that terminal autonomic instability is accompanied by deleterious brainstem depolarization in this model. The lower brainstem AD threshold may increase the risk of death during otherwise recoverable central autonomic dysregulation, and suggests a novel and distinct therapeutic target for the prevention of seizure-related morality.

Title: Melatonin inhibits voltage sensitive Calcium channel mediated neurotransmitter release

Authors: J. KWON[1], T.-Y. CHOI[1], E. S. DURRANCE[1], S.-H. JO[2], K.-T. KIM[3], *S.-Y. CHOI[1]; [1]Sch. of Dent., Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Kangwon Natl. Univ. Sch. of Med., Chuncheon, Korea, Republic of; [3]Pohang Univ. of Sci. and Technol., Pohang, Korea, Republic of

Abstract: Melatonin is involved in various neuronal functions such as circadian rhythmicity and thermoregulation. Melatonin has a wide range of pharmacologically effective concentration levels from the nanomolar to millimolar levels. Recently, the antiepileptic effect of high dose melatonin has been the focus of clinical studies; however, its detailed mechanism especially in relation to neurotransmitter release and synaptic transmission remains unclear. We studied the effect of melatonin at high concentrations on the neurotransmitter release by monitoring norepinephrine release in PC12 cells, and excitatory postsynaptic potential in rat hippocampal slices. Melatonin inhibits the 70 mM K+-induced Ca2+ increase at millimolar levels without effect on bradykinin-triggered Ca2+ increase in PC12 cells. Melatonin (1 mM) did not affect A2A adenosine receptor-evoked cAMP production, and classical melatonin receptor antagonists did not reverse the melatonin-induced inhibitory effect, suggesting G-protein coupled receptor independency. Melatonin inhibits the 70 mM K+-induced norepinephrine release at a similar effective concentration range in PC12 cells. We confirmed that melatonin (100 μM) inhibits excitatory synaptic transmission of the hippocampal Schaffer collateral pathway with the decrease in basal synaptic transmission and the increase in paired pulse ratio. These results show that melatonin inhibits neurotransmitter release through the blocking of voltage-sensitive Ca2+ channels and suggest a possible mechanism for the antiepileptic effect of melatonin.

Title: Ultrastructural changes in astrocyte enwrapping and excitatory synapses in the hippocampal CA1 stratum radiatum following kainic acid induced status epilepticus

Authors: C. CLARKSON[1], M. GIBBONS[2], J. A. WHITE[3], K. S. WILCOX[2], *M. E. RUBIO[1]; [1]Otolaryngology, Univ. of Pittsburgh Med. Sch., Pittsburgh, PA; [2]Dept. of Pharmacol. & Toxicology, [3]Dept. of Bioengineering, Univ. of Utah, Salt Lake City, UT

Abstract: Reactive astrogliosis is a common pathology in both animal models and human epilepsy. However, very little is known about ultrastructural changes that occur in reactive astrocytes at the tripartite synapse. We used electron microscopy to determine the ultrastructural response of astrocytes and synapses to kainic acid (KA) induced-status epilepticus (SE) in the hippocampal stratum radiatum. Rats were implanted with cortical EEG electrodes, administered KA to induce SE, and chronically recorded with video-EEG for 7 days to insure that animals were still within the latent period. Animals were sacrificed and perfused at day 7 following KA. Using 3D reconstructions from images after serial ultrathin sections we determined the percentage of astrocyte enwrapping around CA1 excitatory synapses and investigated ultrastructural changes at presynaptic endings and postsynaptic spines that might indicate changes in normal excitatory transmission. Consistent with previous findings, we qualitatively observed that KA treatment leads to neuronal cell death and consequently to a decrease in spines within CA1 stratum radiatum. Additional analysis of reactive astrocytes revealed thicker processes and increased microtubule content. In addition, presynaptic endings making more than one synaptic contact on different spines were more frequently observed in the KA treatment than in non-treated tissue. Quantitative analysis of astrocyte enwrapping showed an increase in astrocyte plasma membrane apposition around presynaptic endings, but not around CA1 spines. We also observed that KA treatment tended to increase the number of docked synaptic vesicles as well as the length and thickness of the postsynaptic densities. Taken together, our results show ultrastructural remodeling of astrocytes and CA1 excitatory synapses in response to KA induced SE and also imply that understanding excitatory transmission during epileptogenesis should take into account distinct and specific changes in astrocyte ensheathment of synapses.

Title: Overactive Slack channel (KCNT1) mutants lead to epilepsy by two different mechanisms

Authors: *Z. ZHANG, Q.-Y. TANG, F.-F. ZHANG, J. XU;
Physiol. and Biophysics, Xuzhou Med. Col., Xuzhou, China

Abstract: Qiong-Yao Tang, Fei-Fei Zhang, Jie Xu, Zhe Zhang [1]Jiangsu Province Key Laboratory of Anesthesiology, Xuzhou Medical College, Xuzhou, Jiangsu Province, CHINA [2]Jiangsu Province Key Laboratory of Anesthesia and Analgesia Application Technology, Xuzhou Medical College, Xuzhou, Jiangsu Province, CHINA, 221004 So far, 12 sodium-activated potassium channel mutants (KCNT1, Slack) had been linked in severe early-onset epilepsy by whole genome sequence. However, how the biophysical property of Slack channel had been changed by these mutants and the underlying mechanism remain unknown. In this abstract, open probability and sodium affinity of Slack channel mutants that had been found in family epilepsy patients were examined by using inside-out patch recording in Xenopus oocytes expressing system. By measuring the Kd value sodium sensitivity of each mutant and Po, we found some mutants on the RCK2 domain increased the channel open probability without changing sodium binding affinity, but one mutant (Y775H) on the RCK2 domain and 2 mutants on the RCK1 domain do increased channel acitvity and decreased the Kd value of sodium sensitivity.In addition, molecular simulation results suggested that mutant Y775H increased sodium binding affinity by changing the local structure of sodium binding site on the RCK2 domain. Thus, we set up a two-step activation kinetic model to explain the gating mechanism change underlying overactivity of these mutant channels. Also, our data supported that Slack channel possesses two sodium binding sites located on RCK1 and RCK2 domain respectively.

Title: Neurons in the amygdala of enriched rats with acquired reflex epilepsy are activated by a sound-induced seizure

Authors: E. M. O'NEIL, M. G. RODEN, S. E. NYSTROM, H. A. HOLDEN, H. K. ANDERSON, *M. C. ZRULL;
Psychol, Appalachian State Univ., BOONE, NC

Abstract: In reflex epilepsy, an environmental stimulus evokes seizure activity. This disorder is modeled in rat with the neural network for sound-induced or audiogenic seizures (AGS) and its physiology researched primarily in genetically epilepsy prone rats (GEPRs). For AGS in GEPRs, abnormal neural activity begins in the midbrain and spreads to the forebrain via the lateral amygdala (LA). Long-Evans rats are resistant but can be primed for AGS, and it is assumed that the same neural network supporting AGS in GEPRs mediates seizures in rats with acquired reflex epilepsy. Environmental enrichment (EE) can promote change in injured neural systems, which in turn, may promote recovery from behavioral deficits. In this study, seizure-induced neural activity in the LA and basolateral amygdala (BLA) of rats with acquired AGS and experiencing EE or not was examined using the activity marker c-fos. On postnatal day (pnd) 18, Long-Evans rats (n=8) were primed for AGS (120 dB, 10 kHz tone pips, 8 min). Age-matched rats (n=8) served as controls. The primed rats were tested for AGS susceptibility (120 dB noise) 12 times between pnd 32 and 62. During this period, half of the AGS and control rats experienced 18 EE sessions in a cage with ramps, objects, and familiar and novel conspecifics. On pnd 62, after AGS induction for primed rats, all rats spent 60 min in the quiet dark to allow expression of c-fos protein. After sacrifice, brain tissue was Nissl stained or processed for c-fos immunohistochemistry. Sections with LA and BLA were drawn from Nissl material using a projection microscope, and c-fos positive neurons activated by AGS were plotted on to the drawings of LA and BLA using digital microscopy. Counts of plotted neurons were made, AGS brains were compared to controls, and AGS brains with EE were compared to EE controls. LA and BLA from rats with AGS history showed 617% and 139% more c-fos positive neurons, respectively, than LA and BLA from control brains ($p<.05$). Interestingly, LA and BLA from rats with AGS and EE history showed 1,361% and 277% more c-fos positive neurons, respectively, than in EE control brains ($p<.05$). While enhanced amygdala activation in enriched AGS rats is interesting, both groups with acquired AGS susceptibility did exhibit more neural activation in the LA than BLA suggesting the pathway for forebrain recruitment during seizures is similar to that in rats with inherited epilepsy (i.e., GEPRs). Neural pathways underlying epilepsy in other species differ; however, the results indicate that networks for acquired and inherited epilepsy in rat function similarly implying knowledge of one form of epilepsy may advance knowledge and treatment of other forms of seizure disorders.

Title: L-arginine restores synaptic plasticity in the visual cortex of an animal model of developmental epilepsy and dyslexia

Authors: *H. MENDONÇA[1,2], P. CAMPELLO-COSTA[1], K. M. JACOBS[3];
[1]Fluminense Federal Univ., Niterói, Brazil; [2]Univ. Federal do Rio de Janeiro, Rio de Janeiro, Brazil; [3]Virginia Commonwealth Univ., Richmond, VA

Abstract: The rat freeze lesion (FL) model of microgyria replicates pathological features of human 4-layered polymicrogyria associated with epilepsy and dylslexia, including focal loss of deep layers and delayed onset to epileptiform activity. Synaptic plasticity is the main process related to learning and memory, and it has been shown to be modulated after epileptiform activity and to play a role in seizure generation. The expression of layer V synaptic plasticity relies on nitric oxide (NO) and group 1 glutamate metabotropic receptor (mGluRI) signaling. Since we have previously shown that mGluRI activation reverts hiperexcitability, reducing LTP and restoring LTD in microgyral cotex (Mendonça et al - SfN 2013), we aimed to investigate the effects of NO production modulation on visual cortex layer V synaptic plasticity of normal and freeze-lesioned rats. FL were made in the visual cortex of Sprague-Dawley rats on postnatal day (P) 1. From P9 on, animals received daily intraperitoneal injections of l-name (30 mg/kg), l-arginine (750 mg/kg) or vehicle to modulate NO levels. Slices containing the lesion or equivalent regions of control rats ranging from P13 to P17 were used for field potentials recordings. A bipolar stimulating electrode was placed within layer V and the recording one was placed within the same layer at a lateral distance of 0.5 mm, and 0.5 mm from the microgyrus. Synaptic plasticity induction experiments were performed as follows: 50% of maximal amplitude intensity stimuli were applied every 15 s during 10 min of baseline recordings. Long term potentiation (LTP) induction consisted of 5 theta burst trains (1 min intervals), with each train = 4 pulses at 100 Hz, repeated 10 times at 5 Hz. Long term depression (LTD) induction consisted of 900 pulses at 1 Hz. Post test recordings consisted of the same conditions of baseline recording but lasting 30 minutes. Our results show that normal cortex synaptic plasticity depends on NO synthesis, since L-name treatment inhibits LTP and reduces LTD. On the other hand, l-arginine bath application on control slices promoted LTP, whereas l-arginine treatment of control animals occluded high frequency stimulation-induced LTP. In addition, l-arginine treatment promoted

LTD reduction on control cortices. Freeze-lesion reduces the amplitude of LTP and blocks LTD induction in the visual cortex. Although l-name treatment didn't modulated synaptic plasticity in microgyral cortex, l-arginine restored both LTP and LTD, suggesting l-arginine treatment as a possibility to reestablish cognitive, learning and memory functions that are impaired in microgyral animals.

Title: Control of GABAergic synapses by A2A receptors during development

Authors: ***S. ZAPPETTINI**[1,2], S. GILISSEN[3], F. GOMEZ CASTRO[3], M. ESCLAPEZ[1,2], S. LÉVI[3], C. BERNARD[1,2];

Abstract: Consumption of drugs of abuse during pregnancy negatively impact upon brain development. The most widely used psychoactive drug in the world, including during pregnancy, is caffeine. At non-toxic doses, caffeine antagonizes adenosine receptors. In the adult brain, Adenosine (ADO), a degradation product of ATP, controls neurotransmitter release mainly through inhibitory A1 and facilitatory A2A receptors. These receptors appear also important during early phases of development. A2A receptors are present on some types of migrating GABA neurons, and control their migration speed. Here, we present evidence that A2A receptors also control GABAergic synapses. We used hippocampal slices from male GIN mice pups and we recorded CA3 pyramidal cells in voltage clamp whole cell mode in the presence of TTX (1 μM). Our results show that blockade of A2A receptors with SCH58261 (100 nM), a specific antagonist of A2A receptors led to an irreversible decrease of miniature IPSC frequency and amplitude from post natal day 4 to post natal day 12. This decrease was time-dependent and

maximal at postnatal day 6 (-50%). The loss of mIPSCs was clathrin-dependent, suggesting that blockade of A2A receptors triggered the internalization of GABAa receptors. A2A receptors are positively coupled to adenylyl cyclase and protein kinase A signaling cascade. Using a pharmacological approach, we demonstrated A2AR stabilize inhibitory synapses through activation of the AC/cAMP/PKA cascade. We thus hypothesize that a continuous A2A receptors activation stabilizes postsynaptic GABAa receptors during development.

Title: The reduction of Nav1.6 current suppresses high potassium induced seizure-like activity in hippocampal slices

Authors: *B. S. TANAKA[1], A. L. GOLDIN[2];
[1]Microbiology & Mol. Genet., UC Irvine, Irvine, CA; [2]Microbiology & Mol. Genetics; Anat. & Neurobio., Univ. of California, Irvine, Irvine, CA

Abstract: *SCN1A* mutations are the main cause of genetic epilepsy with febrile seizures plus (GEFS+), a disorder characterized by myoclonic seizures, ataxia, absences and atonic seizures. Mutations in the mouse *Scn8a* gene, which encodes the $Na_v1.6$ voltage-gated sodium channel, have shown reduced seizure susceptibility in chemically induced seizure models. To determine the general neuronal population in the hippocampus, excitatory or inhibitory neurons, that contributes to reduced seizure susceptibility, we induced synchronous seizure-like burst activity using elevated extracellular potassium in hippocampal slices from heterozygous $Scn8a^{flox/+}$ mice with restricted deletions of *Scn8a*. Restricted deletions of *Scn8a* in discrete cell types were generated by crossing *Scn8a*-floxed mice with either EMX-Cre (excitatory) or DLX-Cre (inhibitory) mice. Increased latency to the initial epileptiform burst discharge and reduced

frequency of burst discharges was observed in Scn8a$^{flox/+}$;EMX-Cre mice but not Scn8a$^{flox/+}$;DLX-Cre mice. Reduced action potential firing and depolarized spike threshold in CA1 pyramidal neurons suggests that decrease $Na_v1.6$ activity in hippocampal excitatory neurons contribute to reduced susceptibility to seizure-like burst activity by shifting the spike threshold in the depolarized direction. To determine whether the susceptibility to high potassium induced seizure-like activity could be reduced pharmacologically, we selectively targeted $Na_v1.6$ channels with an isoform-specific toxin to block $Na_v1.6$ activity in hippocampal slices. The tetrodotoxin (TTX) metabolite 4,9 anhydrous TTX (ah-TTX) shows potency and a 5-fold selectivity for $Na_v1.6$ channels over $Na_v1.1$ and $Na_v1.2$ channels when expressed in Xenopus oocytes. At a concentration of 100 nM TTX the population spike amplitude in CA3 layer was reduced ~40-50%, however 100 nM ah-TTX did not affect population spike amplitude. Although ah-TTX is not as potent as previously reported, seizure-like activity in hippocampal slices was suppressed by 100 nM ah-TTX, and did not affect sodium channel dependent activity in the DG-CA3 pathway. These results suggest that mutant $Na_v1.6$ channels in hippocampal excitatory neurons are responsible for modulating susceptibility of seizure-like burst activity to prevent hyperexcitability, and that selective targeting of $Na_v1.6$ channels may suppress neuronal hyperexcitability in the hippocampus.

Title: Human gain-of-function Slack (KCNT1) potassium channel mutations increase positive cooperativity between individual Slack channels

Authors: ***J. KRONENGOLD**[1], G. E. KIM[2], I. QURAISHI[3], H. C. MARTIN[4], G. BARCIA[5], J. C. TAYLOR[4], L. COLLEAUX[6], R. NABBOUT[5], L. K. KACZMAREK[1];

[6]Lab. de Génétique Moléculaire, Inst. de Recherche Necker, Hôpital Necker-Enfants Malades, Paris, France

Abstract: The Slack (Slo 2.2, KCNT1) gene encodes a large unitary conductance potassium channel that is widely expressed in neurons. Slack channels are weakly voltage dependent but are activated by elevations in intracellular sodium which contribute to a slow afterhyperpolarization (sAHP) and regulation of spike frequency. We expressed the rat Slack-B channel in Xenopus oocytes and found different patterns of channel activity in single channel patch clamp recordings. Specifically, we observe a low channel open probability pattern when few (1-3) channels are present in the patch and a high channel open probability when 4-5 or more channels are present. On-cell recordings show coupled gating of the fully open state while all points amplitude histograms show a marked deviation from a binomial distribution that is expected for independently gating channels. The different patterns of Slack channel activity likely reflect an allosteric interaction that only occurs when the channels assemble into clusters, as is the case *in vivo*. Recent studies have identified de novo KCNT1 point mutations in Epilepsy of infancy with migrating focal seizures (EIMFS), Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE), and Ohtahara syndrome. In addition to exhibiting early onset epileptic seizures there are devastating effects on development and intellectual function. The mutations are found in RCK1 and RCK2 of the large 900aa cytoplasmic C-terminal domain of Slack with one located in the S5 pore forming domain of the channel. Voltage clamp studies of the ADNFLE (G288S, R398Q, R474H, Y796H, M896I, R928C) EIFMS (G288S, R398Q, R428Q,A934T) and Ohtahara syndrome (A966T) mutations showed 3-12 fold increases in macroscopic currents with no change in levels of channel expression. Single channel studies show no significant changes in unitary conductance except for G288S which shows a 50% decrease. We have found that positive cooperative gating is substantially enhanced in the human gain-of-function Slack point mutations. Mutations show a significant increase in NPo in multichannel patches relative to the wild type multichannel patches Our findings show that the increases in current result not from an intrinsic increase in the open probability of individual channels but from strongly enhanced cooperativity in the opening of individual channel subunits in a cluster. To our knowledge this is the first report of channelopathies that results from altered channel-channel interactions.

Title: Activation of M1 muscarinic acetylcholine receptors on parvalbumin-positive neurons contributes to pilocarpine-induced seizures

Authors: *J. J. LAWRENCE[1,2], E. DECAN[1,2], E. MARCEAU[1,2], K. STOLL[1,2], K. DEISSEROTH[3], F. YI[1,2];
[1]Dept. Biomed. and Pharmaceut. Sci., [2]Ctr. for Structural and Functional Neurosci., Univ. of Montana, Missoula, MT; [3]Dept. of Bioengineering, Stanford Univ., Stanford, CA

Abstract: A common animal model of temporal lobe epilepsy employs the proconvulsant muscarinic acetylcholine receptor (mAChR) agonist pilocarpine, yet the mechanisms underlying pilocarpine-induced epileptogenesis are poorly understood. Global M1 mAChRs knockout mice are resistant to pilocarpine-induced seizures (Hamilton et al. 1997). M1 mAChRs are present on both glutamatergic and GABAergic microcircuits, yet it is unclear how pilocarpine activation of M1 mAChRs disrupts excitation/inhibition balance. Gamma oscillations, generated by fast-spiking parvalbumin-positive (PV) inhibitory interneurons, are associated with seizure onset and are susceptible to depolarization block during epileptiform discharges *in vitro* (Cammarota et al. 2013). Here, we test the hypothesis that M1 mAChR activation of PV interneurons contributes to pilocarpine-induced seizures. PV+ cells were visualized in acute mouse hippocampal slices by stereotaxic injection of a floxed YFP adeno-associated virus (AAV) or by crossing PV-CRE mice with the RosaYFP reporter line (PV-Rosa mice). Action potential (AP) frequency was monitored in loose patch mode. In PV-Rosa mice under loose patch conditions, AP frequency increased in CA1 PV cells after bath application of 200 μM pilocarpine (from 2.3 ± 1.4 Hz to 13.7 ± 4.5 Hz; p=0.044, n=5). In the presence of ionotropic glutamate and GABAA receptor antagonists (DNQX, APV, and gabazine), pilocarpine increased AP frequency (from 3.3 ± 2.8 Hz to 13.8 ± 5.6 Hz, p=0.003, n=9). . In the continued presence of pilocarpine, a subset (6/9) of PV cells progressed to depolarization block (DB). Pilocarpine-induced increases in AP frequency and induction of DB were prevented in mice in which M1 mAChRs were genetically deleted from PV cells (PV-m1KO mice, from 2.1 ± 1.2 Hz to 3.7 ± 1.9 Hz, p=0.68, n=6), consistent with

a direct postsynaptic effect on M1 mAChRs. In whole-cell mode, pilocarpine depolarized PV cells in PV-Rosa mice (from -55.0 ± 1.5 MV to -49.8 ± 1.4 mV, p=0.0015, n=11) but not PV-m1KO mice (from -51.7 ± 2.2 to -49.4 ± 1.4, p=0.21, n=6). In behavioral experiments, WT or PV-m1KO mice were injected with atropine (1 mg/kg i.p.) 30 minutes prior to pilocarpine injection (155 mg/kg i.p.). Pilocarpine-induced seizures were scored blind on a modified Racine scale (0-6). Seizures were less severe in PV-M1KO (3.9 ± 0.5, n=10) than WT (5.4 ± 0.3, n=10, p=0.027) mice at 30 min, which remained significant at 45 min (p=0.004). Therefore, we propose that pilocarpine activation of M1 mAChRs can lead to overexcitation of a subset of PV cells, weakening PV-mediated GABAergic inhibition, dysregulating excitation/inhibition balance, and increasing the susceptibility to seizures.

Title: SCN2A mutations and epilepsy: Is there a meaning in the subthreshold range?

Authors: *U. B. HEDRICH, S. MÜLLER, S. LAUXMANN, H. LERCHE;
Dept. of Neurol. and Epileptology, Hertie-Institute For Clin. Brain Res., Tuebingen, Germany

Abstract: Different *SCN2A* mutations have been shown to cause epilepsy-syndromes, such as benign familial neonatal-infantile seizures (BFNIS), a mild epileptic syndrome presenting within the first days to months of life and subsequent spontaneous resolution of seizures. Functional studies of several $Na_V1.2$ mutations revealed a clear gain of the channel's function including changes in activation and inactivation, accelerated recovery from fast inactivation and an increase in the persistent Na^+ current. For one mutation found in a BFNIS familiy originating from Madagascar we found an increase in the subthreshold Na^+ current elicited by using a single action potential as a voltage stimulus. Here, we analyzed already described as well as novel identified *SCN2A* mutations concerning their subtreshold behaviour to assess the functional consequences of this phenomenon. The studied mutations were engineered using site-directed mutagenesis into adult pCDNA3.1-$hNa_V1.2$. Both wildtype (WT) $hNa_V1.2$ and mutant $hNa_V1.2$ respectively, were coexpressed with pGFP-IRES-beta1 and pCD8-IRES-beta2 in tsA201 cells.

Currents of transfected cells were recorded after 24-48h using the whole-cell patch clamp technique. Single action potentials as well as different voltage ramps were used to study subthreshold sodium currents. Although most of the studied *SCN2A* mutations showed a clear gain of function effect with an increase in window and persistent current, for one of the studied mutations we could not detect any changes in the channel's function compared to the WT. Using a single action potential as physiological voltage stimulus as well as different voltage ramps mimicking the AP stimulus we found an increase in the subthreshold Na^+ currents in some of the studied mutant channels. Even the mutation which did not show any differences in channel gating exhibited an increase in the elicited subthreshold sodium current. We suggest that the observed increase in the subthreshold sodium current found in different *SCN2A* mutations might be adequate to provoke hyperexcitability of neurons and may explain the occurrence of seizures.

Title: Hippocampal synaptic alterations in the nonsense-mediated decay pathway after status epilepticus

Authors: *C. MOONEY, E. M. JIMENEZ-MATEOS, D. C. HENSHALL;
Dept. of Physiol. and Med. Physics, Royal Col. of Surgeon, Ireland, Dublin, Ireland

Abstract: Epilepsy is a common neurological disorder characterised by recurring seizures due to abnormal excessive neuronal firing. The most common form of epilepsy in adults is temporal lobe epilepsy (TLE) in which seizures originate in the temporal lobe. Despite advances in TLE treatment, ~30% of TLE patients remain drug refractory, hence new therapeutic approaches targeting the underlying cause of epileptogenesis and not the symptoms of the disorder are required. The Nonsense-mediated decay (NMD) pathway recognises aberrant mRNA transcripts containing premature termination codons which if allowed to be translated would result in synthesis of truncated proteins with a deleterious effect on the cell. Malfunctioning of this system has been implicated in genetic epilepsies, affecting mainly GABA receptor protein levels

to increase neuronal excitability. However, it is now apparent that NMD also regulates the levels of normal physiological mRNA transcripts, particularly at synapses where it may provide a means of tightly controlled translational regulation. Since modifications in synaptic transmission and GABAergic malfunctions are strongly implicated in epilepsy and little is currently known on its role in sporadic epilepsy, we examined the mechanism of NMD in an experimental model of kainate-induced status epilepticus (SE). Immunoblot analysis determined that protein levels of NMD components Upf1 and Upf3b were bi-directionally altered in a time-dependent manner after SE. Moreover, the transcript levels of the NMD targeted mRNA PSD-95Δexon18 showed an inverse expression pattern to these proteins. Next, immunohistochemical analysis of brain slices showed changes in Upf1 in the dendrites of the hippocampus after SE. To investigate further into changes in the levels of synaptically-located Upf1 we prepared hippocampal synaptoneurosomes from control and SE mice using density centrifugation separation and this also confirmed altered synaptic Upf1 after SE. Subsequently, mass spectrometry analysis of immunoprecipitated Upf1 from synaptoneurosomes revealed known and novel Upf1 interacting proteins after SE, suggesting a change in NMD activity after SE in the hippocampus. Together, these experiments indicate synaptic alterations in NMD processing of mRNA after SE. Further investigation into the role of NMD in SE and its target transcripts could identify new therapeutics in the treatment of epilepsy.

Title: De novo mutations identified in the β subunit of GABAA receptor in patients with infantile spasms (IS) and Lennox-Gastaut syndrome (LGS) by the Epi4K consortium alter GABAA receptor function

Authors: ***V. C. SATPUTE**[1], K. M. VERDIER[2], C. C. HERNANDEZ[2], N. HU[2], T. EPI4K INVESTIGATORS[3], R. L. MACDONALD[2];
[1]The Grad. Program of Neurosci., [2]Dept. of Neurol., Vanderbilt Univ., Nashville, TN; [3]Epi4K Consortium, Durham, NC

Abstract: Exome sequencing of genomes of patients with epilepsy has revealed multiple rare nonsynonymous single nucleotide polymorphisms (nsSNPs). However, determining the precise role of these nsSNPs remains a daunting task, especially for epilepsy with considerable genetic and phenotypic variability. Furthermore, the functional consequences of the amino acid change produced by the nsSNP remains crucial question which needs to be answered empirically since the software predictions are still far from perfect. Thus, we examined the effects of novel de novo mutations identified in GABAA receptor β subunit genes (GABRB1 and GABRB3) by the Epi4K consortium (Allen A et al., 2013). The mutations were present in children suffering from the severe epileptic encephalopathies - IS and LGS, with unaffected parents. Three patients with LGS had unique single nucleotide missense mutations in GABRB3 and two IS patients had unique mutations GABRB1 and GABRB3. GABAA receptors are the primary mediators of synaptic inhibition in the brain and mutations in the α1, β3 and γ2 subunits have been associated with human epilepsy. The β3 subunits are critical, especially during neurodevelopment, and have been implicated in childhood absence epilepsy, while the β1 subunit has not been associated with epilepsy yet. To understand the functional consequences of the β subunit mutations on GABAA receptor function, we used α1β1/3γ2 subunit transfected HEK293T cells, which do not express endogenous GABAA receptors. Using whole cell voltage clamp recordings we found that the all the β subunit mutations altered GABA evoked currents. We used flow cytometry to evaluate whether reduced surface GABAA subunits could contribute to altered currents, and found no reduction in the surface expression levels of the β1/3 or α, γ subunits. In conclusion the β subunit mutations identified in children suffering from epileptic encephalopathies have different effects on the function of GABAA receptors and could result in reduced GABAergic inhibition in patients. Further investigation is needed to understand the mechanisms by which the GABAA receptor β subunit mutations might contribute to epileptogenesis.

Title: The antiepileptic drug levetiracetam suppresses non-convulsive seizure activity and reduces ischemic brain damage in rats subjected to permanent middle cerebral artery occlusion

Authors: V. SBLENDORIO[1], O. CUOMO[1], V. RISPOLI[2], A. LEO[1], A. VINCIGUERRA[3], G. POLITI[2], *M. TAGLIALATELA[4], G. DI RENZO[1], M. CATALDI[1];

Abstract: The antiepileptic drug Levetiracetam (Lev) has neuroprotective properties in experimental stroke, cerebral hemorrhage and neurotrauma. In these conditions, non-convulsive seizures (NCSs) propagate from the core of the focal lesion into perilesional tissue, enlarging the damaged area and promoting epileptogenesis. Here, we explore whether Lev neuroprotective effect is accompanied by changes in NCS generation or propagation. In particular, we performed continuous EEG recordings before and after the permanent occlusion of the middle cerebral artery (pMCAO) in rats that received Lev (100 mg/kg) or its vehicle immediately before surgery. Both in Lev-treated and in control rats, EEG activity was suppressed after pMCAO. In control but not in Lev-treated rats, EEG activity reappeared approximately 30-45 min after pMCAO. It initially consisted in single spikes and, then, evolved into spike-and-wave and polyspike-and-wave discharges. In Lev-treated rats, only rare spike events were observed and the EEG power was significantly smaller than in controls. Approximately 24 hours after pMCAO, EEG activity increased in Lev-treated rats because of the appearance of polyspike events whose power was, however, significantly smaller than in controls. In rats sacrificed 24 hours after pMCAO, the ischemic lesion was approximately 50% smaller in Lev-treated than in control rats. A similar neuroprotection was observed in rats sacrificed 72 hours after pMCAO. In conclusion, in rats subjected to pMCAO, a single Lev injection suppresses NCS occurrence for at least 24 hours. This electrophysiological effect could explain the long lasting reduction of ischemic brain damage caused by this drug.

Title: Epileptic Scn1a mutation reduces action potential firing of pyramidal cells

Authors: *E. VELAZQUEZ[1], B. BOUBION[1], A. ESCAYG[2], A. GOLDIN[1];
[1]Microbiology and Mol. Genet., Univ. of California, Irvine, Irvine, CA; [2]Dept. of Human Genet., Emory Univ., Atlanta, GA

Abstract: Most of the sodium channel mutations that cause epilepsy are in the SCN1A gene. We previously showed that Scn1a-D1866Y, a mutation associated with Genetic Epilepsy with Febrile Seizure Plus (GEFS+), results in gain-of-function of sodium currents in dissociated parvalbumin-expressing (PV) interneurons. Although Scn1a is more abundant in PV interneurons, a mutation in Scn1a can also alter the biophysiological properties of the excitatory neurons. Based on the expression pattern of Scn1a and the gain-of-function in PV interneurons by Scn1a-D1866Y, it is likely that Scn1a-D1866Y would alter the firing properties of excitatory neurons. We predict that this effect will not be present in juvenile mice but in older mice after Scn1a expression reaches adult levels. The overall goal of this study is to determine the mechanism by which the Scn1a-D1866Y leads to the development of seizures. To examine changes in the excitatory neurons resulting from the D1866Y mutation, we recorded action potential firing of pyramidal neurons in the CA1 region of hippocampal slices. We also measured seizure-like activity in the slices by local field recordings. Current clamp recordings from pyramidal neurons in CA1 of P16-P17 mice demonstrated no differences in action potential firing with or without Scn1a-D1866Y. However pyramidal neurons in CA1 from Scn1aD1866Y/+ P21-P24 mice demonstrated reduced action potential firing compared to wild-type littermates. Despite the reduced action potential firing in pyramidal neurons, the hippocampal network demonstrated a lower latency and higher frequency of seizure-like events. Our results indicate that an increase in excitatory neuron firing is not necessary for the induction of seizure-like events in hippocampal slices. The D1866Y mutation reduces excitability of pyramidal neurons, which could be a direct effect on the intrinsic properties of those neurons or a result of increased interneuron inhibition. Since decreased pyramidal cell activity is unlikely to directly cause seizure activity, it is likely that the D1866Y mutation has a significant effect on interneurons that in conjunction with the effect on pyramidal neurons results in an overall increase in synchrony and seizure susceptibility. These results along with the previous analysis of other mutations in the Scn1a demonstrates that different mutations in Scn1a can result in a similar epileptic phenotype by altering different aspects of sodium channel function and neuronal excitability. These differences have important implications, because interventions that alleviate seizures resulting from some mutations may exacerbate seizure activity resulting from other mutations.

Title: Measurement of neuronal population excitability based on selective activation of interneurons

Authors: ***P. BENQUET**[1], D. COSANDIER-RIMELEE[1], U. GERBER[2], O. RAINETEAU[2], G. DIEUSET[1], F. LOPES DA SILVA[3], F. WENDLING[1];
[1]INSERM U1099 -LTSI, Rennes, France; [2]Brain Res. Inst., Univ. of Zurich, zurich, Switzerland; [3]Ctr. of Neurosci., Swammerdam Inst. for Life Sci., Amsterdam, Netherlands

Abstract: Regarding the major importance of GABAergic interneuron function in brain functions, a dysregulation of this cell types naturally lead to many pathological states, including fragile X syndrome, autism spectrum, Down syndrome, schizophrenia, affective disorders, and epilepsy. In the epileptic brain, a functional impairment of interneurons contributes to both interictal, ictal activity. When the inhibitory barrage collapse the focal ictal discharges propagates further across the cortex. The impairment of GABAergic inhibition could result from a decrease of GABAA receptor density, a shift of the chloride reversal potential toward more positive value, a decrease of excitability, a decrease of synapse number or even cell death. Therefore a simple method to selectively probe the functionality of interneuron synapses within a healthy or a pathologic brain tissue would be of a major importance. We have defined a new method of direct bipolar supra-threshold low-frequency neurostimulation, optimally designed, by using combined translational approaches including computational model, patch clamp and field recording in brain slices, field recordings *in vivo*. We show that direct bipolar stimulation is able to selectively activate GABAergic IPSP on pyramidal cells if the stimulation intensity is tuned just above the excitability threshold. Optimum stimulation frequency is around 8Hz. This protocol leads to the selective emergence of the responses of interneurons in healthy and pathological brain tissue. Our first results show that this protocol allows for a quantification of

the degree of excitability of a neuro-glial network. Results and predictions of lumped network computational model, were validated with patch-clamp recordings made on pyramidal cells and putative interneurons in organotypic hippocampal slices, *in vivo* in a mouse model of epilepsy (kaïnate injected in the hippocampus). Moreover, a clinical study is being conducted in this direction in patients undergoing pre-surgical evaluation at the University Hospital of Rennes. Such neurostimulation revealed distinct electrophysiological responses between healthy and epileptogenic brain areas in humans, but could also be useful in other diseases.

Title: Propylparaben reduces the neuronal hippocampal damage as results of pilocarpine-induced status epilepticus in rat: Correlation with the release of GABA and glutamate

Authors: *C. E. SANTANA, SR[1], G. VALLE-DORADO[1], S. OROZCO-SUAREZ[2], L. BRUNO-BLANCH[3], A. TALEVI[3], L. ROCHA-ARRIETA[1];

Abstract: Previous studies indicate that the administration of propylparaben (PPB) (an antimicrobial agent with low toxicity and widely used), reduces the seizure activity induced by pentylenetetrazole and inhibits voltage-dependent sodium channels in isolated adult rat cardiomyocytes. The aim the present study was to determine if PPB is able to induce neuroprotective effects in hippocampus when applied 3 h after status epilepticus (SE). Male Wistar rats previously implanted with a bipolar electrode coupled to a guide cannula into the

right ventral hippocampus, were subjected to microdialysis experiments during which SE was induce by pilocarpine administration (300 mg/kg, i.p., SE group, n=6). Diazepam (DZP 2.5 mg/kg, i.m.) was applied 2 h after the SE establishment. The SE+PPB group (n=6) was manipulated as described above, except that animals received PPB (178 mg/kg, i.p.) administration 1 h after DZP. One day after the SE, the animals were sacrificed and the brain used to evaluate the site of electrode/cannula implantation (Nissl staining) and neuronal damage (FLUORO-JADE B). SE and SE+PPB groups showed similar basal levels of GABA and glutamate of (0.34±0.06 μM and 1.20±0.29 μM, respectively). The SE was established at 43.2±2.5 min after pilocarpine injection. Increased GABA and glutamate release (135% and 140% respectively) was evident the perfusate collected 47 min after SE establishment, a situation that was progressive until the end of the experiment (6.5 h after pilocarpine). DZP administration reduced the behavioral and electrographic epileptic activity, but not GABA and glutamate release (270% and 330% respectively; $p<0.05$, when compared with basal conditions). In contrast, the SE+PPB group showed a progressive decrease of the GABA and glutamate levels after PPB administration (155% and 177%, $p<0.001$; respectively and at the end of the experiment), an effect associated with a significant decrease in the epileptiform electrographic activity. When compared with SE group, SE+PPB group demonstrated decreased neuronal damage in dorsal hippocampus as follows: dentate gyrus (81%, $p<0.05$), CA3 (86%, $p<0.001$) and CA1 (98%, $p<0.001$). PPB reduces the GABA and glutamate release, effect associated with decreased of neuronal damage.

Title: Inhibition of Nav1.6 channels reduces hyper-excitability of Subiculum neurons in epilepsy

Authors: A. NIGAM, *M. K. PATEL;
Anesthesiol., Univ. Virginia Hlth. Sys, CHARLOTTESVLE, VA

Abstract: Temporal lobe epilepsy (TLE) is a common form of adult epilepsy. Seizures in patients with TLE can be difficult to suppress resulting in approximately 30% of patients being classed as therapy resistant. Subiculum neurons serve as the primary output center for the hippocampus, receiving information directly from the CA1 and projecting out to cortex and subcortical regions. Subiculum neurons are spared in TLE and become hyper-excitable. Since sodium (Na) channels play a critical role in the generation of action potentials, alterations in Na channel function would facilitate this hyper-excitability. The tetrodotoxin metabolite, 4,9-anhydro tetrodotoxin (4,9-ah-TTX), has been shown to have greater potency against the Nav1.6 isoform than other neuronally expressed Na channel isoforms. At a concentration of 100 nM, 4,9-ah-TTX inhibited Nav1.6 channel currents by approximately 50%, while having no effect on Nav1.2 channel currents. In this study, we determined the effects of 4,9-ah-TTX on membrane excitability and resurgent (INaR) Na currents in both control and TLE Subiculum neurons. Action potentials (AP) were evoked by a series of depolarizing current injection steps under whole cell current clamp conditions. Subiculum neurons from TLE brain slice preparations had higher AP firing frequencies than control. At a current injection step of 470 pA, frequencies were increased from 36.6 ± 0.4 Hz (n = 16) in control to 44.4 ± 0.4 Hz (n = 7) in TLE. Bath application 4,9-ah-TTX (100 nM) significantly reduced firing frequencies in both control (23.3 ± 0.4 Hz ; n = 7) and TLE neurons (22.8 ± 0.3 Hz; n = 7). Stimulation of the pyramidal cell layer of the CA1 region evoked a burst of APs in control neurons. In TLE neurons, stimulation evoked a greater number of APs and longer durations of depolarizing events. Application of 100 nM 4,9-ah-TTX significantly reduced the number of APs evoked in both control (from 2.1 ± 0.1 APs ; n = 7 to 1.5 ± 0.3 APs ; n = 7) and TLE neurons (from 3.3 ± 0.1 APs ; n = 6 to 1.4 ± 0.3 APs; n = 6). Duration of the depolarizing events were also reduced. INaR currents were also recorded from Subiculum neurons and were increased in TLE. Control amplitudes were increased from -783.4 ± 16.1 pA (n = 5) to -1209 ± 149.7 pA (n = 5) in TLE. Bath application of 100 nM 4,9-ah-TTX reduced the amplitude of INaR currents by 45.7 % in control and 46.8 % in TLE neurons. These data suggest that the Nav1.6 isoform plays an important role in controlling neuronal membrane excitability of Subiculum neurons. Alterations in the activity of Nav1.6 could be important in facilitating neuronal hyperexcitability in TLE.

Title: Newly born neurons in dentate gyrus are functionally integrated into neuronal circuitry in mice exhibiting chronic temporal lobe epilepsy

Authors: *J. LIU, M. HU, X. CHEN, J. ZHANG, P. YANG, Y. LIU;
Xi'an Jiaotong Univ. Hlth. Sci. Ctr., Shaanxi, China

Abstract: Neurogenesis in subgranular zone-granule cell layer (SGZ-GCL) of dentate gyrus (DG) declines substantially in chronic temporal lobe epilepsy (TLE). Some studies have linked this decline to altered basal proliferation rate or neuronal differentiation. However, whether or not altered recruitment of newly-born cells into local circuits also attributes to the decline is still unexplored. To address this issue, we visualized the newly-born cells of DG that extended axons to CA3 area or integrated into memory circuits in mice exhibiting chronic TLE. At chronic stage of pilocarpine induced TLE mouse model (2 months after status epilepticus), newly-born cells in DG were labeled by intraperitoneal injection of proliferation marker 5-bromo-2'-deoxyuridine (BrdU) in chronically epileptic and age-matched mice. Retrograde tracer cholera toxin B subunit (CTB) was injected iontophoretically into CA3b area of hippocampus and the newly-born cells extending axons to CA3 area along the mossy fiber tract were then quantified via dual immunofluorescence of BrdU and CTB. c-Fos, an immediate early gene product, is highly correlated with neuronal firing and can be induced by the recall of spatial memory. To identify the newly-born cells incorporating into dentate gyrus circuits supporting spatial memory, mice were trained in Morris Water Maze either 4 or 6 weeks after BrdU labeling and spatial memory was tested 10 days after the training. Mice were then killed 90 min after the test, and c-Fos and BrdU expression were quantified using immunofluorescence approaches. 23.7±4.1% or 33.1±3.9% of total BrdU+ cells in SGZ-GCL were co-localized with CTB in chronically epileptic hippocampus at 6 weeks or 8 weeks post-BrdU labeling, while the percentage is 25.7±3.0% ($P>0.05$) or 35.1±4.4% ($P>0.05$) respectively in the age-matched intact hippocampus. In the spatial memory test, chronically epileptic animals exhibited spatial cognitive deficits when compared to the age-matched normal animals. After spatial memory test, 20.9±4.4% or 30.1±5.0% of total BrdU+ cells in SGZ-GCL were c-fos positive in chronically epileptic hippocampus at 6 or 8 weeks post-BrdU labeling, in comparison to 21.3±3.9% ($P>0.05$) or 31.1±4.0% ($P>0.05$) such newly-born cells expressing c-fos in the age-matched intact

hippocampus. These results demonstrate that the newly-born cells in chronically epileptic hippocampus are still able to recruit into the existing hippocampal circuitry supporting spatial memory, and largely diminished hippocampal neurogenesis in chronic TLE is not associated with decreased integration ability of surviving newly-born cells.

Title: Reduced GABAergic inhibition in the basolateral amygdala after soman exposure: pathophysiological mechanisms underlying increased anxiety

Authors: ***J. P. APLAND**[1], E. M. PRAGER[2], V. I. PIDOPLICHKO[2], V. ARONIADOU-ANDERJASKA[2], M. F. M. BRAGA[2];
[1]Neurobehavioral Toxicol, USAMRICD, Gunpowder, MD; [2]Anatomy, Physiology, and Genet., Uniformed Services Univ. of the Hlth. Sci., Bethesda, MD

Abstract: The recent sarin attack in Syria killed 1,429 people, including 426 children, and left countless more to deal with the health consequences of the exposure. Prior to the Syrian chemical warfare agent assault, the nerve agent attacks in Japan left many victims suffering from neuropsychiatric illnesses, particularly anxiety disorders, more than a decade later. Uncovering the neuro-pathophysiologic mechanisms underlying the development of anxiety after nerve agent exposure is necessary for successful treatment. Anxiety is associated with hyperexcitability of the basolateral amygdala (BLA). The present study sought to determine the nature of the nerve agent-induced alterations in the BLA, which could explain the development of anxiety. At 24 hours and 14 days after exposure of rats to soman, at a dose that induced prolonged status epilepticus, spontaneous inhibitory postsynaptic currents (sIPSCs) in the BLA were reduced,

along with reduction in the frequency but not amplitude of miniature IPSCs. In addition, activation of $_7$-nicotinic acetylcholine receptors, cholinergic receptors that participate in the regulation of BLA excitability and are involved in anxiety, increased spontaneous excitatory postsynaptic currents (sEPSCs) in both the soman-exposed rats and the controls, but was less effective in increasing sIPSCs in the soman-exposed rats. Despite the loss of both interneurons and principal cells after soman-induced status epilepticus, the frequency of sEPSCs was increased in the soman-exposed rats. Impaired function and cholinergic modulation of GABAergic inhibition in the BLA may underlie anxiety disorders that develop after nerve agent exposure. The experimental protocol was approved by the Animal Care and Use Committee at the United States Army Medical Research Institute of Chemical Defense and all procedures were conducted in accordance with the principles stated in the Guide for the Care and Use of Laboratory Animals and the Animal Welfare Act of 1966 (P.L. 89-544), as amended. Title: Early-life seizures induced synaptic metaplasticity in hippocampal CA1 neurons

Authors: *H. SUN, F. E. JENSEN;
Dept. of Neurol., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Neonatal seizures, often refractory to current drugs, can result in chronic epilepsy and long-term cognitive deficits. Using an established neonatal hypoxic seizure (HS) model, we have previously shown that LTP is occluded in hippocampal slices removed from rats at 48-72h following early life seizures, in part due to seizure-induced decreases in silent synapses. However, our results also show an unexpected occlusion of NMDA-dependent LTD. The threshold for both LTP and LTD can be modulated by priming neuronal network activities, displaying "metaplasticity" - the plasticity of long-term synaptic plasticity. Given HS-induced changes in both LTP and LTD, we hypothesize that HS-induced neuronal hyperactivity evokes a rightward shift of metaplastic modulation of LTP and LTD. HS were induced by graded global hypoxia at postnatal day 10. *Ex vivo* hippocampal slices were prepared from rats at 48-72h following HS as well as littermate controls. Extracellular field potential (fEPSP) recordings were obtained from the apical dendritic layer (stratum radiatum) of the CA1 region by stimulating the Schaffer collateral pathway. fEPSP slopes were measured before and after a train of stimulation at 0.1, 1Hz (1200pulses), 5, 10, 20 Hz (900pulses) and two trains of 100Hz (100pulses, 20s interval). Consistent with previous findings, the potentiation of fEPSP slopes in response to 100Hz stimulation was significantly attenuated in post-HS slices (potentiated by 10.6 ± 7.2%, n=6, $p<0.05$) compared to those from P12-13 controls (potentiated by 58.3 ± 18.7%, n=5). The depression of fEPSP slopes in response to 1Hz stimulation was also significantly attenuated in post-HS slices (reduced by 19.4 ± 7.6%, n=7, $p<0.05$) compared to those from P12-13 controls (reduced by 59.2 ± 11.9%, n=5). In addition, HS induced a rightward shift of the LTP/LTD induction threshold (5Hz: -25.8±5.6%, n=5; 10Hz: -11.2±6.6%, n=6; 20Hz: -12.7±7.6%, n=7) compared to littermate controls (5Hz: -20.5±7.2%, n=4; 10Hz: 3.6±9.2%, n=4; 20Hz: 20.6±5.8%, n=5). Overall, our data reveal a metaplastic modulation of LTP/LTD induction in hippocampus following HS, which indicates a homeostatic modulation of synaptic plasticity following early life seizures. In addition, these data suggest that the early life seizure-induced LTP/LTD impairment might be modifiable and treatable not only by pharmacologic agents but activity or stimulation such as TMS.

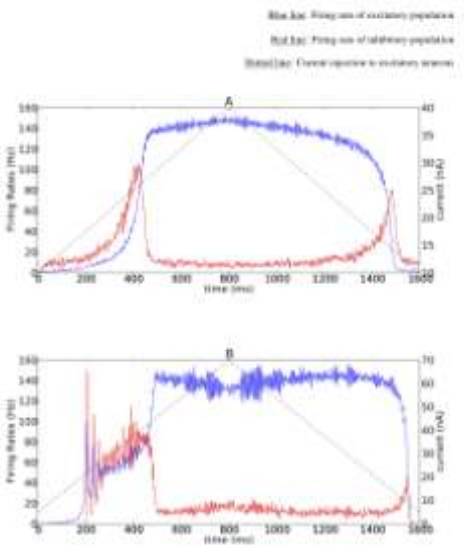
Title: A computational model of the influence of depolarization block on initiation of seizure-like activity

Authors: C. KIM[1], *D. Q. NYKAMP[2];
[1]Sch. of Mathematics, Univ. of Minnesota, MInneapolis, MN; [2]Sch. Mathematics, Univ. Minnesota, Minneapolis, MN

Abstract: Under pathological conditions the interaction of excitatory and inhibitory neurons can become unbalanced, leading to seizure-like activity in the network. The interplay between excitatory and inhibitory neurons has been studied in rat hippocampal CA1, where spontaneous seizure-like activity was produced by blocking potassium ion channels and decreasing magnesium. The main finding from the study is that the excitatory neurons exhibit runaway excitation as the inhibitory neurons enter long-lasting depolarization block. In this study, we employ a modified Wilson-Cowan model to examine the dynamics of an EI network under similar pathological conditions. To model depolarization block, we modified the inhibitory population's activation function so that large input silences the population. Phase plane analysis shows that the network can be in as many as three different states, rest state, active state, and seizure state, where the inhibitory population enters depolarization block in the seizure state. The network can be bistable, where the rest and seizure state coexist, or if the external input to the inhibitory population is reduced, the network can become tristable, where all three state coexist for the same parameters. In addition, convergent connectivity structure from excitatory neurons onto inhibitory neurons is found to facilitate the transition to seizure state by reducing the strength of inhibitory drive when the network is near seizure state. The predictions of Wilson-Cowan model is tested with a network of Morris-Lecar (ML) neurons. We find that both bistable (Figure A) and tristable (Figure B) states are present in the ML network. Hysteresis is observed at the transitions between different states, providing evidence that the emergence of three states is a network phenomenon. It is also observed that the network enters seizure state at a low

current input when the convergent connectivity structure is



promoted.

Title: GMF- deficient mice are protected against MPTP-induced dopaminergic neurotoxicity

Authors: S. ZAHEER[1], M. M. KHAN[1], R. THANGAVEL[1], J. NEHMAN[1], D. KEMPURAJ[1], *A. ZAHEER[1,2];
[1]Neurol., Univ. of Iowa, Iowa City, IA; [2]VAHCS, Iowa City, IA

Abstract: Parkinson's disease (PD), one of the most prevalent and progressive neurodegenerative diseases, is characterized by the loss of dopaminergic neurons in the substantia nigra pars compacta and associated with movement disorders. Recent studies have indicated that glia maturation factor (GMF), a proinflammatory protein, is involved in the pathogenesis of neurodegenerative diseases. However, the exact association and underlying mechanism of GMF in the loss of dopaminergic (DA) neurons in PD is not clear. In the present study, we demonstrate that deficiency of GMF suppresses dopaminergic (DA) neuron loss, glial activation, and expression of proinflammatory mediators in the substantia nigra pars compacta (SN) and striatum (STR) of 1-methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine (MPTP) treated mice. Dopaminergic neuron numbers in the SN and fiber densities in the STR were significantly reduced in wild type (Wt) mice after MPTP treatment compared with GMF-deficient (GMF-KO) mice. We also compared the motor abnormalities caused by MPTP treatment in Wt and GMF-KO mice as measured by Rota rod and grip strength test. Results show that the deficits in motor coordination and decrease in dopamine and its metabolite content were protected significantly in GMF-KO mice after MPTP treatment when compared with control Wt mice under identical experimental conditions. Current data provide the first evidence that deficiency of GMF rescues the DA neuron loss following MPTP administration in mice. Thus depletion of endogenous GMF represents an effective and selective strategy to slow down the MPTP-induced neurodegeneration.

Title: Comparison of glutamate- and hydrogen peroxide-induced HT22 cell death ~ Role of rapid and persistent Erk1/2 activation by oxidative stress ~

Authors: *K. SATO, Y. YAMANAKA, Y. ASAKURA, T. NEDACHI;
Toyo Univ., Gunma, Japan

Abstract: During ischemia reperfusion, excessive glutamate release induces neuronal death in central nervous system. This glutamate toxicity is mediated by at least two distinct mechanisms, induction of oxidative stress caused by the inhibition of cystine/glutamate transporter and glutamate receptor mediated excitotoxicity. HT22 mouse hippocampus neural cells have been often used as a model for studying glutamate induced oxidative stress, because this cell line does not have ionotropic glutamate receptor. It has been demonstrated that the persistent Erk1/2 activation, regulated by oxidative inhibition of Erk phosphatase, plays a central role on this glutamate-induced cell death. However, in the present study, we found hydrogen peroxide (H2O2), the other oxidative stressor, indeed promoted cell death but were independent of persistent Erk1/2 activation in HT22 cells. We herein report the detail comparative analysis how H2O2 and glutamate controls HT22 cell death. Initially, we treated HT22 cells with various concentration of H2O2 or glutamate and examined several cellular responses. We found similar changes of cell fate in response to H2O2 and glutamate (i.e. cell death and the release of growth factors was similarly regulated by H2O2 and glutamate). On the contrary, different time-dependent patterns of ERK1/2 activation were observed. HT22 cells were treated with various concentration of H2O2 and glutamate for different time and Erk1/2 phosphorylation was monitored. Low concentration of H2O2 or glutamate treatments similarly induced acute and transient Erk1/2 phosphorylation within 1 hour; on the other hand, when we elevated glutamate concentration, persistent Erk1/2 phosphorylation was observed 16-24 hours after glutamate treatment. This persistent phosphorylation of Erk1/2 was not stimulated by high concentration of H2O2. Moreover, U0126 inhibited glutamate induced cell death, but was not effective against H2O2 induced cell death. Overall, these results strongly suggest that the persistent ERK1/2 activation in response to high concentration of glutamate plays an important role on glutamate induced cell death; however, H2O2-dependent cell death was controlled by the other mechanisms. mGluRs-dependent signals may be involved in this process since antagonists for mGluRs attenuated U0126-dependent cell protective effect. In conclusion, two oxidative stressors, H2O2 and glutamate, similarly induced HT22 cell death; however, underlying mechanisms were completely distinct. Differential Erk1/2 regulation, glutamate-induced persistent Erk1/2 activation could be a strong candidate to consist the distinct mechanism.

Title: Involvement of endoplasmic reticulum stress and calcium dyshomeostasis in zinc-induced neurotoxicity

Authors: *M. KAWAHARA[1], D. MIZUNO[2];
[2]Bio-analytical Chem., [1]Musashino Univ., Nishitokyo, Japan

Abstract: Zinc (Zn) is abundantly present in brain and secreted from synaptic vesicles into synaptic clefts along with glutamate during neuronal excitation. It is widely accepted that the secreted Zn ion plays crucial roles in the information processing processes and the formation of memory. However, excess Zn secreted after transient global ischemia is toxic and plays central roles in the pathogenesis of vascular type dementia (VD). We have investigated the molecular mechanism of Zn-induced neurotoxicity using GT1-7 cells (immortalized hypothalamic neurons), which are more susceptible to Zn compared to other neuronal cells. The exposure to Zn induced the elevation of intracellular calcium levels. The calcium channel blockers attenuated Zn-induced neuronal death. Our analysis using the DNA microarray revealed that expressions of several genes, such as metal-related genes (metallothionein, zinc transporter 1), endoplasmic reticulum (ER)-stress related genes (GADD34, GADD45, p8), calcium-related genes (activity-related cytoskeleton protein (Arc)) were affected after Zn exposure. We have demonstrated that substances which attenuate Zn-induced neurotoxicity such as carnosine (β-alanyl histidine) or histidine inhibited the expressions of GADD34, p8, and Arc, meanwhile they did not influence the expression of metal-related genes. Furthermore, dantrolene, which prevents calcium release from ER, attenuated Zn-induced neurotoxicity, and thapsigargin, which increases intracellular calcium by blocking influx into ER, enhanced Zn-induced neurotoxicity. Furthermore, the addition of calcium into culture media prevented from Zn-induced neurotoxicity. Our results suggest that ER stress and calcium dyshomeostasis may underlie the molecular mechanism of Zn-induced neurotoxicity, and finally the pathogenesis of VD. Furthermore, we propose carnosine as a possible candidate for drugs of VD considering its beneficial characteristics and published a patent of carnosine (patent No. JP5382633). We also discuss the molecular mechanism of carnosine in preventing VD and other neurodegenerative diseases.

Title: The effects of partial PPARγ agonist on neuroinflammation- induced memory deficits

Authors: *H. D'ANGELO, A. CROCKETT, S. HOPP, S. ROYER, L. ADZOVIC, G. WENK; Neurosci., The Ohio State Univ., Columbus, OH

Abstract: There are numerous neurodegenerative diseases characterized by cognitive impairment, neuroinflammation and metabolic dysfunction. Recent studies have linked neuroinflammation as a possible contributor to the exacerbation of glucose metabolic dysfunction and the related cognitive impairments. Diabetes mellitus is perhaps the most widely known metabolic disease in the periphery. The epidemiological, clinical, and pathological links between type two diabetes mellitus (T2DM) and Alzheimer's disease suggest similar or overlapping mechanisms in neuroinflammation- induced glucose dysregulation. A class of drugs that have been used to treat T2DM, thiazolidinediones, are peroxisome proliferator- activated receptor gamma (PPARγ) agonists and have severe adverse side effects. Our aim was to find a partial agonist of this receptor in order to reduce the severity of the side effects while maintaining a therapeutic effect. We investigated the drug honokiol, a partial PPARγ agonist, on a rat model of neuroinflammation. Three-month-old rats were infused intraventricularly with lipopolysaccharide or artificial CSF and then injected with honokiol or vehicle. After four weeks of the drug treatment, the rats' spatial memory was assessed using the Morris water maze task. Preliminary results indicate promising anti- inflammatory effects of honokiol by the attenuation of the LPS- induced behavioral deficit.

Abstract: Purpose: Ibudilast, a phosphodiesterase inhibitor with glial cell modulation, anti-inflammatory and vasodilator properties, has been used for over 20 years for the treatment of asthma and stroke. Here, we characterized the role of ibudilast on the response of glia and retinal ganglion cells (RGCs) to ocular hypertension (OHT) glaucoma. **Methods:** OHT was induced by injection of hypertonic saline solution into an episcleral vein in Brown Norway rats. Ibudilast or vehicle was administered by intravitreal injection. Animals were euthanized at 3 weeks after OHT induction, and the retinas and optic nerves were collected for histological and biochemical analyses. Tumor necrosis factor α, (TNFα), interleukin 1 (IL-1β), interleukin 6 (IL-6), macrophage migration inhibitory factor (MIF), glial fibrillary acidic protein (GFAP) and ionized calcium binding adaptor molecule 1 (Iba1) expression were evaluated by immunohistochemistry and western blots. RGC soma or axon density was assessed on Brn3a-stained flat-mounted retinas or toluidine blue-stained optic nerve cross sections, respectively. **Results:** Our data demonstrate a striking decrease in the number of GFAP-positive astrocytes and Iba1-labeled microglia in ibudilast-treated glaucomatous retinas and optic nerves compared to vehicle-treated controls. Ibudilast treatment also led to a marked reduction in the levels of the pro-inflammatory cytokines TNFα, IL-1β, IL-6, and MIF in ocular hypertensive eyes compared to vehicle treatment. Ibudilast promoted robust RGC soma (91%, 1884±43 RGCs/mm^2, n=5) and axonal protection (90%, 90639±2657 axons, n=5) with respect to vehicle (68% soma, 1475±95 RGCs/mm^2, n=6; 61% axons, 61318±8112 axons, n=6). Ibudilast did not alter intraocular pressure (IOP) in after hypertonic saline injection; therefore these responses could not be attributed to changes in IOP. **Conclusions:** Our data demonstrate that Ibudilast attenuates glial cell reactivity, reduces production of pro-inflammatory cytokines, and promotes RGC soma and axon protection in experimental glaucoma.

Title: Influence of a postnatal peripheral immune challenge on neuroimmune response in the developing rat brain

Authors: *K. L. JONES[1], K. STREIFEL[2], L. HEUER[1], C. BOOSALIS[2], P. LEIN[2], J. VAN DE WATER[1];
[1]Div. of Rheumatology/Allergy and Clinical Immunology, [2]Univ. of California - Davis, Davis, CA

Abstract: Research suggests that peripheral immune challenge during the perinatal period may modulate neurodevelopment. While the vast majority of this research has focused on infection or inflammation during gestation, there is emerging evidence that immune challenge during early postnatal development may also influence the developing brain. Interestingly, the studies performed to date have focused on viral or bacterial infection as the source of immune challenge. Here we addressed whether a non-pathogenic immune stimulus alters biomarkers of neuroinflammation in the developing brain. We tested Lewis rats, which are genetically predisposed to a Th1 pro-inflammatory response, and Brown Norway rats, which are skewed towards an allergy-promoting Th2 response. Male and female offspring of timed-pregnant Lewis and BN dams were immunized on postnatal day (PD) 10 with one of the following treatments: immune challenge (immune challenge and adjuvant), adjuvant-control (mixture of adjuvant and saline), or saline-control (saline only). The immune challenge treatment consisted of a mixture of rotavirus, diphtheria, tetanus, pertussis, *Haemophilus influenza* type b, pneumococcal conjugate, and inactivated polio vaccines in conjunction with an adjuvant, representing the immunization schedule typically administered to humans at 2 months of age. Serum, spleen and brain samples were collected at 2 or 5 days post-immunization. Cytokine profiles were determined using Luminex multiplex technologies, and microglial and astroglial activation states were assessed using immunohistochemistry. Preliminary results suggest that treatment effects are observed, but may vary due to factors such as sex, strain, sample type, and age. These results indicate that while a non-pathogenic immune challenge during the early postnatal period stimulates cytokine/chemokine production in the developing brain, the effects are complex and influenced by various host factors.

Title: Neuroinflammation and neuronal cell death in the retina and cerebral vision structures in an ocular hypertensive rat model

Authors: *A. SAPIENZA, C. ROUBEIX, C. BOUCHER, D. GODEFROY, J. DEGARDIN, F. BRIGNOLE-BAUDOUIN, W. ROSTÈNE, C. BAUDOUIN, S. MELIK-PARSADANIANTZ; Vision Inst., Paris, France

Abstract: Glaucoma is the second leading cause of irreversible blindness worldwide. It is characterized by a progressive retinal neuropathy generally combined with an ocular hypertension due to trabecular meshwork degeneration. Accumulating evidence demonstrates that glaucoma not only affects the retina, but also damages the central visual pathways. The aim of this study was to analyze, in a rat model of ocular hypertension, neuroinflammation and neuronal cell death emerging from pathological retina propagating to the cerebral visual areas. Ocular hypertension model was performed by cauterization of 3 episcleral veins of right eyes in Long-Evans male rats to induce stable intra-ocular pressure increase (19.4$\pm$1.4 to 33.1$\pm$2.4 mmHg). To observe whether neurodegenerative processes occur, we counted retinal ganglion cells ((RGC) Brn3a positive cells)) in whole flat mounted retinas and parvalbumin immunoreactive (PV-IR) neurons in lateral geniculate nucleus (LGN). Retinas and cerebral vision structures (optic tract (OT), LGN, superior colliculus (SC) and visual cortex (Ctx)) were collected after microdissection by punch technique from 6- and 12-weeks ocular hypertensive and control animals. In retinas and microdissected areas, neuroinflammation was evaluated using mRNA expression levels analyze of proinflammatory cytokines, reactive glial cells, chemokines and oxidative stress markers. Gene expression analysis in 6- and 12-weeks retinas of hypertensive eyes revealed a significant increase in CCL2, IL-1β and in NADPH oxidase 2 mRNA expression compared to contralateral and naive eyes. Furthermore, microglial cells and RGC counting also showed a peripheral RGC loss associated with microglial activation and proliferation at all time point examined. We also demonstrated an up-regulation of proinflammatory markers such as IL-6, IL-1β and CCL2 in OT, LGN, SC and Ctx at 6-and 12-weeks in left-brains compared to right and naive brains. Microglial cells and PV-IR neurons counting in LGN revealed no difference at 6 weeks in left-brain compared to controls. However,

in 12-week ocular hypertensive animals, microglial cell activation was closely correlated to LGN neuron death. Ocular hypertension therefore induces neuroinflammation in retina and in the main brain structures involved in vision. It appears that neuroinflammation spreads from sick neurons to healthy neurons through synaptic connections along anatomic neuronal pathway. These findings open a new avenue in our understanding of how glaucoma develops and how it is able to spread along the cerebral visual structures and may offer new therapeutic approaches.

Title: Acid-sensing ion channels contribute to acidosis-induced neuronal injury in cerebellar slices

Authors: ***X. ZHA**[1], N. JIANG[1,2], Y. JI[2];
[1]Cell Biol. and Neurosci., Univ. of South Alabama, Mobile, AL; [2]Sch. of Life Sci., Shanghai Univ., Shanghai, China

Abstract: Acid-sensing ion channels (ASICs), a family of proton-gated cation channels, are the main proton receptor in brain neurons. Previous studies have shown that ASICs contribute to neuronal injury in cortical, hippocampal and striatal neurons. Whether ASICs mediate acidosis-induced neuronal injury in other brain regions remains unclear. We used here organotypic cerebellar slices to study neuronal injury in cerebellar neurons. We prepared cerebellar slices from postnatal 8-10 day old mice, and cultured them for 10-15 days. After 2 weeks in culture, the overall architecture of the slices was intact. Immunofluorescence labeling showed that Purkinje neurons and cerebellar granule cells were maintained, and PSD-95 clusters formed along the dendrites of Purkinje neurons. We then induced neuronal injury, either by incubating the slices with a pH 6 medium or with oxygen-glucose deprivation (OGD). As expected, pH 6 and OGD treatment induced delayed neuronal injury in these slices. Deleting the ASIC1a gene attenuated

pH 6- and OGD-induced neuronal injury. These data show that organotypic cerebellar slices are a good *ex vivo* system to study mechanisms underlying acidosis-induced neuronal injury.

Title: Early life arsenic exposure causes dopaminergic dysfunction and its reversibility in developing brain of rats

Authors: *L. P. CHANDRAVANSHI[1], R. SHUKLA[1], R. GUPTA[2], Y. DHURIYA[2], V. KHANNA[2];

Abstract: Continuing exposures to arsenic continue to pose a significant threat to public health throughout the world including India due to drinking of arsenic contaminated drinking water. Although a lot of information available on arsenic induced neurotoxicity in adults, knowledge of such effect on children is very little. Studies have been carried out to investigate the impact of early life following arsenic exposure (2 mg/kg and 4 mg/kg body weight, p.o.) to rats from PD22 to PD59 results in various neurobehavioural and neurochemical alterations observed on PD60. In spontaneous locomotor activity test, a significant increased in the total distance (28%, 66%) arsenic exposed groups remarkably compared to control group, and there was a dose-related increase observed. An increase in the binding of DA-D2 receptors in corpus striatum (38%, 56%) and the expression of tyrosine hydroxilase (TH) in corpus striatum (1.93, 2.73 -fold) furthermore associated with a significant increase in the mRNA expression of DAR-D2 (68%, 97%) as compared to controls. Impairment in mitochondrial functional parameters, status of antioxidant enzymes, accumulation of oxidative damage markers, ROS generation, mitochondrial membrane potential and assay of mitochondrial complex I, II and IV with the altered expression of pro-apoptotic, anti-apoptotic proteins were observed in the corpus striatum of rats exposed to arsenic. Increased the content of arsenic (2.65-fold, 4-fold) in the corpus striatum of rats exposed to arsenic in a dose dependent manner was observed as compared to controls. In conclusion, our findings suggest that the postnatal period of brain is more vulnerable to arsenic and most of these changes were persisted 30 days after withdrawal of exposure of arsenic on PD90. This study also

has suggested a correlation between low dose of arsenic exposure and potential dopaminergic neurotoxicity in the corpus striatum of the brain.

Title: Prenatal infection affects the neuronal architecture and cognitive function in adult mice

Authors: ***W. LI**[1], Y.-C. CHANG[1], L.-H. LEE[4,5], L.-J. LEE[1,2,3];
[1]Grad. Inst. of Anat. and Cell Biol., [2]Inst. of Brain and Mind Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan; [4]Neurol. and Envrn. and Occup. Med., Natl. Taiwan Univ. Hosp., Taipei, Taiwan; [5]Div. of Envrn. Hlth. and Occup. Med., Natl. Hlth. Res. Inst., Mialoi, Taiwan

Abstract: Environmental factors such as prenatal infection are involved in the pathogenic processes of neurodevelopmental psychiatric disorders. In the present study, we administered a viral mimic, polyriboinosinic-polyribocytidilic acid (poly I:C, 20 mg/Kg, i.p.), to pregnant B6 mice at gestational day 9.5. Neonates born to these poly I:C-treated dams showed an increase of microglia in the hippocampus, indicating an activation of the immune system in the brains. Moreover, a significant increase in the number of dopamine-producing neurons in the ventral tegmental area (VTA) was observed in adult male poly I:C-offspring compared with age-matched saline-offspring. Poly I:C-offspring also exhibited hypolocomotor activity in a novel open-field arena but did not display signs of anxiety or depression in the elevated plus maze or the forced swim test, respectively. However, the short-term memory of the poly I:C-offspring was impaired in a novel object recognition task. Therefore, the dendritic architecture of granule cells in the dentate gyrus (DG) and pyramidal neurons in the medial prefrontal cortex (mPFC) were examined. The dendritic complexity was reduced in the DG granule cells of poly I:C-offspring and exhibited shorter dendritic length compared with saline-offspring. The density of

dendritic spines in the DG granule cells was also decreased in poly I:C-offspring. Furthermore, the dendritic complexity and spine density was reduced in the layer II/III mPFC pyramidal neurons of the poly I:C-offspring. Together, these data demonstrate impaired short-term memory and altered dendritic architecture in adult poly I:C-offspring, which validates the prenatal infection paradigm as a model for neurodevelopmental psychiatric disorders.

Title: Nicotine administration induces blood-brain barrier breakdown, brain edema formation and neuronal injuries. Exacerbation by cold environment

Authors: *S. SHARMA[1], J. V. LAFUENTE[2], A. NOZARI[3], A. SHARMA[4], Z. TIAN[5], D. F. MURESANU[6];
[1]Uppsala Univ., Uppsala, Sweden; [2]Neurosciences, Univ. of Basque Country, Bilbao, Spain; [3]Anesthesiol. & Critical Care Ctr., Massachusetts Gen. Hospital, Harvard Med. Sch., Boston, MA; [4]Surgical Sciences, Anesthesiol. & Intensive Care Med., Uppsala Univ. Hosp., Uppsala, Sweden; [5]Chem. & Biochem., Univ. of Arkansas, Fayetteville, AR; [6]Clin. Neurosciences, Univ. of Med. & Pharm., Cluj-Napoca, Romania

Abstract: Recent studies show that prenatal exposure of nicotine in small amounts leads to neuronal damages in several brain areas. However, exposure of nicotine to young adults causing brain dysfunction is still not well known. In this investigation we examined a low dose of

nicotine in young adult rats on brain dysfunction e.g., breakdown of the blood-brain barrier (BBB) permeability, brain edema formation and neuronal injuries. Since environmental factors i.e., heat or cold could also influence nicotine neurotoxicity, we examined effects of cold exposure on nicotine neurotoxicity using standard procedures. Young adults male Wistar rats (20 to 25 weeks of age) were exposed to Nicotine hydrochloride (9 mg/kg, s.c.) once daily for 1 week either at room temperature (21±1°C) or at cold environment (+8±1°C). On the 8th day, BBB permeability to Evans blue albumin and brain water content was examined. The neuronal damages were evaluated using Nissl or Haematoxylin & Eosin methods using standard histopathological procedures. Rats subjected to nicotine exposure at room temperature showed 64 % increase in Evans blue albumin extravasation as compared to saline treated rats under identical conditions. These nicotine treated rats also exhibited increase in brain water content by 0.6 to 0.9 % from the saline group. A significant increase in number of neuronal distortion and damages were seen in in the brain stem, cerebral cortex and cerebellum following nicotine exposure in rats as compared to saline treated group at room temperature. Interestingly, nicotine exospore in rats at cold environment further exacerbated the brain pathology in wide areas of the brain. Thus, the neuronal damages were intensively seen in hippocampus, striatum and thalamus apart from brain stem, cerebral cortex and cerebellum. The breakdown of the BBB to Evans blue was further increased by 80 to 120 % from the identically exposed animals to nicotine at room temperature. The brain edema formation as measured using brain water content was enhanced by 1.5 to 2 % in cod environment following nicotine exposure as compared those treated at room temperature. Taken together these results demonstrate that small doses of nicotine is able to induce profound neurotoxicity in young adult rats and this neurotoxicity is further exacerbated when identical nicotine exposure is made under cold environments. Further studies are in progress to find out the role of oxidative stress in causing nicotine induced neurotoxicity.

Title: Repulsive guidance molecule-a is involved in neuronal damage induced by Th17 cells in experimental autoimmune encephalomyelitis

Authors: *S. TANABE, T. YAMASHITA;
Dept. of Mol. Neurosci., Grad. Sch. of Med, Osaka Univ., Osaka, Japan

Abstract: Multiple sclerosis is a chronic autoimmune disease, characterized by various symptoms such as motor dysfunction and visual problem. In multiple sclerosis, immune cells such as T cells and monocytes infiltrate to central nervous system (CNS) and induce inflammation, resulting in demyelination and neurodegeneration. It has been reported that the pathogenesis of multiple sclerosis is attributed to acquirements of autoimmunity to CNS component such as myelin sheath. Moreover, earlier studies revealed that CD4+ helper T cells are known to play crucial roles for inducing inflammation in CNS. In particular, T helper type 17 cells (Th17 cell), CD4+ T cells characterized by producing interleukin 17 (IL-17), are recently identified as critical drivers of autoimmune diseases including multiple sclerosis. Repulsive guidance molecule-a (RGMa) is a glycosylphosphatidylinositol (GPI)-anchored membrane protein known to play a role in axonal growth repulsion. We previously reported RGMa is expressed in dendritic cells and involved in activation of T cells in experimental autoimmune encephalomyelitis (EAE), which is mouse model of multiple sclerosis. We injected RGMa neutralizing antibody to active EAE immunized with myelin oligodendrocyte glycoprotein (MOG35-55) and observed attenuation of EAE severity. However, we did not assess the possible role of RGMa in other immune cells than dendritic cells. Here, we demonstrate RGMa is involved in neurodegeneration in EAE. We found the high expression of RGMa in Th17 cells and RGMa depletion attenuated the severity of EAE induced by adoptive transfer of MOG specific Th17 cells. Moreover, RGMa depletion reduced axonal damage in inflammatory lesions without altering immune responses. In *in vitro* co-culture system, Th17 cells induced death of cortical neurons by a mechanism dependent on RGMa. Thus, RGMa is involved in Th17 cells-mediated neuronal damage.

Title: CB_1-dependent lack of social novelty preference in the sub-chronic PCP rat model of schizophrenia

Authors: *A. SEILLIER, A. GIUFFRIDA;
Pharmacol., UTHSCSA, SAN ANTONIO, TX

Abstract: We previously showed that social withdrawal in the PCP rat model of schizophrenia resulted from deficient endocannabinoid-induced activation of CB_1 receptors. To understand the underlying cognitive mechanisms of the social deficit in PCP-treated rats, we developed a behavioral test adapted from "the three-chamber social approach task" to assess sociability (i.e. social approach) and social novelty preference (which relies on social recognition). In contrast to the mouse experimental protocol, our rats were tested in an open arena virtually divided in quadrants. In the sociability phase, rats were allowed to explore the arena with two wire mesh cages at the opposite corners, one of which contained an unfamiliar rat, whereas the other one was left empty. As expected, control rats spent more time exploring the cage containing the unfamiliar rat, showing a clear preference for a "social" versus a "neutral" object. In the social novelty phase, a new rat was placed in the empty wire mesh cage, whereas the previously unfamiliar rat, now familiar, remained in the cage at the opposite corner. During this phase, rats spent more time exploring the "novel" rather than the "familiar" cage. In contrast, PCP-treated rats showed intact sociability, but lacked social novelty preference. To test whether the deficit in novelty discrimination was due to impaired social recognition or lack of novelty preference, we assessed the ability PCP-treated rats to discriminate between social (bedding from their home or a different cage) and non-social (new bedding or no bedding) olfactory cues contained in Petri dishes. Both saline- and PCP-treated animals were able to discriminate the social versus non-social cues. However, control animals showed a slight preference for the bedding from a different cage, whereas PCP-treated rats preferred the bedding from their home cage. Preliminary data indicate that the lack of social novelty preference in PCP animals is reversed by the CB_1 antagonist AM251, suggesting that increased activity at CB_1 receptors contributed to this behavioral deficit. In agreement with this hypothesis, the cannabinoid agonist CP55,940, which had no effect on sociability, dose-dependently suppressed the preference for social novelty in control animals. Taken together, these data suggest that PCP-treated rats have a deficit in social cognition resulting from a diminished interest for social novelty, possibly induced by increased stimulation of CB_1 receptors. This deficit, however, does not contribute to the social withdrawal observed in PCP-treated animals, as the latter is due to deficient, rather than increased, CB_1 stimulation.

Title: Assessment of chronic perampanel treatment on hyperactivity and hippocampal reactivity of GluA1 lacking mice

Authors: *M. MAKSIMOVIC[1], E. R. KORPI[1,2];
[1]Pharmacol., Inst. of Biomedicine, Helsinki, Finland; [2]Pharmacol., Yong Loo Lin Sch. of Medicine, Natl. Univ. Hlth. System, Neurobio. and Ageing Programme, Life Sci. Institute, Natl. Univ. of Singapore, and SINAPSE, Singapore Inst. for Neurotechnology, Singapore, Singapore

Abstract: Neurotransmitter glutamate mediates most of excitatory transmission and is involved in essential functions of the brain, but also plays a role in pathophysiological conditions. Glutamatergic signalling is therefore important therapeutic target, like in neuropsychiatric disorders. Gria1−/− mouse line with knocked-out Gria1 gene encoding for GluA1 subunit of ionotropic AMPA glutamate receptor display some behavioural features of schizoaffective disorder, for which they have been suggested as a putative model. The hyperactivity provoked by novelty in the Gria1−/− is the dominant behavioural feature of this mouse line. Here we have tested a novel antiepileptic drug, a non-competitive antagonist of AMPA receptors, perampanel, for its efficacy in attenuating hyperactivity of Gria1−/− mice. Four-week treatment with the perampanel at the dose of 60 mg/kg, supplemented in the diet, blocked novelty-induced locomotor hyperactivity of the Gria1−/− mice, while doses of 6 and 30 mg/kg were ineffective. We also sought to see if the blockade of AMPA receptors could reverse the strong induction of neuronal activity in the dorsal hippocampus of Gria1−/− mice, by monitoring the immediate early gene c-Fos protein expression as a marker of neuronal activity. Perampanel treatment (60 mg/kg) reduced the higher c-Fos expression of Gria1−/− mice in the dentate gyrus and normalized excessive c-Fos levels of Gria1−/− mice in the CA1 subfield to the levels of WT mice. In summary, abnormal glutamatergic transmission underlies at least partly the hyperactive phenotype of the Gria1−/− mouse model, which could be particularly exploited for *in vivo* screening of novel drugs that target glutamatergic transmission.

Title: Serotonin receptor 2B knockout mice present an antipsychotic-sensitive schizophrenic-like phenotype

Authors: *P. M. PITYCHOUTIS[1,2], J. ADRIEN[3], L. MAROTEAUX[2];
[1]Dept of Biol. & TREND, Univ. of Dayton, Dayton, OH; [2]INSERM UMR-S 839, Univ. Pierre et Marie Curie, Inst. du Fer à Moulin, Paris, France; [3]INSERM UMR-S 677, Neuropsychopharmacologie, Univ. Pierre et Marie Curie 06, Paris, France

Abstract: Impulsivity, very broadly defined as action without foresight, novelty-seeking and hyperlocomotion, shares common playground with numerous mental disorders, such as schizophrenia. In a recent study conducted in a Finish cohort, we reported that a population-specific serotonin 2B receptor (5-HT2BR) receptor stop-codon (i.e. HTR2B Q20*) predisposes to severe impulsivity. Moreover, the genetic ablation of the 5-HT2BR gene in mice (5-HT2B−/−) yielded a hyperlocomotor and novelty-seeker phenotype, characterized by enhanced impulsivity. In the same cohort, psychosis was numerically more prevalent in HTR2B Q*20 carriers, with early-onset schizophrenia being observed in this group. However, the extent to which 5-HT2BR is implicated in the neurobiology of schizophrenia has never been studied. Therefore, in the present study we investigated the effects of the genetic ablation of the 5-HT2BR, across a battery of schizophrenia-relevant behavioral paradigms and demonstrate herein that loss of function of 5-HT2BR confers a wide spectrum of schizophrenic-like behavioral and psychopharmacological phenotypes in mice. Adult male 5-HT2B-/- mice and their respective wild-type (WT) controls were used in the present study. Domains related to the positive, negative and cognitive symptom-clusters of schizophrenia were affected in 5-HT2B-/- mice that closely resemble the behavioral alterations observed in schizophrenic patients. In particular, genetic ablation of the 5-HT2BR induced deficits in sensorimotor gating, selective attention, and learning and memory processes. Moreover, 5-HT2B-/- mice presented with enhanced locomotor response to the psychostimulant properties of dizocilpine and amphetamine, as well as robust alterations in sleep architecture. At the neurochemical level, ablation of the 5-HT2BR induced a region-dependent decrease of dopamine (DA) concentrations in the dorsal striatum (dSTR) and glutamate content in the nucleus accumbens (NAC) accompanied by respective alterations in dopaminergic and glutamatergic receptors' expression. Importantly, most of these schizophrenic-like phenotypes and endophenotypes were rescued by chronic treatment with the typical antipsychotic haloperidol. In conclusion, the present study reveals that 5-HT2BR deficiency may induce a

panel of schizophrenic-like behavioral phenotypes accompanied by robust region-distinctive dopaminergic and glutamatergic neurochemical alterations. The latter implies an important role for 5-HT2BR in the harnessing of dopaminergic and glutamatergic activity.

Title: Cortex-specific disruption of p90 Ribosomal S6 kinase 2 augments 5HT2A signaling *in vivo*

Authors: ***H. ZHU**[1], R. T. STRACHAN[2], D. J. URBAN[2], M. S. FARRELL[3], A. HANAUER[4], B. L. ROTH[3];
[1]Dept. of Pharmacol., Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; [2]Duke Univ., Durham, NC; [3]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [4]Univ. of Strasbourg, Illkirch, France

Abstract: Coffin-Lowry syndrome (CLS) is an X-linked syndromic form of mental retardation characterized by various skeletal anomalies. It is caused by mutations of the p90 ribosomal s6 kinase 2 (RPS6KA3) gene that encodes for the growth factor-regulated serine/threonine kinase, ribosomal S6 kinase 2 (RSK2). In our previous study, we found that RSK2 protein interacted with the 5-HT2A serotonin receptor intracellular loop 3 and phosphorylated Ser-314 within that loop, which led to a tonic inhibition of 5HT2A receptor signaling *in vitro*. To test whether RSK2 inhibits 5-HT2A receptor signaling *in vivo* and whether the disruption of RSK2 leads to schizophrenia-like psychosis in CLS patients, we crossed a floxed RSK2 mouse with Emx1-Cre mice to selectively disrupt the RSK2 gene in cortical pyramidal neurons. Cortex-selective disruption of RSK2 gene augmented 5-HT2A receptor signaling, which was demonstrated by the significant increase of DOI-induced c-fos activation and head-twitching behavior. 5-HT2A receptor antagonists did not normalize the PCP-induced hyperlocomotion and disruption of prepulse inhibition, which indicated the decreased sensitivity of receptor to its antagonist. The augmentation of 5-HT2A receptor signaling was not due to the alteration of receptor expression,

which was normal in the cortex. In conclusion, we found that cortex-specific disruption of RSK2 augments 5-HT2A receptor signaling and decreases the antagonist 5-HT2A sensitivity without altering receptor expression. Thus, RSK2 modulates both agonist and antagonist properties of 5HT2A receptor *in vivo* and disruption of RSK2 leads to schizophrenia-like behaviors in animals.

Title: Prenatal kynurenine treatment in mice: Effects on placental and fetal brain kynurenines

Authors: *S. BEGGIATO[1], K. V. SATHYASAYKUMAR[1], F. NOTARANGELO[1], F. GIORGINI[2], P. J. MUCHOWSKI[3], R. SCHWARCZ[1];
[1]Psychiatry, Maryland Psychiatric Research, Univ. of Maryl, Baltimore, MD; [2]Dept. of Genet., Univ. of Leicester,, Leicester, United Kingdom; [3]Gladstone Inst. Neurol. Dis., San Francisco, CA

Abstract: Studies in animals and humans suggest a pathophysiologically significant association between elevated brain kynurenic acid (KYNA) levels and cognitive dysfunction in schizophrenia (SZ) (Schwarcz et al., Nat. Rev. Neurosci., 2012). The increase in KYNA in the disease may be secondary to a genetic disruption of kynurenine 3-monooxygenase (KMO), a pivotal kynurenine pathway (KP) enzyme with links to SZ endophenotypes (Wonodi et al., Arch. Gen. Psychiat., 2011). Prenatal exposure to kynurenine (the direct bioprecursor of KYNA) induces cognitive impairments reminiscent of SZ in adult rats (Pocivavsek et al., Psychopharmacology, 2014), suggesting a developmental dimension to the link between KYNA and SZ. To begin exploring the possible role of KMO in this scenario, we now exposed pregnant wild-type (WT= Kmo+/+), heterozygous (HET = Kmo+/-) (Giorgini et al., J. Biol. Chem., 2013) C57BL/6 mice to kynurenine (10 mg/day, given with chow) during the last week of gestation, i.e. from embryonic days (ED) 10/11 to ED17/18. The dams were euthanized on ED17/18, and

the levels of KYNA and 3-hydroxykynurenine (3-HK), the product of KMO, were determined in placenta and fetal brain of HET and KMO knockout (KO = Kmo-/-) mice (from HET parents). Compared to WT animals (from WT parents), basal levels of KYNA in both placenta and fetal brain tended to be higher in these HET and KO mice. In contrast, basal 3-HK levels in placenta and fetal brain were lower in both groups of mutant animals, reaching a significant reduction in the fetal KO brain ($p<0.05$ vs. WT). Preliminary data indicated that prenatal treatment with kynurenine caused a significantly larger increase in KYNA levels in the placenta and in the fetal brain of KO as compared to WT mice; a trend toward higher KYNA levels compared to WT mice was also observed in both tissues of HET animals. Conversely, 3-HK levels in placenta and fetal brain of kynurenine-treated HET and KO mice were lower than in the corresponding tissues of the WT animals (all $p<0.01$). Jointly, these results revealed that the ratio between KYNA and 3-HK, which are believed to have opposing functions in the brain, is greatly skewed towards KYNA in the fetal brain when KMO is compromised or eliminated. As qualitatively similar phenomena were observed in the placentas of the mutant mice, it remains unclear if the effects seen in the fetal brain of the mutants are tissue-autonomous or secondary to placental biochemistry. The present data therefore raise the possibility that KP activity in the placenta exerts an important influence on fetal brain development (Hsiao and Patterson, Dev. Neurobiol., 2012) and may thus contribute to the development of adult mental disorders including SZ.

Title: Examinations of conditioned taste aversion and episodic memory for schizophrenia-like rats

Authors: *A. C.-W. HUANG, F.-Y. WU, C.-W. WU;
Psychol, Fo Guang Univ., Yilan County, Taiwan

Abstract: The second author has an equal contribution to the first author. 1 **Abstract** Many cognitive dysfunctions occurred at schizophrenia patients. Of particular, deficits of explicit and implicit memory may be important symptoms for schizophrenia. However, the emerged issue remains unclear in the animal model. At the beginning of the experiment, methamphetamine (MAMPH) or its vehicle normal saline was intraperitoneally administrated once every other day to develop behavioral sensitization reflecting in hyperactivity served as the animal model of schizophrenia. Thus, all of rats were assigned into Saline and MAMPH groups. Later, all of rats were trained to freely drink a 0.1 % saccharin solution (conditioned stimulus, CS) to associate with 0.15 M lithium chloride (unconditioned stimulus, US) to form conditioned taste aversion learning (CTA); indicating one of implicit memory. Moreover, all rats encountered the procedure of E-maze task to acquire episodic memory; indicating one of explicit memory. The results showed that rats with MAMPH administrations induced hyperactivity to develop an animal model of schizophrenia. MAMPH-induced schizophrenia-like rats would impair implicit memory-conditioned taste aversion as well as explicit memory-episodic memory. The findings of the present study may provide a good animal model for treating schizophrenia. Further, how schizophrenia affects the explicit and implicit memory. The emerged issues should be discussed further. *Keywords:* Methamphetamine, schizophrenia, implicit memory, explicit memory, conditioned taste aversion, episodic memory 2

Title: Reverse translation animal preparations of hippocampal glutamatergic dysfunction in schizophrenia: GluN1, plasticity changes and genetic manipulations

Authors: *S. SOUTHCOTT[1], M. YANAGI[2], J. LISTER[3], C. TAMMINGA[4];
[1]Psychiatry, Univ. of Texas Southwestern Med. Ctr., Dallas, TX; [2]Kinki Univ. Sch. of Med., Osaka-Sayama, Japan; [3]Yale, New Haven, CT; [4]Psychiatry, UT Southwestern Med. Ctr., Dallas, TX

Abstract: The molecular, cellular and circuit mechanisms of schizophrenia (SZ) are unknown, hugely disadvantaging animal model research. Current research in this area comes largely from preparations based on risk genes and psychosis-relevant pharmacology, without reference to molecular targets. Nonetheless, animal models are necessary because of their dynamic and experimental characteristics. As tissue findings of SZ neurobiology advance, there is a greater opportunity for validating animal preparations. Neurobiological studies in serious brain diseases assess *in vivo* imaging outcomes and postmortem tissue pathology, among other biomarkers. Considerable clinical data suggest hippocampal involvement in schizophrenic psychosis, a body of knowledge to which our laboratory has contributed. We have verified the reported increase in *in vivo* hippocampal perfusion in the illness and demonstrated GluN1 reductions in dentate gyrus (DG) and increased synaptic plasticity markers in CA3 which could underlie hippocampal neuronal hyperactivity, including increased GluN2B, PSD95, and BDNF as well as increased spines on CA3 pyramidal apical dendrites, suggesting synaptic strengthening (Tamminga, et al., 2010; Stan et al., 2014: Li et al., 2014). This has allowed us to target these molecular changes, and also neuronal activity markers in CA3 in animals as molecular and cellular characteristics of SZ psychosis. We are developing animal preparations of SZ psychosis through reverse translation, directly mimicking the biology of the human condition in the mouse. To proceed, we crossed a POMC-Cre mouse line with a floxed P-GluN1 mouse to create a DG-specific knock down of GluN1 protein. These animals have reduced levels of GluN1 restricted to DG ($p<0.0001$). Behaviorally, these mice show decreased pre-pulse inhibition, reduced learning in the Morris Water Maze (MWM), increased freezing in a fear conditioning (FC) paradigm and an increased latency to respond in the passive avoidance (PA) paradigm. Although these animals generated a true behavioral phenotype, the tissue phenotype did not obtain; therefore, we drove the DG KO with PCP sub-chronically. Here, both the appropriate behavioral phenotype described above and the molecular outcomes derived from patient tissue including both the DG GluN1 reduction and the CA3 increased GluN2B ($p=0.035$). We have additional mouse lines on which to test animal preparations for psychosis-related findings, including the Disc1 transgenic mouse (Hikida, et al, 2007) and early environmental stressors. We base our assessment of psychosis animal model validity on the closeness of its fit with the biology of the human SZ psychosis condition.

Title: Structural basis of heteromeric comunication between 5-HT2A and mGlu2 receptors and its role in schizophrenia

Authors: *J. L. MORENO[1], P. MIRANDA-AZPIAZU[2], A. GARCIA-BEA[2], R. DIEZ-ALARCIA[2], A. M. GABILONDO[2], J. LOPEZ-GIMENEZ[3], G. MILLIGAN[4], J. MEANA[2], J. GONZALEZ-MAESO[1];

Abstract: 5-Hydroxytryptamine 2A (5-HT2A) and metabotropic glutamate 2 (mGlu2) receptors are G protein-coupled receptors (GPCRs) that have been linked to the pathophysiology of schizophrenia, as well as to the mechanism of action of atypical antipsychotic drugs (e.g., clozapine and risperidone), and the new class of potential antipsychotic drugs acting as agonists of mGlu2/3 receptors (e.g., LY379268 and LY404039). GPCRs have been thought to function as monomers. Nevertheless, extensive evidences corroborates the existence of GPCR homo- and hetero-dimers/oligomers that differentially alter receptor-G protein coupling preferences and consequently G protein-dependent signaling. We previously demonstrated that the Gq/11-coupled 5-HT2A receptor and the Gi/o-coupled mGlu2 receptor form a GPCR heteromeric complex through which serotonin and glutamate ligands modulate the pattern of G protein coupling in tissue culture and mammalian brain frontal cortex. Using flow cytometry-based FRET, our previous findings show that any two of the three residues (A6774.40, A6814.44, A6854,48) located at the intracellular end of the transmembrane domain 4 are necessary for the mGlu2 to be assembled as a GPCR heteromeric complex with the 5-HT2A receptor. Here we focused our attention on the ability of the mGlu2 receptor to crosstalk and activate Gq/11 protein-dependent signaling through the 5-HT2A-mGlu2 heteromeric receptor complex. By measuring elevations of intracelullar [Ca2+], we show that expression of 5-HT2A and mGlu2 as a GPCR heteromer is necessary to induce Gq/11 protein-dependent signaling by the mGlu2/3 receptor agonist LY379268. We also demonstrate that although co-expression of mGlu2 receptor together with a mutant 5-HT2A receptor defective in G protein activation abolishes LY379268-induced Gq/11 protein-dependent signaling, an mGlu2 receptor that couples to and activates G proteins is also required to encode this particular signaling outcome. In addition, we show that the signaling crosstalk between the components of the 5-HT2A-mGlu2 heteromeric receptor is dysregulated in postmortem frontal cortex of schizophrenic subjects. These findigns may help in the development of more specific and effective therapeutic antipsychotic drugs for the treatment of schizophrenia. Supported by R01MH084894

Title: Prenatal kynurenine exposure alters maturation of the conditioned fear response: Normalization with an α7nAChR partial agonist

Authors: *M. L. PERSHING[1], D. H. LINDQUIST[1], A. POCIVAVSEK[2], K. Y. TSENG[3], R. SCHWARCZ[2], J. P. BRUNO[1];
[1]Psychology, The Ohio State Univ., Columbus, OH; [2]Univ. of Maryland Sch. of Med., Baltimore, MD; [3]Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: Schizophrenia (SZ) is a neuropsychiatric disorder involving maturational alterations in brain circuitry. Symptoms emerge post-puberty and include core cognitive deficits that are ineffectively treated with current pharmacotherapies. Elevations in kynurenic acid (KYNA), an endogenous α7 nicotinic acetylcholine receptor (nAChR) and NMDAR antagonist, may underlie cognitive deficits in SZ. We have reported that elevating KYNA in developing rats alters cortical maturation and yields deficits in prefrontal cortex (PFC)-mediated tasks. Trace fear conditioning (TFC), in which a tone must be associated with a later occurring footshock, requires intact cholinergic/glutamatergic signaling and sustained firing of layer 2/3 PFC neurons. We predicted that rats sustaining elevated KYNA levels during fetal development [embryonic days (ED) 15-22] would exhibit altered cholinergic/glutamatergic gene expression and impaired TFC when tested as adults but not as juveniles; furthermore, that administration of SSR180711, an α7nAChR partial agonist, would ameliorate TFC deficits, given its ability to increase α7nAChR expression and glutamate release. Pregnant Wistar rats were fed a mash diet (ECON) or a diet containing L-kynurenine (the bioprecursor of KYNA; 100 mg/dam/day; EKYN) during the last prenatal week (ED15-22). Brain mRNA levels (α7nAChR and NMDAR subunits) and TFC - 10 pairings of a 15 sec tone and 1 sec footshock, separated by a 10 sec trace interval - were assessed on postnatal days (PD) 31-33 (juvenile rats) and PD65-80 (adult rats). A separate group of adult

EKYNs was tested on TFC following SSR180711 administration (1 mg/kg, i.p.). Brain KYNA was increased in EKYN fetuses (470%, forebrain) and adults (80%, PFC), relative to age-matched ECONs. Freezing behavior was assessed after TFC. Adult EKYNs, relative to ECONs, froze significantly less during the tone (58 ± 3% vs 72 ± 5%) and trace interval (57 ± 4% vs 69 ± 4%). In contrast, juvenile EKYNs demonstrated increased freezing during the tone (68 ± 6% vs 55 ± 5%) and trace interval (71 ± 7% vs 56 ± 6%) compared to ECONs. Preliminary data suggest that NR2B mRNA was increased in EKYNs at PD32 (+48%) and PD65 (+13%). Expression of α7nAChR mRNA was reduced (-11%) on PD65. SSR180711 administration restored conditioned freezing in PD65 EKYNs, to ECON levels, across the tone and trace interval. Taken together, these results, obtained in an animal model with face and construct validity, suggest that a sustained impairment of α7nAChR/NMDAR function may contribute to deficits in executive function in SZ, and support the proposition that α7nAChRs constitute promising targets for therapeutic intervention.

Title: Acute elevations of brain kynurenic acid induce working memory deficits: Relative contributions of α7 nicotinic and NMDA receptor activity

Authors: *D. PHENIS[1], S. A. VUNCK[1], R. SCHWARCZ[2], J. P. BRUNO[1];
[1]The Ohio State Univ., Columbus, OH; [2]Univ. Maryland Sch. of Med., Baltimore, MD

Abstract: Core cognitive deficits in attention and working memory are present in schizophrenia (SZ) but remain largely unresolved by current drug interventions. Patients with SZ have elevated kynurenic acid (KYNA) levels in the brain which may contribute to cognitive impairments through either negative allosteric modulation (NAM) of α7 nicotinic acetylcholine receptors (α7nAChR) or antagonism of N-methyl-D-aspartate receptors (NMDAR) at the glycineB site. Acute elevations of brain KYNA in animals also lead to cognitive deficits (e.g. contextual

learning, spatial working memory, attentional set-shifting). The present studies were designed to determine whether a) acute increases in KYNA in rats induce performance deficits in the operant delayed non-match-to-position (DNMTP) working memory (WM) task and b) using drugs selective for the two receptor populations, whether these deficits reflect antagonism at α7nAChRs or NMDARs. The DNMTP task is divided into three components sample, retention, and choice phases. The daily sessions consisted of 120 trials delays were 5, 10 & 15 sec. The test compounds administered to separate groups of rats were kynurenine (KYN the bioprecursor of KYNA), galantamine [GAL a positive allosteric modulator of α7nAChR], 4-chloro-kynurenine [4-Cl-KYN bioprecursor of 7-chlorokynurenic acid (7-Cl-KYNA), an antagonist of NMDAR/glycineB], and D-cycloserine (DSC an agonist at NMDAR/glycineB). Dose-response curves were generated for KYNA and 7-Cl-KYNA, and alleviation of deficits was attempted using co-administration of GAL or DSC. Acute elevation of KYNA via a KYN injection (100 mg/kg) produced delay-dependent deficits in DNMTP % choice accuracy (5 sec VEH 96% vs KYN 84% 10 sec VEH 85% vs KYN 72% 15 sec VEH 78% vs KYN 50%). Deficits resulting from elevated KYNA were fully reversed by GAL (3 mg/kg) (15 sec KYN 50% vs KYN+GAL 78%). Acute elevation of 7-Cl-KYNA, via its precursor 4-Cl-KYN (100 mg/kg), reduced DNMTP performance but independent of delay length (5 sec VEH 95% vs 4-Cl-KYN 48% 10 sec VEH 88% vs 4-Cl-KYN 41% 15 sec VEH 79% vs 4-Cl-KYN 36%). Deficits following an elevation in 7-Cl-KYNA were reversed by DSC (30 mg/kg) but were unaffected by GAL (15 sec GAL 36% vs DSC 78%). Our results support antagonism of α7nAChRs as opposed to NMDAR/glycineB inhibition as the mechanism underlying KYN-induced reductions in WM. The reversal of KYN-induced, delay-dependent deficits in performance of the WM task with GAL support continued focus on allosteric modulation of α7nAChRs as a target for cognition enhancement in SZ. Performance deficits following antagonism of the glycineB site do not resemble those seen following KYN in either profile or reversibility.

Title: Rats exposed to elevated brain levels of kynurenic acid during the prenatal period exhibit an enhanced vulnerability to working memory deficits as adults

Authors: *S. A. VUNCK[1], D. PHENIS[1], K. Y. TSENG[2], R. SCHWARCZ[3], J. P. BRUNO[1]; [1]The Ohio State Univ., Columbus, OH; [2]The Chicago Med. Sch. at Rosalind Franklin Univ. of Med. and Sci., Chicago, IL; [3]Maryland Psychiatric Res. Center, Univ. Maryland Sch. of Med., Baltimore, MD

Abstract: Schizophrenia (SZ) is a debilitating neuropsychiatric disorder arising from neurodevelopmental alterations in brain circuitry. These changes underlie core deficits in cognitive control that are predictive of outcome yet are poorly addressed with current pharmacotherapies. Kynurenic acid (KYNA) is a negative allosteric modulator at α7 nicotinic acetylcholine receptors (α7nAChR) and an antagonist at NMDA/ glycineB receptors. KYNA levels are elevated in the brains of patients with SZ, and increased KYNA levels produce cognitive deficits in animals. We previously reported that chronic perinatal (ED15-PD21) exposure to KYNA's bioprecursor kynurenine (KYN) elevates KYNA throughout development and adulthood, and leads to deficits in hippocampus- and prefrontal cortex-mediated cognitive tasks. The current study used the operant delayed non-match to position (DNMTP) task to determine if adult rats exposed prenatally to elevated KYN exhibit overt working memory (WM) deficits or a vulnerability that can be exposed through pharmacological challenges. Pregnant Wistar dams received KYN (100 mg/day in mash) during the last prenatal week (ED15-22) (EKYNs) or regular mash (ECONs). KYNA levels were determined on ED21 and PD56. Cognition was assessed at PD56-80, using the DNMTP task (delays 5, 10 & 15 sec). Animals were challenged acutely with KYN or 4-chlorokynurenine (4-Cl-KYN; the bioprecursor of the selective NMDAR antagonist 7-Cl-KYNA) and tested for alleviation of deficits following co-administration of the positive α7nAChR modulator galantamine (GAL 3 mg/kg; i.p.). EKYN rats had elevated brain KYNA levels compared to ECONs [ED21 (+470%) and PD56 (+80%)]. Adult EKYNs and ECONs acquired the task at similar rates. However, EKYNs, but not ECONS, exhibited enhanced vulnerability to WM deficits following acute challenge with drugs/doses that further compromised choice accuracy (%) by antagonizing either the α7nAChR (KYN 25 mg/kg; ECON 77% vs EKYN 43% at 15 sec delay) or the NMDAR (4-Cl-KYN 25 mg/kg; ECON 65% vs EKYN 39% at 15 sec delay). Deficits from acute drug challenges of KYN, but not 4-Cl-KYN, were fully reversed by co-administration of GAL (ECON 90% vs EKYN 89% at 15 sec delay). Our results demonstrate that acquisition of an operant WM task in adulthood is not impaired by embryonic exposure to elevated KYNA. However, this prenatal treatment appears to cause maturational changes in circuits underlying WM, resulting in an enhanced vulnerability to pharmacological challenges that antagonize glutamatergic or cholinergic activity. This work supports further research using prenatal KYNA elevation to study cognitive deficits and vulnerabilities related to SZ.

Title: D-cycloserine affects pyridoxal-5-phosphate complex causing a lowering of kynurenic acid formation

Authors: *H. BARAN[1,2], B. KEPPLINGER[1,3];
[1]Karl Landsteiner Res. Inst. Mauer, Mauer-Amstetten, Austria; [2]*Neurological Inst. Med. Univ. Vienna, Vienna, Austria; [3]SeneCura Neurorehabilitation Ctr., Kittsee, Austria

Abstract: The anti-mycobacterial drug, D-cycloserine has the capacity to lower significantly the kynurenic acid (KYNA) synthesis in mammalian and human brains in an *in vitro* study (H. Baran and B. Kepplinger, Eur. Neuropsychopharmacol., 2014). D-Cycloserine, a partial agonist at the glycine modulatory site of the glutamatergic NMDA receptor improves cognitive function and exerts anticonvulsive activities. The present study further evaluated the inhibitory action of D-cycloserine on kynurenic acid synthesis. The activity of enzymes synthesizing KYNA, kynurenine aminotransferases I, II and III (KAT I, KAT II and KAT III) in human brain in the presence of D-cycloserine or in the presence of drug with nootropic/neurotropic effects Citicholine (Startonyl) in an *in vitro* study was measured. Parallel to KYNA measurement we searched the alteration of pyridoxal-5-phosphate complex content in the incubation medium. Human post mortem samples of frontal cortex from the Neurological Institute of Medical University Vienna (N = 5) were used. The study was carried out according to the ethical regulations of Austria. Determining KATs activities as previously described we found that D-cycloserine but not Startonyl lowered dose-dependently and significantly KATs activities, respectively KYNA level, of human brain homogenate. Furthermore, D-cycloserine but not Startonyl lowered dose-dependently and significantly the content of pyridoxal-5-phosphate complex in the incubation medium. Interestingly, lowering of pyridoxal-5-phosphate complex was accompanied by formation of new peak probably pyridoxal or its derivate. No formation of such peak could be seen in the presence of Startonyl. Higher doses of D-cycloserine (>ca 800 μM) blocked KATs activities and lowered the levels of pyridoxal-5-phosphate complex most completely. Revealed data demonstrate that D-Cycloserine but not Startonyl is able to affect KYNA synthesis and this due to lowering of pyridoxal-5-phosphate complex which is required for transamination. Lowering of KYNA content due to D-cycloserine action might be involved in

the improvement of symptoms like dementia, cognition and/or delusion in Schizophrenia, Alzheimer's, HIV-1 infected patients or Parkinson's patients. Notable, metabolites formed due to degradation of pyridoxal-5-phosphate complex could be toxic and in part be responsible for the side effects of D-cycloserine. The nootropic/neurotropic effects of Startonyl are not involve in alteration of KYNA formation in the brain, at least *in vitro* study. Startonyl was provided by Chiesi Farmaceutici S.p.A., Italy. Supported by NFB - Life Science, Austria, LS 10-032. *former facility

Title: Role of 5-HT1A and 5-HT7 receptors in the sub-chronic PCP-induced executive function deficit in C57BL/6 mice

Authors: *L. RAJAGOPAL[1], B. W. MASSEY[1], E. E. MICHAEL[1], Y. OYAMADA[1,2], M. MIYAUCHI[1,2], M. HUANG[1], H. Y. MELTZER[1];
[1]Psychiatry and Behavioral Sci., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL;
[2]Dainippon Sumitomo Pharma Co., Ltd., Osaka, Japan

Abstract: Introduction: The atypical antipsychotic drug (APD), lurasidone, a dopamine D2, serotonin (5-HT)2A, and 5-HT7 receptor antagonist, and tandospirone, a 5-HT1A partial agonist, has been reported to improve some domains of cognitive function in schizophrenia, including executive functioning, a predominantly cortical function. Executive functioning can be studied in an operant reversal learning (ORL) task in rodents. To approximate the hypoglutamatergic deficit which may contribute to the cognitive deficit in schizophrenia, the N-methyl-d-aspartate antagonist, phencyclidine (PCP) was administered sub-chronically to C57BL/6 mice followed by withdrawal. Sub-chronic PCP has been shown to impair performance in reversal learning deficits in rats. However, there has been a paucity of studies in this model in mice, despite the growing use of mouse as a subject in genetic and molecular studies of schizophrenia. Hence, in the present study, we aimed to evaluate the effects of sub-chronic PCP treatment (10 mg/kg) in

C57BL/6 mice and to investigate the role of 5-HT1A and 5-HT7 receptors in this model. Materials and methods: Two cohorts of C57BL/6 male mice and one cohort of 5-HT7 knock-out (KO) (-/-) mice were used as subjects. Both C57BL/6 and 5-HT7KO(-/-) mice were trained to perform ORL, following which, C57BL/6 mice received sub-chronic PCP (10 mg/kg) or vehicle intraperitoneally (i.p.) twice daily for 7 days, followed by 7-day washout. In experiment 1, PCP treated C57BL/6 mice received acute lurasidone (1 or 3 mg/kg; i.p.), tandospirone (5 mg/kg; i.p.), or co-administration of the 5-HT1A antagonist, WAY100635 (0.6 mg/kg) + lurasidone (3 mg/kg; i.p.). In experiment 2, PCP treated mice received the 5-HT7 antagonist, SB269970 (0.5 or 4 mg/kg), and the 5-HT7KO(-/-) received saline. Results: Sub-chronic PCP significantly impaired the percentage correct responding, total incorrect trials, and total incorrect response in the reversal phase performance ($P<0.05$), with no effect in the initial phase. Parenteral administration of acute lurasidone 3 mg/kg, but not 1 mg/kg, tandospirone 5 mg/kg, or SB269970 4 mg/kg, but not 0.5 mg/kg reversed the PCP-induced deficit in ORL in C57BL/6 mice. Co-administration of the 5-HT1A antagonist, WAY100635, blocked the ability of lurasidone to restore ORL. 5-HT7 receptor knock-out mice showed no deficit in ORL, and performed similarly to vehicle controls. Conclusion: These results indicate that 5-HT1A partial agonism and 5-HT7 antagonism may restore ORL in sub-chronic PCP-treated mice, similar to results we and others have reported for declarative memory, a temporal lobe measure.

Title: Acute phencyclidine-induced increase in locomotor activity, cognitive deficit and cortical and striatal glutamate and serotonin efflux is suppressed in 5-HT7 knockout mice

Authors: *M. HUANG, L. RAJAGOPAL, S. KWON, E. E. MICHAEL, H. Y. MELTZER; Psychiatry and Behavior Sci., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Background: Phencyclidine (PCP), a N-methyl-D-aspartate receptor (NMDAR) non-competitive antagonist, is the basis for a widely investigated model of cognitive impairment and psychosis in schizophrenia. There is extensive preclinical evidence supporting 5-HT_7 receptor antagonism as a promising mechanism for the treatment of cognitive deficits in schizophrenia as well as depression. The selective 5-HT_7 receptor antagonist SB-269970, as well as the atypical antipsychotic drugs (APDs), lurasidone and amisulpride, which along with other pharmacologic properties, are also potent 5-HT_7 receptor antagonists, have been found to improve the cognitive deficit induced by sub-chronic administration of PCP in rodents. The purpose of this study was to examine the effect of 5-HT_7 receptor blockade on acute PCP-induced hyperlocomotion, cognitive deficit (novel object recognition test, NOR) and efflux of monoamines and amino acids in mouse cortex and dorsal striatum (dSTR). **Method:** The effects of SB-269970 and PCP on locomotor activity, NOR deficit and the efflux of multiple neurotransmitters were studied in medial prefrontal cortex (mPFC) and dSTR by microdialysis following pretreatment in C57Bl/6 wild type (WT) and 5-HT_7 receptor constitutive knockout mice. The selective 5-HT_7 antagonist, JNJ18038683 to acutely reverse the deficit NOR produced by subchronic PCP treatment in WT mice was also studied. **Results:** Acute PCP (10 mg/kg, ip) induced hyperlocomotor activity, NOR deficit, and increased dopamine (DA), serotonin (5-HT), norepinephrine (NE), glutamate (Glu) and acetylcholine (ACh) in the mPFC and dSTR of wild type mice. The effects of PCP on locomotor activity and 5-HT and Glu, but not DA, NE or ACh, efflux, were suppressed in both regions of 5-HT_7 receptor knockout mice or after systemic pre-treatment with SB 269970 (3.0 mg/kg) in WT mice. JNJ18038683 acutely reversed the effect of subchronic PCP on NOR. C**onclusion:** These findings suggest that 5-HT_7 receptor blockade is an important target for improving cognitive impairment and possibly reducing psychotic symptoms. 5-HT_7R blockade can be incorporated into multi-receptor blocking agents, e.g. lurasidone and amisulpride, or added on, e.g. JNJ18038683. The reduced locomotor activity and NOR deficit induced by PCP after 5-HT_7R blockade or in 5-HT_7 receptor knockout mice, may be due to suppression of glutamatergic or serotonergic neurotransmission, or both.

Title: Effects of phencyclidine in social groups of rats: Homecage monitoring of rodent behaviour

Authors: *R. R. BRETT[1], B. ALLISON[2], J. D. ARMSTRONG[3,2], J. A. PRATT[1];
[1]Strathclyde Inst. of Pharm. and Biomed. Sci., Univ. of Strathclyde, Glasgow, United Kingdom; [2]Actual Analytics, Edinburgh, United Kingdom; [3]Sch. of Informatics, Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Testing the effects of manipulations of animals on behaviour in the homecage in established social groups is limited by the difficulty of automatically recognising and monitoring individual animals and depends on time-consuming manual scoring. Using a prototype system which pairs high-quality video recording under infrared lighting with synchronised reads from a radio-frequency identification (RFID) baseplate using a grid of antennae reading at approximately 2Hz, we recorded group-housed animals continuously in their homecage. From location data, we derived each subject's position for each frame of video, giving rise to measures of locomotion and relative position between the animals. 18 male Sprague-Dawley rats (10-12 wks) housed in groups of 3 were implanted with RFID transponders. After habituation to the cage, environment and ip injection, rats were monitored for 72 hrs following an initial saline injection 15 min before lights out. At 24 hrs, one rat per cage received 5 mgkg-1 phencyclidine (PCP) ip and the others saline; at 48 hrs all rats received 5 mgkg-1 PCP. PCP administered to all animals induced a modest increase in locomotor activity over the first 2 hrs (mean distance moved/5 min after saline 14.9 ± 0.6 m, after PCP 16.8 ± 0.6 m, $p=0.05$) and a small but highly significant ($p<0.00001$) decrease in mean separation between cagemates. In the mixed treatment condition, we inferred which animal had received PCP, using a Wald test on a logistic regression with predictors for distance, separation and occupancy of centre zones. Decreased distance moved was modestly predictive ($p=0.078$); centre cage occupancy was highly predictive ($p<0.00001$). In this condition, acute PCP (15-45 min after injection, 1st 30 mins of dark period) significantly altered behaviour; by contrast with saline-treated rats, grooming and resting was virtually absent (resting: saline 685s/30min ± 184s; PCP 10s/30min ± 6s; grooming: saline 488s/30min ± 137s; PCP 19s/30min ± 9s), and treated rats showed head-weaving (76s/30min ± 15s) and rotation behaviour (41s/30min ± 13s). Interestingly, in established social groups of this age, little social behaviour was manifest at this time. We have demonstrated the feasibility of monitoring social groups of animals in the homecage over several days, with automatic scoring of locomotor and derived behaviours and manually scoring of social interactions of individual

animals. Work is ongoing to develop algorithms for automatic scoring of social behaviours to provide a platform for investigation of preclinical models of social deficit relevant to schizophrenia and autism research.

Title: Glutamate stimulates astrocyte release of ATP: A potential mechanism for riluzole's antidepressant action

Authors: *T. YAMANASHI[1], M. KUSUNOSE[1], T. YAMAUCHI[1], K. T. OTA[2], M. IWATA[1], R. S. DUMAN[2], K. KANEKO[1];
[1]Neurophychiatry, Tottori Univ., Tottori, Japan; [2]Mol. Psychiatry, Yale Univ., New Haven, CT

Abstract: Stress decreases neurogenesis and synaptogenesis in the adult hippocampus, leading to depressive-like behavior; however the mechanism by which stress causes neuronal damage is unknown. We previously demonstrated that stress increases ATP in the hippocampus, which stimulates the release of interleukin-1β (IL-1β) and causes decreased neurogenesis and depressive behavior. Those changes are ameliorated by the purinergic P2X7 receptor (P2X7R) antagonist (A-804598), indicating that ATP is critical for stress-induced depression. Here, we investigated the source of ATP induced by stress. Glutamate, an excitatory neurotransmitter, is another molecule that we have previously confirmed to be increased by stress. The released glutamate is taken up by the surrounding astrocytes and transformed into glutamine to maintain homeostasis of the synapse. Thus, we hypothesized that stress increases glutamate that is sensed by astrocytes, which in turn release ATP as a gliotransmitter. To test this hypothesis, we used rat astrocyte primary cell culture to examine ATP release. We found that glutamate (2 to 10 μM) releases ATP in astrocyte cell culture; thus the excess glutamate is a potential stimulus for stress-induced changes in ATP and inflammatory responses in the brain. We next investigated whether inhibition of excess glutamate can ameliorate the stress response induced by immobilization stress. Cortisol is a well-known stress marker, and we first confirmed that P2X7R antagonist (A-804598) suppresses the increase of cortisol, indicating that ATP regulates the increase of cortisol. Cortisol is easy to measure by peripheral blood, so we employed it as an indicator of stress reaction. Riluzole is a drug used for the treatment of amyotrophic lateral sclerosis, and it is thought to prevent glutamate release from presynaptic terminals and stimulate glutamate uptake in the synapse. We thus employed riluzole to reduce glutamate and then measured cortisol levels.

Riluzole was administered intraperitoneally one hour prior to 40 minutes of immobilization stress. The concentration of cortisol in serum was measured by ELISA. Riluzole decreased the increase of cortisol caused by immobilization stress. Together, the results support the hypothesis that stress increases glutamate, which is sensed by astrocytes and induces ATP release, which in turn induces pro-inflammatory responses, including up-regulation of cortisol. Riluzole is thought to be a potential drug for depression, and these mechanisms may contribute to its antidepressant effects.

Title: Pregnenolone sulfate normalizes schizophrenia-like behaviors in dopamine transporter knockout mice through AKT/GSK3β signaling via the NMDA pathway

Authors: Y. SZE, P. WONG, C. CHANG, *X. ZHANG;
Duke-NUS GMS Singapore, Singapore, Singapore

Abstract: Schizophrenia is a complex disorder with multiple pathophysiologies. Apart from anti-psychotics, there have been recent advances in the treatment of schizophrenia with alternative pharmacological agents such as neurosteroids. Pregnenolone sulfate (PregS), an endogenous neurosteroid in the central nervous system, is a positive allosteric modulator of the NMDA receptor and plays a role in the modulation of learning and memory. It was found that acute treatment of 80 mg/kg PregS could rescue hyperactivity, stereotypic activity and pre-pulse inhibition deficits in dopamine transporter knockout (DAT KO) mice, an established mouse model of schizophrenia. Additionally, ten day 40 mg/kg PregS treatment also rescued the cognitive deficits of DAT KO mice in the novel object recognition test and social transmission of

food preferences test. To elucidate the pathway in which PregS exerts its effects on, wild type (WT) mice were treated with 0.1 mg/kg MK-801, a known NMDA receptor antagonist. Acute PregS treatment (80 mg/kg) was found to completely abrogate MK-801-induced hyperactivity and pre-pulse inhibition deficits in WT mice, which suggests that the efficacy of PregS relies on NMDA receptor signaling. Since it is known that schizophrenic patients have impaired AKT/GSK3β signaling and that DAT KO mice have decreased GSK3β phosphorylation, we further investigated the possible involvement of the NMDA-mediated AKT/GSK3β signaling pathway in the action of PregS. WT and DAT KO mice were treated with 80 mg/kg PregS for 15, 30, and 60 min, and the phosphorylation levels of AKT and GSK3β in the striatum were measured by Western blotting. An increase in AKT and GSK3β phosphorylation levels, persistent for up to 60 min after drug administration, was observed in PregS-treated DAT KO mice. Moreover, long-term treatment with 40 mg/kg PregS also increased expression levels of NR1 subunit of the NMDA receptor in the hippocampus of DAT KO mice. Thus, it is likely that PregS rescues behavioral anomalies of DAT KO mice by directly exerting its effect through the NMDA receptor-mediated, AKT/GSK3β signaling pathway, and is therefore another potential alternative therapy in the treatment of schizophrenia.

Title: Behavioral and electrophysiological abnormalities in mice deficient in kynurenine 3-monooxygenase; relevance to schizophrenia

Authors: *L. SCHWIELER[1], A. POCIVAVSEK[3], X. LIU[1], F. GIORGINI[4], P. J. MUCHOWSKI[5], G. ENGBERG[2], P. SHEPARD[3], S. ERHARDT[1], R. SCHWARCZ[3]; [2]Dept of Physiol. & Pharmacol., [1]Karolinska Inst., Stockholm, Sweden; [3]Maryland Psychiatric

Res. Ctr., Univ. of Maryland Sch. of Med., Baltimore, MD; [4]Dept. of Genet., Univ. of Leicester, Leicester, United Kingdom; [5]Neurolog. Dis., Gladstone Inst., San Fransisco, CA

Abstract: Dysregulation of the kynurenine pathway of tryptophan degradation has been implicated in the pathophysiology of schizophrenia and depression. Kynurenine 3-monooxygenase (KMO) is a key metabolic and regulatory enzyme in a pathway that includes several neuroactive metabolites including kynurenic acid (KYNA), an endogenous antagonist of α7 nicotinic acetylcholine and NMDA receptors (Sathyasaikumar et al., Schizophr. Bull., 2011). KMO activity is reduced in the brains of individuals with schizophrenia, and a polymorphism in the KMO gene has been linked to cognitive endophenotypes in the disorder (Wonodi et al., Arch. Gen. Psych., 2011). The decrease in cerebral KMO activity in schizophrenia is paralleled by increased brain levels of KYNA. Elevated KYNA levels are associated with behavioral deficits in rodents and may contribute to cognitive dysfunction. Mice (FVB/N background) with a targeted deletion in the KMO gene were recently generated in our laboratories (Giorgini et al., JBC, 2013). Homozygous (Kmo-/-) animals show chronically elevated brain KYNA levels comparable to those observed in post-mortem tissue from patients with schizophrenia. In the present study, we assessed and compared matched wild-type (WT), heterozygous (Kmo+/-), and Kmo-/-mice in 3 behavioral paradigms and measured the electrophysiological responses of dopaminergic neurons in the ventral tegmental area (VTA). Kmo+/- and Kmo-/- mice displayed deficits in a passive avoidance task including a significant reduction in avoidance latency during the retention trial (WT: 73 ± 9 sec; Kmo+/-: 43 ± 9 sec; Kmo-/-: 33 ± 9 sec; $P<0.05$). Kmo-/- mice also spent significantly more time in the closed versus the open arm of an elevated plus maze (WT: 13.75 ± 5.81 %, Kmo-/-: 4.33 ± 1.98 %, $P < 0.05$). Although Kmo+/- mice did not differ from WT mice in the elevated plus maze, they took longer to acclimate to an open field and showed an increase in rearing after an amphetamine challenge (2 mg/kg, i.p.). Extracellular single unit recordings obtained from anesthetized mice revealed an increase in the spontaneous firing rate of putative VTA dopamine neurons in Kmo+/- (5.6 ± 1.1 Hz) and Kmo-/- mice (5.6 ± 1.0 Hz) relative to WT mice (3.0 ± 0.4 Hz). These results indicate that reduction or elimination of KMO in mice is associated with deficits in contextual memory and an increase in anxiety accompanied by elevated activity in the mesolimbic dopamine system. Collectively, these findings provide new insights regarding the domains of psychopathology likely to be altered as a consequence of a dysregulated kynurenine pathway.

Title: Positive allosteric modulators (PAMs) of the alpha7 nicotinic receptor potentiate the mesolimbic regulation of prefrontal glutamate release: Differential effects of Type I and Type II PAMs

Authors: *D. M. BORTZ[1], J. D. MIKKELSEN[3], J. P. BRUNO[2];
[2]Psychology and Neurosci., [1]The Ohio State Univ., Columbus, OH; [3]3Neurobiology Res. Unit, Univ. Hosp. Rigshospitalet, Copenhagen, Denmark

Abstract: Research on cognition-enhancers has focused on drugs that act as agonists at the alpha7 nicotinic acetylcholine receptor (α7nAChR). More recently, effects of positive allosteric modulators (PAMs) of the α7nAChR have been investigated. PAMs are considered to better preserve cholinergic transmission because, unlike direct agonists, PAM are only effective when endogenous ACh/choline are present in concentrations able to activate the α7nAChR . NMDA stimulation of the nucleus accumbens shell (NACsh) in rats produces dose-dependent increases in PFC glutamate release that is mediated by increased activity at the α7nAChR, and this cortical nicotinic transmission is considered reduced in patients with schizophrenia (SZ). Because stimulation of the NACsh evokes the release of both ACh and glutamate, as well as promotes performance in a sustained attention task, we tested the hypothesis that PAMs would potentiate PFC glutamate release, but the magnitude of this potentiation would depend upon the dose of NMDA. We also tested compounds that are different in their ability to reduce α7nAChR desensitization (type II) or not (type I). Adult male Wistar rats were implanted with infusion cannulae into NACsh and a glutamate-sensitive biosensor in the ipsilateral mPFC. Rats received either vehicle (5% DMSO/8% solutal/saline), AVL3288 (type I), or PNU120596 (type II) for 3 consecutive test days. On a test day, rats were infused with NMDA at one concentration (vehicle, 0.05, or 0.30 µg/0.5 µL) and extracellular levels of glutamate were measured. Vehicle injections into NACsh did not evoke glutamate release and neither PAM affected this. Type I PAMs: The low dose of AVL (1 mg/kg) potentiated, relative to vehicle, the glutamate release seen after both the low (0.05 µg; 33.4% increase) and high (0.30 µg; 68.3% increase) doses of NMDA. The high dose of AVL (3 mg/kg) enhanced (152%) the low dose of NMDA but had no effect on the higher dose. Type II PAM: the lower dose of PNU (3 mg/kg) failed to potentiate either dose of NMDA. The higher dose of PNU (9 mg/kg) amplified (154%), relative to vehicle conditions, the low dose of NMDA but had no effect on the higher dose of NMDA. These *in vivo* data demonstrate that

the effects of PAMs on glutamate release in PFC vary as a function of the activity of local α7nAChRs. They also suggest important differences in the potentiation by Type I and II PAMs, making further comparisons very important in order to determine the conditions in which Type I or II would be indicated as a strategy for cognition enhancement.

Title: Activation of nucleus accumbens stimulates the release of glutamate and dopamine in prefrontal cortex: Role of local nicotine receptors

Authors: *V. VALENTINI[1], D. M. BORTZ[2], V. PERRA[1], G. P. SERRA[1], G. DI CHIARA[1], J. P. BRUNO[2];
[1]Dept. of Biomed. Sci., Univ. of Cagliari, Cagliari, Italy; [2]Psychology and Neurosci., The Ohio State Univ., Columbus, OH

Abstract: Reciprocal interactions, within a distributed neural system containing the nucleus accumbens (NAC), basal forebrain (BF), medial dorsal thalamus, and prefrontal cortex (PFC) are dysregulated in several neuropsychiatric disorders (e.g. schizophrenia, ADD, drug addiction). Previously we demonstrated that stimulation of the NACshell with NMDA evoked ACh release in PFC. This release was cognitively beneficial, increasing resistance to distractors in a sustained attention task. We also demonstrated, using a biosensor with sec-to-sec resolution, that such NMDA activation elevates prefrontal glutamate levels. The goals of the present experiments were to determine if a) NAC-evoked glutamate levels were also observed using more traditional microdialysis methods; b) NAC activation also increased DA release in PFC; and c) nicotinic (and alpha7) receptor activation, from the enhanced cholinergic transmission, was necessary for elevations in glutamate and DA levels. Adult male Wistar rats were implanted with an infusion cannula into the shell region of the NAC and either a biosensor (MEA) or microdialysis probe in the ipsilateral mPFC. NMDA (0.05, 0.15, or 0.30 μg/0.5 μL) was infused and extracellular levels of glutamate and DA were measured. In a separate group of animals, the role of nicotinic (alpha7) receptors in this stimulated release was determined following local perfusions of mecamylamine (10.0 or 100.0 μM) or α-bungarotoxin (α-BGT; 1.0 μM). Intra-NAC infusions of

NMDA produced dose dependent increases in extracellular glutamate as measured with the MEA (2.01± 0.32, 3.34 ± 0.37, and 4.56 ± 0.42 μM above baseline for each of the 3 doses, respectively). The evoked glutamate signal was rapidly cleared to basal levels in ~30 sec. Microdialysis-based measures also revealed an NMDA (0.30 μg) stimulation of glutamate efflux in PFC (75% increase). These levels were not cleared to baseline until 20 min later. Intra-NAC NMDA also increased prefrontal DA levels in PFC (100% increase). Evoked levels of glutamate and DA efflux (microdialysis) were dependent upon activation of nicotinic receptors (alpha7) as mecamylamine (10 μM) or α-BGT blocked the increases. Using two different methods, the results confirm the mesolimbic stimulation of prefrontal glutamatergic transmission. The marked difference in clearance times suggest different pools of glutamate may be sampled by the MEA vs the dialysis probe. Activation of NAC also stimulates DA release in PFC. The evoked release of glutamate and DA appear to be secondary to the release of ACh and a subsequent activation of local nicotinic (alpha7) receptors on glutamate and DA terminals.

Title: MAPK signaling correlates with the antidepressant effects of ketamine

Authors: ***G. Z. RÉUS**[1], F. G VIEIRA[2], H. M ABELAIRA[2], M. MICHELS[3], M. B DOS SANTOS[2], D. D LEFFA[4], D. B TOMAZ[2], A. S CARLESSI[2], F. PETRONILHO[4], J. QUEVEDO[4];
[1]The Univ. of Texas Hlth. Sci. Ctr. At H, Houston, TX; [2]Univ. of Southern Santa Catarina, Criciuma, Brazil; [3]Univ. do Sul de Santa Catarina, Tubarao, Brazil; [4]The Univ. of Texas Med. Sch. at Houston, Houston, TX

Abstract: Studies have pointed to a relationship between MAPK kinase (MEK) signaling and the behavioral effects of antidepressant drugs. So, in the present study we examined the behavioral and molecular effects of ketamine, an antagonist of the N-methyl-Daspartate receptor (NMDA), which has been shown to have an antidepressant effect after the inhibition of MEK signaling in Wistar rats. Our results showed that acute administration of the MEK inhibitor PD184161, produced depressive-like behavior and stopped antidepressant-like effects of ketamine in the forced swimming test. The phosphorylation of extracellular signal-regulated kinase 1/2 (pERK 1/2) was decreased by PD184161 in the amygdala and nucleus accumbens, and the effects of ketamine on pERK 1/2 in the prefrontal cortex and hippocampus were inhibited by PD184161. The ERK 2 levels were decreased by PD184161 in the nucleus accumbens; and the effects of ketamine were blocked in this brain area. The p38 protein kinase (p38MAPK) and proBDNF were inhibited by PD184161, and the MEK inhibitor prevented the effects of ketamine in the nucleus accumbens. In addition, ketamine increased pro-BDNF levels in the hippocampus. In conclusion, our findings demonstrated that an acute blockade of MAPK signaling lead to depressive-like behavior and stopped the antidepressant response of ketamine, suggesting that the effects of ketamine could be mediated, at least in part, by the regulation of MAPK signaling in these specific brain areas.

[2]Pharmacol. & Neurosci., [1]Univ. North Texas Hlth. Sci. Ctr., FORT WORTH, TX; [3]Radiology, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: It continues to be a challenging task to a) identify animal models that can mimic and b) identify reliable *in vivo* methods for screening novel chemical entities for antipsychotic activity. Behavioral pharmacology studies have indicated that hallucinogenic drugs are capable of inducing psychotic episodes and cognitive deficits in humans that resemble some of the symptoms observed in schizophrenia patients. We previously reported on the ability of D2-like and D2 dopamine receptor selective compounds to attenuate the head twitch response (HTR) in DBA/2J mice. For these studies the HTR was induced by the administration of the hallucinogen 2,5-dimethoxy-4-methylamphetamine (DOI), which is an agonist of 5-HT2a and 5-HT2c serotonin receptors. In these studies, D3 dopamine receptor selective compounds of varying binding selectivity and intrinsic efficacy were evaluated for the ability to attenuate the DOI-dependent HTR. DOI (5 mg/kg i.p.) was administered 5, 60, 180 and 360 minutes after a test compound. The HTR was then monitored for 30 min after DOI administration. The effect of the *N*-phenylpiperazine WC 10, which is a D3 dopamine receptor antagonist that exhibits 40-fold binding selectivity for D3 vs. D2 dopamine receptors, was investigated. WC 10 administration produced a dose-dependent decrease in the DOI-induced HTR (IC50 = 3.7 mg/kg). WC 44, a full D3 receptor selective agonist, also inhibited the DOI-induced HTR (IC50 = 5.1 mg/kg). The effect of two partial agonists, WW-III-55 and LAX-4-136, (800- and 150-fold D3 vs. D2 binding selectivity, respectively), were also evaluated. Both compounds inhibited the DOI-induced HTR with similar potency but with different maximum efficacies. At a dose of 5 mg/kg WW-III-55 produced a HTR inhibition of 95%, while LAX-4-136 produced 50% inhibition. Finally, an assessment of the motor and coordination effects of our test compounds was performed using a rotarod test. None of the test compounds caused significant alterations in the motor activity and coordination. These results suggest that the D3 dopamine receptor selective phenylpiperazine analogs may represent a class of novel antipsychotic/antihallucinogenic drugs devoid of the motor side effects associated with the blockade of the D2 dopamine receptor subtype.

Title: In lithium treated mice β-catenin translocates to nuclei of thalamic neurons in TCF7L2-dependent manner

Authors: K. MISZTAL[1], N. BROZKO[1], A. NAGALSKI[1], L. SZEWCZYK[1], M. B. WISNIEWSKA[1,2], *J. KUZNICKI[1];

Abstract: Lithium has been used as a common mood stabilizer and the most effective treatment of bipolar disorder. Yet, its mechanism of action in the brain remains obscure. *In vitro* lithium stabilizes β-catenin level in the cytoplasm by inhibiting glycogen synthase kinase α/β (GSK3α/β), what leads to translocation of β-catenin to the nucleus and subsequent activation of LEF1/TCFs dependent gene transcription. Here we analyze how chronic lithium treatment affects brain β-catenin *in vivo*. C57BL/6 mice were given LiCl in drinking water for 7 days which resulted in the serum and brain levels of lithium known to be therapeutic for patients. By immunoblotting of cellular fractions we detected in the thalamus two-fold increase in nuclear β-catenin level. However, no changes in β-catenin were observed in nuclear fractions from the hippocampus and cortex. Using primary neuronal cultures we investigated the mechanism underlying activation of β-catenin in the thalamus. We hypothesized that TCF7L2, a transcription factor that is highly expressed in thalamic neurons, promotes its nuclear translocation. Using shRNA technology we found that TCF7L2 is indispensable for β-catenin nuclear localization in thalamic cells. Even when β-catenin accumulated upon proteasome inhibition, it stayed in the cytoplasm in TCF7L2 knocked-down cells. On the other hand, in cortical neurons where β-catenin is normally undetectable in the nucleus, LiCl treatment and the ectopic expression of TCF7L2 stabilized β-catenin and induced its transfer to nuclei. Thus, under experimental conditions, TCF7L2 transcription factor is indispensable for β-catenin nuclear localization in neurons. We earlier showed that TCF7L2 is highly expressed in the thalamus and acts as a regulator of several genes for voltage-gated ion channels and neurotransmitter receptors that are predominantly expressed in the thalamus. We conclude that *in vivo* lithium treatment can activate β-catenin signaling pathways specifically in the thalamus to maintain excitability of thalamic neurons.

Title: Does the bipolar disorder risk gene ankyrin 3 have a synaptic function?

Authors: *M. P. LEUSSIS[1], O. DURAK[2], M. SAITO[3], E. M. BERRY-SCOTT[4], F. CALDERON DE ALDA[2], L.-H. TSAI[2], T. L. PETRYSHEN[3];

Abstract: Ankyrin 3 (ANK3) is a significant risk gene for bipolar disorder identified in recent genome-wide association studies (GWAS). Investigating the disease-relevant function of ANK3 in brain may increase our understanding of the pathological processes implicated in bipolar disorder. We hypothesize that ankyrin G has a synaptic function in the mammalian brain, perhaps through scaffolding critical proteins to the post-synaptic membrane, similar to its role at the axon initial segment. This study sought to establish the presence of ankyrin G at the post-synaptic density. Further, it evaluated whether reductions in Ank3 expression could alter synapse-associated markers including PSD-95 and assessed dendritic spine density of neurons in mice with decreased Ank3 expression by either RNA interference or conventional transgenic knockout of Ank3. We also conducted Scholl analyses to evaluate differences in dendritic branching patterns following Ank3 reduction in mouse brain. We detected several isoforms of ankyrin G in postsynaptic fractions prepared from C57BL/6 mouse forebrain, indicating that ankyrin G is present at the synapse and may have several functions mediated by different isoforms. Decreased ankyrin G levels, by RNA interference or in Ank3+/- or -/- mice, were associated with altered dendritic synaptic spine density and expression of the synapse associated proteins PSD95 (postsynaptic) and synapsin (presynaptic) in the hippocampus. The changes in spine density were dependent on the location along the dendritic arbor, suggesting these changes may have different effects on neuronal activity. Further, alterations in synaptic proteins were largely normalized by chronic treatment with the mood stabilizer lithium. Mice with reduced Ank3 also exhibited a decrease in dendritic branching complexity in neurons of the granule cell layer of the hippocampal dentate gyrus. The presence of ankyrin G at the postsynaptic density implies a synaptic role for this protein in this dynamic neuronal structure. This is further supported by the changes observed in synaptic-associated proteins in mice with reduced Ank3 expression. The importance of these findings to bipolar disorder is yet to be determined, however reversal of the synaptic changes by chronic lithium treatment strongly supports such a potential role. Synaptic disturbances have been increasingly implicated in numerous psychiatric diseases

including bipolar disorder. Extending the known functions of ANK3 in the brain may help elucidate the neurobiological processes contributing to bipolar disorder.

Abstract: Bipolar disorder (BD) is a type of mental illness, specifically a mood disorder, characterized by episodes of an agitated mood known as mania, with or without distinct episodes of depression. There is an emerging body of data suggesting that BD is associated with the dysregulation of PKC signaling cascade as well as dynorphin opioid neuropeptide system. In this context, the present study aims to investigate the effect of mood stabilizers lithium (LiCl) and valproate (VPA) on the protein expression of phospho-PKC δ and mRNA expressions of the prodynorphin and substance P in the prefrontal cortex and hippocampus of mice undergoing treatment with the pro-maniac agent d-amphetamine (d-AMP). Mice were pretreated with LiCl

or VPA for consecutive five days, then were given d-AMP for ten days continuously. Locomotor activity was assessed directly 30 minutes or 24 hours after the last dose of d-AMP and expressions of phosho-PKC δ, prodynorphin, and substance P were examined in prefrontal cortex and hippocampus. LiCl or VPA significantly attenuated d-AMP-induced hyperlocomotion. Increases in protein expression of phospho-PKC δ, mRNA expression of substance P, while decreases in mRNA expression of prodynorphin induced by d-AMP was also attenuated by treatment of LiCl or VPA. To confirm the role of PKC δ, prodynorphin and substance P in d-AMP-induced mania model, we applied PKC δ knockout and prodynorphin knockout mice, or in combination with neurokinin 1 (substance P) receptor antagonist L-733060**.** D-AMP-induced hyperlocomotion was significantly attenuated in PKC δ knockout and prodynorphin knockout mice, as well as in combined treatment with L-733060. Taken together, the results of this study suggest that PKC δ, prodynorphin, or substance P gene plays a mechanistic role in the pathogenesis of BD. Title: Identification of possible bipolar 1 disorder related brain areas and lithium drug targets via iPSC derived neurons

Authors: *C. D. PERNIA, B. TOBE, A. CRAIN, A. WINQUIST, E. SNYDER;
The Sanford Burnham Med. Res. Inst., La Jolla, CA

Abstract: Bipolar 1 Disorder (BD1) is a psychiatric illness that affects 2.6% of the adult US population and is characterized by severe fluctuations between manic and depressive episodes. One of the foremost therapeutics for BD1 is lithium, which interestingly is not efficacious for

any other major psychiatric disorder. Lithium is a potent mood stabilizer but clinicians reluctantly prescribe it due to its serious medical side effects. How and where in the brain lithium acts to treat BD1 has yet to be elucidated. Psychiatric disorders have historically been difficult to study at the cellular and molecular level because of the lack of relevant animal behavioral models, and the ethical dilemma of studying human subjects. We hypothesized that studying the lithium response pathway in mixed neuronal cultures derived from human BD1 iPSCs would reveal novel insights into the mechanism of action of lithium in BD1, and by utilizing expression data of lithium sensitive targets indicate regions of the human brain involved with BD1. This study utilizes a comparative proteomic approach, sensitive to post-translational modifications, combined with human iPSC technologies for understanding the therapeutic mechanism of lithium on BD1. Our *in vitro* screen identified at least 15 proteins that are affected by lithium treatment in human BD1 derived neurons, which we cross-referenced with brain structure microarray data from the Allen Brain Atlas to identify areas of the brain where therapeutic action, and perhaps regions of lithium action and or BD1 pathology, could be most pertinent. Four brain areas were identified by their high expression levels of these proteins of interest, which we compared to the expression profiles of other brain areas postulated to be associated with BD1. Our findings substantiate previous human fMRI studies' assertions of specific brain areas being implicated in BD1, and identifies new areas that have yet to be systematically studied in BD1, and also provides a list of relevant drug targets for future research.

Title: mTOR hyperactivation and behavioral deficits in a Notch1 mouse model: Implication in major mental illness, especially schizophrenia

Authors: *H. JAARO-PELED[1], M. A. LANDEK-SALGADO[1], T. CASH-PADGETT[1], S. LEE[1], H. HIYAMA[1,2], K. NI[2], A. SAWA[1];

Abstract: The Notch pathway is one of the major cell-cell signaling pathways regulating cell differentiation and development. The role for Notch during brain development is fully established, but the significance of Notch signaling in adult brain remains elusive. In the present study, we initially came across the Notch cascade as a pathway robustly down-regulated in olfactory “neuronal” epithelium in schizophrenia patients compared with normal controls. Similar down-regulation was also observed in the prefrontal cortex of a mouse model of psychosis elicited by sub-chronic administration of phencyclidine. Based on these foundations, we have studied Notch1 haploinsufficient mice with emphasis on prefrontal cortex-dependent behaviors. We found that although Notch1 males behaved normally in the sociability phase of the three-chamber social interaction test, they did not show a preference towards a novel mouse in the social novelty phase of the test. Since the Mechanistic target of rapamycin (mTOR) pathway has been shown to be involved in perseverative behavior in autism mouse models, we assayed mTOR activity in the prefrontal cortex of the Notch1 mice and detected hyperactivation. Hence we treated the mice with the mTOR complex 1 inhibitor rapamycin during the three habituation days to the three-chamber apparatus. This treatment rescued the social novelty deficit. We are currently testing whether antipsychotics, which in general are not very efficient against negative and cognitive symptoms of schizophrenia, can also rescue this behavior. Interestingly, females Notch1 mice seem to behave normally in the social novelty test. Thus we are currently also assessing the mTOR pathway in female Notch1 mice. To conclude, the ability to rescue the social behavior by short treatment in adulthood suggests that the impaired social behavior is dependent on the real-time function of mTOR downstream of Notch1 and not on the developmental roles of Notch1.

Title: Subchronic pharmacologic nmda receptor antagonism with MK801 activates Akt signaling pathways

Authors: S. TAKAGI[1,2], D. T. BALU[1], *J. T. COYLE[1];
[1]McLean Hosp., Belmont, MA; [2]tokyo medical and dental university, Tokyo, Japan

Abstract: NMDA receptor (NMDAR) hypofunction is a powerful hypothesis for the pathophysiology of schizophrenia, because in part, NMDAR antagonists like phencyclidine and MK801 cause symptoms in healthy subjects that are similar to schizophrenia. Therefore, NMDAR antagonists have been used as a tool to induce NMDAR hypofunction in animals as a pharmacologic model of schizophrenia. Our laboratory has previously generated serine racemase-null mutant (SR-/-) mice, which display constitutive NMDAR hypofunction due to the lack of the NMDAR co-agonist, D-serine. SR-/- mice have deficits in multiple pathways, including V-akt murine thymoma viral oncogene (Akt) signaling and glycogen synthase 3 kinase (GS3K), which parallel what is observed in schizophrenia. Although some pharmacological NMDAR hypofunction models utilize sub-chronic NMDAR antagonist administration (5-7 days), our SR-/- mice have life-long NMDAR hypofunction. Thus, we analyzed intracellular signaling pathways in MK801 sub-chronically (0.15 mg/kg; o.d; 5 days) treated adult wild-type mice that are reduced in SR-/- mice and schizophrenia. We found that in contrast to SR-/- mice, the phosphorylation (activated) states of Akt1, GS3K, and mammalian target of rapamycin (mTOR) were increased in MK801 treated mice. Furthermore, there is a notable age-dependent change in the behavioral reaction of people to NMDAR antagonists. We therefore administered the same dosing regimen of MK801 to juvenile mice (3-4 weeks old) and compared them to juvenile SR-/- mice. Our findings demonstrate that sub-chronic, pharmacologic NMDAR antagonism has different effects on Akt/GS3K/mTOR signaling than constitutive NMDAR hypofunction caused by a deficit in D-serine. Considering the concordance with schizophrenia, our results suggest that SR-/- mice are a more accurate NMDAR hypofunction model of schizophrenia.

Title: A double hit mouse model of schizophrenia: Chronic stress impairs latent inhibition in CHL1 deficient mice

Authors: *J. D. OBRAY, B. Z. YANG, B. GUERCIO, M. BUHUSI, C. V. BUHUSI;
Dept. of Psychology, Utah State Univ., Logan, UT

Abstract: Latent inhibition (LI) is an adaptive attentional phenomenon in which preexposure to a neutral stimulus decreases the future associability of the preexposed stimulus. LI is attenuated in patients with schizophrenia, and is reinstated by administration of typical antipsychotic medications. A number of genetic mutations and gene polymorphisms have been found to be associated with an increased risk for the development of schizophrenia. The close homolog of L1 (CHL1) adhesion molecule is involved in brain development and plasticity. CHL1-deficient mice exhibit anatomical changes also observed in individuals with schizophrenia. In individuals with a genetic predisposition to schizophrenia it may be necessary for a precipitating event (such as stress) to occur, constituting a double hit, for symptoms of schizophrenia to appear. In this study, we have evaluated the effects of stress on inducing behavioral deficits characteristic of schizophrenia (impaired latent inhibition) in CHL1 knockout mice (KO), heterozygous mice (HET), and wild type littermate controls (WT). Mice were divided into two groups: mice in the STRESS condition received 6 weeks of chronic mild stress beginning at about 6 weeks of age, while NO-STRESS mice were not manipulated. Upon reaching adulthood (12 weeks of age), all mice were tested in the LI paradigm as follows: Mice were repeatedly exposed to a preexposed (PE) stimulus. Following preexposure, a foot shock was paired with both the PE stimulus and a new, non-preexposed (NPE) stimulus. Conditioned freezing during the PE and NPE stimuli was then assessed two days following conditioning, and the results were analyzed statistically. The results indicate that preexposure reliably decreases freezing, and that the preexposure effect is

reliably larger in the NO-STRESS condition. Most importantly, analyses also indicated a reliable interaction between stress and genotype: While KO mice in the NO-STRESS condition showed reliable LI (significant decrease in freezing to the PE relative to the NPE stimulus), KO mice in the STRESS condition did not show LI (no difference in freezing to the PE and NPE stimuli), indicating an interaction between genotype and stress in latent inhibition, thus providing support for a double hit model of schizophrenia.

Title: The effect of lithium on the alleviation of neuromorphological and behavioral deficits in AKT-promoted P19 embryonal carcinoma cells and Akt1 mouse model of schizophrenia

Authors: *C.-Y. CHANG[1], D.-Z. DA[1], T.-W. WANG[4], W.-S. LAI[1,2,3];
[1]Psychology, [2]Grad. Inst. of Brain and Mind Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan; [4]Dept. of Life Sci., Natl. Taiwan Normal Univ., Taipei, Taiwan

Abstract: Schizophrenia is a severe neuropsychiatric disorder with a strong genetic predisposition. Accumulating evidence from human genetic and animal studies suggests that AKT1 is a susceptibility gene for schizophrenia. Emerging evidence indicates that a sex-specific role of Akt1 in the modulation of methamphetamine induced hyperlocomotion, depression-like behavior, sensorimotor gating function, and neuromorphology. Our recent study also revealed that Akt1-deficit mice are insensitive to antipsychotic drugs, but GSK3 (a key downstream kinase for Akt1) inhibitor could have therapeutic potential. Given the fact that lithium is a GSK3

inhibitor and a mood-stabilizing drug for the treatment of bipolar disorder, it is of great interest to evaluate the therapeutic potential of lithium on the alleviation of Akt1-related deficits. Taking advantage of P19 embryonal carcinoma cells and Akt1 heterozygous mutant (Akt1+/-) mice as our models, a series of experiments was conducted *in vitro* and *in vivo*. In study 1, using Ascl1 to differentiate P19 embryonal carcinoma cells into neurons, we examined the effect of AKT1/2 inhibitor on the neuromarphological alterations in DIV2 and the rescue effect of lithium *in vitro*. Quantitative analyses of Tuj1-immunostained P19-derived neurons revealed that AKT1/2 inhibitor resulted in a 33% reduction of neurite length but no difference was found in the number of differentiated neurons. The reduction of neurite outgrowth was rescued by the treatment of Lithium (0.5 & 1 mM). In study 2, based on our previous and current findings, Akt1+/- female mice and their wild-type littermate controls were used and they received chronic treatment of lithium (100 mg/kg, i.p., twice per day) or saline. A set of 3 behavioral tasks were performed. Compared to WT controls, chronic treatment of lithium alleviated behavioral impairments in the tail suspension task and acoustic PPI in Akt1+/- mice. The treatment of lithium also dampened methamphetamine-induced stereotypic behaviors in both groups compared to their saline controls. Collectively, out findings imply the therapeutic potential of lithium for the treatment of schizophrenia and the importance of GSK3 as a new therapeutic target.

Title: The effects of fingolimod administration in dysbindin-1 null-mutant mice, a genetic model for cognitive deficits

Authors: *D. D. BECKER-KRAIL[1], A. LAVIN[2];
[2]Neurosci., [1]Med. Univ. of South Carolina, Charleston, SC

Abstract: Schizophrenia is a complex, heritable neuropsychiatric disorder characterized by a range of positive, negative, and cognitive type symptoms. Schizophrenia related deficits in sociability and memory may be associated with diminished expression of the dystrobrevin-

binding protein 1 (dysbindin-1). The lab has previously shown lacking dysbindin-1 reduces glutamate release in the prefrontal cortex (PFC) through decreases in the ready releasable pool of synaptic vesicles, decreased rates of exo- and endocytosis, and diminished expression of L- and N-type Ca^{2+} channels. Fingolimod, a drug historically used to treat multiple sclerosis and rett syndrome, is known to increase endogenous levels of brain derived neurotrophic factor (BDNF), and in turn, it has been shown that BDNF increases N-type Ca^{2+} channels. To explore a potential means of restoring glutamate release, and perhaps improving the cognitive deficits, we investigate the effects of fingolimod using a dysbindin-1 null mutant mouse. The mice were divided into two groups: saline or fingolimod treatment (1 mg/kg, IP injection; 7 days). We assessed sociability and memory across three genotypes (WT, HET, and MUT) using both the social choice/approach and preference for social novelty tasks. For both groups, we assayed BDNF concentration in PFC homogenate using an ELISA, and analyzed presynaptic intracellular $[Ca^{2+}]$ in a crude PFC synaptosome preparation using a Fluo-4 Ca^{2+} assay. Relative to WT mice, non-treated dysbindin-1 MUT mice demonstrated impairments in novel social interaction, deficits in memory as measured through preference for social novelty, and a lower presynaptic intracellular $[Ca^{2+}]_{PFC}$. However, fingolimod treated null MUT mice show a significant increase in social interaction with novel mice, significantly improved memory as measured through preference for social novelty, higher $[BDNF]_{PFC}$, and an increase in presynaptic intracellular $[Ca^{2+}]_{PFC}$. These results show promise for counteracting social and cognitive deficits associated with schizophrenia, and may illuminate the possible role of dysbindin-1 in symptom pathogenesis.

Title: Magnetic resonance imaging reveals neuroanatomical and neurochemical homologies between the serine racemase knockout mouse and schizophrenia

Authors: *M. D. PUHL, D. MINTZOPOULOS, J. E. JENSEN, T. E. GILLIS, G. T. KONOPASKE, M. J. KAUFMAN, J. T. COYLE;
Psychiatry, Harvard Med. School, McLean Hosp, Belmont, MA

Abstract: Schizophrenia results from a complex combination of genetic, epigenetic, and environmental factors. A prominent hypothesis proposes that activity of the N-methyl-D-aspartate receptor (NMDAR) is decreased in individuals with schizophrenia compared to healthy controls. This NMDAR hypofunction may, in part, be due to decreased availability of D-serine, an NMDAR co-agonist. In fact, the genes encoding serine racemase (SR; the synthetic enzyme for D-serine), D-amino acid oxidase (DAAO; the degradation enzyme for D-serine), and the DAAO activator G72 are risk genes for schizophrenia. Evidence suggests that one of the consequences of NMDAR hypofunction is a compensatory increase in glutamate and/or glutamine in the medial prefrontal cortex (mPFC), which, in turn, may lead to overstimulation of fast-firing, parvalbumin-positive γ-aminobutyric acid (GABA) interneurons and increased GABA levels. It is thought that these abnormalities directly relate to the negative symptoms and cognitive impairments that are hallmarks of the disorder. Furthermore, schizophrenia is characterized by neuroanatomical abnormalities, including cortical atrophy accompanied by ventricular enlargement. Given the complexity of the disease, it is essential that valid animal models are developed so that neural substrates and novel therapeutic targets can be identified. Our laboratory has developed a transgenic mouse line with a constitutive deletion of exon 1 of the SR gene, which encodes the catalytic domain of the enzyme. Null mutants (SR-/-) from this line exhibit NMDAR hypofunction. Using ultra-high magnetic field (9.4 Tesla) *in vivo* magnetic resonance structural imaging (MRI) and ultra-short echo time proton magnetic resonance spectroscopy (MRS), the current study investigated whether the neuroanatomical and neurochemical abnormalities similar to those evident in schizophrenia also occur in SR-/- mice. SR-/- mice and wildtype (WT) controls were anesthetized with isoflurane for MRI and MRS scans. Compared to WT controls, SR-/- mice exhibited an increase in ventricular volume ($p<0.05$). Additionally, in a 15 µl mPFC voxel, SR-/- mice exhibited significantly increased GABA/creatine and GABA/water ratios ($ps<0.01$), similar to findings in treated and untreated humans with schizophrenia. Collectively, these data demonstrate *in vivo* neuroanatomical and neurochemical homologies between the SR-/- NMDAR hypofunction mouse model and humans with schizophrenia.

Title: D2 and DTNBP1 genetic interaction: Relevance to schizophrenia

Authors: *S. GUADAGNA[1], H. HUANG[1], E. BORRELLI[2], T. BALLARD[3], F. PAPALEO[1]; [1]Dept. of Neurosci. and Brain Technol., Italian Inst. of Technol., Genoa, Italy; [2]Dept. of Microbiology and Mol. Genet., Univ. of California, Irvine, CA; [3]Neurosci. Discovery, pRED, F. Hoffmann-La Roche Ltd, Basel, Switzerland

Abstract: Schizophrenia is a complex polygenic disorder with a strong genetic component. Despite other systems possibly being implicated, the pathophysiology of schizophrenia, its treatment and aspects of the associated cognitive deficits have been consistently linked to dysregulation of dopaminergic neural transmission and in particular of dopamine D2 receptor pathways. Two distinct isoforms of D2 receptors are encoded by the D2 gene: the short form D2S and the long form D2L. Interestingly, recent results indicate that functional genetic variants in the D2 gene might modulate schizophrenia-related phenotypes by modifying D2S/D2L ratio. Dystrobrevin-binding protein 1 (DTNBP1) is one of the leading candidate susceptibility genes for schizophrenia. DTNBP1 gene expression and its protein levels are reported to be significantly reduced in patients with schizophrenia. Moreover, genetic variations reducing DTNBP1 expression impact cognitive abilities and lead to up-regulation of D2 receptors on the neural surface. Based on this biological evidence, we generated a novel mouse model bearing selective mutations of both the D2 and DTNBP1 schizophrenia-susceptibility genes. We then predict that synergistic effects of a reduced dysbindin-1 (dys) expression and an increased D2S/D2L ratio in the same subject might alter the dopamine/D2 signaling triggering cognitive- and schizophrenia-

relevant symptoms. Using this model we are finding alterations of the startle response and prepulse inhibition in the dys/D2L double heterozygous knock-out (KO) mice but not in single heterozygous KO mice. Preliminary tests with a 5-choice serial reaction time task paradigm revealed also increased impulsivity in these mice compared to wild type and single dys and D2L heterozygous KO mice. Taken together, these results represent the first evidence suggesting a functional interaction between mutations in the DTNBP1 and D2 genes in the expression of behavioral phenotypes relevant to schizophrenia.

Title: The involvement of Akt1 in the modulation of immune responses and behavioral consequences in Akt1 deficient mice after neonatal poly(I:C) challenge

Authors: *W.-R. WONG[1], C.-H. HUANG[2], W.-S. LAI[1,2,3];
[1]Grad. Inst. of Brain and Mind Sci., [2]Dept. of Psychology, [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Schizophrenia appears to be a multifactorial disorder with a strong genetic predisposition. Accumulating evidence from human and animal studies suggests that AKT1 (protein kinase Bα) may contribute to susceptibility to schizophrenia and Akt1-deficient mice displayed neuromorphological and behavioral abnormalities as well. In addition to genetic predisposition, immuno-precipitated neurodevelopmental mouse models displayed aberrant behavioral functions and altered Akt1 expression after prenatal immune challenge. However, the precise role of Akt1 in the modulation of neonatal immune responses and behavioral consequence remains unclear. The objective of this study is to examine the effect of early infection alone and its interaction with Akt1 deficiency on the alterations of neonatal immune responses and behavioral consequence in both neonate and adulthood. Akt1 heterozygous pups and their wild-type littermate controls received daily injections of polyriboinosinic-polyribocytidylic acid (poly(I:C)) from postnatal days 2 to 6. Using cytometric bead array, our cytokine analysis revealed a 30% reduction of TNFα level in Akt1 deficient pups right after the last daily poly(I:C) challenge. Behavioral result from neonatal developmental milestones also revealed that male Akt1 deficient pups had decreased body weight and their performance on negative geotaxis reflex was impaired after neonatal poly(I:C) challenge. Besides, a battery of behavioral tasks, including open field, Y maze, social preference, social recognition, USVs playback approaching paradigm, tail suspension, and prepulse inhibition tests, were conducted in another batch of adult mice. In consideration of sex difference, an interaction between genotype and treatment in social recognition task was found in male mice, suggesting that the ability of social recognition in adulthood might be affected by Akt1 deficiency and neonatal poly(I:C) challenge. An impairment of sensorimotor gating function was also found in Akt1-deficent females. Collectively, our data indicated that neonatal poly(I:C)-induced immune response can be altered by Akt1 deficiency, especially during neonatal period. But it appears to have minor impact on behavioral performance in adulthood. Further neurochemical analysis is still in progress. Findings from this study will provide clues to understanding the involvement of Akt1 in the early infection-induced model of schizophrenia.

Title: Htr2a expression responds rapidly to environmental stimuli in an Egr3-dependent manner suggesting a functional link between two schizophrenia susceptibility genes

Authors: *A. M. MAPLE, X. ZHAO, D. I. ELIZALDE, A. L. GALLITANO;
BMS, Univ. of Arizona Col. of Medicine-PHX, Phoenix, AZ

Abstract: The serotonin system has been implicated in the etiology of schizophrenia, however the mechanisms by which serotonin influences susceptibility to this severe mental illness are poorly understood. The serotonin 2A receptor (5-HT_{2A}R) has been of particular interest as agonists of this receptor cause psychosis in normal individuals and antagonism of the 5-HT_{2A}R is thought to be an important function of atypical antipsychotics. In addition, *Htr2a*, the gene that encodes the 5-HT_{2A}R, is one of the most well-replicated schizophrenia candidate genes in genetic association studies, and numerous *in vivo* and post-mortem studies have found decreased 5-HT_{2A}Rs in the brains of schizophrenia patients. We recently reported that 5-HT_{2A}R binding levels are decreased by approximately 70% in the prefrontal cortex of mice lacking the immediate early gene (IEG) early growth response 3 (*Egr3*), paralleling 5-HT_{2A}R deficits in schizophrenia patients. We have previously shown that mice lacking *Egr3* display schizophrenia-like behaviors and responses to antipsychotics. In humans, *EGR3* has been associated with schizophrenia risk and *EGR3* mRNA is reduced in the brains of schizophrenia patients. These findings suggest that *Egr3* may regulate expression of *Htr2a*. As an environmentally induced transcription factor that is required for synaptic plasticity, *Egr3* may influence both the environmental and the genetic contributions to schizophrenia risk. In this study, we tested the hypothesis that the 5-HT_{2A}R is also regulated in response to environmental stimuli, and that this regulation requires the activity of *Egr3*. To determine whether *Htr2a* can be regulated an environmental stressor, we used a sleep deprivation paradigm in mice. We found that this stimulus increased *Htr2a* mRNA expression in the cortex, using quantitative RT-PCR. Next, we tested whether this activation required *Egr3*, (which is induced by sleep deprivation). We found that the activation of *Htr2a* by sleep deprivation was not observed in *Egr3*-/- mice. These data suggest *Egr3* may rapidly modulate *Htr2a* in response to the acute environmental stimulus of sleep deprivation. Furthermore, they provide a functional link between two schizophrenia candidate genes and a possible explanation of how genetic and environmental factors influence risk for schizophrenia.

Title: A dual hit mouse model for schizophrenia: Neural correlates of stress and latent inhibition

Authors: *B. M. GUERCIO[1], D. O'BRAY[2], C. BUHUSI[1], M. BUHUSI[1];
[1]Psychology, Utah State Univ., Logan, UT; [2]psychology, Utah state university, Logan, UT

Abstract: Latent inhibition (LI) is an adaptive attentional phenomenon in which preexposure to a neutral stimulus decreases the future associability of the preexposed stimulus. LI has been shown to be attenuated in patients with schizophrenia, although the cause is not fully understood. A number of genetic mutations and gene polymorphisms have been found to be associated with an increased risk for the development of schizophrenia, including mutations in the CHL1 gene. The close homolog of L1 (CHL1) adhesion molecule is involved in neuron development and plasticity, particularly neuronal migration, development of neuronal connections, as well as cellular signaling pathways. In mice lacking the CHL1 adhesion molecule, anatomical changes have been found to parallel anatomical changes observed in individuals with schizophrenia. In this study, we have evaluated the effects of stress on inducing behavioral deficits characteristic of schizophrenia (impaired latent inhibition) in CHL1 knockout mice (KO), and wild type littermate controls (WT). Mice were divided into two groups: mice in the STRESS condition received 6 weeks of chronic mild stress beginning at about 6 weeks of age, while NO-STRESS mice were not manipulated. Upon reaching adulthood (12 weeks of age), all mice were tested in the LI paradigm as shown in the poster "A double hit mouse model of schizophrenia: Chronic stress impairs latent inhibition in CHL1 deficient mice," in which LI was found to be impaired in stressed KO but not WT mice, as predicted by the dual hit hypothesis. Following LI testing c-fos immunohistochemistry stainining was performed to assess neuronal activation in the prelimbic cortex (PrL), infralimbic cortex (IL), basal lateral amygdala (BLA), nucleus accumbens shell (NacSH), and nucleus accumbens core (NacC), which are all known to contribute to LI. We found that c-fos activation was increased in the IL, and NacSH in the stress condition. Additionally KO mice showed significantly more activation than WT mice in the IL. These results enhance current understanding of the neural circuits involved in attentional deficits induced by stress and genetic predisposition in models of schizophrenia.

Title: Impairment of synaptic functions and local network activity in dysbindin-1 deficient mice

Authors: *J. ZHAO[1], J. NORDMAN[1], S. KOLACHANA[1,2], Z. LI[1];
[1]NIMH/NIH, Bethesda, MD; [2]Thomas Jefferson High Sch. for Sci. and Technol., Alexandria, VA

Abstract: Dysbindin-1 has been reported as a susceptibility gene of schizophrenia. Both miRNAs and proteins of dysbindin-1 are significantly decreased in the hippocampus of schizophrenia patients. In neurons, dysbinidin-1 is distributed at both presynaptic and postsynaptic sites, suggesting that it is involved in synaptic regulation. In mice deficient in dysbindin-1 expression, dopamine D2 receptors (D2R, a member of the D2-like subfamily of dopamine receptors) are increased on the cell surface. D2R dysfunction has long been recognized to play an important role in schizophrenia. In schizophrenia brains, D2R density is increased. In hippocampal, cortical and striatal neurons, brief activation of D2R inhibits NMDA currents. However, whether D2R-mediated changes in synaptic transmission affect the structure of synapses (such as dendritic spines, tiny dendritic protrusions) has not been experimentally tested. Neural oscillation has been implicated in information integration and cognitive processing by electrophysiological recordings of individual neurons, local field potentials and EEG. Clinical studies suggest that abnormal perception and cognition of schizophrenia patients may be associated with abnormal neural synchrony activity. The role of dysbindin in neural oscillation has not been investigated. In this study, we used the sandy mouse (carrying a deletion mutation in dysbindin-1 and expressing no dysbindin-1 proteins) as a genetic model of schizophrenia. We measured the strength of synaptic transmission by analyzing miniature excitatory postsynaptic currents (mEPSCs) with whole-cell voltage clamp. In adolescent sandy mice, mEPSC frequency was significantly reduced, whereas its amplitude was comparable with that in wild-type mice. The reduction in mEPSC frequency in sandy mice was abolished by injecting lentivirus expressing D2R siRNAs, indicating that it is caused by D2R overactivation. We further study whether synaptic dysfunctions influence on neural network synchronization in sandy mice. By analyzing the local field potentials in sandy mice hippocampus, we found gamma band oscillation was marked decreased. These results indicate the impairment of local neuronal

network function were associated with dysbindin-1. In the further, we will focus on the mechanism of neuronal network activity impairment associated with dysbindin pathway.

Title: Constant light exacerbates behavioral deficits in the dysbindin-1 mutant mouse model of schizophrenia

Authors: ***S. BHARDWAJ**, K. STOJKOVIC, N. CERMAKIAN, L. K. SRIVASTAVA; Douglas Mental Hlth. Univ. Institute, McGill Univ., Montreal, QC, Canada

Abstract: Alterations in sleep and circadian rhythms are often reported in schizophrenia. However, the mechanisms underlying such disruptions and their relationship with schizophrenia symptoms remain elusive. Here, we assessed the impact of constant light, a condition known to disrupt circadian rhythms, in sdy mice with a mutation in the schizophrenia susceptibility gene dysbindin-1. First, we recorded running wheel activity of homozygous mutants (sdy) and wild-type (WT) male mice under different lighting conditions: 12h light:12h dark (LD), constant darkness (DD) and constant light (LL; 20 or 200 lux). Parameters such as free-running period and distribution of activity over the 24h day were evaluated. While the free-running period in LL was longer than in DD, the increase was even larger in sdy mice. Moreover, we observed a higher subjective day/subjective night ratio of activity in sdy mice. We then assessed if the schizophrenia-relevant behavioral abnormalities described in sdy mice are affected under LL. Spontaneous locomotor activity, prepulse inhibition (PPI) of acoustic startle and anxiety-like behavior (elevated plus maze) were assessed first under baseline (2 weeks in LD), then in LL (3 weeks, 200 lux), and then again in LD (3 weeks). Spontaneous locomotor activity was not significantly different between sdy and WT at baseline; however, following LL exposure, sdy animals showed an increase compared to WT animals, and this enhanced activity persisted even after 3 weeks of LD exposure. PPI data showed a similar pattern of behavioral deficits induced

by LL: PPI was significantly decreased in sdy mutants after LL compared to WT. However, after 3 weeks in LD, while the PPI deficit was still present, it was attenuated. LL exposure led to a significant increase in anxiety-like behavior in WT animals that was fully reversed after 3 weeks in LD. Interestingly, this effect of LL on anxiety-like behavior was not observed in the sdy mutants. Altogether, our data suggest that dysbindin-1 deficiency leads to altered circadian activity in mice, and that constant light causes sustained behavioral deficits in mice with this mutation. Our results reveal lighting condition as a novel environmental factor interacting with genetic susceptibility to potentiate schizophrenia-like symptoms.

Title: Altered regulation of cAMP/PKA signaling by PDE10A and PDE4 in DISC1 mutant mice

Authors: ***A. NISHI**[1], M. KUROIWA[1], T. SHUTO[1], N. SOTOGAKU[1], Y. HANADA[1], M. MORITA[2], A. SAWA[3], T. HIKIDA[2];

Abstract: A transgenic mouse model with a putative dominant-negative DISC1 under expression control of the prion protein promoter, DISC1-DN-Tg-PrP, is susceptible to social isolation stress, resulting in alteration of dopamine signaling and psychosocial behaviors (Niwa et al., 2013). In this study, we investigated whether PDE10 and/or PDE4 are involved in alteration of cAMP/PKA signaling in the striatum (dorsal) and nucleus accumbens (NAc, ventral striatum) of DISC1 mutant mice without or with isolation stress for 3 weeks. Treatment of striatal slices with a PDE10A inhibitor, papaverine, increased the phosphorylation of GluA1 and

DARPP-32 at PKA-sites in a dose-dependent manner. The effect of papaverine was larger in DISC1 mutant mice than in wild-type mice. After isolation stress, the effect of papaverine was largely reduced only in DISC1 mutant mice. The altered responses to papaverine in the striatum were not observed in the NAc. As predicted, the stimulatory effect of a D1 receptor agonist, SKF81297, on the phosphorylation of PKA-sites in the striatum of DISC1 mutant mice was smaller, but became comparable with wild-type mice after isolation stress. In contrast to the results with papaverine, analysis using a PDE4 inhibitor, rolipram, revealed the alteration of cAMP/PKA signaling in the NAc of DISC1 mutant mice after isolation stress. The stimulatory effects of rolipram on the phosphorylation of PKA-sites (GluA1 and DARPP-32) in the NAc were similar in wild-type and DISC1 mutant mice, but largely enhanced only in DISC1 mutant mice after chronic stress. Such altered responses to rolipram were not observed in the striatum. Isolation stress enhanced the stimulatory effects of SKF81297 on DARPP-32 phosphorylation in wild-type mice, but the enhancement was smaller in DISC1 mutant mice. Thus, PrP-dnDISC1 mice shows the alteration of PDE10A function in the striatum before isolation stress, but the alteration of PDE4 function in the NAc becomes dominant after isolation stress, leading to the derangement of dopamine/cAMP/PKA signaling in DISC mutant mice.

Title: Social isolated DISC1 mutant mice displayed high sensitivity to chronic cocaine exposure and rolipram treatment

Authors: ***T. HIKIDA**[1], M. MORITA[1], M. NIWA[2], M. KUROIWA[3], A. SAWA[2], A. NISHI[3]; [1]Med. Innovation Ctr., Kyoto Univ. Grad. Sch. of Med., Kyoto, Japan; [2]Dept. of Psychiatry, Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [3]Dept. of Pharmacol., Kurume Univ. Sch. of Med., Kurume, Japan

Abstract: Development of drug addictive behaviors is modulated by both genetic and environmental risk factors. To address the role of gene-environment interaction (GXE) in drug addiction, we combined a transgenic mouse model with a putative dominant-negative DISC1 under expression control of the prion protein promoter, DISC1-DN-Tg-PrP as a genetic model (G) and adolescent social isolation stress as an environmental factor (E), established in Niwa et al., 2013. We studied cocaine-related bahaviors of four groups of mice: wild-type mice without isolation (control); wild-type mice with isolation (E group); DISC1-DN-Tg-PrP without isolation (G group); and DISC1-DN-Tg-PrP with social isolation stress (GXE group). Acute and chronic cocaine exposure induced significantly higher locomotion in GXE group than in other groups. In conditioned place preference (CPP) test, GXE group mice exhibited significant place preference conditioned with lower dose of cocaine than other groups. These results indicate that the gene-environment interaction enhanced sensitivity to chronic cocaine exposure and lead to development of cocaine addictive behaviors. Next, we examined molecular and biochemical changes in nucleus accumbens of GXE model mice and found significant increases in mRNA expression level and enzyme activity of phosphodiesterase 4 (PDE4). Then, we addressed whether PDE4 could be involved in the development of cocaine addictive behaviors. When we injected PDE4 inhibitor rolipram before place conditioning of mice with cocaine in the CPP test, rolipram completely inhibited conditioned place preference induced by chronic cocaine exposure in GXE group. These results suggest the utility of GXE model to analyze the pathophysiology of drug addiction.

Title: Targeting Hippocampus-Prefrontal cortex pathway in the Df(22q11.2)/+ mouse model of Schizophrenia

Authors: A. TRIPATHI[1], E. SCHENKER[2], M. SPEDDING[2], *T. M. JAY[1];
[1]INSERM U894, Physiopathologie Des Maladies Psychiatriques, Univ. Paris Descartes, Paris, France; [2]Inst. de Recherches Servier, Suresnes, France

Abstract: Modelling neuropsychiatric disorders such as schizophrenia (SCZ) have proved to be extremely difficult due to the diverse symptoms that characterized the disease: positive symptoms, negative symptoms and cognitive deficits. However, probable genetic causation of SCZ and involvement of copy number variations provide us a means to create better animal models for investigation of underlying abnormalities and potential pharmacological approaches. Deletion in 22q11.2 loci has been reported to be the largest genetic risk factor for SCZ. A transgenic mouse with syntenic deletion at this locus, the Df(h22q11)/+ mice(1), therefore lends itself to be a good model to investigate the anomalous functional connectivity in prefrontal networks and their disruption that has emerged to be of special importance in psychiatric diseases, particularly in SCZ and thought to underlie the cognitive abnormalities that characterize the disease. Following our recent characterization of the ventral hippocampus (vHipp) input to the medial prefrontal cortex (mPFC) in C57 BL/6J mice, we here investigated in Df(h22q11)/+ mice the functional connectivity of this pathway, essential for transmitting information about mnemonic and emotional processing. *In vivo* mPFC responses to low and high frequency stimulation (HFS) of the vHipp were recorded using excitatory postsynaptic field potentials (PSPs). In wild type animals, an increase in PSP amplitude was obtained and stabilized for an hour after HFS application. This increase in PSP amplitude after HFS was significantly reduced in Df(h22q11)/+ mice as compared to the wild type mice indicating a decrease in long term potentiation (LTP) i.e. mPFC synaptic plasticity. Besides, deficits in long term synaptic plasticity, Df(h22q11)/+ mice also showed a decrease in the number of Parvalbumin (PV) positive interneurons in layers 5 and 6 of the mPFC as compared to the wild type mice. The reduction in the number of PV inhibitory neurons in mPFC may contribute to physiological deficits in Df(h22q11)/+ mice and add further credibility to this mouse model of SCZ. Further physiological and behavioral studies that are in progress in these mice will be presented. The present work will serve as a framework for assessing the role of the vHipp-mPFC in expanded phenotyping of this and related models of SCZ. The observed behavioral and systems-level activity changes may lead to a better understanding of this complex disease and open new therapeutic strategies. (1) Df(h22q11)/+ mice were created and provided by by H. Lundbeck A/S.

Title: Alterations in the E to I balance in PGC-1α deficient mice are caused by dysfunction of inhibition from perisomatic targeting interneurons in the hippocampus

Authors: *A. F. BARTLEY[1], Q. LI[1], R. M. COWELL[2], J. J. HABLITZ[1], L. E. DOBRUNZ[1]; [1]Neurobio., [2]Psychiatry and Behavioral Neurobio., Univ. of Alabama At Birmingham, BIRMINGHAM, AL

Abstract: Complex brain disorders such as schizophrenia and autism are disorders of circuit function, caused by an imbalance between excitatory and inhibitory synaptic transmission (E/I). Short-term plasticity differentially alters synaptic response of excitatory and inhibitory synapses; as a result, the E/I ratio is dynamic, continuously changing as a function of stimulus frequency. However, nothing is known about how the dynamics of the E/I ratio are affected by changes in inhibition as seen in disorders such a schizophrenia. Transcriptional dysregulation in interneurons, particularly those containing parvalbumin, is a consistent pathophysiological feature of schizophrenia. PGC-1α (peroxisome proliferator activated receptor γ coactivator 1α) is a transcriptional co-activator localized to interneurons. Loss of PGC-1α results in decreased parvalbumin expression and alterations in GABAergic inhibition. PGC-1α-/- mice are therefore a model of interneuron transcriptional dysregulation that mimics some molecular aspects of schizophrenia. In this study, PGC-1α-/- mice are used to investigate the effects of interneuron transcriptional dysregulation on the dynamic E/I balance at the synaptic and circuit level in the CA1 region of hippocampus. In particular, we recorded from CA1 pyramidal cells in acute hippocampal slices from young adult wildtype and PGC-1α-/- mice. We find that loss of PGC-1α causes a decrease in the E/I ratio in response to Schaffer collateral stimulation, and that the underlying mechanism is enhanced basal inhibition. This decreases the spread of activation in CA1 measured with voltage-sensitive dye imaging, and dramatically limits the spiking of CA1 pyramidal cells, thereby reducing the output from hippocampus. Our data indicate that these alterations are mainly mediated by dysfunction in perisomatic targeting interneurons, specifically parvalbumin basket cells. However, the E/I ratio and impaired circuit function are partially restored at higher frequencies, caused by reduced recruitment of interneurons. These studies will greatly advance our understanding of the dynamics of E/I ratio and provide insights into new

strategies for correcting E/I imbalances and circuit dysfunction. Interestingly, PGC-1α -/- mice have been shown to have reduced inhibition in cortex, suggesting that the effects of PGC-1α on circuit function are region specific. Developing a complete understanding of the effects of interneuron transcriptional dysregulation on circuit function in different brain regions will allow us to develop therapeutic targets to overcome the communication breakdown seen in complex brain disorders.

Title: Vasoactive intestinal peptide receptor 2 deficient mice exhibit dopamine D1 receptor upregulation

Authors: *D. R. GEHLERT, M. MORIN;
Lilly Res. Lab., INDIANAPOLIS, IN

Abstract: Recent human genetic studies have associated duplications of the upstream region of the gene encoding Vasoactive Intestinal Peptide Receptor 2 (VIPR2) with significant risk for schizophrenia[1]. Increased VIPR2 transcription and signaling were reported in lymphocytes isolated from patients exhibiting these duplications, however, little is known about the consequences of VIPR2 expression or deletion in the brain. Conventional antipsychotic drugs work through antagonizing brain dopamine receptors and have no known interaction with VIPR2 receptors. Therefore, we conducted studies to understand the potential link between alterations in VIPR2 expression and the dopaminergic system in mice. In the present studies, VIPR2 deficient mice[2] and age matched controls were sacrificed and slide mounted coronal sections of fresh frozen brain tissue were obtained. Consecutive sections were labeled for D1-like receptors (^{3}H-SCH23390), D2-like receptors (^{3}H-Raclopride) and the dopamine transporter (^{3}H-WIN 35,428, DAT). The binding was detected and quantitated using standard autoradiographic techniques. In these studies, no statistically significant difference was noted in the expression of D2-like receptors or DAT in any of the brain regions evaluated. However, there were statistically significant increases in the expression of ^{3}H-SCH23390 binding in the Caudate-Putamen

(45.5±5.2 nCi/mg vs. 22.5±3.1 nCi/mg, $p<0.05$), Nucleus Accumbens Core (16.7±1.9 nCi/mg vs. 9.8±1.6 nCi/mg, $p<0.05$) and Olfactory Tubercle (32.6±3.3 nCi/mg vs. 13.3±1.5 nCi/mg, $p<0.05$) of VIPR2 knockout mice when compared to wild type controls. No differences in D1 expression were noted in the Shell of the Nucleus Accumbens or the Lateral Septum. These results are consistent with a role for VIPR2 receptor expression in the normal development and expression of the D1 receptors in specific brain regions in mice. Additional studies will be undertaken to assess the functional consequences of the increased binding densities. Title: Deconstructing the BLOC-1 complex: Effects of pallid and dysbindin gene mutation on recognition memory

Authors: *K. H. KARLSGODT[1], S. SPIEGEL[2], A. S. JAMES[3], J. JENTSCH[3];
[1]Psychiatry Res., Feinstein Inst. for Med. Res., Glen Oaks, NY; [2]Thomas Jefferson Sch. of Med., Philadelphia, PA; [3]Univ. of California Los Angeles, Los Angeles, CA

Abstract: Numerous studies have implicated DTNBP1, the gene encoding dystrobrevin-binding-protein or dysbindin, as a candidate risk gene for schizophrenia, though this relationship remains somewhat controversial. Variation in dysbindin and in its location on chromosome 6p have been shown to influence cognitive processes, including those relying on a complex system of glutamatergic and dopaminergic interactions. Dysbindin is a part of the larger Biogenesis of Lysosome-related Organelles Complex 1 (BLOC-1) which includes seven other protein subunits: palladin, muted, cappuccino, snapin, BLOS1, BLOS2, and BLOS3. Data suggests that multiple sububit proteins must be present in order to form a functional oligomeric BLOC-1 complex, such

that dysbindin protein levels are lower in pallid mice, while pallid levels are lower in dysbindin mice. Accordingly, a mutation leading to underexpression of either of these proteins should show phenotypic effects. Palladin is normally expressed in the brain, and a null model of palladin mutation has been used to study the BLOC-1 complex. Although dysbindin and palladin have similar distribution patterns in the mouse and human hippocampi, including in axon terminal fields of glutamatergic neurons in dentate, CA2 and CA3, cognition has been investigated as related to alterations in dysbindin but not palladin. Therefore, we sought to test whether palladin was associated with neurocognitive deficits similar to those associated with dysbindin, which would indicate that any disruption of BLOC-1 function may result in impairment. We employed two tests designed to assess the rodent analogue of recognition memory, the Novel Object Recognition Task (NORT) and Social Novelty Recognition Task (SNRT). Our overall findings indicate that mice with a mutation in either the palladin or dysbindin genes show an appreciable memory deficit on both SNRT and NORT when compared to dysbindin heterozygous (dys-/wt) and wild type (wt/wt) mouse lines. The pallid and null mutant (dys-/dys-) mice lack any preference for novel stimuli, as shown by a ratio of novel/familiar object exploration ≈1. This is compared to the wt/wt and dys-/wt ratio of ≈2, indicating increased preference for the novel mouse or object. We have shown deficits in recognition memory across tasks, indicating that this impairment represents a generalized recognition memory deficit. This novel finding holds significant implications about the role of the palladin gene in relation to dysbindin. Both the SNRT and NORT showed this memory deficit. This leads us to infer that disruption of the BLOC-1 complex, from either palladin or dysbindin mutation, has an effect on memory.

Title: Using auditory steady state responses to characterize neural connectivity in mice models of schizophrenia

Authors: Y. SHAHRIARI[1], S. MACDONALD[1], Y. SUREKHA[2,3], J. CHOI[2,3], *D. J. KRUSIENSKI[1];
[1]Electrical & Computer Engin., Old Dominion Univ., Norfolk, VA; [2]Ctr. for Neurosci., Korean Univ. of Sci. and Technol., Seoul, Korea, Republic of; [3]Dept. of Neural Sci., Univ. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Abnormal neural oscillations can reflect dysfunction between neural pathways in the brain and can be characteristic of certain neurological disorders. It has been shown that patients with schizophrenia can exhibit EEG abnormalities in event-related potentials, spectral power, neural synchrony, and brain connectivity. In particular the 40 Hz auditory steady state response (ASSR) in schizophrenic subjects has been shown to have reduced power and phase synchronization to the auditory stimulus. The ASSR is an auditory-evoked potential that can be elicited by a click train and is observed in various parts of the brain including the auditory and frontal cortex. The goal of the study is to investigate ASSR interrelations between EEG channels which is expected to further elucidate differences in neural pathologies associated with schizophrenia. In this study EEG data was obtained from two PLC-beta1 mutant mice as models of schizophrenia, as well four wild control mice. Four channels of scalp EEG were recorded: two over the left and right auditory cortex and two over the left and right frontal cortex. The mice were presented with separate auditory stimuli at 20, 30, 40 and 50 Hz. The power spectrum of the controls showed the expected characteristic frequency modulated pattern at the respective stimulus frequencies. Such distinct and consistent spectral patterns were not observed in the mutants. Various connectivity measures were examined including phase-locking value (PLV), which quantifies the degree of phase synchrony between two EEG channels but does not provide any information about the causal relationships and direction of information flow between different brain regions. Therefore, partial-directed coherence (PDC) was also evaluated. The various connectivity measures indicate a generally weaker neural synchronization and connectivity in mutants compared to the controls, particularly the fronto-temporal relationships. These results support the notion that synchrony of gamma oscillations is disturbed in schizophrenia and that this deficit is related to clinical symptoms such as auditory hallucinations.

Title: Altered spatial learning in mice with a deficit in hippocampal parvalbumin-expressing GABA-ergic interneurons leads to apparent cognitive inflexibility

Authors: *S. P. PASKEWITZ[1], S. WEISS[2], B. INBAR[1], M. E. ROSS[4], H. MOORE[3];
[1]Integrative Neurosci., New York State Psychiatric Inst., New York, NY; [3]Psychiatry, [2]Columbia Univ., New York, NY; [4]Weill Cornell Med. Col., New York, NY

Abstract: Expression of parvalbumin - a calcium-binding protein characteristic of certain classes of GABA-ergic interneurons - is reduced in the hippocampi of people with schizophrenia (Konradi et al., 2011). The resulting disregulation of hippocampal processing may lead to excess activity in the mesencephalic dopamine system (Floresco et al., J Neurosci, 2001). We have recently modeled these functional outcomes of a deficit parvalbumin-expressing (PV+) interneurons using mice lacking the gene cyclin D2 (Ccnd2 KO). These mice display a partial (approximately 40%) PV+ interneuron deficit in the hippocampus, but no changes in other interneuron populations. Ccnd2 KO mice display hippocampal disinhibition, impaired hippocampus-dependent fear-conditioning and altered midbrain dopamine neuron activity (Glickstein et al., Development, 2007; Gilani et al., Proc Natl Acad Sci USA, 2014). In this experiment we examined cognitive flexibility and different forms of spatial navigation in Ccnd2 KOs (c.f. Ragozinno et al., J Neurosci, 1999). Mice - starting on different trials from the "east" and "west" arms of a cross-maze - were trained to find sucrose-pellets hidden in the "north" and "south" arms according to either a egocentric rule (e.g. "turn left") or an allocentric rule (e.g. "turn north"). After mice achieved a criterion level of performance, the rule was switched. We predicted that the hippocampal dysfunction of Ccnd2 KO mice would hinder learning of the allocentric rule (Packard and McGaugh, Neurobiol Learn Mem, 1996), while excess ventral striatal dopamine might impair cognitive flexibility (Haluk and Floresco, Neuropsychopharmacology, 2009). Ccnd2 KO mice initially learned both rules as rapidly as wild type controls (WTs). However, they took longer to switch from an egocentric rule to an allocentric one. This effect is explained by the fact that WT, but not KO, mice showed accelerated learning of the allocentric rule when it came second in order. We propose that WT mice automatically encoding a spatial map while learning the egocentric rule, a process impaired by hippocampal PV+ interneuron deficits. Further, Ccnd2 KO mice showed signs of increased perseveration when switching from an allocentric rule to an egocentric one. These results suggest that Ccnd2 KO mice learn allocentric rules in a different, less flexible manner than WTs (c.f. O'Keefe and Nadel, The Hippocampus as a Cognitive Map, 1978).

Title: Mitochondrial deficits in fast-spiking interneurons lead to elevated anxiety, impaired sensory gating and social dysfunction

Authors: ***M. INAN**[1], M. ZHAO[2], M. MANUSZAK[1], M. V. BOBOILA[3], I. DINCHEVA[4], V. PICKEL[1], F. S. LEE[4], A. M. RAJADHYAKSHA[3], T. H. SCHWARTZ[2], P. GOLDSTEIN[5], G. MANFREDI[1];

Abstract: Patients affected by mitochondrial disease often develop neuropsychiatric symptoms. At the same time, deficits in the function of parvalbumin-expressing, "fast-spiking" cortical interneurons (PV cINs) have been associated with neuropsychiatric disorders. PV cINs have high bioenergetic demands, making them highly susceptible to mitochondrial impairment. Thus, there is a logical convergence between mitochondrial metabolism and PV cINs, and their mutual involvement in the pathogenesis of neuropsychiatric symptoms in mitochondrial diseases. Here, we link the mitochondrial dysfunction and interneuronopathy hypotheses of neuropsychiatric symptoms by studying transgenic mice with conditional ablation of Cytochrome c oxidase, a key enzyme of the oxidative phosphorylation (OXPHOS) machinery, restricted to PV neurons (PV CKO). First we found that PV cINs have the highest mitochondrial content among other cIN populations, consistent with their fast-spiking activity. Further, analyses of PV CKO mice revealed a progressive decline in OXPHOS function. In parallel with the biochemical phenotype, inhibitory synaptic transmission was reduced and excitability of the cortical circuitry was progressively increased. At the behavioral level, cortical function defects correlated with lack of sensory gating, increased anxiety and impaired sociability, all of which are hallmark symptoms of neuropsychiatric disorders, such as schizophrenia and autism spectrum disorders. Taken together, our results support the hypothesis that bioenergetic impairment in PV cINs can

contribute to the pathogenesis of neuropsychiatric symptoms. Furthermore, from these findings, mitochondria in PV cINs emerge as potential therapeutic targets for neuropsychiatric symptoms.

Title: Contrasting expression patterns for immaturity and maturity marker genes in the dentate gyrus between mouse lines with 'immature dentate gyrus' and mice overexpressing glucocorticoid receptor

Authors: *H. KOSHIMIZU[1,2], H. HAGIHARA[1,2], K. TAKAO[3,2], T. MIYAKAWA[1,2]; [1]ICMS, Fujita Hlth. Univ., Toyoake, Japan; [2]CREST, JST, Kawaguchi, Japan; [3]Ctr. for Gene. Anal. of Behav., NIPS, Okazaki, Japan

Abstract: Adequate maturation of hippocampal neurons is thought to be crucial for normal cognitive function and emotional behavior, and dysregulation of cellular maturity in the hippocampus could be involved in mental disorders. Previously, we identified the 'immature dentate gyrus (iDG)' phenotype, in which almost all the granule cells in the dentate gyrus (DG) exhibit a pseudo-immature status, in several gene-targeted mouse lines that display behavioral abnormalities related to schizophrenia. On the other hand, the research group led by Huda Akil has reported that overexpression of glucocorticoid receptor (GR) in the forebrain throughout the lifetime and in early life causes increased depression-like and/or anxiety-like behaviors in mice (Wei et al., PNAS, 2004; Biol. Psychiatry, 2012), raising the possibility that mice overexpressing GR (GRov mice) may represent a potential animal model for mood disorders, such as depression and anxiety disorder. In addition, overexpresson of GR causes an 'aging-like' neuroendocrine phenotype and mild cognitive dysfunction in young mice (Wei et al., J. Neuroscience, 2007). In

this study, we evaluated the transcriptional maturation status of GRov mouse DG by using a bioinformatics tool, NextBio, and publicly available microarray data sets. The DG of GRov mice exhibited an contrasting patterns of immaturity and maturity marker gene expression to those in the developing DG (P14 compared to P30) in wild-type (WT) mice, while the gene expression patterns of those marker genes in iDG of Schnurri-2 knockout (Shn2 KO), alpha CaMKII heterozygous KO, and forebrain-specific calcineurin KO mice are similar to those in the developing DG (P14 compared to P30) of WT mice. Contrasting gene expression patterns were found between the DG of GRov mice and the mouse lines showing iDG phenotype. These observations indicated that maturation status of the DG in GRov mice may be changed potentially toward 'over-maturity'.

Title: Knockout of the schizophrenia candidate gene neuregulin 3 impairs synaptic transmission and behavior

Authors: *D. J. FIGUEIREDO, C. SHEN, X. SUN, W.-C. XIONG, L. MEI;
Neurosci., Georgia Regents Univ., Augusta, GA

Abstract: Neuregulin 3 (Nrg3) is a member of the Neuregulin family of growth factors that are encoded by six individual genes. The EGF-like domain of Nrg3, located in the N-terminal extracellular region, is ~30% identical in amino acid sequence to Nrg1. In human, the Nrg3 gene is positioned at 10q22-23, a locus associated with schizophrenia. Many single nucleotide polymorphisms (SNP's) of the Nrg3 gene, especially in the first intronic region, are associated with schizophrenia and with smoker cessation success rate.Nrg3 is thought to act by activating the receptor tyrosine kinase ErbB4. However, unlike Nrg1, a well-characterized schizophrenia susceptibility gene, little is known about the function of Nrg3. We have characterized Nrg3 expression the brain. Western blot analysis indicated that in adult mice, Nrg3 was primarily in

the brain,but not detectable in the liver, heart, bone or skeletal muscle. In the brain, it was detectable in various regions, relatively high in the cortex and midbrain. The expression of Nrg3 is developmentally regulated, being highest at P16. Studies of cortical cells in culture indicated that Nrg3 was detectable in neurons, but not astrocytes. To study its function *in vivo*, we generated floxed Nrg3 mice. Brain-specific knockout by hGFAP-Cre, led to reduction of Nrg3 level in the brain. The mutant mice were viable and fertile, without gross anatomic deficits. However, they appeared to spend less time in the center in open-field tests, suggesting increased anxiety. Preliminary electrophysiological studies indicate abnormal transmission and synaptic plasticity in mutant hippocampal slices. These observations support the hypothesis that Nrg3 may play a role in regulating neural activity. Further characterization of mutant phenotypes and investigation of underlying mechanisms may shed light on pathophysiological mechanisms relevant to schizophrenia or nicotine addiction.

Title: Alterations in regulation of inhibition by dopamine D4 receptors in a mouse model of interneuron transcriptional dysregulation

Authors: *L. BRADY, A. F. BARTLEY, L. E. DOBRUNZ;
Neurobio., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: GABAergic interneurons that express parvalbumin play an essential role in proper network activity. Parvalbumin is regulated by the transcriptional coactivator PGC-1α, and PGC-1α-/- mice have decreased expression of parvalbumin in interneurons, similar to that observed in schizophrenia postmortem tissue. Pilot studies from our lab have shown that the inhibition/excitation (I/E) ratio is increased at the Schaffer collateral (SC) pathway in PGC-1α-/-

mice. This is caused by enhanced inhibition, which reduces the spread of activation in CA1 as measured by voltage-sensitive dye imaging. The mechanism for the enhanced inhibition is not yet known. Acute application of haloperidol, an antipsychotic that blocks dopamine D2-like receptors, has been shown to increase excitatory synaptic transmission in CA1. Consistent with this, we observed that haloperidol increased the spread of activation in wildtype (WT) slices. We tested whether haloperidol could alleviate the I/E imbalance in slices from PGC-1α-/- mice, but found instead that haloperidol significantly decreased the spread of activation. Haloperidol appears to make the I/E imbalance worse, suggesting that there are alterations in dopamine regulation of synaptic transmission in PGC-1α-/- mice. To date, it is not known whether PGC-1α has a direct regulatory effect on the dopamine system in hippocampus, or how this might affect GABAergic inhibition. We investigated alterations in the regulation of GABAergic inhibition by the dopamine system using field potential recordings in hippocampal slices from PGC-1α-/- mice. We found that dopamine has a disinhibitory effect in the SC-CA1 pathway, although there was no difference in the magnitude between WT and PGC-1α-/-. However, dopamine activates multiple receptors with opposing effects. Surprisingly, there was no difference in the effects of a D2 receptor antagonist between WT and PGC-1α-/-. However, blocking D4 receptors caused an increase in the field potential in PGC-1α-/- slices due to disinhibition, which was not seen in WT slices. These data suggest that there is a tonic effect of D4 activation that enhances feed-forward inhibition in PGC-1α-/- slices, which may contribute to the enhanced I/E ratio in these mice. Alterations in the dopamine system's modulation of inhibition, through changes in D4 receptor effects, may therefore be involved in the circuit dysfunction caused by loss of PGC-1α. These results may lead to a greater understanding of circuit dysfunction in disorders of I/E imbalance such as schizophrenia, and provide information for the development of alternate pharmacotherapeutic approaches.

Title: Disruption of Nrg1-ErbB4 signaling in specific GABAergic interneurons alters cortical activity and sensory processing

Authors: *R. BATISTA-BRITO[1], J. MOSSNER[1], U. KNOBLICH[1], J. A. CARDIN[1,2]; [1]Neurobio., [2]Kavli Inst., Yale Univ., New Haven, CT

Abstract: Neuregulin1 (Nrg1) is a diffusible trophic factor in the brain that activates a tyrosine kinase receptor, ErbB4. Genetic studies have shown a strong correlation between schizophrenia and mutations in the genes Nrg1 and ErbB4. Studies in mice further suggest that loss of Nrg1 or ErbB4 results in schizophrenia-like phenotypes. Previous work suggests that Nrg1-ErbB4 signaling is necessary for the function of GABAergic, parvalbumin-expressing inhibitory interneurons (PV-INs) in the brain. However, the impact of ErbB4 disruption on cortical network function and the balance of excitation and inhibition *in vivo* remain unknown. Furthermore, it is unclear whether Nrg1-ErbB4 signaling is important for the normal function of non-PV expressing interneurons. In order to understand the role of ErbB4 in inhibitory function in cortical networks we removed ErbB4 from either all interneurons or in specific interneuron subtypes, including PV-, SST- and VIP-expressing interneurons. To assess how Nrg1-ErbB4 signaling affects cortical activity patterns, we recorded spontaneous and visually evoked activity in the primary visual cortex (V1) of awake behaving mice. We used arrays of tetrodes to simultaneously measure local field potentials and make single-unit recordings of large numbers of neurons in V1. Waveform analysis of clustered units allowed us to identify many putative pyramidal cells and fast-spiking (FS) interneurons with high fidelity. In a subset of experiments, we used Cre-dependent optogenetic tagging to record the activity of target interneuron populations. We observed altered spontaneous and visually evoked LFP activity when ErbB4 was removed from all interneurons, as well as from PV and VIP interneurons specifically. ErbB4 deletion from PV and VIP interneurons also altered firing rates and visually evoked spike responses. In contrast, ErbB4 deletion from SST interneurons had no impact on V1 activity at the LFP or spike levels. Our findings suggest that the Nrg1-ErbB4 signaling pathway is important for both the excitatory-inhibitory balance and patterned activity of cortical networks *in vivo*.

Title: Interrogation of dysregulated hippocampal activity in a mouse model of psychosis

Authors: *M. O. CHOHAN[1,2], H. MOORE[1,2];
[1]Integrative Neurosci., New York State Psychiatric Inst., New York, NY; [2]Psychiatry, Columbia Univ., New York, NY

Abstract: Deficits in the number or function of cortical GABAergic interneurons have been hypothesized as a core pathophysiology in schizophrenia (SCZ). GABAergic interneuron hypofunction may contribute to a resting hypermetabolic state in the hippocampus (HIPP), a phenotype that predicts psychosis, which may underlie cognitive and other behavioral impairments seen in SCZ. We previously tested this hypothesis in mice with a null mutation of the cyclin D2 gene (Ccnd2). Ccnd2 is expressed within the medial ganglionic eminence (MGE) of the embryonic brain where it regulates early development of the parvalbumin-expressing interneurons (PV+IN) of the cortex. Ccnd2 nulls show partial and selective decrease in the density of HIPP PV+IN and a corresponding increase in *in vivo* HIPP metabolic activity, an increase in midbrain dopamine (DA) neuron activity and response to amphetamine, and disrupted cognition. Transplanting interneuron precursors derived from the MGE into the adult HIPP normalized these psychosis relevant phenotypes. Here, we aimed to determine the effects interneuron precursor transplants had on HIPP milieu by characterizing HIPP neuronal sub-type activity. Using well-established in-vivo extracellular single-unit recording methods in anesthetized mice, we recorded HIPP neuronal activity from excitatory projection and inhibitory neurons. Ccnd2 nulls showed increased excitatory neuron spiking and a decrease in the density of spontaneously active INs. Preliminary analyses showed no statistically significant differences in spiking activity of detectable INs or the density of excitatory projection neurons; however, the sample size must be increased before we can be confident that these characteristics are unchanged. These findings establish the plausibility of a causative link between hippocampal IN deficits, hippocampal hyperactivity and DA system dysregulation in psychotic disorders.

Characterization of HIPP neuronal activity following IN precursor transplants is ongoing which will further help elucidate mechanisms used by these transplanted cells that help normalize hyper-metabolic state in the hippocampus in these mice.

Abstract: Dopamine transporter (DAT) knockout (KO) mice show numerous behavioral alterations, including hyperlocomotion, cognitive deficits, impulsivity and impairment of

prepulse inhibition of the startle reflex (PPI), phenotypes that may be relevant to frontostriatal disorders such as schizophrenia. Dendritic spine changes of pyramidal neurons in the dorsolateral prefrontal cortex (DLPFC) are among the most replicated of findings in postmortem studies of schizophrenia. The mechanisms that account for dendritic changes in the DLPFC in schizophrenia are unclear. Here, we report basal spine density of pyramidal neurons in the medial prefrontal cortex (mPFC), the motor cortex, the CA1 region of the hippocampus, and the basolateral amygdala in DAT KO mice. Pyramidal neurons were visualized using DAT KO mice crossbred with a Thy1-GFP transgenic mouse line. We observed a significant decrease in spine density of pyramidal neurons in the mPFC and the CA1 region of the hippocampus in DAT KO mice compared to that in WT mice. On the other hand, no difference was observed in spine density of pyramidal neurons in the motor cortex or the basolateral amygdala between DAT genotypes. These results suggest that decreased spine density could cause hypofunction of the mPFC and the hippocampus, and contribute to the behavioral abnormalities observed in DAT KO mice, including cognitive deficits. This might suggest that aberrant dopaminergic signaling may trigger dystrophic changes in dendrites of hippocampal and prefrontocortical pyramidal neurons in schizophrenia.

Title: Biochemical and physiological deficits in gabaergic signaling in a disc1 model of schizophrenia

Authors: S. N. REID[1], M. C. GONDRÉ-LEWIS[1], *K. S. JONES[2];
[1]Anat., Howard Univ. Sch. of Med., Washington, DC; [2]Biol., Howard Univ., Washington, DC

Abstract: The etiology and pathophysiology of schizophrenia (SZ) are unclear. Increasing evidence suggests that mutations in the disrupted-in-schizophrenia-1 (DISC1) gene can dramatically increase the risk for developing SZ or bipolar disorder by as much as 50-fold. Postmortem brain tissue from SZ patients show deficits in biochemical markers of several components of GABA signaling, but how these deficits impact inhibitory neurophysiology remain unknown. Here we examine putative alterations in biochemistry and physiology of GABAergic neurotransmission in subcortical regions of a mouse model which expresses a truncated version of the human DISC1 protein [hDISC1] in excitatory forebrain neurons (Pletnikov, et al 2010). Biochemical and immunohistochemical data suggest expression of hDISC1 appears to reduce expression of the calcium binding protein, parvalbumin, and glutamate receptor subunits, NR1 and GluR1, in the hippocampus and amygdala. These data imply alterations in the function of parvalbumin-expressing, GABA-ergic fast-spiking interneurons (FSIs) and reduced excitatory receptor transmission at glutamatergic synapses may mediate DISC1 pathology. Since FSIs are highly implicated in the etiology of schizophrenia, the impact of hDISC1 expression on cortical and subcortical FSIs was examined using physiological approaches. Whole-cell patch-clamp recordings demonstrate that dnDISC1 expression reduced the frequency of spontaneous excitatory post-synaptic current (sEPSC) of FS cells and these sEPSCs were less sensitive to blockade by an NMDA receptor antagonist. The electrophysiology data corroborate our biochemical findings and support the notion that NMDA signaling may be impaired in hDISC1 mice. Because the hDISC1 transcript is expressed predominantly in principal cells, the biochemical and physiological deficits we observe maybe mediated via non-cell-autonomous mechanisms, which at present are undefined.

Title: Involvement of the receptor for advanced glycation end-product (RAGE) in redox dysregulation and neuroinflammation in an animal model of schizophrenia

Authors: D. DWIR[1], J.-H. CABUNGCAL[1], P. STEULLET[1], R. TIROUVANZIAM[2], *K. Q. DO[1];
[1]Ctr. for Psychiatric Neurosci., Prilly-Lausanne, Switzerland; [2]Res. Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Schizophrenia is a major psychiatric disease which involves both genetic and environmental factors. Glutathione (GSH), an important cellular antioxidant and redox regulator, is decreased in CSF and brain of patients. The key GSH synthesizing genes present polymorphisms associated with the disease. Thus, a redox dysregulation during neurodevelopment is a critical risk factor for schizophrenia, on which converge genetic impairments of glutathione synthesis and environmental vulnerability factors generating oxidative stress. Increasing evidence also points to immune dysregulation in schizophrenia. Anomalies in peripheral immune cells as well as dysregulation of immune-related genes have been reported in schizophrenia brain. However the causes and the underlying mechanisms of this subclinical, inflammatory-like state are still unclear. As oxidative stress is known to induce inflammatory processes, the latter were studied in a transgenic animal model with GSH deficit (GCLM-/-). RAGE represents one potential link between oxidative stress and inflammatory process, as it is activated by ROS and induces inflammatory gene expression. We compared by immunohistochemistry proteins involved in RAGE pathway and microglia activation markers in the anterior cingulate cortex between GCLM-/- and WT mice at P40 and at P90 following oxidative stress induction by a dopamine uptake blocker between P30 and P40 or between P80 and P90. At both time-points, the number of Iba1-immunoreactive (IR), CD11b-IR and CD68-IR cells were increased in GCLM-/- compared to WT at basal level with no further increase after an additional oxidative stress. Interestingly, microglia activation was found only in regions where oxidative stress was increased in the GCLM-/-, suggesting a pro-inflammatory state induced by oxidative stress. RAGE shedding was to be induced in neurons in both genotypes. At P40, RAGE shedding was increased in GCLM-/- while it was decreased following oxidative stress induction compared with WT at basal level. However, at P90, RAGE shedding was decreased in GCLM-/- compared to WT. In addition, S100b, a ligand of RAGE, followed the same pattern as RAGE shedding at both time points, suggesting a feedback regulation of this ligand. RAGE shedding might be induced by MMP9, as this metalloproteinase was increased in GCLM-/- at P40. Finally, we investigated NFkB activation by RAGE using an Adeno-Associated Virus containing GFP under a promoter activated by NFkB. In this work we propose that an interaction between redox dysregulation and pro-inflammatory condition via RAGE is a potential trigger of structural and morphological impairments related to schizophrenia.

Title: Ethanol inhibits GABA neurons in the ventral tegmental area and dopamine release in the nucleus accumbens via presynaptic α6 nicotinic receptors on GABA terminals

Authors: *T. J. WOODWARD[1], S. I. SHIN[1], J. K. MABEY[1], A. C. NELSON[1], N. D. SCHILATY[1], D. H. TAYLOR[2], J. WU[2], M. MCINTOSH[3], S. C. STEFFENSEN[1]; [1]Brigham Young Univ., Provo, UT; [2]Barrow Neurolog. Inst., Phoenix, AZ; [3]Univ. of Utah, Salt Lake City, UT

Abstract: The prevailing view is that enhancement of dopamine (DA) transmission in the mesocorticolimbic system underlies the rewarding properties of alcohol and nicotine (NIC). Dopamine neurotransmission is regulated by inhibitory ventral tegmental area (VTA) GABA neurons, whose excitability is a net effect of glutamate (GLU) and GABA neurotransmission that are modulated by NIC cholinergic receptors (nAChRs) on afferent terminals. We have shown previously that VTA GABA neurons are inhibited by EtOH (EtOH), and adapt to chronic EtOH exposure, evincing marked hyperexcitability during withdrawal. The aim of this study was to evaluate the role of α6 nAChRs in EtOH effects on VTA GABA neurons as well as DA release in the nucleus accumbens (NAc). In electrophysiology studies, superfusion of low doses of EtOH (5 mM) enhanced the frequency (25%) and amplitude (24%) of mIPSCs recorded in acutely dissociated VTA GABA neurons from GAD GFP mice. The α6 nAChR antagonist α-conotoxin P1A (10 nM) did not affect mIPSCs, but prevented the EtOH-induced increase in mIPSC frequency. In the slice preparation of the VTA, superfusion of low doses of EtOH (5 mM) increased eIPSC amplitude in VTA GABA neurons (52%). The α6 nAChR antagonist α-conotoxin MII (100nM) did not affect eIPSCs, but prevented the eIPSC changes caused by EtOH. Additionally, in slice preparation of the VTA, superfusion of low doses of EtOH (5 mM) decreased the firing rate in VTA DA neurons (54%) while high doses (50 and 100 mM) increased VTA DA firing rate (40% and 42%, respectively). The α6 nAChR antagonist α-

conotoxin MII (100nM) did not affect firing rate, prevented the decrease seen at low doses, but was without effect at EtOH enhancement of firing rate at high doses of EtOH. These findings have been further supported by selective stimulation of GABA inputs using optogenetic VGAT-ChR2-YFP BAC transgenic mice. CPP studies have further shown the involvement of α6 nAChR in EtOH modulation, as α6 KO mice evinced less preference for the EtOH compartment. Using FSCV in slice preparation, EtOH inhibited DA release in the NAc. Superfusion of α-conotoxin MII did not affect DA release, but prevented EtOH inhibition of DA release. These findings suggest that EtOH enhancement of GABA inhibition of VTA GABA neurons is mediated by α6 nAChRs, which have been shown to be located on GABA terminals. In addition, GABA inhibition of DA release at terminals in the NAc may be mediated by α6 nAChRs on terminals from projecting VTA GABA neurons. Results from this study could provide a preclinical pharmacologic rationale for considering drugs that act selectively on nAChRs as therapeutic agents for the treatment of alcohol dependence and alcohol and NIC co-dependence.

Title: Neurosteroids block the inhibitory effects of ethanol through GABA(A) receptors on dopamine terminals in the nucleus accumbens

Authors: ***N. SCHILATY**, D. M. HEDGES, T. D. OKELBERRY, A. W. PEREZ, S. C. STEFFENSEN;
Psychology, Brigham Young Univ., Provo, UT

Abstract: GABA(A) receptors are ligand-gated chloride-ion channels of a wide variety in the central nervous system (composed of a variety of five subunits of α, β, γ, δ, ε, π, θ, or ρ), with the most common composition being an α2β2γ subunit construct. Given the purported evidence of the δ-subunit on GABA regulation of dopamine (DA) release in the nucleus accumbens (NAc), it

is likely that this is a possible avenue for ethanol modulation of DA release. Neurosteroids have long been known to act on GABA(A) receptors. It has been theorized that the δ-subunit may have a neurosteroid binding site. Thus, using fast scan cyclic voltammetry (FSCV), we performed experiments on brain slices in the NAc by superfusing various GABA(A)R-modulating neurosteroids - allopregnanolone, DHEAS, and estrone sulfate. We also tested trilostane, which enhances the endogenous expression of DHEAS via block of 3 β-hydroxysteroid dehydrogenase. DHEAS (20 μM) enhanced DA release in the NAc by 20 %, while allopregnanolone, estrone sulfate, and trilostane did not significantly alter DA release. Ethanol (20 - 160 mM, IC50 = 80 mM) reduced DA release in wild type (WT) mice. Superfusion of DHEAS (20 μM) significantly attenuated ethanol inhibition of DA release, however, the other neurosteroids tested only had partial effects on attenuating the inhibition of DA release by ethanol. The selective GABA δ-subunit antagonist Ro15-4513 (10 μM) enhanced DA release by 26 % and reduced ethanol inhibition of DA release to 91 % of baseline levels. In addition, we found a lack of attenuating effects of ethanol (20 - 160 mM) on DA release with GABA δ-subunit knockout mice (δKO) as compared to controls. Based on this pharmacological and genetic data, we conclude that ethanol is partially acting in the NAc via GABA δ-subunit receptors on DA terminals, and that indirect antagonism of GABA(A) receptors (via DHEAS or Ro15-4513) in the NAc enhances DA release.

Title: Functional switch in GABA(A) receptors on VTA GABA neurons by chronic ethanol

Authors: ***A. NELSON**[1], T. J. WOODWARD[1], J. K. MABEY[1], S. I. SHIN[1], R. TING-A-KEE[2], H. VARGAS-PEREZ[2], D. VAN DER KOOY[2], S. C. STEFFENSEN[1];

Abstract: Past research has demonstrated that the motivational effects of opiates and ethanol switch from a dopamine (DA)-independent to a DA-dependent pathway when the animal is in a drug-dependent state. A corresponding change occurs in ventral tegmental area (VTA) GABA(A) receptors in opiate-dependent animals, which switch from a GABA-induced hyperpolarization of VTA GABA neurons to a GABA-induced depolarization. The aim of this study was to evaluate VTA GABA neuron excitability, GABA synaptic transmission to VTA GABA neurons and GABA-mediated DA release in the nucleus accumbens (NAc) under ethanol-naïve and dependent conditions. To accomplish these studies, we used standard whole-cell and attached-cell mode electrophysiological techniques to evaluate acute and chronic ethanol effects on VTA GABA neurons in CD-1 GAD GFP mice, which enabled the visual identification of GABA neurons in the slice preparation. In naïve animals, superfusion of ethanol (IC_{50} = 30 mM) and the GABAA receptor agonist muscimol (IC_{50} = 100 nM) decreased VTA GABA neuron firing rate in a dose-dependent manner. Compared to either saline-injected or air-exposed controls, in animals made dependent on ethanol by twice daily injections of 2.0 g/kg ethanol or ethanol vapor (200 mg% BAL), neither ethanol nor muscimol significantly affected VTA GABA neuron firing rate on average. Indeed, some cells were excited by ethanol and muscimol, while others remained partially inhibited, producing the average of no change in firing rate of the whole population. While microdialysis studies typically show that ethanol enhances DA release in the NAc, we and others have found that ethanol decreases DA release at terminals, as measured by fast scan cyclic voltammetry. We have recently reported that ethanol inhibition of DA release at terminals in the NAc of ethanol-naïve animals is mediated by GABA, possibly from VTA GABA neurons that project to the NAc. Thus, we evaluated the effects of ethanol on DA release in the same ethanol-dependent animals. Compared to air-exposed controls, superfusion of ethanol did not significantly affect DA release. Taken together, these findings suggest that VTA GABA neurons undergo a switch in GABA(A) receptor function in ethanol-dependent animals, similar to opiate-dependent animals, which results in a corresponding switch in DA release, perhaps resulting from adaptations in VTA GABA neuron input to the NAc.

Title: Transcriptome analysis on ethanol-induced brain injury among primary cultures of brain cells and slices

Authors: *K. SUGIMOTO[1], H. TANAKA[2], R. KATADA[1], K. IGARASHI[1], M. YOSHIDA[1], H. MATSUMOTO[1];
[1]Dept. of Legal Med., Osaka Univ. Grad. Sch. of Med., Suita, Osaka, Japan; [2]Ritsumeikan Univ., Kusatsu, Japan

Abstract: Most of alcoholics have cognitive deficiencies such as learning, memory and motor skills. These functions constitute signal transduction, neural transmission, and so on via molecules and receptors such as dopamine, GABA and glutamate. However, any roles of brain cells in ethanol-induced brain injury remain unclear. In the present study, we evaluated the effects of ethanol on the mRNA expression in the rat brain slices and primary cultures of astrocytes, microglia and neuron from the rat. First, the experiment with organotypic brain slice cultures was performed to examine the effects of ethanol on various genes expression. Male Wistar rats (8 weeks old) were carbon dioxide-anesthetized and quickly decapitated. After dissection of the brain and removal of the frontal and occipital poles (including the cerebellum), the specimens were sliced into 200 μm thick sections on a LEICA VT1000S tissue slicer. After culturing for 3 hours, the slice was incubated in the medium with or without 50-mM ethanol for 12 hours. Thereafter, the expression of various mRNAs in the specimens was revealed by a quantitative real-time RT-PCR system. Ethanol treatment significantly increased the expression of oxidative stress-, ion channel- and glutamate receptor-related genes compared as non-treatment with ethanol. Of course, these organotypic brain slices consist of neurons, astrocytes, microglial cells, NG2 glial cells, oligodendrocytes and so on. Then, we investigated what kind of brain cells might contribute to ethanol-induced expression of mRNAs in the brain slice experiments. Neurons and glial cells were isolated from the hippocampus of E18-19 rat embryos and the forebrain of newborn rats, respectively. We confirmed the differences in the ethanol-induced expression of mRNA among these cells. Therefore, these findings suggested differential effects of ethanol on the brain injury among brain cells.

Title: A comparison of neuroimmune alterations produced by acute ethanol exposure in late adolescent, adult, and aged Fisher 344 rats

Authors: *A. GANO, T. L. DOREMUS-FITZWATER, T. DEAK;
Psychology, Binghamton Univ., Binghamton, NY

Abstract: Prior studies have established that the aging brain transforms toward a more inflamed state during senescence, as evidenced by increased microglial activation and increased cytokine response. Our recent work has shown that acute ethanol exposure (4 g/kg) increased expression of interleukin-6 (Il-6) in both the hippocampus (HPC) and paraventricular nucleus of the hypothalamus (PVN) 3 hr after ethanol, whereas interleukin-1 (Il-1) and tumor necrosis factor α (Tnfα) were suppressed at this time point. The goal of the present study was to examine whether ethanol challenge would differentially alter the cytokine response in aged Fisher 344 rats. In this 3 (age group: late adolescent (~PND50), young adult (~PND100), aged (~18 month) x 3 (drug exposure: ethanol, vehicle, homecage) between-subjects design (N = 48, n = 4-6 per group), rats received acute intraperitoneal injections of either 3.5 g/kg 20% v/v ethanol, or equivolume saline, or remained unmanipulated in the homecage. Brain tissue and blood were collected 3 hours later for analysis of blood ethanol concentrations (BECs), plasma corticosterone (CORT), and gene expression of cytokines in the PVN and HPC. As an initial test of behavioral sensitivity to ethanol, Loss of Righting Reflex (LORR) was assessed between exposure to drug and tissue collection. Although BECs did not vary across ages (range: 337-361 mg/dl), adolescents recovered LORR substantially faster than adults and aged rats. Elevated basal concentrations of CORT were observed in aged rats (relative to adolescent) prior to ethanol, yet ethanol exposure produced an equivalent increase in CORT in all age groups. These effects were mirrored by ethanol-induced C-fos expression in the PVN (but not hippocampus). Ethanol increased Il-6 in the PVN and HPC of all rats regardless of age. Interestingly, the pattern of cytokine changes in the hippocampus largely recapitulated what we have observed in adult Sprague Dawley rats (increased Il-6; decreased Il-1 and Tnfα), whereas in the PVN ethanol increased Il-6, Il-1 and Cd14, with Tnfα being suppressed. Overall, age-related increases in Il-1 in the hippocampus and Cd14 in the PVN indicated typical aging-associated increases in neuroimmune status. These findings provide an important foundation for understanding how heightened neuroimmune status in the aging brain might impact the evoked neuroimmune response produced by ethanol challenge during senescence.

Title: Activity of the striatal indirect pathway neurons alters ethanol seeking behaviors in mice

Authors: *M. B. BLEGEN, R. BOCK, M. F. ADROVER, V. A. ALVAREZ;
Section on Neuronal Structure, Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD

Abstract: Investigating the neural circuitry that mediates ethanol seeking and drinking is a critical step in understanding and preventing the development of alcohol use disorders. The nucleus accumbens (NAc), a key region in the mesolimbic reward circuit, is involved in alcohol seeking behaviors. Medium spiny neurons (MSNs) form the main output of the NAc and consist of two populations: direct and indirect pathway MSNs. Indirect-pathway MSNs (i-MSNs) are thought to inhibit striatal output and facilitate behavioral inhibition, but the role of this pathway in alcohol seeking and drinking remains unclear. The goal of this study was to develop a model of operant ethanol self-administration in mice and test how manipulating the activity of i-MSNs changes operant ethanol drinking behaviors. Mice (*Adora2a-cre*$^{+/-}$ and *Adora2a-cre*$^{-/-}$, males and females, 5-8 weeks old) were given intermittent access to 20% ethanol for 4h during the dark cycle for 5 days/week for 3 weeks. Subsequently, mice were trained on a cued operant self-administration task to earn 20% ethanol (no sucrose) as a reinforcer in 2h sessions for 4 weeks. Most mice acquired the behavior within 7 sessions during which the ratio of active to inactive nose-pokes increased and plateaued at 4.6. Mice earned an average of 50 rewards/2h, which corresponded to 2.25 ± 0.07 g/kg/day of ethanol. Blood ethanol concentrations (BECs) averaged 59 ± 6.8 mg/dl during the intermittent access phase and 68 ± 2.9 mg/dl during the operant phase, ranging from 23 to 172 mg/dl. When ethanol was substituted with water and cues were removed during extinction sessions, the ratio of active to inactive pokes fell to 2. Together, these results show that ethanol, even without sucrose, is a potent reinforcer in mice and that pairing intermittent ethanol access with operant ethanol drinking is a good model from which to study circuitry controlling ethanol seeking and drinking. Manipulations of i-MSNs were performed using Designer Receptor Exclusively Activated by Designer Drug (DREADD) to selectively

inhibit i-MSN output with Gi–coupled DREADDs or activate i-MSN output with Gq-coupled DREADDs. Inhibition of i-MSNs had no effect on operant ethanol seeking or consumption. However, when paired with an aversive stimulus, quinine adulteration, inhibition of the i-MSNs appeared to increase operant ethanol seeking while activation of the i-MSNs caused a robust 60% decrease in active pokes for quinine adulterated ethanol. These results provide strong evidence that indirect pathway neurons play an important role in regulating alcohol seeking under conditions that require behavioral inhibition, which engage this circuit.

Title: Alcohol and the prescription opioid analgesic, oxycodone, disrupt opioid peptide-mediated long-term depression of excitatory transmission in the dorsal striatum

Authors: *B. K. ATWOOD, D. LOVINGER;
LIN, NIAAA, Rockville, MD

Abstract: Prescription opioid analgesic and alcohol abuse are two forms of drug abuse that present profound socioeconomic burdens in the United States. Understanding the long-term effects of opioid and alcohol use on brain function is increasingly important. Both opioid analgesics and alcohol alter the function of brain opioid receptors, but the consequences of these alterations on synaptic plasticity are unknown. The dorsal striatum is a brain region that is important for goal-directed and habitual action selection and is a site of importance for drug-induced neuronal plasticity. We recently reported evidence that exogenously applied and endogenously released opioids produce long-term depression of excitatory inputs to the dorsal striatum (OP-LTD) in mice and rats (Atwood et al., 2014). OP-LTD is mediated by three different receptors: the mu, delta and kappa opioid receptors. Mu and delta OP-LTD are both presynaptically expressed and occur throughout the dorsal striatum. However these forms of LTD are dissociable in that they summate, differentially occlude endocannabinoid-LTD, and inhibit different striatal inputs. Mu OP-LTD inhibits thalamostriatal inputs, but not inputs from

motor cortex. Conversely, delta OP-LTD inhibits motor cortex inputs but does not affect inputs from thalamus. Kappa OP-LTD shows a unique subregional expression within striatum and has a less clear site of action. A single *in vivo* exposure to the opioid analgesic, oxycodone, disrupts mu OP-LTD and endocannabinoid-LTD, but not delta or kappa OP-LTD. The effect of oxycodone on mu OP-LTD is long-lasting as it is disrupted for three days following a single *in vivo* exposure. Similar to the effects of oxycodone on endocannabinoid-LTD, a recent report indicates that two weeks of chronic intermittent ethanol exposure followed by three days of withdrawal disrupts endocannabinoid-LTD (DePoy et al., 2013). Using a similar ethanol administration paradigm, we find that ethanol exposure also disrupts mu OP-LTD. These data reveal novel, opioid-mediated forms of long-term striatal plasticity that are likely important mediators of striatal-dependent learning and behavior. In addition we find that both the opioid analgesic oxycodone and alcohol have similar negative impacts on mu OP-LTD and endocannabinoid-LTD. The effects of these drugs on these forms of striatal plasticity may underlie some components of the transition from casual drug use to drug abuse and addiction.

Title: Ethanol decreases the spontaneous firing rate of a specific subset of Globus Pallidus neurons

Authors: *K. P. ABRAHAO, D. M. LOVINGER;
Laboratoy of Integrative Neurosci., NIAAA/NIH, Rockville, MD

Abstract: The Globus Pallidus external segment (GPe) is a sub-cortical brain structure containing neurons that generate high-frequency autonomous pacemaker activity which helps to control basal ganglia output. The GPe receives strong GABAergic afferent input from the

striatum as well as glutamatergic innervation from the subthalamic nucleus. Both inhibitory and excitatory components control the spontaneous firing rate of GPe neurons. Alcohol is one of most widely abused drugs and has known actions on brain GABAergic and glutamatergic synaptic transmission. Ethanol can also alter spontaneous neuronal firing in midbrain neurons. However, little is known about ethanol actions in GPe. Thus, we performed whole-cell patch-clamp recordings from neurons in mouse GPe brain slices to examine acute ethanol actions. Different studies describe specific electrophysiological and biochemical characteristics for different GPe neuron populations. We were able to identify three clusters of GPe neuronal types based on the distribution of the firing rates recorded in slices from 21-58 day old C57BL/6J male mice. Type 1, 2 and 3 neurons exhibited firing rates of (mean ± standard deviation) 9.49 ± 4.02, 27.50 ± 5.46 and 69.45 ± 22.49, respectively. The firing rate was significantly positively correlated with the resting membrane potential (r=0.37) and the voltage sag at hyperpolarized potentials (r=0.41), but negatively correlated with the input resistance (r=-0.38). Bath application of 40 mM ethanol decreased the firing rate of the type 1 GPe neurons by ~25% but it did not alter the firing rate of type 2 or 3 neurons. Ongoing studies are examining the effects of other doses of ethanol as well as the effect of *in vivo* chronic ethanol exposure on the firing rate of GPe neurons. We are also identifying biochemical markers of the type 1 neurons, and examining what mechanisms contribute to ethanol-induced decreases in the firing rate of these neurons. This knowledge may provide better understanding of the mechanisms contributing to ethanol effects on the CNS and behavior.

Title: Rapid adaptation of dopamine D2 receptors in brain and blood following acute ethanol administration

Authors: *E. JANG, R. J. FOLSOM, J. R. LINZEY, L. FRIEND, C. F. BURNETT, S. H. BURNETT, S. C. STEFFENSEN;
Psychology, Brigham Young Univ., Provo, UT

Abstract: Dopamine (DA) D2 receptor expression parallels DA levels in the brain and chronic ethanol exposure alters the expression of these autoreceptors in the brain. We have previously shown that DA D2 receptor expression following chronic ethanol exposure is down-regulated in the ventral tegmental area (VTA) of the midbrain where DA neurons originate and in their terminals in the nucleus accumbens (NAc), likely a result of lowered DA levels. All five subtypes of DA receptors, including D2 receptors, also have been discovered on T-lymphocytes in mice. The aim of this study was to evaluate short-term D2 receptor adaptation in the brain and blood by acute ethanol in anesthetized rats. First, we measured DA release following injection of ethanol (2.5 g/kg, IP), the D2 agonist quinpirole (0.1 mg/kg, IV), and the D2 antagonist eticlopride (1.0 mg/kg, IP) in the NAc using *in vivo* fast scan cyclic voltammetry (FSCV). Second, we determined that there is a population of DA D2 receptors found on activated monocytes. Activated monocytes are a type of immune cell that leaves the blood and enters interstitial fluid. We sampled blood at hourly intervals in anesthetized rats before and after systemic administration of saline, ethanol, quinpirole, or eticlopride and measured D2 receptor expression using RT-PCR. Systemic administration of eticlopride markedly enhanced (250%) the amplitude of the evoked DA signal, which remained elevated for 2-3 hrs. The expression of D2 receptor mRNA in blood decreased at 2 hrs by 35-64% following ethanol or eticlopride injection. In contrast to both groups, injection of quinpirole increased the expression of D2R mRNA by 176% at 2 hrs. These findings suggest that acute doses of drugs not only yield rapid changes in central D2 receptor expression, but elicit changes in peripheral D2 receptor expression as well. These results have significant clinical potential as changes in D2 receptor expression could be monitored and used for the treatment of addiction as well as other diseases involving DA including Parkinson's disease.

Title: Social isolation stress affects dopamine signaling and kappa opioid receptor system in the nucleus accumbens and the basolateral amygdala

Authors: *A. KARKHANIS, J. ROSE, B. A. MCCOOL, J. L. WEINER, S. R. JONES;
Wake Forest Sch. of Med., Winston-Salem, NC

Abstract: Chronic early life stress, such as neglect during childhood, results in increased risk for alcohol use disorders during adulthood. Similarly, rats reared in social isolation (SI) during adolescence show increased ethanol (EtOH) intake compared to group housed controls (GH). Stress elevates dynorphin levels, a kappa opioid receptor (KOR) ligand, which regulates dopamine (DA). Activation of KORs inhibits DA release in the NAc and BLA. NAc and BLA are highly interconnected and play integral roles in the neurobiology of stress, anxiety, and reward-seeking behavior. Recent literature shows that the kappa opioid receptor (KOR) system regulates drug seeking following chronic exposure to ethanol. Therefore, in order to understand the potential underlying mechanisms driving the isolation-induced increased EtOH intake, the effects of acute EtOH on DA in the presence and absence of nor-binaltorphimine (norBNI), a KOR antagonist, were examined in the NAc and the BLA. Moreover, the sensitivity of KORs was examined in NAc slices of SI and GH rats. DA in the NAc and BLA was measured using dual-probe *in vivo* microdialysis in freely moving rats that were either housed in groups (4 rats/cage) or individually (1 rat/cage) for six weeks (PD 28 - 74). Acute EtOH (1 or 2 g/kg, i.p.) was administered after establishing stable DA baselines. A separate group of rats was pre-treated with norBNI (10 mg/kg; i.p.) 24 hrs prior to EtOH challenge. To examine the sensitivity of KORs, *ex vivo* voltammetry was used to assess the effects of U50,488 (10 - 1000 nM), a KOR agonist, on DA release in NAc slices from GH and SI rats. The baseline levels of DA were not different in the NAc of SI and GH rats, but significantly lower in the BLA of SI compared to GH rats. KOR activation increased baseline DA levels in NAc and BLA. The SI rats showed increased DA responses to EtOH (2 g/kg) in both NAc (200% of baseline) and BLA (280% of baseline) and this increase was significantly greater in BLA compared to NAc. EtOH augmented DA responses in the NAc of SI rats pre-treated with norBNI, and attenuated it in the BLA. The inhibitory effects of U50,488 on DA release were enhanced in the NAc of SI compared to GH rats suggesting that chronic stress sensitizes KORs. Increased DA elevations after EtOH in both regions of SI rats is consistent with the stimulant literature, however the mechanisms behind the distinct effects of EtOH-induced DA in presence and absence of norBNI in NAc and BLA are unclear. It is possible that these differences may explain the effects of EtOH on behaviors related to specific brain areas, e.g., augmentation of DA in the NAc results in increased reinforcement, whereas augmentation in DA in the BLA may contribute to decreased anxiety.

Title: CRF-R1 modulation of extracellular serotonin and dopamine in mice given intermittent access to alcohol

Authors: ***L. S. HWA**, E. HOLLY, A. SHIMAMOTO, J. F. DEBOLD, K. A. MICZEK; Psychology, Tufts Univ., Medford, MA

Abstract: Excessive and harmful alcohol drinking can be characterized by recurring cycles of binge drinking and withdrawal. Intermittent access to 20% alcohol (IAA) and water in C57BL/6J mice can generate dependent-like drinking and withdrawal, approximating the human condition. Our previous findings have shown that IAA can cause an activation of corticotropin-releasing factor type 1 receptors (CRF-R1) in extrahypothalamic sites, including the serotonergic dorsal raphé nucleus (DRN) and the dopaminergic ventral tegmental area (VTA). The present studies investigate the dysregulation of neurotransmitters during the transition to dependence in the IAA schedule. Adult, male C57BL/6J mice were given IAA for at least 4 weeks. Animals were implanted with microcannula into the DRN and microdialysis probes into the medial prefrontal cortex (mPFC) for measurement of extracellular serotonin in an efferent site after intra-DRN microinjection of a CRF-R1 antagonist. Another group of IAA mice were implanted with microcannula targeting the VTA and probes into the nucleus accumbens (NAcc) for measurement of extracellular dopamine in an efferent site after intra-VTA microinjection of a CRF-R1 antagonist. Using *in vivo* microdialysis, mice were tested for either serotonin or dopamine 24 hours after alcohol had been removed, and when the next set of alcohol and water were to be presented in the IAA schedule, three hours into the dark phase. Samples were collected before and after microinjection of a CRF-R1 antagonist, CP-154,526, and analyzed with high performance liquid chromatography. Microinjection of CP-154,526 into the DRN

increased extracellular serotonin levels in the mPFC in mice with a history of IAA. A positive control, naltrexone, did not have a significant on serotonin under the same conditions. Ongoing studies are confirming whether CRF-R1 antagonists blunt increased dopamine in NAcc after ethanol consumption (assessing the effect of CP-154,526 on dopamine in the NAcc). Also, we are exploring the transition to dependence by measuring dopamine after the first IAA episode compared with dopamine in the post-dependent mouse. These findings suggest that CRF-R1 interacts with serotonin neurons in the DRN, perhaps the CRF-R1 antagonist disinhibits 5-HT impulse flow or alternatively, CRF acts upon an alternative mechanism, like CRF-R2, to activate serotonin flow.

Title: Monoamine oxidase (MAO) inhibitors and knockdown of MAO transcriptional activator, Kruppel-like Factor 11, exhibit neuroprotective effects against ethanol-induced neurotoxicity and cell death in SH-SY5Y cells

Authors: *J. W. DUNCAN[1,2], S. HARRIS[1], X. ZHANG[1], X.-M. OU[1], C. A. STOCKMEIER[1,2,4], J. WANG[1,2,3];
[1]Psychiatry and Human Behavior, [2]Grad. Program in Neurosci., [3]Pathology, Univ. of Mississippi Med. Ctr., Jackson, MS; [4]Psychiatry, Case Western Reserve Univ., Cleveland, OH

Abstract: Alcoholism is the 3rd leading cause of preventable death in the U.S. and has an annual cost burden of ~$223.5 billion/year (CDC). Due to the health-related risks and morbidity associated with alcohol dependence, new pharmacological targets to reduce subsequent neurotoxicity and brain cell death from ethanol exposure could be beneficial. We have demonstrated that a 50mM-100mM concentration range (a physiologically relevant blood level observed in alcohol abuse) of ethanol in cell culture models increases Monoamine Oxidase-B (MAO-B) transcriptional activator, Kruppel-like factor 11 (KLF11), MAO-B expression, and

MAO-B catalytic activity which collectively results in neuronal cell death. Much of the literature has suggested the application of MAO-B inhibitors, such as Selegiline and Rasagiline, for the treatment of neurodegenerative diseases as they increase expression of anti-apoptotic Bcl-2 proteins and oxidative stress scavenging enzymes in neurodegenerative cell models. Whether these neuroprotective effects persist in the presence of ethanol is currently being investigated. In the present study, new generation MAO-Is (Rasagiline and M30) were concomitantly administered with ethanol to examine their neuroprotective properties in cultured human neuroblastoma (SH-SY5Y) cells. Furthermore, cells transfected with siRNA targeting KLF11 provided a similar degree of neuroprotection to that of MAO-I administration. Cell viability was significantly enhanced in ethanol-exposed [75mM-150mM] cells treated with KLF11 siRNA or MAO-Is (.025nM - 100nM concentrations) compared to ethanol-exposed control cells. Moreover, western blot analysis revealed a KLF11 knockdown and MAO-I drug effect on the expression of anti-apoptotic proteins and oxidative stress scavenging enzymes, leading to an overall increase in cytoprotective markers. Together, these results further support the efficacy of KLF11 RNA interference (RNAi) and MAO-I pharmacotherapy to combat ethanol-induced neurotoxicity and cell death. Further exploration of these two novel candidate neuroprotective strategies may afford potential avenues to alleviate ethanol-induced neurotoxic consequences.

Title: Activity of D1R MSNs in the dorsomedial striatum is essential for voluntary alcohol consumption

Authors: *J. WANG, Y. CHENG, X. WANG;
Dept. of Neurosci. & Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr., Bryan, TX

Abstract: Dopamine D1 receptor-expressing (D1R) medium spiny neurons (MSNs) in the striatum give rise to the direct pathway that contributes to selection of “Go” actions in rewarding

behaviors. We recently found that excessive alcohol intake enhances synaptic strength in D1R MSNs of the dorsomedial striatum (DMS) in mice. The enhanced synaptic strength in D1R MSNs may contribute to the maintenance of excessive alcohol intake by increasing "Go" actions that are associated with alcohol intake. Here, we examined whether manipulation of D1R MSN activity in the DMS alters voluntary alcohol consumption. We infused in the DMS of drd1a-Cre mice with a viral vector containing Cre-dependent hM4Di. The selective expression of hM4Di in D1R MSNs allows us to downregulate the activity of these neurons and to examine their contribution to alcohol drinking behaviors. Mice were trained to consume high levels of alcohol using the intermittent access 2-bottle choice drinking procedure. After a stable baseline of alcohol intake is achieved, CNO, the ligand of hM4Di, was systemically administered, and alcohol intake was measured for 30 min, 4 hrs, and 24 hrs. We found that CNO administration causes significant reduction of alcohol intake in 30 min and 4 hrs, but not in 24 hrs. The reduction of alcohol intake is accompanied by a decrease in alcohol preference. However, CNO administration does not alter water intake. Together, our results suggest that the activity of D1R MSNs in the DMS, which contribute to "Go" actions, is required for the maintenance of excessive alcohol consumption.

Title: The role of VTA GABA(A) receptors in maladaptive decision making and increased phasic dopamine release following chronic adolescent alcohol intake

Authors: *A. G. SCHINDLER, K. T. TSUTSUI, H. H. N. HOANG, J. J. CLARK;
Univ. of Washington, Seattle, WA

Abstract: Alcohol is the most commonly abused substance among adolescents and shows the highest liability of all abused drugs. We have previously demonstrated that voluntary

consumption of alcohol by adolescent rats results in increased maladaptive risk-taking behavior and nucleus accumbens (NAc) phasic dopamine release in adulthood, as assessed by a probability discounting task and fast scan cyclic voltammetry (FSCV) respectively. These finding suggest that adolescent alcohol exposure-induced changes in NAc dopamine release could bias choice by assigning greater value to the risky option, but the underlying mechanisms remain unknown. GABA(A) receptors located in the VTA are a potential candidate for mediating these effects, and we hypothesize that adolescent alcohol intake confers persistent changes to risk-taking behavior through alcohol-mediated, GABA(A) receptor-induced modulation of NAc dopamine release. Using electrical stimulation of the pedunculopontine nucleus (PPT) afferents to VTA DA neurons, here we demonstrate that adult rats previously exposed to alcohol during adolescence showed increased NAc phasic dopamine release, as compared to controls. Conversely, NAc phasic dopamine release via electrical stimulation of the medial forebrain bundle (MFB) did not differ between alcohol and control rats, suggesting that increased dopamine release following adolescent alcohol intake occurs via changes within the VTA. PPT stimulation elicits GABA(A) receptor dependent current in VTA DA neurons, raising the possibility that adolescent alcohol intake produces this increased phasic dopamine release through downregulation of GABA(A) receptors on VTA DA neurons. Systemic administration of L-838,417, a GABA(A) receptor α2, α3, and α5 subunit allosteric agonist, caused a dose-dependent decrease in phasic DA release elicited by PPT stimulation in control rats, and this decrease was enhanced in rats exposed to alcohol during adolescence. In order to investigate this phenomenon further, imaging flow cytometry was used to measure expression of GABA(A) receptor subunits on individual neurons of the ventral midbrain. Taken together, these results provide unique insight into the potential role that GABAergic modulation of dopamine neurons plays in the maladaptive risk-taking behavior seen following adolescent alcohol intake and highlights new potential therapeutic targets.

Title: Up-regulation of novel synaptic GABA-A receptor subtypes contributes to altered mIPSC kinetics and pharmacology in rat hippocampus after acute or chronic ethanol intoxication

Authors: *R. W. OLSEN[1], A. K. LINDEMEYER[1], X. M. SHAO[2], J. LIANG[1];
[1]Dept Mol. & Med. Pharmacol., Geffen Sch. of Med. At UCLA, LOS ANGELES, CA;
[2]Neurobio., Geffen Sch. of Med. at UCLA, Los Angeles, CA

Abstract: Alcohol (EtOH) intoxication causes long-lasting plastic changes of various γ-aminobutyric acid type A receptors ($GABA_A$Rs) in the brain. These alterations contribute to EtOH-induced changes in synaptic and extrasynaptic physiology and pharmacology involving decreased sensitivity to EtOH enhancement of extrasynaptic $GABA_A$R-mediated tonic inhibitory currents and increased EtOH sensitivity of GABAR-mediated miniature inhibitory postsynaptic currents (mIPSCs) (Liang et al., 2006). This is believed to play a crucial role in alcohol dependence and withdrawal symptoms. Previously we showed that in rat hippocampus and other brain regions, acute and chronic EtOH administration to rodents by gavage results in decreased cell surface expression of $GABA_A$R subunits δ and α1 while γ2 and α4 are up-regulated. Modulation of synaptic and extrasynaptic $GABA_A$R-mediated inhibitory currents are consistent with contribution of α to mIPSCs. Here, we report also an increase in surface expressed α2 and γ1 subunits. Co-immunoprecipitation experiments reveal an increase in $GABA_A$Rs composed of α4/β/γ2 and α2/β1/γ1 at synaptic sites. The two subtypes have rather similar BZ pharmacology, consistent with a role for either α 4 or α 2 subunit-containing $GABA_A$Rs in the EtOH-dependent rodent. Two-pulse EtOH experiments were used to identify the receptor subtype showing sensitivity to EtOH application, measuring the temporal sequence of changes in $GABA_A$R cell surface expression and mIPSC sensitivity to EtOH. Studies on α4 KO mice, which reveal increased EtOH drinking in the TBC assay, demonstrate an EtOH-sensitive synaptic current in mice lacking the α 4 subunit, untreated with EtOH. They show elevated α2, γ2, and γ1, suggesting possible involvement of α2-containing receptors in EtOH-sensitivity. Furthermore, mIPSC analysis with an optimally scaled template algorithm is consistent with significant presence of α 2 mIPSCs in rat hippocampus, especially after CIE and in α 4 KO mice, and they appear to be enhanced by acute EtOH. These studies, coupled with human genetic linkage of α2 to AUD, suggest that besides up-regulated α4/β/γ2 receptor subtypes, also α2-containing $GABA_A$Rs are involved in withdrawal syndromes and alcohol dependence including increased drinking.

Title: Intermittent and binge-like alcohol drinking in Gabra2 knock-in mice with benzodiazepine- or ethanol-insensitive α2 subunits

Authors: *E. L. NEWMAN[1], G. GUNNER[1], P. HUYNH[1], S. MOSS[2], U. RUDOLPH[3], J. F. DEBOLD[1], K. A. MICZEK[1,2];
[1]Psychology, Tufts Univ., Medford, MA; [2]Neurosci., Tufts Univ. Sackler Sch. of Grad. Biomed. Sci., Boston, MA; [3]Lab. of Genet. Neuropharmacology, McLean Hospital, and Dept. of Psychiatry, Harvard Med. Sch., Belmont, MA

Abstract: Benzodiazepines and alcohol may disinhibit drug-taking behavior via positive allosteric modulation of heteromeric GABA-A receptors. Endophenotypic analyses have identified GABRA2 single nucleotide polymorphisms as predictors of an individual's predisposition to alcohol dependence. To further characterize the role of the GABA-A α2 subunit, knock-in mice rendered selectively insensitive to benzodiazepines (H101R) or ethanol (S270H/L277A) were assessed for binge-like or dependence-inducing ethanol intake. In a 4-day drinking in the dark procedure, male mutant and C57BL/6J wild type mice received 2-hour access to 20% ethanol (EtOH) on three consecutive days. On the fourth day, access was extended to 4 hours to measure binge-like EtOH consumption. *Gabra2* (H101R) males with benzodiazepine-insensitive α2 subunits drank significantly more (7.9 g/kg) than WT or *Gabra2* (S270H/L277A) mutants (5.5-6 g/kg) during the 4-hour access period. As a comparison, mutant and WT mice were also evaluated for dependence-inducing alcohol intake in a chronic, intermittent access protocol. On alternating days, EtOH-drinking animals received 24-hour, 2-bottle choice access to 20% EtOH (w/v) and water while water-drinking control mice always received two bottles of water. Under intermittent EtOH conditions, WT and *Gabra2* (H101R) males consistently drank 18-20 g/kg/24h, suggesting that benzodiazepine-sensitive GABA-A α2 subunits are not required for high EtOH intake in this protocol. After eight weeks of chronic intermittent EtOH-drinking, wild type mice were assessed in a social approach protocol 6-8 hours after removal of their 20% EtOH bottles. During withdrawal, these mice expressed

reduced durations of social approach behavior as compared to water-drinking controls. Current investigations assess chronic intermittent alcohol drinking and social measures of withdrawal in *Gabra2* males with benzodiazepine (H101R) - or ethanol (S270H/L277A) -insensitive GABA-A α2 subunits.

Title: Zebrafish and conditioned place preference: A translational model of drug reward

Authors: *D. J. ECHEVARRIA[1], A. D. COLLIER[2], E. M. CAMARILLO[2], K. M. KHAN[2]; [1]Dept Psychol, Univ. Southern Mississippi, HATTIESBURG, MS; [2]Univ. of Southern Mississippi, HATTIESBURG, MS

Abstract: Addiction and substance abuse amass hundreds of billions of dollars annually in costs associated with healthcare, crime and lost productivity, solely within the United States. Efficacious treatments remain few in number, the development of which will be facilitated by comprehension of environmental, genetic, pharmacological and neurobiological mechanisms implicated in the pathogenesis of addiction. Animal models such as the zebrafish (Danio rerio) have gained momentum within various domains of translational research, and as a model of complex brain disorders (e.g., drug abuse). Behavioral quantification within the conditioned place preference (CPP) paradigm serves as a measure of the rewarding qualities of a given substance. If the animal develops an increase in preference for the drug paired environment, it is inferred that the drug has positive-reinforcing properties. This study reports the effects of acute (1 day) and chronic (14 days) exposure of ethanol, nicotine and caffeine on CPP behavior in zebrafish.

Title: Incubation of alcohol craving is dependent on alcohol cue-activated neurons in the nucleus accumbens core

Authors: *C. MONTANARI[1], N. SUTO[1], T. KERR[1], D. WATRY[1], B. STARR[1], B. T. HOPE[2], P. P. SANNA[1], F. WEISS[1];
[1]Mol. and Cell. Neurosci., Scripps Res. Inst., La Jolla, CA; [2]Behavioral Neurosci. Br., NIDA/IRP/NIH, Baltimore, MD

Abstract: The core subregion of the nucleus accumbens (NAcore) has been implicated in relapse-promotion by alcohol cues. We examined the effects of selective disruption of alcohol cue-activated neurons localized within in the NAcore on 1) alcohol cue-activated operant responding or 'alcohol seeking', and 2) time-dependent increases or "incubation" of this behavior (an animal model of progressive enhancement in drug craving observed during protracted abstinence). Selective disruption of 'cue-activated' neurons was accomplished by the Daun02 method in cFos-lacZ rats. In this transgenic rat strain, the inactive prodrug Daun02 is catalyzed into the cytotoxin daunorubicin by beta-galactosidase (ß-gal) only in Fos-positive 'activated' neurons, and thereby induces selective apoptosis. Fos-negative 'non-activated' neurons express neither Fos nor ß-gal such that Daun02 is not converted to daunorubicin in these cells and cellular disruption is prevented. Male cFos-lacZ rats were trained for operant self-administration of alcohol (10%, v/v; oral). Insertion of an 'active-lever' and illumination of a house-light signaled alcohol availability during a single-daily alcohol self-administration session. Each delivery of alcohol (0.1 ml) was paired with illumination of a cue-light. Alcohol self-

administration then was discontinued and rats remained in their home cages until testing for alcohol seeking on the first, third, fourteenth, and forty-second days of the abstinence (D1, D3, D14, and D42). All stimulus conditions during these tests were identical to those in effect during alcohol self-administration, except that sessions were conducted under extinction conditions (with water substituted alcohol). Daun02 or vehicle was bilaterally microinjected into the NAcore on D1 following the first test session. In vehicle-treated rats, a transient, time-dependent increase in alcohol seeking was observed (evident on D14), as reported previously. Daun02-induced selective disruption of alcohol cue-activated neurons on D1 prevented this time-dependent increase, but spared alcohol seeking itself (evident on D3, D14 and D42). Thus, the incubation rather than the execution of alcohol seeking per se appears to be dependent on alcohol cue-activated neurons localized within the NAcore. Title: Genetic influence of Kcnn3 on extinction learning identifies a novel target for enhancing inhibitory learning of alcohol-associated cues

Authors: ***J. T. GASS**, L. JAMES, J. T. MCGONIGAL, P. J. MULHOLLAND; Neurosciences, Med. Univ. South Carolina, CHARLESTON, SC

Abstract: Exposure to alcohol-related cues contributes to high rates of relapse in treatment-seeking alcoholics. The ability to facilitate the extinction of alcohol-associated cues using cognitive enhancers is a promising therapeutic approach to reduce relapse rates. Previous work in our laboratory has shown that we can facilitate the extinction of alcohol-seeking behavior with

the mGluR5 positive allosteric modulator CDPPB. Interestingly, mGluR5 activation produces a long-lasting decrease in small-conductance calcium-activated potassium (KCa2) channel currents. KCa2 channels have been implicated in synaptic plasticity, cognition, and addiction, and modulating these channels can enhance the extinction learning for food-seeking behavior and fear expression. Recent evidence has also demonstrated that genetic factors can influence extinction learning in mice. However, the specific genes that regulate extinction learning have not been identified, and it is currently unknown if modulating KCa2 channels can facilitate extinction of alcohol-associated memories. Thus, the purpose of this study was to determine if the genes that encode KCa2 channels (Kcnn1-3) predict extinction learning in BXD recombinant inbred (RI) strains of mice and if blocking KCa2 channels enhances extinction learning of alcohol cues. Preliminary evidence showed that Kcnn3 transcript levels in the prefrontal cortex (PFC) of BXD RI strains of mice were correlated with the number of trials to extinguish responding for food-related cues ($R2 = 0.607$, $p < .05$; $n = 7$ strains). We found that lower transcript levels of Kcnn3 in the PFC were associated with faster extinction (i.e., enhanced learning). To complement our genetic findings, we examined the ability of apamin, a KCa2 channel allosteric inhibitor, to facilitate extinction of alcohol-seeking behavior. Wistar rats were trained to self-administer 10% EtOH and then exposed to extinction training. Vehicle or apamin was administered 30 min prior to each extinction session. Apamin significantly enhanced the extinction of alcohol-seeking behavior [$F(13,130)=3.8$, $p < 0.001$; $n = 6$]. This was evidenced by significantly reduced responding on multiple days of extinction (p values < 0.05) and fewer sessions required to reach extinction criteria [$t(10)=5.6$, $p <0.001$]. These data indicate that PFC Kcnn3 transcript levels regulate extinction learning and that modulation of KCa2 channels by either direct inhibition or indirect activation of mGluR5 receptors facilitates extinction learning of alcohol-seeking behavior. KCa2 channels may be a novel pharmacogenomic target for enhancing cue exposure therapy in the treatment of alcohol use disorders.

Title: Synaptic activity through GluN2A-containing NMDA receptors mediates ability of BDNF-TrkB signaling to suppress cocaine-seeking in rats

Authors: *B. GO, J. F. MCGINTY;
Dept. of Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Brain-derived neurotrophic factor (BDNF) is an important modulator of excitatory synaptic transmission. BDNF increases cell surface expression of AMPARs and NMDARs through phosphorylation and translocation events. Intra-dorsomedial PFC (dmPFC) infusion of BDNF immediately after the last cocaine self-administration (SA) session suppresses cocaine-seeking and normalizes a cocaine-induced decrease in basal extracellular glutamate levels in the nucleus accumbens (NAc). Such an intra-dmPFC BDNF infusion rescues cocaine SA-induced ERK and CREB dephosphorylation in the dmPFC. TrkB receptors are expressed in postsynaptic density regions of cortical pyramidal neurons and their stimulation leads to ERK activation through interaction with synaptic NMDARs. Therefore, in the present study we examined whether the ability of intra-dmPFC BDNF to suppress cocaine seeking is mediated by BDNF-induced recovery of synaptic activity in the dmPFC. Immediately after the last cocaine SA session (2 hr/day x 2 weeks, 0.2 mg/infusion), a mixture of the AMPA receptor antagonist, CNQX (0.1nmol/0.5ul/side), and the NMDA receptor antagonist, LY235959 (10ng/0.5ul/side) or 1%DMSO, was infused into the dmPFC 30 min before BDNF or PBS. Rats infused with CNQX/LY235959 before BDNF showed significantly higher active lever pressing during a post-abstinence relapse test (PA test) and cue-induced reinstatement test (cue test) than rats that received 1% DMSO followed by BDNF. This suggests that AMPA/NMDA activity is necessary for BDNF's suppressive effect on cocaine-seeking in rats with a cocaine SA history. Then we checked the specific role of GluN2A-containing NMDA receptors in the BDNF-mediated suppression of cocaine seeking. Immediately after the end of cocaine SA), the GluN2A receptor antagonist, TCN-201 (0.1nmol/0.5ul/side) or 2% DMSO, was infused into the dmPFC 20 min before BDNF or PBS. Rats infused with TCN-201 before BDNF showed significantly less active lever pressing during a PA test and cue test than rats that received vehicle followed by BDNF. This suggests that GluN2A-containing NMDARs are required for BDNF's ability to suppress cocaine-seeking in rats with a cocaine SA history.

Title: Role of calcium-permeable AMPA receptors in the mPFC in cue-induced reinstatement of cocaine seeking

Authors: *J. I. PEÑA BRAVO, A. LAVIN;
Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: Drug addiction is characterized by chronic relapse episodes following attempts of abstinence. Vulnerability to relapse in addicts has been attributed to an increase in reactivity to environmental stimuli (previously neutral in nature) that, through repeated compulsive drug use, become strongly associated with drug consumption and trigger drug seeking. A circuit that has been extensively studied in addiction in rodents involves the interplay between cortical and striatal structures such as the medial prefrontal cortex (mPFC) and the nucleus accumbens (NAc) respectively. Of interest to us is the bimodal modulation that the mPFC exerts onto the NAc, with the pre-limbic (PL-mPFC) projections to the core of the NAc driving cocaine seeking and the infralimbic (IL-mPFC) projections to the NAc shell inhibiting cocaine seeking after extinction training. Previous studies describe an accumulation of calcium-permeable AMPA receptors (Cp-AMPARs) in the NAc following a month of withdrawal from extended access cocaine self-administration. We investigated the hypothesis that alterations in Cp-AMPAR plasticity in the mPFC, after cue-induced reinstatement, modulate the drive in cocaine seeking behavior in self-administering rats. In the current study, whole-cell patch clamp electrophysiological recordings of mPFC brain slices were performed using a CsCl-based internal solution containing spermine (0.1mM) to measure AMPAR rectification index (RI). This method allows an indirect measure of Cp-AMPARs levels in the PL-mPFC and IL-mPFC. Preliminary results show that 24 hrs after cue exposure, there is an opposing switch in AMPAR subunit composition between the IL-mPFC (increase in AMPAR RI) and PL-mPFC (decrease in AMPAR RI) projection neurons. These results suggest an experience-dependent reactivation or renewal of the cocaine-cues association memory after extinction training that leads to a delayed increase in IL-mPFC Cp-AMPARs and a corresponding increase in activity of the IL-mPFC to NAc shell projection neurons.

Title: Effects of baclofen on cue-induced cocaine-reinstatement in the rat

Authors: *T. D. WOLINSKY, C. FROGER-COLLÉAUX, C. RONDEAU, S. PAILLARD, V. CASTAGNE;
Porsolt, Le-Genest Saint-Isle, France

Abstract: Treating relapse of drug-seeking behavior is considered the most challenging part of the treatment for addictive disorders. Relapse can be modeled in laboratory animals using reinstatement paradigms, whereby extinguished behavioral responding for a drug is reinstated by different factors, such as cues or stress. Activation of GABAB receptor complexes may be a promising pharmacotherapy for diminishing relapse potential to reinforcing drugs. We therefore assessed the effects of baclofen (a prototypic γ-aminobutyric acid B (GABAB) receptor agonist) on cue-induced cocaine-reinstatement in the rat. Male Sprague Dawley rats, implanted with i.v. jugular catheters, were submitted to 2-hr daily sessions during which they could receive i.v. infusions of cocaine under a fixed ratio-1 (FR1) schedule of lever pressing. At the beginning of each daily session rats received a non-contingent infusion of cocaine. During these sessions a cue light was turned on for 3 sec when rats pressed the active lever. After 2 sec of cue light, a tone signal was turned on for 1 sec together with activation of the infusion pump. Each infusion was followed by a 30-sec timeout. Once cocaine self-administration (SA) behavior was acquired, rats were moved to extinction sessions in which active lever presses no longer had consequences. Rats were considered to have extinguished behavior when they exhibited an average of < 12 active lever presses during 2 consecutive sessions. Rats were tested in the first reinstatement session, the following day after the rats had met the extinction criteria. The rats were then re-submitted to at least 2 further extinction sessions followed by a second reinstatement session. Rats were pretreated 30 minutes before the reinstatement sessions with vehicle or baclofen. The cue reinstatement sessions began with a tone (1 sec) and cue light (3 sec). The remainder of the 2 hr session was identical to the SA session except that cocaine was not delivered. During the first reinstatement session, half of the rats received vehicle and the other half received baclofen. On the second reinstatement session, the inverse was applied. Baclofen 2.5 and 5 mg/kg, dose-dependently decreased the number of active lever presses during cue reinstatement (8.0 ± 2.5 for

baclofen at 2.5 mg/kg versus 16.9 ± 2.1 for vehicle and 6.4 ± 4.5 for baclofen at 5 mg/kg versus 27.3 ± 3.5 for vehicle), producing 81.2 and 99.6% inhibition respectively. These data suggest the potential anti-craving efficacy of baclofen for the treatment of cocaine drug-seeking.

Title: More than a replacement therapy: Amphetamine treatment reverses the behavioral and neurochemical consequences of long-access cocaine self- administration

Authors: *C. SICILIANO[1], E. S. CALIPARI[2], S. R. JONES[1];
[1]Wake Forest Sch. of Med., Winston Salem, NC; [2]Mount Sinai Sch. of Med., New York, NY

Abstract: Cocaine abuse and dependence is a major health problem with no FDA-approved pharmacotherapies. Although amphetamine (AMPH) has been examined as a potential treatment for cocaine addiction, with promising behavioral results in rodents, monkeys and humans, the mechanism for AMPH-induced decreases in cocaine reinforcement has yet to be elucidated. It has been proposed that AMPH acts as an agonist replacement therapy; however, our data suggest that these effects may be a result of AMPH-induced stabilization of the dopamine (DA) system. Fixed-ratio 1 self-administration of cocaine in daily six-hour sessions (long-access) has been shown to result in increased intake, or "escalation". This escalation is often used as a pre-clinical model of the switch from recreational abuse to addiction. We found that treatment with 5 mg/kg/day AMPH s.c., delivered continuously via osmotic mini-pump for 14 days, significantly attenuated the development of escalation, suggesting that amphetamine treatment has a

protective effect against increased cocaine intake. Because cocaine's reinforcing effects have been shown to be dependent on its ability to inhibit the DA transporter and elevate accumbal DA levels, we used fast scan cyclic voltammetry in brain slices containing the nucleus accumbens core to measure cocaine inhibition of the DA transporter. We found that long-access reduced cocaine potency for DA uptake inhibition, suggesting that tolerance is driving escalation whereby animals increase intake to compensate for reduced subjective effects of the compound. Further, in line with the behavioral data, AMPH treatment blocked the development of cocaine tolerance when administered during cocaine self-administration. Providing more evidence that the effects of AMPH on cocaine intake are independent of agonist replacement, AMPH, when administered after cocaine self-administration, completely reversed cocaine tolerance. Taken together, these data suggest AMPH reduces cocaine self-administration, at least in part, by reversing the cocaine-induced changes in the DA system. Although previous literature has shown promising behavioral results suggesting AMPH is a potentially effective treatment for cocaine abuse, this is, to our knowledge, the first investigation of the neurochemical mechanisms for these results. While agonist therapies for cocaine addiction are controversial and AMPH has a high abuse potential, these data may be able to define a mechanism for some of AMPH's therapeutic effects, which could drive the design of more targeted pharmacotherapies with less abuse liability.

Title: Inactivation of the lateral habenula reduces the anxiogenic response of both undrugged and cocaine-treated rats in the elevated plus maze

Authors: *K. SHELTON, K. BOGYO, M. B. KURLAND, T. SCHICK, S. SVED, S. JANUSONIS, A. ETTENBERG;
Dept. of Psychological and Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Solomon and Corbitt's (1974) Opponent Process Theory of motivation states that all affective stimuli produce diametrically opposite and temporally dissociated actions. Human users of cocaine report just such a response after taking the drug; an initial euphoric state followed by a period of dysphoria and anxiety. While the euphoric effects of cocaine have long been studied, the anxiogenic aspects of the drug remain largely unexplained. Recent work has suggested a role for the lateral habenula (LHb) in the behavioral response to anxiogenic stimuli. The current study was therefore devised to examine whether the LHb might play a role in cocaine-induced anxiety. An elevated plus maze was used to measure the anxiogenic response of rats following permanent or reversible inactivation of the LHb. Three groups of male albino rats served as subjects. One group had permanent LHb inactivation produced by bilateral intracranial infusions of kainic acid; another experienced reversible inactivation of the LHb via bilateral intracranial pretreatment with a baclofen/muscimol infusion prior to behavioral testing; and a third group consisted of sham-lesioned control subjects. Each animal was habituated to the elevated plus apparatus during an initial 5-min baseline trial. Testing then consisted of two 5-min sessions on two separate days during which rats each received either a 1.0 mg/kg IV cocaine injection (in volume of 0.1 ml), or a comparable volume of saline in a counterbalanced order. This was dose selected on the basis of prior work demonstrating its dual positive and anxiogenic actions. The dependent measures were latency to enter the open arms of the apparatus, and the total time spent in the open arms during each 5-min test session. Animals that underwent LHb inactivation (either by kainic acid lesion or by IC pretreatment with baclofen/muscimol) were faster to enter, and spent more time in, the open arms of the maze during baseline indicating that LHb activation reduced the subjects' inherent anxiety associated with placement into the unfamiliar apparatus. This effect of LHb inactivation was accentuated when subjects were pretreated with IV cocaine. These results are therefore consistent with a habenular complex involvement in the processing of anxiogenic stimuli, including the administration of cocaine. Supported by PHS grant DA033370 awarded to AE.

Title: Intra-ventral tegmental area infusions of the nonselective CRF receptor antagonist astressin B reduces the anxiogenic response of rats to cocaine in a runway model of drug self-administration

Authors: *S. COTTEN, III, A. K. KLEIN, M. A. BRITO, T. OHANA, B. MARGOLIN, A. WEI, A. ETTENBERG;
Psychological & Brain Sci., UC Santa Barbara, Santa Barbara, CA

Abstract: In addition to its positive/rewarding effects, cocaine has also been shown to have negative/anxiogenic properties. Much is known about the underlying neuronal mechanisms responsible for the appetitive properties of cocaine, but what of cocaine's negative effects? Of particular relevance to this question has been recent work demonstrating that alterations in the release of the stress hormone corticotropin releasing factor (CRF) within the ventral tegmental area (VTA) can produce alterations in the cocaine-seeking behavior of rats. To further investigate these findings we employed a straight-arm runway model of drug self-administration. Animals running a straight alley once a day for an IV injection of cocaine develop over trials a unique behavior characterized by a rapid approach toward the goal, a stop at the goal threshold, and then an abrupt "retreat" back toward the start box. These retreats have been shown to reflect an approach-avoidance conflict stemming from the subjects' association of the goal box with the mixed positive and negative properties of cocaine. The runway model therefore provides a tool with which to explore the appetitive (approach) and the anxiogenic (avoidance) qualities of cocaine in the same animal on the same trial. In the current study, 3 groups of male rats were trained over 15 consecutive days to run the alley for single daily injections of 1.0 mg/kg IV cocaine delivered upon goal-box entry. Prior to each trial, rats received bilateral intra-VTA infusions of one of three doses of the non-specific CRF receptor antagonist astressin B (0.0, 0.5 or 1.0 ug/side) 10 min after which they were tested in the runway. The latency to leave the start box, the time to enter the goal box (run time), and retreat frequency was recorded on every trial. Start latencies progressively increased over the course of testing for all groups indicating that the positive incentive (appetitive) properties of cocaine remained intact across subjects. The vehicle-pretreated group demonstrated increases in approach-avoidance retreats over trials, while rats pretreated with the CRF antagonist demonstrated reliable reductions in retreats (the high dose attenuated and the low dose completely eliminated the behavior). This effect of the antagonist was not due to some nonspecific action of the peptide since, in a subsequent test, astressin B was found to have no effects on the rats' spontaneous locomotor behavior. These results are therefore consistent with the growing body of literature demonstrating that CRF release within the VTA plays a role in the negative/anxiogenic effects of cocaine. This research was supported by PHS grant DA-033370 awarded to AE.

Title: Episodic social defeat stress escalates dopamine release and cocaine self-administration in mice

Authors: *X. HAN, L. ALBRECHET-SOUZA, M. R. DOYLE, E. Y. ZHANG, J. F. DEBOLD, K. MICZEK;
Dept. of Psychology, Tufts Univ., Medford, MA

Abstract: Social stress can contribute to the initiation and maintenance of drug use. In preclinical studies, social defeat stress, as generated by repeated confrontations with an aggressive resident, is associated with long-term neural adaptations, which may escalate subsequent drug intake. However, how the intensity and timing of social defeat stress alters these effects have not been well characterized. Here we investigated the effects of distinct social defeat stress intensities and durations (brief vs. moderate) on cocaine self-administration, and explored dopamine (DA) release in the nucleus accumbens shell (NAcSh) by using *in vivo* microdialysis. Adult male CFW mice experienced 10 days of social defeat stress, either brief (15 attack bites in ca. 2 min) or moderate (30 attack bites in ca. 5 min), and compared to controls that were handled daily. Six days after the last social defeat, mice were implanted either with catheters for intravenous cocaine self-administration, or guide cannulae aimed at NAcSh for microdialysis. After recovery, mice were allowed to self-administer cocaine (0, 0.3, 0.6 and 1.0 mg/kg/infusion) according to a FR1 schedule. Another cohort of mice was assessed for DA levels in the NAcSh in response to acute amphetamine (1.5 mg/kg, i.p.) 10 days after the last defeat. Mice in both brief and moderate stress groups self-administered more cocaine (0.3 mg/kg/infusion) than the controls. Moreover, both brief and moderate stress groups showed a larger and more prolonged increase in DA concentration after d-amphetamine challenge than controls did. These findings suggest that the neuroadaptation in the dopaminergic system resulting from repeated social defeat stress may contribute to escalated cocaine intake.

Title: Taking STEPs to reduce cocaine-seeking behavior

Authors: *B. M. SIEMSEN[1], M. CHATTERJEE[2], P. L. LOMBROSO[2], J. F. MCGINTY[1]; [1]Med. Univ. of South Carolina, Charleston, SC; [2]Child Study Ctr., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Relapse to drug seeking is a main clinical obstacle pertaining to the treatment of cocaine addiction in humans. One hypothesis as to why addicts continually seek cocaine is hypoactivity within the prefrontal cortex during withdrawal, leading to the inability to initiate executive control to inhibit relapse when presented with conditioned stimuli associated with drug use. In rats trained to self-administer cocaine, extracellular regulated kinase 1/2 (pERK1/2) and cAMP response-element binding protein (pCREB) phosphorylation is decreased in the dorsal-medial prefrontal cortex (dmPFC) two hours after the end of cocaine self-administration (early withdrawal), but returns to baseline levels 20 hours later. These dynamic fluctuations in protein expression facilitate context, cue, and cocaine prime-induced relapse to drug-seeking following abstinence and extinction training, respectively. Reversing pERK1/2 and pCREB deficits with a single BDNF infusion into the dmPFC immediately after the last cocaine self-administration session reduces context, cue, and cocaine prime-induced relapse and results in normalized pERK1/2 and pCREB expression in the dmPFC during early withdrawal (Berglind et al., 2007; Whitfield et al, 2011). Additionally, Striatal Tyrosine-Enriched Phosphatase (STEP) is up-regulated in the dmPFC two hours after the final session of cocaine self-administration, and is suspected to result in the reduction of pERK1/2 and its downstream target pCREB during early withdrawal from cocaine (Sun et al., 2013). Recently, 10 mg/kg of the small molecule STEP inhibitor TC-2153 has been shown to increase levels of pERK1/2 in the frontal cortex of mice, and reverse cognitive deficits in an Alzheimer's disease mouse model (Xu et al., 2014). We hypothesized that systemic administration of TC-2153 immediately after the final cocaine self-administration sessions (2 hr/day x 14 days) would attenuate context, cue, and cocaine prime-

induced relapse to drug seeking after abstinence and extinction training through a reversal of ERK1/2 dephosphorylation that occurs during early withdrawal. Preliminary results indicate that TC-2153 (5 mg/kg, i.p.) reduces context-induced cocaine-seeking in rats abstinent from cocaine for one week. Cue and cocaine prime-induced reinstatement tests after extinction training are ongoing. Future experiments will focus on increasing sample size as well as preferentially targeting the dmPFC with TC-2153 microinfusions immediately after cocaine self-administration, and analysis of western blots for pERK, pCREB, and STEP in the dmPFC two hours after cocaine self-administration.

Title: The role of src family kinases in the suppressive effect of prefrontal cortical BDNF on cocaine seeking

Authors: *S. M. BARRY, J. F. MCGINTY;
Neurosci. Inst., Med. Univ. of South Carolina, Charleston, SC

Abstract: Relapse to drug seeking remains a major obstacle in the treatment of cocaine addiction in human addicts. Animal models of relapse have demonstrated that neuroadaptations in reward circuits following cocaine self-administration underlie reinstatement to drug seeking. Specifically, dysregulation of the pathway from the prefrontal cortex (PFC) to the nucleus accumbens (NAc) is implicated in reinstatement. Brain-derived neurotrophic factor (BDNF) is synthesized in PFC pyramidal neurons and antereogradely transported to the NAc where it is the primary source of BDNF in the NAc. Our lab has shown that a single BDNF infusion into the prelimbic cortex following a final cocaine self-administration session results in attenuation of reinstatement to cocaine seeking through normalization of basal and cocaine primed extracellular

glutamate levels in the nucleus accumbens. This attenuating effect can be blocked by blocking either BDNF's receptor TrkB, the members of its associated intracellular signaling cascade, or AMPA/NMDA receptors. These results imply that the interaction between glutamate mediated synaptic activity and TrkB signaling is imperative to BDNF's suppressive effect on drug seeking. Src family kinases are involved in both NMDA/AMPA mediated activation of TrkB and TrkB mediated phosphorylation of NMDA receptors. Thus src family kinases serve as a likely link between these two signaling systems. We hypothesized that infusion of the src family kinase inhibitor PP2 into the prelimbic cortex prior to a BDNF infusion will block BDNF's attenuation of both context and cue induced reinstatement. PP2 blocked BDNF's suppressive effect on context-induced reinstatement, while there was no significant effect for cue-induce reinstatement. Future directions will include analysis of phosho-GluN2B levels to determine if PP2's blocking action occurs from dysregulation of TrkB mediated NMDA receptor activation.

Title: The role of HDAC3 in the acquisition and extinction of cocaine-cue memories

Authors: *Y. ALAGHBAND[1], J. L. KWAPIS[1], M. ASTARABADI[1], J. D. RAYBUCK[2], D. P. MATHEOS[1], K. M. LATTAL[2], M. A. WOOD[1];
[1]Neurobio. and Behavior and Ctr. for the Neurobio. of Learning & Memory, Univ. of California, Irvine, Irvine, CA; [2]Oregeon Hlth. and Sci. Univ., Portland, CA

Abstract: Environmental cues associated with the rewarding properties of drugs are a major cause of relapse among addicts. Specifically, drug-cue memories are formed as a result of associating cues in the environment with drug taking after repeated pairings of an environmental context with the positive effects of drugs. Conditioned place preference (CPP) is used to study contextual cue-elicited drug-seeking. Because drug-paired cues evoke memories that influence drug-seeking and relapse, a better understanding of the neurobiological basis for this phenomenon will aid the development of novel, biologically-based therapies for drug addicts. Given that drug-cue memories are persistent and stable, it is hypothesized that the same molecular mechanisms responsible for long-term memory formation also underlie the formation and maintenance of drug-cue memories. Chromatin modification is a molecular mechanism for both long-term memory formation and cocaine-induced neuroplasticity and behavior. Histone deacetylases (HDACs) are chromatin modifying enzyme that have been implicated as powerful negative regulators of memory processes. Previous work from our laboratory has shown that inhibition of HDAC3 (the most highly expressed Class I HDAC in the brain) not only facilitates the acquisition of cocaine-CPP, but also modulates the extinction of drug-seeking behavior in a manner that is subsequently resistant to reinstatement (Malvaez et al., 2013; Rogge et al., 2013). Little is known, however, regarding the specific neural loci where HDAC3 plays this critical role in the acquisition and extinction of cocaine-cue memories. In these experiments, we explore the role of HDAC3 in the cocaine-cue memories using a genetic and viral approach. To investigate the role of HDAC3 in the dorsal hippocampus and infralimbic cortex during the acquisition and extinction of cocaine-cue memories using the CPP model, C57BL/6J male mice received infusions of viruses which either overexpressed the Hdac3 gene or had a dominant negative mutation of the gene. Our findings demonstrate a critical role for HDAC3 in the molecular mechanisms underlying cocaine-cue memories.

Title: The role of neuron specific nucleosome remodeling complex subunit BAF53b in cocaine-associated behaviors

Authors: *A. WHITE[1], M. A. WOOD[2];
[1]Neurobio. and Behavior, UC Irvine, Irvine, CA; [2]Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA

Abstract: Recent evidence suggests that epigenetic mechanisms have a critical role in the development of drug-seeking behavior. However, there is currently very little known about the role of nucleosome remodeling, a major epigenetic mechanism, in drug-induced behavioral changes. In this study, we examined the role of BAF53b, a neuron-specific subunit of the nBAF (Neuron-specific Brg1-Associated Factor) nucleosome remodeling complex, in cocaine-associated behaviors. In these studies, we examined Baf53b+/- heterozygous knockout mice as well as transgenic mice expressing a dominant-negative BAF53b (CaMKIIα-BAF53bΔHD). To assess cocaine-seeking behaviors, both types of BAF53b mutant mice (n= 10-15 per group) and their respective wild-type littermates were subject to cocaine-induced conditioned place preference (CPP) using 5mg/kg or 10mg/kg doses. Also, cocaine sensitivity (10mg/kg) was examined in Baf53b+/- heterozygous mice. We demonstrate that BAF53b is necessary for the acquisition/consolidation of some but not all cocaine-induced behaviors. Both the Baf53b+/- heterozygous knockout mice and the CaMKIIα-BAF53bΔHD transgenic mice had deficits in cocaine-induced CPP. In contrast, Baf53b+/- heterozygous mice exhibited normal cocaine sensitization. This study provides the first evidence that a neuron-specific nucleosome remodeling complex (nBAF) has a role in drug-associated behaviors. Using two different genetic manipulations, we established a differential role for BAF53b in cocaine-induced conditioned place preference, but possibly not in cocaine sensitization. These findings demonstrate that nucleosome remodeling, a major epigenetic mechanism, is critically involved in context-cocaine associated memory formation.

Title: A histone deacetylase 3 inhibitor enhances extinction and attenuates reinstatement of self-administration in rats

Authors: *L. N. HITCHCOCK[1], J. D. RAYBUCK[1], M. A. WOOD[2], K. M. LATTAL[1]; [1]Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR; [2]Neurobio. & Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Addiction is a chronic, often relapsing disease that causes compulsive drug seeking. The neurobiological basis of relapse in humans is often studied with an animal model of reinstatement. In the acquisition phase of this paradigm, animals press a lever to receive reinforcing intravenous cocaine infusions. During extinction, reinforcers are then withheld and the animal eventually inhibits this lever-pressing behavior. But like humans, rats will relapse, or renew this drug-seeking behavior once they are removed from the extinction context or exposed to drug-associated cues. Given that there are no long-term therapies for cocaine addiction to date, I investigated whether a novel and selective epigenetic drug (RGFP966) could promote extinction and weaken reinstatement. After rats were trained to self-administer cocaine to stable and high rates, rats were given a subcutaneous injection of RGFP966 (histone deacetylase (HDAC) 3 inhibitor) prior to the first extinction day (no cocaine reinforcers). As a result, RGFP966-injected rats responded significantly less during extinction and reinstatement tests than vehicle-injected rats. These effects were not likely due to a performance deficit or a change in motivation to self-administer cocaine, as injections of RGFP966 had no effect on stable responding during a fixed or progressive ratio schedule of cocaine self-administration in subsequent studies. Results suggest that a systemic injection of RGFP966 enhanced extinction and suppressed reinstatement after cocaine self-administration by inhibiting HDAC3 activity. Future studies will determine whether brain region specific decreases in HDAC3 activity further suppress drug seeking.

Title: Bi-directional role of CRHR1 in control of dopamine signalling during cocaine relapse

Authors: *R. E. BERNARDI[1], L. BROCCOLI[1], A. C. HANSSON[1], J. M. DEUSSING[2], R. SPANAGEL[1];
[1]Psychopharmacology, Central Inst. of Mental Hlth., Mannheim, Germany; [2]Max Planck Inst. of Psychiatry, Munich, Germany

Abstract: The ability of many drugs of abuse, including cocaine, to mediate reinforcement and drug-seeking behaviors is in part mediated by the corticotropin releasing hormone (CRH) system, in which CRH exerts its effects partly via the CRH receptor subtype 1 (CRHR1) in extra-hypothalamic areas. Most of these previous studies have used pharmacological means to address the role of CRHR1 in drug dependence. The current study examined cocaine-induced locomotor sensitization and cocaine self-administration and reinstatement measures in mice with an inducible knockout of the CRHR1 receptor using the Cre-loxP system (ERT2) in either dopamine transporter (DAT)-containing neurons or dopamine receptor 1 (D1)-containing neurons. For sensitization testing, mice received 5 daily injections of cocaine (15 mg/kg IP), with tests for locomotion on days 1, 5, and following a 7-day withdrawal period. For self-administration, mice received daily sessions of self-administration in which presses on the active of two levers resulted in an intravenous infusion of cocaine (0.5 mg/kg per infusion) paired with a cue light. Following 8 days of self-administration, mice were given extinction trials in which the cue was omitted and no cocaine was delivered. After reaching criterion for extinction, mice were given reinstatement sessions as follows: cue reinstatement, yohimbine-induced reinstatement (stress), yohimbine + cue reinstatement, and cocaine reinstatement. Between reinstatement tests, mice were given daily extinction sessions to once again reach criterion. There were no differences in the acute or sensitized locomotor response to cocaine in CRHR1-DATCreERT2 or CRHR1-D1CreERT2 mice and their respective controls. Furthermore, both CRHR1-DATCreERT2 and CRHR1-D1CreERT2 mice reliably self-administered cocaine at the level of wild-type littermates. However, CRHR1-DATCreERT2 mice demonstrated a significant increase in cue-induced reinstatement relative to controls, whereas CRHR1-D1CreERT2 mice demonstrated a significant decrease in cue-induced reinstatement relative to controls. Interestingly, despite the well-known role for CRHR1 in stress responsivity, there were no

differences in stress-induced reinstatement in CRHR1-DATCreERT2 or CRHR1-D1CreERT2 mice and their respective controls. or cocaine-induced reinstatement of drug-seeking behavior. These data further demonstrate the involvement of CRHR1 in cue-induced reinstatement following cocaine self-administration, and implicate a bi-directional role of CRHR1 in presynaptic negative feedback and postsynaptic feed-forward control of dopamine signalling during relapse-like behavior.

Title: One-trial cocaine-induced behavioral sensitization in preweanling rats: role of dopamine and serotonin receptor subtypes

Authors: M. J. STONE, A. MOHD-YUSOF, A. E. GONZALEZ, M. L. BECKER, J. A. MORTOLA, A. VELIZ, *S. A. MCDOUGALL;
Dept. of Psychology, California State Univ., San Bernardino, CA

Abstract: In rodents, accumulating evidence indicates that the underlying processes and neural mechanisms mediating one-trial behavioral sensitization differ markedly between the preweanling period and adulthood. For example, there is abundant evidence that contextual conditioning does not influence the one-trial behavioral sensitization of preweanling rats, whereas drug-environment associations are necessary for the occurrence of one-trial behavioral sensitization in older animals. Additionally, the D_1 antagonist SCH23390 blocks the induction of one-trial cocaine-induced behavioral sensitization in adult rats, while not affecting the sensitized

responding of preweanling rats. In adult rats, the neural mechanisms mediating behavioral sensitization involve multiple receptor systems, because D_2 receptor antagonists (e.g., raclopride), as well as serotonin 5-HT_2 and 5-HT_3 receptor antagonists (ritanserin and ondansetron, respectively), are capable of blocking the induction of cocaine-induced behavioral sensitization. The purpose of the present study was to determine whether antagonism of the same dopamine and serotonin receptor systems would block the induction of behavioral sensitization in preweanling rats. On the pretreatment day [i.e., postnatal day (PD) 19], preweanling rats were injected with saline, ritanserin (0.3, 1, or 3 mg/kg), ondansetron (0.03, 0.1, or 0.3 mg/kg), raclopride (0.1, 0.5, 1, or 5 mg/kg), or a combined administration of SCH23390 (0.5 mg/kg) and raclopride (0.5 mg/kg) 15 min before a single injection of cocaine (30 mg/kg). Locomotor activity was measured for 30 min. One or two days later (i.e., on PD 20 or PD 21), rats were challenged with cocaine (20 mg/kg) and locomotor sensitization was assessed across a 120 min testing session. Results showed that raclopride, but not ritanserin or ondansetron, acutely blocked cocaine-induced locomotor activity on the pretreatment day. On the test day, however, cocaine-induced locomotor sensitization was evident regardless of whether rats had been pretreated with ritanserin, ondansetron, raclopride, or SCH23390 + raclopride. These results suggest that the neural mechanisms mediating behavioral sensitization vary across ontogeny. This conclusion is based on the finding that 5-HT_2, 5-HT_3, and D_2 receptor antagonism blocks the induction of behavioral sensitization in adult rats, while leaving the sensitized responding of preweanling rats unaffected.

Title: Role of amygdalar CaMKII in cocaine-associated memory reconsolidation and extinction

Authors: *M. T. RICH[1], T. ABBOTT[2], K. STONE[2], L. CHUNG[2], C. COLANGELO[2], A. NAIRN[2], J. R. TAYLOR[2], M. M. TORREGROSSA[1];

Abstract: Memories of environmental cues associated with drug use contribute to relapse to drug-taking, which is prevalent in addiction. Evidence suggests that protein kinase activity within the amygdala regulates both the reconsolidation and extinction of drug-induced memories and manipulating this activity may serve as a potential treatment for addictive disorders. One such protein, calcium/calmodulin-dependent protein kinase II (CaMKII), has been shown to directly phosphorylate synaptic proteins, contributing to memory storage via modulation of synaptic activity. Here, we show that phosphorylation of CaMKIIα, specifically at Ser331 may be differentially involved in the extinction and reconsolidation of a drug-induced memory. Additionally, intra-basolateral amygdala (BLA) infusion of KN-62, a specific CaMKII inhibitor, seems to impact these same memory processes, leading to an alteration in drug-seeking behavior. Rats trained to self-administer cocaine paired with an audiovisual cue underwent a test session in which the drug-cue memory was either reactivated by brief presentation to induce reconsolidation, or extinguished by multiple unreinforced presentations. Proteomic analysis of tissue from the BLA revealed a decreased expression of pSer331 CamKIIα following memory reconsolidation and an increased expression following cue extinction. Furthermore, inhibition of CaMKII in the BLA via KN-62 resulted in decreased responding on a cue-induced reinstatement test both in rats that had undergone cue reactivation and in those in which the memory had been extinguished. Therefore, CaMKII activity may be critical for the maintenance of drug-associated memories and inhibitors of CaMKII might be useful adjuncts to extinction training in the prevention of relapse in addiction.

Title: Glutamatergic transmission during adolescence is critically involved in the rewarding effects of cocaine in rats: Effects of early life stress

Authors: *R. M. O' CONNOR[1], R. D. MOLONEY[2], S. VLACHOU[4], J. F. CRYAN[3];
[1]Dept. of Anat. and Neurosci., [2]Alimentary Pharmabiotic Ctr., [3]Dept. of Anat. and Neurosci. and Alimentary Pharmabiotic Ctr., Univ. Col. Cork, Cork, Ireland; [4]Dublin City Univ., Dublin, Ireland

Abstract: Adolescence marks a critical time when the brain is highly susceptible to pathological insult yet also uniquely amenable to therapeutic intervention. Furthermore, it is during adolescence that the onset of the majority of psychiatric disorders, including substance use disorder (SUDs), occurs. Individuals affected by a SUD experience compulsions to seek and consume drugs, a loss of control over drug intake and the emergence of a negative emotional state. Risk factors present during adolescent development include high levels of impulsivity and immature reward circuitry. Furthermore, it has been well established that stress, particularly during early development, can contribute to the pathological changes which contribute to the development of SUDs. Glutamate is the main excitatory neurotransmitter in the mammalian CNS and plays a key role in regulating reward; glutamatergic innervations can converge on the nucleus accumbens increasing salience to drug-related stimuli. As such, reducing glutamatergic signalling in circuits associated with reward processing and impulsive control may serve to attenuate the rewarding and physiological effects of drugs of abuse in adolescents potentially attenuating stress-induced vulnerability to SUD development. To test this hypothesis we assessed the effects of reducing glutamatergic signalling using the glutamate transporter activator riluzole and the NMDA receptor antagonist memantine on intravenous self-administration of cocaine in rats. We induced early-life stress in male Sprague Dawley rats by separating pups from dams from PND 2-12 for 3 hours/day. During the adolescence (3 - 6 weeks) rats received 21 days treatment with riluzole (1, 3, 10 mg/kg or vehicle; i.p.) or memantine (3, 10, 30 mg/kg or vehicle; i.p.). Intravenous catheters were implanted and following recovery animals were allowed to self-administer cocaine in one hour daily sessions for 5 days/week with escalating dose being provided each week (0.125, 0.25 and 0.5 mg/kg/infusion respectively). Interestingly, maternally separated (MS) rats self-administered less cocaine in all three doses tested while riluzole at 3 and 10 mg/kg and memantine at all three doses tested attenuated this. Potentially, MS animals possess a reward deficit and as such rewarding stimuli do not engage the reward circuitry to the same degree as in non-separated animals (NS). These data suggests reducing glutamatergic signalling may be a viable therapeutic strategy for treating vulnerable individuals at risk of developing SUDs including certain adolescent populations, particularly those which may have experienced early-life stress.

Title: Caffeine's neuroprotective properties against the reinforcing effects of cocaine

Authors: *L. B. MALAVE[1,2], P. A. BRODERICK[1,2,3];
[1]Dept. of Physiology, Pharmacol. and Neurosci., Sophie Davis Sch. CCNY, New York, NY;
[2]Biol., CUNY Grad. Ctr., New York, NY; [3]Neurol., NYU Langone Med. Ctr., New York, NY

Abstract: Caffeine has biphasic effects that are highly dose-dependent. The exact mechanism caffeine has on the adenosine system is still being extensively studied. Caffeine increases dopamine (DA) release within the brain acting on adenosine 1 receptors and adenosine A2 receptors and causes effects similar to cocaine at specific doses. However, although cocaine and caffeine are both stimulants, when combined together, caffeine has neuroprotective abilities on the reinforcing effects of cocaine that are dose dependent. These results are consistent over a number of behavioral and biochemical paradigms, including DA release *in vivo*, locomotor activity, conditioned place preference, pre-pulse inhibition, and estrus cycle changes. We propose important findings that provide insight into cocaine abuse. We suggest that inhibition of the adenosine system at specific doses and involvement of specific receptors may aid in the adverse effects of cocaine. Furthermore, we link our results to possible therapeutic options in mental disorders, such as schizophrenia, with malfunction of the DA circuit.

Title: Arc and BDNF expression after cocaine self-administration or cue-induced reinstatement of cocaine-seeking in adolescent and adult male rats

Authors: A. WHITE[1], C. LI[2], J. F. MCGINTY[3], *K. J. FRANTZ[1];
[1]Georgia State Univ., Atlanta, GA; [2]Anat. and Cell Biol., Temple Univ., Philadelphia, PA; [3]Dept. of Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: In our laboratory, male rats that self-administer cocaine as adolescents exhibit lower levels of cue-induced reinstatement of cocaine-seeking, as compared with adults. Activity-regulated cytoskeletal-associated gene (arc) and brain-derived neurotrophic factor (bdnf) are two important neuroplasticity-related genes that influence drug-seeking behavior, change over development, and may play a role in age differences we observe. For the present study, we predicted that levels of cocaine-seeking correlate negatively with differential expression of Arc and BDNF in reward and reinforcement-related brain regions. Adolescent and adult rats were allowed to acquire lever-pressing maintained by i.v. infusions of cocaine in daily two-hour sessions over 13 days. A subset of rats in both age groups received only saline infusions. At three experimental time points (immediately after the last self-administration session, after extinction and reinstatement at 1 day abstinence from cocaine, and after extinction and reinstatement at 60 days abstinence), rats were sacrificed and brain tissue was collected. Arc and BDNF mRNA levels were analyzed by *in situ* hybridization and densitometry in the prelimbic and infralimbic cortex, nucleus accumbens core and shell, claustrum, caudate putamen, and motor cortex. Although Arc expression varied by drug treatment and time in region-dependent ways, Arc expression was similar across age groups in almost all cases. In contrast, BDNF expression was higher in adolescent compared to adult rats. Additionally, BDNF expression was higher in cocaine-experienced rats and rats sacrificed at the first and last experimental time points. These data generally support the hypothesis that higher levels of BDNF mRNA in reward and reinforcement-related brain regions during adolescence could attenuate some long-term effects of cocaine. Future studies should entail mechanistic analysis of BDNF mRNA and protein, as well as the role of BDNF receptors in age-dependent cocaine-related behaviors.

Title: Orexin/hypocretin in the paraventricular nucleus of the thalamus induces cocaine-seeking behavior in rats: reversal with specific orexin/hypocretin receptor antagonists

Authors: *A. MATZEU, F. WEISS, R. MARTIN-FARDON;
The Scripps Res. Inst., La Jolla, CA

Abstract: Growing evidence implicates a role for orexin/hypocretin (Orx/Hcrt) neurons that originate in the lateral hypothalamus (LH) and project to the paraventricular nucleus of the thalamus (PVT) in drug addiction. Although this thalamic region has not traditionally been thought of as part of the drug addiction circuitry, recent evidence indicates that the PVT modulates reward function in general and drug-directed behavior in particular. Our working hypothesis was that cocaine-induced dysregulation of the Orx/Hcrt system modifies Orx/Hcrt-PVT transmission, an effect that is long-lasting. We previously reported that administration of orexin-A/hypocretin-1 (Orx-A/Hcrt-1) in the PVT reinstates extinguished cocaine-seeking behavior in animals with short access (ShA, 2 h/day) or long access (LgA, 6 h/day) to cocaine and sweetened condensed milk (SCM) seeking but with different dose-response profiles. Knowing that Orx-A/Hcrt-1 interacts with both orexin receptor 1 (Hcrt-r1) and receptor 2 (Hcrt-r2), this study sought to investigate the extent to which Hcrt-r1 and Hcrt-r2 are involved in Orx/Hcrt-induced cocaine or SCM seeking. This was accomplished by co-administering Orx-A/Hcrt-1 (0.5 μg) with a specific Hcrt-r1 antagonist (SB334867) or Hcrt-r2 antagonist (TCSOX229) into the PVT. The 0.5 μg Orx-A/Hcrt-1 dose was selected based on earlier findings that showed that it was the minimal dose that produced comparable and significant reinstatement in all of the groups (i.e., SCM, ShA, and LgA). Male Wistar rats were trained to self-administer cocaine for 2 h/day (ShA) or 6 h/day (LgA) or SCM (30 min/day) for 21 days. Immediately following self-administration training, the animals were subjected to daily extinction training for

14 days. The following day, the animals were tested for the ability of SB334867 (0-15 μg) and TCSOX229 (0-15 μg) to reverse Orx-A/Hcrt-1-induced reinstatement. Unexpectedly, SB334867 did not have any effects on Orx-A/Hcrt-1-induced reinstatement in any of the groups (i.e., SCM, ShA, and LgA) at any dose. In contrast, co-administration of TCSOX229 with Orx-A/Hcrt-1 decreased cocaine seeking only, an effect that was more pronounced in the LgA group. This suggests that Hcrt-r1 in the PVT is not directly implicated in the Orx-A/Hcrt-1 priming effect and that a history of cocaine self-administration dysregulates Orx/Hcrt-PVT neurotransmission at the level of Hcrt-r2. These results shed light on molecular targets (i.e., Hcrt receptors) that are dysregulated by a history of cocaine dependence and further identify a possible therapeutic approach to preventing drug seeking without affecting normal motivated behavior toward natural reward.

Title: Temporary inactivation of the paraventricular nucleus of the thalamus specifically blocks cocaine-seeking behavior: Comparison with natural reward seeking

Authors: *R. MARTIN-FARDON, F. WEISS, A. MATZEU;
MCND, The Scripps Res. Inst., LA JOLLA, CA

Abstract: Drug addiction is a chronic relapsing disorder characterized by compulsive drug seeking and use. However, it is unclear what differentiates neural signaling related to normal appetitive behavior vs. compulsive behavior that results from long-term drug exposure. One hypothesis concerning the control of drug-seeking behavior may be that the neural circuits that mediate these effects are common motivational circuits that are not specific to addiction-related events that are more robustly activated by drug-related stimuli. Although not included the “drug

addiction circuitry," recent evidence indicates that the paraventricular nucleus of the thalamus (PVT) is involved in the modulation of drug-directed behavior. The PVT is known to play a key role in energy homeostasis, arousal, endocrine regulation, and reward. Data from this laboratory have shown that the PVT is recruited during the conditioned reinstatement of cocaine seeking but not sweetened condensed milk (SCM) seeking. This activation was specifically correlated with cocaine-seeking behavior but not SCM-seeking behavior, suggesting that a history of cocaine intake alters the neural systems that regulate motivation that is normally directed toward natural rewards toward a preferential role in mediating the effects of stimuli that are conditioned to drugs vs. natural rewards. To test whether the PVT plays a pivotal role during cocaine seeking, the aim of this study was to investigate whether temporary inactivation of the PVT selectively prevents the cue-induced reinstatement of cocaine seeking but not SCM seeking. Male Wistar rats were trained to associate a discriminative stimulus (SD) with the availability of cocaine or SCM (S+) vs. saline or non-reward (S-) for 10 consecutive days. Following the extinction of cocaine- and SCM-reinforced responding, the rats were presented with the respective S+ or S- alone. The cocaine S+ and SCM S+ elicited identical levels of reinstatement, whereas the non-reward S- did not produce any reinstatement. Intra-PVT administration of the GABAA/GABAB agonists baclofen/muscimol (0.6/0.06 mM) prior to the presentation of the cocaine or SCM S+ completely prevented the conditioned reinstatement of cocaine seeking, with no effect on SCM-seeking behavior. These data show that the PVT plays an important role during cocaine-seeking behavior but not during natural reward-seeking behavior, further supporting the hypotheses that (i) the PVT is involved in drug addiction circuitry and (ii) a history of cocaine self-administration produces dysregulation within this thalamic structure and may tilt its function toward drug-directed behavior.

Title: Cocaine history sensitizes postsynaptic GABA receptors on dorsal raphe serotonin neurons in a stress-induced relapse model in rats

Authors: *C. LI, L. KIRBY;
Ctr. for Substance Abuse Res., Temple Univ. Sch. of Med., Philadelphia, PA

Abstract: The serotonin (5-hydroxytryptamine, 5-HT) system plays an important role in stress-related psychiatric disorders and substance abuse. Stressors can inhibit the dorsal raphe nucleus (DR)-5-HT system, which composes the majority of forebrain-projecting 5-HT. This inhibition is mediated via stimulation of GABA synaptic activity at 5-HT DR neurons by the stress neurohormone corticotrophin-releasing factor. Recent data from our laboratory indicate that morphine history sensitizes 5-HT DR neurons to GABAergic inhibitory effects of stress. Moreover, GABAA receptor-mediated inhibition of the serotonergic DR contributes to stress-induced reinstatement of morphine conditioned place-preference. In our current experiment, we tested the hypothesis that GABAergic sensitization of 5-HT DR neurons is a neuroadaptation elicited by multiple classes of abused drugs across multiple models of stress-induced relapse. Whole-cell patch-clamp recordings of GABA synaptic activity in 5-HT DR neurons were conducted in brain slices from Sprague-Dawley rats that underwent yohimbine stress-induced reinstatement of previously extinguished cocaine self-administration. Behavioral data indicate that the chemical stressor yohimbine triggered reinstatement of cocaine self-administration. Electrophysiology data indicate that 5-HT neurons in the cocaine group exposed to stress had increased amplitude of inhibitory postsynaptic currents compared to yoked-saline controls exposed to stress or unstressed animals in both drug groups. These data, together with previous findings, indicate that interaction between psychostimulant or opioid history and stress may increase postsynaptic GABA receptor density and/or sensitivity in 5-HT DR neurons to GABAergic inhibition. Such mechanisms may result in serotonergic hypofunction and consequent dysphoric mood states which confer vulnerability to stress-induced drug reinstatement.

Title: Excitability of mPFC pyramidal neurons was abnormally increased in Fisher F344 rats after low doses of cocaine self-administration

Authors: *W. N. WAYMAN[1,2], L. CHEN[1,2], X.-T. HU[1,2], T. C. NAPIER[1,2,3];
[1]Pharmacol. Department,, [2]Ctr. for Compulsive Behavior and Addiction, [3]Psychiatry, Rush Univ., Chicago, IL

Abstract: The medial prefrontal cortex (mPFC) regulates reward-motivated behavior. Chronic exposure to cocaine disrupts the mPFC which contributes to drug-craving, drug-seeking and relapse to drug-taking during protracted abstinence. Our laboratory has shown that mPFC activity is upregulated in adult male Sprague Dawley rats 2-3 weeks after 14 days of cocaine self-administration wherein cocaine was given as 1.0mg/kg/infusion and resulted in a 2hr daily session total of ~20mg/kg. Adult male Fisher rats self-titrate much lower doses of cocaine, and it is not known if this also is sufficient to alter mPFC activity. We reasoned that if changes in mPFC activity reflect neuronal plasticity induced by cocaine-mediated reward rather than the dose of cocaine per se, then enhanced mPFC neuronal excitability would occur in the F344 rats, despite the strain-specific differences in the amount of cocaine self-administered. This hypothesis was tested using Fisher (F344) rats that self-administered cocaine ~1mg/kg/2hr session/day for 14 days (COC-SA), or saline (SAL)-Yoked controls. Fourteen days after the last self-administration session, forebrain slices were prepared and whole-cell patch-clamp recordings of mPFC pyramidal neurons were performed. We determined that pyramidal neurons from cocaine-exposed rats fired more frequently than those from SAL-Yoked rats. This increased firing was associated with a membrane depolarization, and reductions in action potential amplitude and the amplitude of the afterhyperpolarization. These physiological alterations were similar to those we previously observed in Sprague Dawley rats, which self-administer much higher quantities of cocaine. Thus, the positive value of cocaine may differ between the rat strains but the enduring consequence of self-titrated cocaine (wherein the rats can balance positive reinforcing value by the amount self-administered) on the mPFC is similar. Further testing with, e.g., Sprague Dawley rats cocaine-yoked to self-administering F344 rats would help to validate this interpretation.

Title: Using a rodent model of simultaneous cocaine and alcohol use to screen medications to prevent cocaine relapse

Authors: *B. STENNETT, L. KNACKSTEDT;
Univ. of Florida, Gainesville, FL

Abstract: Cocaine addiction is a significant public health problem in the United States today. One of the difficulties in successful treatment of cocaine addiction is reducing the high risk of relapse that exists even after long periods of abstinence. Relapse can be modeled in animals using the extinction-reinstatement paradigm. This paradigm involves training animals to lever-press for cocaine reinforcement in an operant chamber. The operant response is then extinguished and reinstated either with cues previously paired with the response made to attain cocaine delivery, or an IP injection of cocaine. Previous research has established the role of nucleus accumbens glutamate transmission in the reinstatement of cocaine-seeking and has shown that the antibiotic ceftriaxone prevents relapse to cocaine seeking in rats. However, it is estimated that 60% to 90% of cocaine addicts use alcohol with cocaine. The combination of alcohol and cocaine potentially produces unique neuroadaptations that differ from those produced by either drug alone. Therefore, we used a model of poly-drug addiction in which rats self-administered cocaine for two hours in an operant chamber and subsequently drank alcohol (20% v/v) from bottles in the home cage for 6 hours. Following two weeks of drug consumption, animals then underwent extinction training for a minimum of two weeks. Animals were treated with IP ceftriaxone (100 or 200 mg/kg) or vehicle for 6 days prior to being tested for cue- and cocaine-primed reinstatement. Preliminary data indicates that ceftriaxone was not effective in preventing relapse in animals which consumed alcohol in addition to cocaine. These findings indicate that the neurobiological underpinnings of relapse to cocaine are altered when animals consume alcohol with cocaine.

Title: The role of nucleus accumbens glutamate in the context-primed relapse of cocaine-seeking after abstinence

Authors: *L. A. KNACKSTEDT, M. SCHWENDT;
Psychology, Univ. of Florida, Gainesville, FL

Abstract: Cocaine addiction is a chronic disorder and the risk of relapse remains high even after long periods of abstinence. Animal models of relapse have been developed to screen pharmacological treatments for addiction. The extinction-reinstatement model has been extensively used to identify the neural circuitry involved in relapse, with glutamate release in the ventral striatum being identified as a key mediator of reinstatement. A second animal model is the abstinent-relapse model in which animals do not undergo extinction training following self-administration but instead experience abstinence in the home cage. Animals are then re-exposed to the drug-taking environment (operant chamber) for a context-induced relapse test. MTEP and ceftriaxone modulate glutamatergic transmission and have previously been shown to attenuate reinstatement of cocaine-seeking following extinction training. Here we screened them for their ability to attenuate cocaine relapse after abstinence. Rats were trained to self-administer cocaine for 2 hr/day for 12 days in a standard operant chamber. Following three weeks of abstinence in the home cage, animals were placed back into the operant chamber for a context-induced relapse test. A subset of animals received one of 3 doses of MTEP (0.5, 1, or 5.0 mg/kg) or vehicle immediately prior to the relapse test. A second group of animals received either chronic ceftriaxone (100 or 200 mg/kg) or vehicle once daily for 5 days prior to the relapse test. We found that both MTEP and ceftriaxone attenuated context-primed relapse following abstinence. Ceftriaxone significantly increased GLT-1 expression and reduced GluR1 expression in the nucleus accumbens. Microdialysis conducted during the context-primed relapse test showed a significant increase in glutamate release in the nucleus accumbens. These results implicate glutamatergic transmission in context-primed relapse following abstinence.

Title: Glucagon-like peptide-1 receptor activation in the VTA or accumbens core attenuates cocaine taking and seeking in rats

Authors: *E. G. MIETLICKI-BAASE, K. Y. IGE, D. R. OLIVOS, R. C. PIERCE, M. R. HAYES, H. D. SCHMIDT;
Psychiatry, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Glucagon-like peptide-1 receptor (GLP-1R) signaling in the CNS is pharmacologically and physiologically relevant for energy balance control. The GLP-1R agonist exendin-4 (Ex-4) decreases intake of palatable food when administered into mesolimbic nuclei including the ventral tegmental area (VTA) and the nucleus accumbens (NAc) core. Since the VTA and NAc mediate the reinforcing effects of food and drugs of abuse, we hypothesized that GLP-1R activation in these two brain regions would suppress cocaine taking and seeking. Here, we show that administration of Ex-4 (0, 0.005, and 0.05 μg/100nl) directly into the VTA dose-dependently attenuated cocaine self-administration when rats were maintained on a progressive ratio schedule of reinforcement, as well as attenuated cocaine priming-induced reinstatement of drug seeking. Intra-VTA Ex-4 at these doses had no effect on sucrose reinstatement, suggesting that the cocaine effects are not due to locomotor impairment. To further investigate the role of mesolimbic GLP-1Rs in cocaine seeking, we assessed the ability of Ex-4 microinfusions into the NAc core to suppress the reinstatement of cocaine seeking. Ex-4 (0, 0.005, and 0.05 μg/100nl) microinjected directly into the NAc core attenuated the ability of an acute priming injection of cocaine (10 mg/kg, i.p.) to reinstate cocaine seeking. No effects of intra-NAc core Ex-4 on the reinstatement of sucrose seeking were observed. Previous and current research demonstrates that cocaine self-administration increases plasma levels of corticosterone during drug taking. Furthermore, the expression of endogenous CNS GLP-1 in the nucleus tractus solitarius (NTS) is increased by corticosterone, and these NTS GLP-1-producing neurons project monosynaptically to the VTA and NAc core. Taken together, these findings indicate that, during cocaine taking, increased corticosterone may increase mesolimbic GLP-1 signaling to stop or reduce the ongoing drug-taking behavior. Here, we show that 4th i.c.v. injection of corticosterone (0, 0.05, and 0.5 μg/1μl) decreases cocaine taking on a progressive ratio schedule of reinforcement. This finding

is consistent with our working hypothesis that cocaine-induced increases in plasma corticosterone increase NTS GLP-1 expression and subsequent GLP-1 signaling in the VTA and NAc core. Increased mesolimbic GLP-1R signaling may therefore represent a homeostatic response to cocaine taking that functions as an “emergency brake” mechanism to decrease further cocaine self-administration.

Title: The dorsal agranular insular cortex bidirectionally regulates drug-prime vs. cue-induced reinstatement of cocaine-seeking behavior

Authors: *C. V. COSME, R. T. LALUMIERE;
Univ. of Iowa, Iowa City, IA

Abstract: Previous findings have demonstrated the medial prefrontal cortex plays a critical role in mediating drug seeking. However, fewer studies have examined how regions of the lateral prefrontal cortex (lPFC) influence such behavior, despite evidence based on anatomical connections and human studies suggesting this area plays a potential role in regulating drug-seeking behavior. In particular, limited animal work has suggested that a subregion of the lPFC known as the dorsal agranular insular cortex (AId) is involved in the reinstatement of drug-seeking behavior. However, studies have only investigated the AId in contextual renewal of cocaine seeking and have yet to clarify the mechanisms by which this influence may be occurring. Thus the present study examined how the AId regulates different types of reinstatement of cocaine-seeking behavior. Male Sprague-Dawley rats underwent surgery for implantation of bilateral guide cannulae aimed at the AId or the posterior insular cortex (PIc) and implantation of an intravenous jugular catheter. After undergoing cocaine self-administration for at least 12 days (2 h daily), rats underwent extinction training prior to reinstatement testing. Reinstatement tests consisted of cue-induced, cocaine-prime, and cue-induced + cocaine-prime

(cue +cocaine) reinstatement. AId inactivation, via microinjections of the GABA receptor agonists baclofen and muscimol, attenuated drug seeking during cued reinstatement but, surprisingly, potentiated cocaine-prime reinstatement. AId inactivation had no effect on cue + cocaine reinstatement. PIc inactivation had no effect on any of the reinstatement types that were tested. Due to the relatively dense expression of corticotropin-releasing factor (CRF)-1 receptors in the AId and the potential involvement of CRF in mediating the negative interoceptive cues that are processed in the AId, we investigated the role of these receptors in the AId during reinstatement. CRF1 blockade, via microinjections of the CRF1 antagonist antalarmin into the AId, significantly reduced cue-induced reinstatement and potentiated cocaine primed reinstatement, similar to what was observed during AId inactivation. These findings suggest the AId has opposing influences over cued and cocaine-prime reinstatement, resulting in a bidirectional regulation of cocaine-seeking behavior depending on the type of reinstatement trigger. Moreover, the present study indicates that this influence is specific to the AId, and not the PIc, and that activation of CRF1 receptors within the AId appears to mediate this influence.

Title: The role of nuclear histone deacetylase 5 in cocaine addiction behavior

Authors: *M. B. CARREIRA[1,2], M. TANIGUCHI[3], D. GUZMAN[2], E. B. LARSON[4], D. W. SELF[2], C. W. COWAN[3];

Abstract: The transition from cocaine use to abuse is a poorly understood phenomenon. Extensive evidence in the literature suggests that this transition to abuse may be mediated by changes in nervous system structure and function, including chromatin remodeling and epigenetic mechanisms. Recently, we reported that cocaine administration induces transient nuclear accumulation of the class IIa histone deacetylase, HDAC5, which functions to limit the development of cocaine reward behavior. Furthermore, the nuclear accumulation of HDAC5 in a key reward region, the nucleus accumbens (NAc), was sufficient to attenuate cocaine reward. We sought to explore the role of nuclear HDAC5 on the NAc in a model with high face validity for cocaine addiction, the self-administration model. For this purpose, we have developed adeno-associated virus (AAV) that express either the wild type (WT) form of the protein or a nuclear mutant full-length HDAC5. Targeted over-expression into the NAc revealed an attenuating role for nuclear HDAC5 in cocaine prime-dependent reinstatement behavior. This effect appears to be unique to primed-reinstatement as cue-dependent and stress-dependent reinstatement remains unchanged from controls. Furthermore, we observe no differences across groups during extinction of lever pressing in the absence of cocaine. These findings suggest that nuclear HDAC5 acts by reducing the rewarding properties of cocaine, and ongoing studies are testing whether the nuclear, dephosphorylated HDAC5 reduces sensitivity to cocaine. The downstream mechanisms by which HDAC5 suppresses cocaine reward and prime reinstatement is not yet clear, but we observe that nuclear, dephosphorylated HDAC5 dramatically suppresses MEF2-dependent gene expression, and our HDAC5 ChIP-seq findings indicate that HDAC5 associates with genomic DNA predominantly in regions containing MEF2 consensus binding sites. Together, our findings begin to elucidate the key roles and regulation of HDAC5 in cocaine addiction-relevant behaviors.

Title: The selective and intake-dependent plasticity in group 1 metabotropic glutamate receptor signaling following cocaine self-administration

Authors: *M. GHASEMZADEH, M. VUONCINO, P. HEASLIP, D. FABRIS, R. DIDOMINICIS, C. SZEWCZYK, C. GWINN, G. RIES, J. R. MANTSCH;
Dept Biomed. Sci., Marquette Univ., MILWAUKEE, WI

Abstract: A major obstacle in the treatment of addiction has been the propensity to relapse, often mediated by drug-associated cues, even after prolonged period of abstinence from drug use. Repeated exposure to cocaine leads to enduring alterations in glutamatergic signaling in the brain reward circuitry that play an important role in long-lasting molecular, cellular and behavioral neuroadaptations. Therefore, glutamate signaling has been investigated as a target for the development of treatment for addiction. Recent studies have suggested that the group I metabotropic glutamate receptors (mGluR1/5) play important roles in drug reinforcement and seeking and, therefore, have been pursued as promising targets for drug development. Here, we examined the role of mGluR1/5 receptors in abstinence drug seeking using animal models of cocaine self-administration. Sprague-Dawley rats were trained to self-administer cocaine (FR1; 1.0 mg/kg/200 µl/inf) during either 2-hr (ShA) or 6-hr sessions (LgA) for 14 days. Subsequently, animals were left undisturbed in home cage for 3, 10, or 60 days. Following abstinence period, rats were tested under extinction condition for cocaine seeking after either saline or an mGluR1/5 receptor antagonist administration (MTEP or JNJ16259685). Following a short abstinence period (3 or 10 days), the blockade of mGluR5 receptor reduced drug seeking only in ShA subjects without affecting the LgA animals, while mGluR1 receptor blockade were equally effective in reducing drug seeking in both groups. However, after a long abstinence period (60 days), the blockade of either of receptors significantly reduced drug seeking in ShA and LgA rats. Furthermore, mGluR5 blockade was effective in reducing drug taking (cocaine self-administration) in a dose dependent manner by ShA subjects but not by LgA animals. The results suggest that exposure to cocaine produced a transient intake dependent plasticity in mGluR5 signaling in the brain. The observed plasticity is specific to mGluR5 signaling since blockade of mGluR1 receptors reduced drug seeking similarly in both ShA and LgA animals. In order to identify the anatomical substrates contributing to the selective modulation of mGluR5 signaling, site-specific blockade of mGluR5 receptors in the nuclei of motive circuit will be performed. The selective, intake dependent, and transient plasticity in brain mGluR5 signaling mediated by exposure to cocaine suggest an important role for mGluR5 in cocaine mediated neuroadaptations and addiction behaviors. Understanding the mechanism of cocaine mediated effects may reveal new molecular targets for therapeutic development for the treatment of cocaine addiction.

Title: Sex differences in attenuation of cocaine conditioned cue reinstatement by the central oxytocin receptor agonist FE-202739

Authors: *L. ZHOU, S. M. GHEE, J. PETERS, R. E. SEE, C. M. REICHEL;
Dept. of Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Sex differences clearly exist in psychostimulant addiction patterns. However, potential therapies and the underlying neurobiology have typically only been studied in males. In both males and females, systemic oxytocin treatment attenuated reinstatement of cocaine seeking in a self-administration/reinstatement model of relapse. However, as with all neuroactive peptides, the question remains as to whether enough systemic oxytocin crosses the blood brain barrier to an extent that will exert a central effect. Oxytocin also binds to vasopressin receptors, so the involvement of this system also remains unclear. Here, we compared the impact of systemic and centrally administered oxytocin and a novel oxytocin receptor agonist, FE-202739, on cocaine seeking in male and female rats. FE-202739 specifically binds to oxytocin receptors and does not have a central effect when administered systemically. Rats underwent 10 days of 2 hr cocaine self-administration followed by at least seven days of extinction. In the first experiment, FE-202739 was intraperitoneally injected before reinstatement of cocaine seeking induced by cocaine prime or conditioned cues. Unlike systemic oxytocin, systemic FE-202739 had no effect on reinstatement to cocaine seeking. In the second experiment, oxytocin and FE-202739 were infused intracerebroventricular (ICV). When given centrally, both compounds significantly attenuated cocaine-primed reinstatement in males and females. However, cue-induced reinstatement was only reduced in males, but not females. Based on these findings, a central action on the oxytocin receptor is necessary for the attenuation of cocaine seeking in males and females in response to a cocaine prime. However, in response to conditioned cues, central actions on the oxytocin receptor were only relevant in males because in females, both ICV oxytocin and FE-202739 were without effect. This sex difference for cue-induced cocaine

seeking may relate to the well-known sex differences in the role of oxytocin on peripheral organ sites of actions in females relative to males.

Title: Withdrawal periods following extended access cocaine self-administration do not alter drug intake during binge or resistance to punishment

Authors: *D. M. DIETZ, D. N. ADANK, A. GANCARZ-KAUSCH;
Dept. of Pharm and Tox; Res. Inst. on Addictions; Program in Neurosci., State Univ. of New York At Buffalo, Buffalo, NY

Abstract: Several of the key characteristics of drug addiction include: (i) a progression from recreational to compulsive drug-taking behavior, (ii) difficulty in limiting intake, and (iii) a high propensity to relapse following drug cessation. Changes in subjective drug craving have been reported to increase with periods of abstinence. Another facet of addiction is the continued use of drugs despite negative consequences (e.g., health complications, risk of incarceration, etc.). While there have been many studies correlating the length of the withdrawal period with drug craving and seeking, this phenomenon does not seem to apply to traditional drug-induced relapse models. Here, we investigated the effects of various withdrawal periods on relapse to cocaine self-administration (SA) “binge” and resistance-to-punishment models. Following 1, 14 or 30 d of withdrawal from extended access to cocaine SA, rats were tested on a cocaine binge (12 hr unlimited access). Surprisingly, there was no effect of withdrawal time on drug-taking performance during the binge. The second experiment evaluated the effect of withdrawal (1 or 14 d) on the persistence to responding for cocaine when the drug delivery was associated with a punishment. During this test, responding resulted in the delivery of both the drug and an iv injection of histamine. Similarly, rats exposed to a 14 d withdrawal self-administered the same amount of drug as rats exposed to a 1 d withdrawal. However, SA during the extended access was positively correlated with the degree of SA during the resistance-to-punishment test. These findings demonstrate the stability of drug-taking behavior despite long periods of drug

withdrawal and suggest that forced abstinence in clinical interventions is insufficient to decrease future drug relapse. Forthcoming studies will examine the transcriptional mechanisms that mediate such behavioral stability in an attempt to identify novel molecular targets that may provide an additional therapeutic intervention

Title: In a warm environment hyperthermia induced by 3,4-methylenedioxy-N-methylamphetamine (MDMA) is dependent on locomotion

Authors: *M. V. ZARETSKAIA, D. V. ZARETSKY, P. J. DURANT, D. E. RUSYNIAK; Dept.Emergency Med., IU Sch. of Med., INDIANAPOLIS, IN

Abstract: The central mechanisms through which MDMA causes life-threatening hyperthermia are not well described. Recently, we have demonstrated that inhibiting the dorsomedial hypothalamus (DMH) or the medullary raphe pallidus in rats given MDMA in warm environment, did not prevent non-shivering thermogenesis or cutaneous vasoconstriction. Despite this, inhibiting the DMH, but not the raphe pallidus, decreased hyperthermia and prevented mortality. Unlike inhibition of the raphe, suppression of neuronal activity in the DMH suppresses locomotion produced by MDMA. We hypothesized that hyperthermia after administration of MDMA in warm environment is dependent on locomotion. To separate the role of locomotion from other DMH-mediated effects that might contribute to hyperthermia from MDMA (e.g., blood pressure, metabolic rate) we conducted the following experiment. Male Sprague-Dawley rats were implanted with telemetric transmitters measuring core temperature and microinjection cannulas targeting the DMH bilaterally. After recovering from surgery, rats were familiarized to running on a treadmill for 5 days. On the day of the experiment they were

randomized to microinjections of either muscimol (80 pmol/100nl) or artificial CSF and to i.v. injections of either MDMA (7.5 mg/kg) or equal volume of saline. Rats were adapted to warm environment for at least 60 min and microinjected with muscimol or aCSF. Five min later MDMA or saline were administered i.v., rats were immediately placed on the treadmill at a fixed speed (10 m/min at zero incline) in an environmental chamber at an ambient temperature of 32°C. Under these conditions, the temperature responses in animals given MDMA and microinjected with muscimol were identical to control animals (CSF/MDMA). We conclude that locomotion, mediated through the DMH, is a key contributor to MDMA-evoked hyperthermia in warm environment. These results are important as they represent a significant change in our understanding of how MDMA causes hyperthermia. Based on our results we suggest life-threatening hyperthermia from MDMA is similar to exertional heat stroke.

Title: Modeling orexinergic neurotransmission in temperature responses to methamphetamine

Authors: *A. BEHROUZVAZIRI[1], D. FU[3], P. TAN[4], Y. YOO[2], M. ZARETSKAIA[5], D. RUSYNIAK[5], D. V.ZARETSKY[5], Y. MOLKOV[2];
[2]Dept. of Mathematical Sci., [1]Inidna Univ. Purdue Univ. Indianapolis, Indianapolis, IN; [3]Park Tudor Sch., Indianapolis, IN; [4]Carmel High Sch., Carmel, IN; [5]Dept. of Emergency Med., Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Amphetamines are widely abused. Deaths from hyperthermia have been reported after intentional overdose but there have also been deaths with low doses. Unfortunately, complex pharmacology of amphetamines is far from being understood. At room temperature, temperature

responses to methamphetamine are multiphasic, include both hypothermic and hyperthermic phases, and have non-trivial dose-dependence. Recently, we demonstrated the involvement of orexinergic neurotransmission in Meth-induced temperature responses. Low dose of SB-334867 (SB, 10 mg/kg), an antagonist of orexin receptors (ORX1), was injected 30 min prior to various doses of Meth. While this dose of antagonist clearly suppressed the response to low (1 mg/kg) and intermediate (5 mg/kg) doses of Meth, the effect was statistically significant only during the late phase ($t > 60$ min) of the response to intermediate dose. In the early phase ($t < 60$ min) any drug-related changes were marred by stress-induced temperature fluctuations resulting from two intraperitoneal injections. In a separate set of experiments a high dose of the same antagonist (30 mg/kg), suppressed the effect of low doses of Meth even more, but in contrast, it significantly amplified the responses to the higher doses (5 and 10 mg/kg) of Meth. To interpret the data, we advanced a model we recently described. The dose-dependent temperature responses to Meth could be modeled by interaction of two excitatory drives (low dose [Exc] and high dose[HD]) and one inhibitory drive, which are all activated by Meth. The extended model suggested that activation of excitatory (Exc) and inhibitory nodes, by Meth and stress, are mediated by activation of ORX1 receptors. In turn, amplification by SB of immediate responses to high dose of Meth cannot be explained by suppression of inhibitory drive, as we initially hypothesized. Instead, disinhibition of HD, with inhibitory tone coming directly from inhibitory node, perfectly fits. Presence of inhibition can explain why HD node requires high doses of Meth to be activated. However, disinhibition of HD required higher dose of SB. This points to non-specific effects of the ORX1 antagonist. Our modeling studies detail involvement of orexin receptors into temperature responses to Meth. Also, our data caution that administration of orexin antagonists may increase a risk of life-threatening hyperthermia from amphetamine-like stimulants.

Title: Locomotion-thermoregulatory coupling in responses to methamphetamine (Meth)

Authors: *D. V. ZARETSKY[1], M. V. ZARETSKAIA[1], Y. YOO[2], A. BEHROUZVAZIRI[2], D. E. RUSYNIAK[1], Y. MOLKOV[2];
[1]Dept Emergency Med., Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Dept.Mathematical Sci., IUPUI, Indianapolis, IN

Abstract: Administration of Meth increases temperature and locomotion. Recently, we successfully designed a firing-rate based neural network model that accurately predicts the temperature responses to various doses of Meth. The temporal dynamics of one of the network nodes was surprisingly similar to patterns of locomotor responses observed in the same experiment. When we replaced the predicted time series of this node with the data of locomotor responses, we found that our neural network accurately reproduced experimental data from a low and high dose of Meth with one exception. Within 60 min of injection, the temperature prediction of the modified model with locomotion term significantly overestimated experimental values in responses to high doses. This means that initial locomotor responses to high doses of Meth are not accompanied by corresponding temperature response unlike late responses or responses to low doses. We sought to compare locomotion-thermoregulatory coupling in various paradigms. First, we estimated locomotion-induced changes in body temperature in rats running on a treadmill at various speeds (up to18 m/min at zero incline) and ambient temperatures. To our surprise, rate of heat accumulation at room temperature was not different between rats running and rats sitting on the treadmill. When the ambient temperature was increased to 32°C, rate of heat accumulation correlated with running speed. We conclude that running evokes compensatory thermoregulatory changes to offset heat generated by physical exercise. Furthermore, we conclude that these compensatory changes are no longer effective in a warm environment. Therefore, initial locomotor response to high doses of Meth is similar to running on the treadmill in terms of locomotor-thermoregulatory coupling. In contrast to running, chemical stimulation of the dorsomedial hypothalamus (DMH) causes locomotor responses that are correlated with hyperthermia at room temperatures. Locomotion coupled with hyperthermia is typical for mild stress, such as cage switch, and can be suppressed by inhibition of the neuronal activity in the DMH. Increases of locomotion and body temperature induced by Meth are also mediated by activation of neurons in the region of the DMH. This activation appears to be a common feature in various paradigms characterized by both locomotor activation and hyperthermia. We conclude that Meth evokes two types of locomotor responses in relation to thermoregulation - one which is accompanied by thermoregulatory response (early high dose, similar to running on treadmill) and another one which is not (low dose or late high dose, similar to responses mediated by the DMH).

Title: Prior nicotine self-administration attenuates dopaminergic deficits induced by subsequent high-dose methamphetamine administration

Authors: *M. G. BALADI[1], S. M. NIELSEN[1], G. R. HANSON[1,2], A. E. FLECKENSTEIN[1]; [1]Dept. of Pharmacol. and Toxicology, Univ. of Utah, Salt Lake City, UT; [2]Sch. of Dent., Univ. of Utah, Salt Lake city, UT

Abstract: Methamphetamine (METH) use and abuse is a serious public health problem and can produce long-term changes in dopaminergic (DAergic) neurons. Of relevance are findings that METH abusers have an increased likelihood of developing Parkinson's disease (PD). Furthermore, METH abusers report high rates of cigarette smoking and interestingly, preclinical studies indicate that non-contingent nicotine exposure attenuates METH-induced DAergic deficits. However, it is unclear whether nicotine exposure that closely models tobacco use in humans (i.e. extended access to nicotine self-administration) attenuates these effects of METH. To address this issue, male, Sprague Dawley rats were allowed access to intravenous nicotine (0.032 mg/kg/infusion, fixed ratio 5) or saline for 23 h/day for 14 days and subsequently (i.e. 1 h after the final self-administration session) treated with methamphetamine (4 x 7.5 mg/kg/injection, s.c.) or saline (4 x 1 ml/kg/injection, s.c.). Results indicate that prior nicotine self-administration attenuated METH-induced decreases in striatal dopamine transporter activity as assessed 24 h after treatment. In addition, this ability of nicotine to attenuate the effects of METH was not due to prevention of METH-induced hyperthermia. Elucidating mechanisms underlying the interaction between nicotine and METH may contribute to the development of

selective therapeutic strategies to attenuate DAergic neuronal degeneration as well as understanding the etiology of disorders involving alterations in DAergic systems, such as PD.

Title: Effects of early adolescent methamphetamine and nicotine exposure on behavior and cognition in adolescent mice

Authors: J. M. BUCK, *J. A. SIEGEL;
Psychology, Sewanee: The Univ. of the South, Sewanee, TN

Abstract: The neurotoxic effects of methamphetamine (MA) can lead to deficits in behavior and cognition. The rising rates of adolescent MA use necessitate that we understand effects of MA exposure on the adolescent brain. Adolescents in treatment for MA abuse show higher levels of depression and suicide ideation compared to those being treated for other substances. Adolescents using MA also show high rates of nicotine use. Previous research has shown that nicotine can mediate the effects of MA in the brain. However, the interaction between MA and nicotine in the adolescent brain, and the effects of these two substances, has not been examined. This research assesses the effects of early adolescent MA and nicotine exposure on cognition and behavior in male C57BL/6J mice later in adolescence. Current experiments are ongoing to study the effects of early adolescent MA and nicotine exposure on behavior in the open field test, the novel object recognition test, the Porsolt forced swim test, and Morris water maze to evaluate locomotor activity and anxiety-like behavior, object memory, depression-like behavior, and spatial memory, respectively. Based on previous data in late adolescent mice, we expect early adolescent MA exposure to impair cognition and increase depression-like behavior. We also predict that concurrent MA and nicotine exposure during early adolescence will attenuate the effects of MA exposure on behavior and cognition in late adolescence. These findings will

contribute to a greater understanding of how MA and concurrent nicotine exposure alters behavior and cognition in an age group that has been relatively understudied.

Title: Role of BDNF-TrkB signaling in depression-like behaviors in mice after withdrawal from repeated administration of methamphetamine

Authors: ***Q. REN**, M. MA, C. YANG, W. YAO, J.-C. ZHANG, K. HASHIMOTO;
Chiba Univ. Ctr. Forensic Mental Hlth., Chiba, Japan

Abstract: Depression is highly comorbid with methamphetamine (METH) abuse. METH can cause depression and psychosis during active use and withdrawal, and these symptoms persist in early abstinence. Several lines of evidence suggest the key role of brain-derived neruotrophic factor (BDNF) and its specific receptor, tropomyosin-related kinase (TrkB), signaling in the pathophysiology of depression. In this study, we examined whether BDNF-TrkB signaling plays a role in the depression-like behaviors in mice after withdrawal from repeated administration of METH. In the tail-suspension test, forced swimming test, 1% sucrose preference test, repeated administration of METH (3 mg/kg/day for 5 days) caused depression-like behaviors in mice, and depression-like behavior persisted more than 2-weeks after the final administration of METH. Western blot analysis showed that BDNF levels in the nucleus accumbens (NAc) of METH treated mice were significantly higher than those of control mice although BDNF levels in the other regions, including prefrontal cortex, hippocampus, were no different. Interestingly, METH-induced depression-like behavior could be improved after subsequent repeated administration of TrkB antagonist ANA-12. These findings suggest that BDNF-TrkB signaling plays a role in the depression-like behavior after withdrawal from repeated METH administration, and that TrkB

antagonists would be potential therapeutic drugs for depression associated with METH withdrawal in humans.

Title: Clobenzorex-treatment induces amphetamine-like neurotoxicity

Authors: *G. S. ROJAS, V. PALAFOX-SÁNCHEZ, G. RAMÍREZ-GARCÍA, A. PATRICIO, D. LIMÓN;
Neuropharm. Lab., Benemerita Univ. Autonoma De Puebla, Puebla, Mexico

Abstract: Clobenzorex (Clx) is a derivative of amphetamine which is prescribed as anorectic in Mexico and its treatment has been correlated with the induction of abnormal movements. Also, Clx has been illegally used to increase motor activity, attention and arousal by drug abusers. This study was carried out in order to examine the physiological, behavioral and cellular effects of a sub-chronic Clx-treatment in rats. Wistar male rats were used and divided in groups: vehicle (n=4, v.o and s.c), amphetamine (n=4, 3mg/kg s.c) and Clx (n=4: 30, 50, 70 and 110 mg/kg, v.o), all treatments were given once daily during fifteen days. Motor activity was evaluated in the open field after drug administration in the 1st, 5th, 10th and 15th days of the experiment, we evaluated the number of squares crossed; also, rats were monitored every 30min during 3h after drug administration and were recorder in order to detect if there was a change in their behavior. Rectal temperature was measured to evaluate if Clx could raise it as an amphetamine treatment does. Brains were extracted and an immunostaining was performed to tyrosine hydroxylase (TH) in the substantia nigra pars compacta (SNpc). In this work we demonstrate that after a sub-chronic Clx-treatment motor activity decreased over time and stereotypes are induced as an amphetamine treatment. Hyperthermia and the loss of immunoreactivity to TH in the SNpc could be related to stereotypes because dopamine deregulation in the SNpc modifies the basal ganglia

crosstalk. The mechanism of neurotoxicity of Clx is poorly understood and because of that is necessary to study it furthermore.

Title: Age-dependent effects of nicotine pretreatment on methamphetamine-induced dopaminergic deficits: role of alpha4* and alpha6* nicotinic receptor subtypes

Authors: *P. L. VIEIRA-BROCK[1], L. M. MCFADDEN[1], S. M. NIELSEN[1], G. R. HANSON[2], A. E. FLECKENSTEIN[1];
[1]Dept. of Pharmacol. and Toxicology, [2]Sch. of Dent., Univ. of Utah, Salt Lake City, UT

Abstract: Epidemiological studies have demonstrated an inverse correlation between cigarette smoking and risk of Parkinson's disease (PD). Clinical and preclinical studies have indicated that nicotine (NIC) might be neuroprotective against toxicities to dopamine systems. The neuroprotective mechanisms involving NIC are not fully understood, although a role for alpha4* and alpha6* subtypes of nicotinic acetylcholine receptors (nAChRs) has been suggested. Of relevance to this study, high-dose methamphetamine (METH) administration causes persistent dopaminergic (DAergic) deficits resembling some aspects of PD. Accordingly, the current study assessed the impact of chronic NIC pre-administration on the expression of alpha4* and alpha6* nAChRs and on DAergic neuronal function in adolescent and adult METH-treated rats. Results revealed that METH alone caused persistent deficits in both striatal dopamine transporter (DAT) function and expression and alpha6* nAChR expression. In addition, METH alone did not decrease alpha4* nAChRs expression, indicating that alpha6* nAChRs are differentially sensitive to METH. In contrast, in NIC-pre-treated adolescent or adult rats, the ability of METH

to disrupt DAT function and expression was reduced. However, despite protecting against persistent METH-induced DAT function and expression deficits, NIC pre-treatment did not attenuate METH-induced alpha6* nAChRs expression deficits. In summary, these data indicate that NIC is neuroprotective against DAergic deficits caused by METH and NIC neuroprotection might occur via mechanisms that are not limited to the involvement of alpha4* or alpha6* nAChRs. Title: Multidimensional assessment of responses to a drug-associated cue in healthy humans

Authors: *L. M. MAYO, H. DE WIT;
Psychiatry & Behavioral Neurosci., Univ. of Chicago, Chicago, IL

Abstract: Drug use is strongly influenced by associations made between psychoactive drug effects and environmental stimuli (cues) present during the drug experience. Conditioning, the process by which a cue becomes associated with drug through repeated pairings, is the focal point of many theories of addiction, and is believed to contribute to the acquisition, maintenance, and relapse to problematic drug use. Drug-related cues can promote drug craving, seeking, and consumption, even after long periods of drug abstinence. Although cues are known to play a crucial role in the cycle of addiction, few studies have examined the acquisition process and the behavioral features of conditioned responses in humans. Therefore, we have developed a novel human drug conditioning paradigm to determine whether a cue paired with a typical drug of abuse (i.e. methamphetamine, MA) will acquire conditioned properties in humans. We have employed a multidimensional approach to determine the various ways in which the responses manifest and examined individual differences in conditioning. Healthy, non-dependent humans came in for 6 sessions, including a pre-test, 4 conditioning sessions, and a post-test. At the pre-test, we assessed how participants responded to two visual cues using the following measures:

behavioral preference, subjective ratings of "liking", emotional reactivity (as indicated by facial electromyography of zygomatic and corrugator facial muscle activity), and attention. Subjects then came in for the 4 conditioning sessions; 2 with drug (20mg MA) and 2 with placebo, administered under double-blind conditions in alternating order. For each subject, one study cue was always presented during drug sessions, while the other was presented during placebo sessions. Participants then came in for the post-test sessions where we again measured responses to study cues, with an interest in how the responses have changed as a result of experiencing one cue in the presence of drug, and the other in the absence. We found that participants demonstrated conditioned responses towards the drug-paired cue, including enhanced behavioral preference, enhanced positive emotional reactivity, and a bias in attention. Interesting, changes in emotional reactivity and attention were negatively correlated. However, subjective drug response (from conditioning sessions) predicted the increase in attentional bias. This research is critical to address the current knowledge gaps in drug conditioning research, identify individuals especially at risk for cue-elicited drug seeking and consumption, and inform future efforts to prevent or attenuate cue-facilitated drug seeking and relapse.

Abstract: Ginsenoside Re (Re), a protopanaxatriol-type saponin, is one of the main constituent of Panax ginseng and known to have antioxidant and anti-inflammatory properties. Recently, we reported that Re significantly attenuates methamphetamine (MA)-induced neurotoxicity by inhibiting impaired enzymatic antioxidant systems, mitochondrial oxidative stress, and mitochondrial translocation of protein kinase C (PKC) δ. To extend our understanding, we examined the effect of Re on the pro-inflammatory changes induced by MA. First, we evaluated the spatial pattern of microglial and astroglial activation in the dopaminergic system after MA treatment. Significant and robust microglial activation was observed in the striatum, but not in the substantia nigra, at 1 day and 2 days after the final MA injection. However, significant astroglial activation was shown in both striatum and substantia nigra, indicating that MA-induced neuroinflammatory changes seem to be specific in the striatum. To clarify the phenotype of activated microglia, we examine the mRNA expression of M1 (e.g. CD16, CD32, and CD86) and M2 (e.g. arginase 1 and CD206) phenotype markers. MA treatment significantly increased the mRNA expression of M1 microglia phenotype markers, but did not affect that of M2 phenotype markers. These pro-inflammatory changes were significantly attenuated by Re. Interestingly, PKCδ gene depletion also significantly attenuated MA-induced microglial activation and increases in the mRNA expression of M1 phenotype markers, and Re did not provide any further attenuation on the pro-inflammatory changes induced by MA in PKCδ gene knockout mice. Consistently, MA-induced dopaminergic toxicity and behavioral impairment were significantly attenuated by Re. Our results suggest that Re provides neuroprotection in response to MA-induced dopaminergic degeneration via inhibition of pro-inflammatory changes [supported by a grant (No. 110113-3) form the Korea Institute of Planning and Evaluation for Technology in Food, Agriculture, Forestry, and Fisheries (IPET), Korea. Title: The relationship between amphetamine-induced cerebrovascular and neurotoxicity to changes in the expression of genes related to the immune system present in circulating blood

Authors: *J. F. BOWYER[1], N. M. CRABTREE[1], K. M. TRANTER[2], N. I. GEORGE[3], J. P. HANIG[4], R. P. SCHLEIMER[5];
[1]Neurotoxicology, [2]Toxicologic Pathology Associates, [3]Bioinformatics and Biostatistics, NCTR/FDA, Jefferson, AR; [4]FDA/CDER, Silver Spring, MD; [5]Allergy and Immunol., Northwestern Feinberg Sch. of Med., Chicago, IL

Abstract: The magnitude of cerebrovascular damage and neurotoxicity correlates with the degree of hyperthermia produced during exposure to either amphetamine (AMPH) or methamphetamine (METH) and may be exacerbated by damage to muscle and organ systems outside the CNS. AMPH- and METH-induced damage to peripheral tissues may trigger immune signals in the circulating blood which could influence the CNS immune response and neurotoxicity. The present studies in Sprague-Dawley rats examined the gene expression (mRNA) and cytokine changes in whole blood under conditions where AMPH produced hyperthermia, cerebrovascular damage and striatal neurotoxicity (75% dopamine depletions). Four injections of D-AMPH (5, 7.5, 10 and 10 mg/kg) were given with 2 hr between each injection. Our objectives were to identify biomarkers of AMPH neurotoxicity and determine the immune-related responses in circulating blood. The AMPH hyperthermic group was compared to: a saline control group; a group given the same AMPH exposure but remained normothermic due to a cool environment (16°C); and environmentally-induced hyperthermia (EIH, AMPH-free in an ambient environment of 39°C) group, which is similar to heat stroke. EIH has adverse effects on peripheral organs and brain vasculature but does not produce damage to dopamine terminals in the striatum. The AMPH normothermic group remained normothermic and did not exhibit striatal neurotoxicity; however, their cerebrovasculature damage has not yet been determined. Relative to controls, all three treatments showed significant increases in mRNA expression in blood (*Cd14, Il1b, IL17ra and Ccr2*) as well as increases in the cytokines IL-6 and IL-10, indicating they elicited an innate immune response to varying degrees. Hundreds of genes (≈500) were differentially expressed between the EIH and AMPH hyperthermic groups but most were not directly related to the immune system. The mRNA expression of *Cd52, Cd82* and *Cd97*, which code for immune-related cell surface proteins, were significantly different between these two groups, and the interleukin-related genes *Il1rap*, *Il22ra2* and *Il6st* had higher expressions in the AMPH hyperthermic group. Unexpectedly, the AMPH normothermic group had almost 300 genes with significant expression differences from all other groups. Using bioinformatics approaches, we are now identifying the most prominent or characteristic genes, as well as the fewest necessary, needed to classify samples in the different treatment groups.

Title: Neurotoxic administration of methamphetamine alters microtubules within rat striatal dopaminergic axons

Authors: *B. A. KILLINGER[1], A. MOSZCZYNSKA[2];
[1]Dept. of Pharmaceut. Sciences, EACHPS, [2]Wayne State Univ., Detroit, MI

Abstract: Methamphetamine (METH) is a commonly abused psychostimulant, which can induce neurotoxicity to dopaminergic (DAergic) terminals in the striatum without affecting DA cell bodies in the substantia nigra pars compacta (SNc). METH neurotoxicity is primarily characterized by reductions in striatal DAergic markers such as dopamine transporter (DAT) and tyrosine hydroxylase (TH) that indicate loss of DAergic axons. Multiple studies have demonstrated that striatal DAergic markers partially recover in experimental animals and humans, given a sufficient period of abstinence from METH. Most striatal DAergic markers require axonal transport to be replenished; therefore,we have hypothesized that the deficits in striatal DAergic markers are, in part, due to dysfunction of axonal transport in surviving DAergic axons. Currently, it is unknown whether METH alters axonal transport in striatal DAergic neurons. To test our hypothesis, we assessed post translational modifications (PTMs) of α-tubulin and neuron specific tubulin isoform ßIII tubulin in lysates from the whole striatum and within rat striatal DAergic axons at 3 days following neurotoxic METH administration (4 x 10mg/kg, every 2h, i.p.). In lysates, there was a statistically significant loss of detyrosinated α-tubulin (-14%, $p<0.05$) whereas the levels of acetylated α-tubulin, tyrosylated α-tubulin and ßIII tubulin remained unchanged. The decrease in detyrosinated α-tubulin was concurrent with significant reductions in striatal tissue levels of both TH and DAT (-43% and -68%, $p<0.05$).

None of the assessed indices were affected in the SNc. DAergic axons constitute less than 1% of striatal components. To determine whether alterations in tubulin PTMs occur in DAergic axons, we employed immunofluorescence confocal microscopy. Double labeling of striatal slices for TH and PTMs revealed a loss of acetylated α-tubulin (R = 0.24, Saline vs. R = 0.075, METH, $p<0.05$, Pearson's correlation) and overall α-tubulin (R = 0.28, Saline vs. R = 0.19, METH, $p<0.05$) in METH-treated rats as compared to saline controls. Furthermore, we observed a selective increase in cololocalization of ßIII tubulin with TH (R = 0.14, Saline vs. R = 0.07, METH, $p<0.05$) in the striatum following METH. No such differences were found in the SNc. Our results suggest that neurotoxic METH causes persistent changes to structure and stability of microtubules within surviving DAergic axons. This data supports the hypothesis of axonal transport impairment in striatal DAergic axons following neurotoxic METH.

Title: Chronic methamphetamine accelerates pacemaking activity in the substantia nigra pars compacta

Authors: *S. M. GRAVES[1], J. N. GUZMAN[1], E. ZAMPESE[1], E. ILIJIC[1], J. H. KORDOWER[2], B. K. YAMAMOTO[3], D. J. SURMEIER[1];
[1]Physiol., Northwestern Univ., Chicago, IL; [2]Neurolog. Sciences, Neurosurg., Rush Univ., Chicago, IL; [3]Neurosciences, Univ. of Toledo, Toledo, OH

Abstract: Methamphetamine (METH) is a potent psychostimulant used to treat ADHD and exogenous obesity but is also abused by 13 million people in the US (NSDUH). Recent evidence indicates that METH use increases the risk of developing Parkinson's disease (PD) by nearly two-fold (Callaghan RC et al., Drug Alcohol Depend 120:35 2012). PD is a common

neurodegenerative movement disorder that results from the progressive degeneration of dopamine neurons in the substantia nigra pars compacta (SNc). Recent evidence indicates that Cav1.3 L-type Ca2+ channels that participate in pacemaking of SNc dopamine neurons are involved, as Ca2+ entry through Cav1.3 channels leads to mitochondrial oxidant stress (Sulzer D & Surmeier DJ, Mov Disord 28:715 2013). One-way in which METH might increase PD risk would be to increase the pacemaking of SNc dopamine neurons, which might increase Ca2+ entry and mitochondrial oxidant stress. To test this hypothesis, cell attached recordings of SNc dopamine neurons were performed. Acute METH (10μM bath application) in *ex vivo* brain slices from naïve mice significantly reduced SNc pacemaking (control median: 1.4hz; 10μM METH median: 0.4). In contrast, chronic METH (2.5mg/kg/day for 14d) led to increased pacemaking (control median: 1.9hz; METH median: 2.2hz) after withdrawal. These results suggest that chronic METH-induced inhibition of SNc pacemaking led to rebound acceleration of pacemaking. Experiments are underway to determine whether the METH-induced increase in pacemaking frequency elevates Ca2+ entry and mitochondrial oxidant stress.

Title: Methamphetamine induces direct effects on microglia

Authors: ***J. AREDO**[1], K. CONANT[2], A. KASSARDJIAN[2], K. MAGUIRE-ZEISS[2];
[2]Neurosci., [1]Georgetown Univ. Med. Ctr., Washington, DC

Abstract: The use of methamphetamine (MA) has become an increasing societal problem as it is the second most widely abused illegal substance worldwide. MA targets dopamine neurons via transporter-specific entry, and results in extensive vesicular dopamine release, oxidative stress, and eventual neuronal death. Interestingly, studies in animal models demonstrate that microglial activation in the brain of MA-treated animals precedes neuronal death. The mechanism of this glial activation and if microglia contribute to MA-induced pathology remain unknown. In this

study, we sought to determine whether MA directly alters microglial function. We employed two models: primary microglia (PMG) exposed to MA and mice injected with MA. Here we show that MA-treated PMG exhibit a change in morphology that is reminiscent of classically activated microglia. MA also induces a rapid increase in the nuclear translocation of p65 NF-κB. This transcription factor is known to regulate the expression of proinflammatory cytokines, reactive oxygen species, and anti-oxidant response proteins. PMG do not produce significant levels of prototypical proinflammatory molecules (i.e., TNF-α, nitric oxide) following MA treatment. However, PMG do exhibit robust expression of the anti-oxidant enzyme, heme oxygenase-1. Finally, striatal tissue harvested from mice following a single intraperitoneal dose of MA (40 mg/kg) show an increase in the microglial marker, Iba1. We have previously demonstrated that this dose of MA results in an increase in striatal MMP-9; also known to be regulated by NF-κB. Overall, we demonstrate that MA directly incites a morphofunctional change in PMG and increases markers of glial activation *in vivo*.

Abstract: The vesicular monoamine transporter-2 (VMAT2) is responsible for packaging cytoplasmic monoamines into synaptic vesicles throughout the central nervous system - a function that is altered by numerous psychostimulants, including methamphetamine (METH). METH reduces the dopamine (DA) uptake capacity of VMAT2 within presynaptic dopaminergic terminals of the striatum, which has been tied to a shift in presynaptic VMAT2 localization. Analysis of presynaptic vesicle fractions isolated from striatal synaptosomes by differential centrifugation indicates METH reduces VMAT2 content within a non-plasma membrane-associated fraction. Importantly, these acute METH-induced changes in VMAT2 localization and function are linked to persistent striatal dopaminergic deficits. How altered VMAT2 localization within *ex vivo* subcellular fractions translates into changes in physical distribution within striatal DA neurons is unknown, but likely a key component in understanding the process by which METH disrupts presynaptic DA regulation. Resolving the size, shape and orientation of VMAT2 synaptic vesicle distribution within presynaptic terminals using light microscopy is difficult given that the limits of confocal microscopy resolution (~200 nm) exceed the predicted size of synaptic vesicles (~50 - 100 nm). To overcome this barrier, biplane single molecule localization-based super-resolution microscopy was employed and METH-induced alterations in VMAT2 synaptic vesicles were assessed. Using this method, the size, shape and orientation of VMAT2 vesicle distribution was evaluated in three dimensions (3D), with resolutions reaching 20 nm in the XY plane and 50 nm in the Z plane, and given cellular context by co-staining presynaptic active zone and axonal proteins. Findings indicate that METH exposure causes widespread loss of organization in striatal presynaptic VMAT2 distribution that may be tied to a disruption of the presynaptic active zone.

Title: Pathological brain hyperthermia induced by MDMA (ecstasy) in rats under conditions associated with human ‘rave parties’: critical role of peripheral vasoconstriction

Authors: *E. A. KIYATKIN, A. H. KIM, K. T. WAKABAYASHI, M. H. BAUMANN, Y. SHAHAM;
Behavioral Neurosci Br., NIDA-IRP, NIH, DHHS, Baltimore, MD

Abstract: MDMA (Ecstasy) is an illicit drug used by young adults at hot, crowed “rave” parties, yet the data on potential health hazards of its abuse remain controversial. Here, we examined the effect of MDMA on temperature homeostasis in male rats under standard laboratory conditions and under conditions that simulate human drug use. We chronically implanted thermocouple microsensors in the nucleus accumbens (a brain reward area), temporal muscle, and skin to measure temperature continuously from freely moving rats. While focusing on brain hyperthermia, temperature monitoring from the two peripheral locations allowed us to evaluate the physiological mechanisms (i.e., intra-cerebral heat production and heat loss via cutaneous vasoconstriction) that underlie MDMA-induced brain temperature responses. Our data confirm previous reports on high individual variability and relatively weak brain hyperthermic effects of MDMA under standard control conditions (quiet rest, 22-23°C), but demonstrate dramatic enhancements of drug-induced brain hyperthermia during social interaction (exposure to male conspecific) and in warm environments (29°C). Importantly, we identified peripheral vasoconstriction as a critical mechanism underlying the activity- and state-dependent potentiation of MDMA-induced brain hyperthermia. Through this mechanism, which prevents proper heat dissipation to the external environment, MDMA at a moderate non-toxic dose (9 mg/kg or ~1/5 of LD50 in rats) can cause fatal hyperthermia under environmental conditions commonly encountered by humans. Our results demonstrate that doses of MDMA that are non-toxic under cool, quiet conditions can become highly dangerous under conditions that mimic recreational use of MDMA at rave parties or other hot, crowded venues.

Title: The role of CDCrel-1 in methamphetamine-induced impairment of VMAT2 vesicle trafficking

Authors: *H. D. CHAUHAN, A. MOSZCZYNSKA;
Pharmaceut. Sci., Eugene Applebaum Col. of Pharm. and Hlth. Sci., Detroit, MI

Abstract: Methamphetamine (METH) is a widely abused psychostimulant. In experimental animals and humans, METH is toxic to dopaminergic (DAergic) nerve terminals in the striatum when administered at high doses. An early event in METH neurotoxicity is a release of dopamine (DA) from VMAT2 storage vesicles and its subsequent autoxidation, followed by an oxidative stress within the terminals. The vesicular monoamine transporter 2 (VMAT2) plays a neurprotective role by transporting cytoplasmic DA back into vesicles for storage and protection from oxidation. It has previously been shown that METH neurotoxicity is associated with impaired VMAT2 trafficking and oxidative damage to the ubiquitin proteasome system (UPS). The UPS regulates the levels of CDCrel-1, a protein involved in inhibition of exocytosis. The objective of our study was to determine whether CDCrel-1 and VMAT2 interact with each other and how these interactions affect trafficking of VMAT2 vesicles after METH administration. We have hypothesized that METH-induced inhibition of the UPS increases the levels of CDCrel-1, which leads to entrapment of VMAT2 vesicles at the plasma membrane, preventing their recycling and sequestration of cytosolic DA. To test this hypothesis, we examined all synaptosomal populations and DAergic synaptosomes in rat striatum for the levels of and interactions between VMAT2 and CDCrel-1. Adult male Sprague Dawley rats were treated with binge METH (4 x 10 mg/kg, every 2 h, i.p) or saline and sacrificed 1 h or 24 h after the last injection. Striatal synaptosomal fractions were subjected to SDS-PAGE and western blotting with CDCrel-1 and VMAT2 antibodies. As compared to saline controls, CDCrel-1 levels increased in DAergic as well as overall population of striatal synaptosomes in METH-treated rats at 1 hour after the last METH dose (+6.3%; +20%, $p<0.05$). VMAT2 immunoreactivity didn't travel from the plasma membrane to the cytosol in METH-exposed striatum, suggesting that the vesicles might be trapped at the plasma membrane by CDCrel-1. In support of this notion, co-immunoprecipitation detected an increased protein-protein interaction between CDCrel-1 and VMAT2 in rat striatal synaptosomes. Furthermore, plasma membrane-associated striatal vesicles from METH-treated rats had lower DA content than those from saline controls. In summary, our findings suggest that METH-induced accumulation of CDCrel-1 inhibits VMAT2 vesicles trafficking, thus impairing proper sequestration of DA to storage vesicles. Keywords: Methamphetamine, VMAT2, CDCrel-1

Title: Neurotensin modulates the METH-induced striatal apoptosis through darpp32 phosphorylation, nitric oxide accumulation and glial cell activation

Authors: *Q. LIU[1,2], A. HAZAN[1], E. GRINMAN[1], J. A. ANGULO[1];
[1]Biol. Dept., Hunter College, City Univ. of New York, New York, NY; [2]Biochem. Dept., Grad. Ctr., City University of New York, NY

Abstract: Methamphetamine (METH) is a widely abused psychostimulant second only to cannabis in popularity. METH abuse can impair cognitive functions and induces neurodegeneration in the striatum. Dysfunction of dopamine neurotransmission is found to play a critical role in METH-induced neurotoxicity. Acute METH (30mg/kg, i.p.) can induce striatal neurotoxicity characterized by striatal neuron apoptosis and dopamine terminal degeneration. We used this animal model of METH-induced toxicity to investigate the role of neurotensin. We observed that the neurotensin receptor 1 (NTR1) agonist PD149163, injected intraperitoneally, attenuated the METH-induced striatal apoptosis in a dosage-dependent manner. Also, infusion of 20 uM of the NTR1 antagonist, SR48692, into the striatum, augmented the METN-induced apoptosis. These data demonstrate that neurotensin modulates METH-induced striatal apoptosis through NTR1 in the striatum. To further investigate the corresponding mechanism, we assessed its effect on glial cell activation, nitric oxide accumulation and DARPP32 phosphorylation in the striatum, which are all believed to aggravate such neurodegeneration. We found that the NTR1 agonist attenuated the effects of METH on all three of these markers. The results also show that NTR1 agonist alone has no effect on glial cell activation and nitric oxide accumulation, but leads to a decrease in phosphorylation of DARPP32 at Thr34 by 54%. Since the DARPP32 phosphorylation pathway participates in all neurotransmission into the striatal projection neurons, neurotensin possibly modulates its phosphorylation through regulation of dopamine and glutamate neurotransmission. We conclude that neurotenisn modulates METH-induced striatal apoptosis through diverse mechanisms involving glial cell activation, nitric oxide accumulation and DARPP32 phosphorylation in the striatum. Additionally, the agonist of neurotensin, PD149163, may be considered a potential drug for METH toxicity treatment. (Supported by R01 DA020142 from NIDA/NIH)

Title: Cannabinoid CB1 receptor mediates dopaminergic neurotoxicity induced by methamphetamine

Authors: *H.-C. KIM, D.-K. DANG, T.-T. NGUYEN, H.-Q. TRAN, Y. NAM, E.-J. SHIN; Col. of Pharm., Kangwon Natl. Univ., Chunchon, Korea, Republic of

Abstract: Accumulating evidences indicated that Cannabinoid CB1 receptor (CB1R) plays a modulatory role in dopaminergic system. However, the pharmacological mechanism mediated by CB1R remains to be elucidated. In the present study, we examined the role of CB1R in the MA-induced dopaminergic toxicity. We observed that treatment with MA (7 mg/kg, i.p., 4 times with a 2 hours' interval) resulted in a significant increase in the striatal CB1R mRNA expression of CB1R wild-type (WT) mice. MA-induced hyperthermia, behavioral impairment and dopaminergic toxicity (i.e., decrease in dopamine level and tyrosine hydroxylase expression) were significantly abolished in CB1R (-/-) mice. In addition, MA-induced pro-apoptotic factors expression (i.e., Bax and caspase 3), oxidative stress (i.e., ROS, lipid peroxidation and protein oxidation), and cleaved-PKCδ expression were significantly attenuated in CB1R (-/-) mice. These attenuations were also observed in WT mice treated with AM251 or Rimonabant, CB1R antagonists. Consistently, we observed that multiple high doses of CB1R agonist (WIN 55,212-2 or ACEA) produce dopaminergic toxicity (as shown by decreases in dopamine level and tyrosine hydroxylase expression), behavioral impairments (as shown by hypolocomotor activity and impairment in rota-rod performance), oxidative stress and pro-apoptotic changes in the striatum of mice. In addition, WIN (36 mg/kg) or ACEA (16 mg/kg) significantly increased cleaved-PKCδ expression in the striatum after the final injection of WIN or ACEA. Our results suggest that CB1R mediates MA-induced dopaminergic toxicity, and that CB1R activation requires proteolysis of PKCδ gene for induction of pro-apoptosis. Thus, inhibition of CB1R may be a useful target for protection against MA-induced dopaminergic toxicity [DK Dang, TTL Nguyen,

Title: Intravenous administration of nicotinamide adenine dinucleotide significantly reduces self report craving ratings associated with opiate and alcohol withdrawal

Authors: ***S. L. BROOM**[1], R. F. MESTAYER[2], E. STULLER[3], D. W. COOKE[4], J. M. CARSON[2], K. R. SIMONE[2], P. NORRIS[2], P. HOTARD[2];

Abstract: Introduction: Treatment of substance abuse disorders continues to challenge clinicians and "cravings" for the abused substance are often impediments to sobriety. Nicotinamide Adenine Dinucleotide (NAD) has been used in the past with claims of having anti-craving properties. Previous data from this clinic using a similar formulation of NAD support the use of NAD as a valid treatment for drug cravings. Methods: *This pilot study retrospectively examined the anti-craving properties of NAD in a group of 60 patients*. The patients were adult males and females with addictions to primarily opiates and alcohol. The treatment comprised IV infusions of NAD as well as vitamins, oral amino acids and variable prescription medications for an average of 10 consecutive days ranging from 5 to 10 hours daily. Self-reported craving ratings (1-10 Scale) were collected on Day 1 (before starting treatment), Day 5, and on Day 10 (after completion of treatment). Findings: 1) All patients were able to achieve an abrupt cessation of their use of abused drug by the end of Day 1 of the 10-day treatment. 2) Self-reported ratings showed that patients experienced a continually increasing alleviation of the adverse consequences associated with drug withdrawal throughout the treatment. *Specifically, patients reported significantly reduced craving ratings at both Day 5 and Day 10.* 3) Respondent interviews at 3 and 6 months post treatment suggest that NAD was effective in reducing the

number and magnitude of relapse episodes, as well as severity of drug cravings. Discussion: These data suggest that NAD is an effective detox treatment for alcohol and opiate addicts. Furthermore, NAD shows potential as a long-term therapy in maintaining sobriety through minimizing drug cravings and preventing relapse.

Title: The neural correlates of reorganizing attachment in mothers with unresolved trauma

Authors: *U. IYENGAR[1,2], S. KIM[1,3], L. STRATHEARN[1,2,3];
[1]Pediatrics, Baylor Col. of Med., Houston, TX; [2]Clinical, Educational, and Hlth. Psychology, Univ. Col. London, London, United Kingdom; [3]Psychiatry and Behavioral Sci., Menninger, Houston, TX

Abstract: Attachment theory emphasizes the quality of early relationships and its impact on adult functioning, especially with regard to the development of interpersonal relationships. Mothers classified as having unresolved trauma (Utr) based on the Adult Attachment Interview (AAI) tend to be compromised in their ability to respond sensitively to emotional cues of their own infant, reflected in their dampened amygdala responses when viewing their own infant's sad face (Kim et al, 2014). One newly defined aspect of attachment is "reorganization", which refers to the process by which individuals are changing their understanding of past and present experiences, in the direction of secure attachment. While still not "secure" in attachment, the process of reorganization indicates positive adaptation to new circumstances and life events. No study to date has explored the neural correlates of reorganizing attachment. Our fMRI study

examines patterns of brain response in mothers with and without reorganizing attachment in a clinical sample of substance-abusing mothers (with a high prevalence of Utr). Twenty-three substance-abusing mothers completed AAIs, and their 3- to 12-month old infants were videotaped to obtain images for use in a subsequent scanning session. All mothers who had Utr were dichotomized into those reorganizing towards secure attachment (N=6) and those who were not (N=17). Mothers returned for a scanning session, in which they viewed unique stimuli of own and unknown infant faces randomly presented for 2 seconds as part of an event-related design. The mothers' brain response to happy images of their own infants was contrasted with that of unknown infants. The between-group effects for the own vs. unknown happy contrast were evaluated in a 2 (infant identity) x 2 (reorganizing status) random effects ANOVA. Preliminary analysis revealed that reorganizing mothers demonstrated bilateral activation of the striatum (putamen; q(FDR) <.05, p<.008) when viewing images of their own versus unknown infant, while striatal activation was absent in non-reorganizing mothers. This differential brain response between reorganizing and non-reorganizing mothers in the striatum, a key reward-processing region of the brain, suggests that the process of reorganization toward secure attachment may involve increased reward processing of salient infant cues. This may translate into improved infant-directed behavior in these mothers, and improved developmental and attachment-related outcomes in the child. Title: Optogenetically inspired deep brain stimulation reverses drug-evoked plasticity

Authors: ***M. CREED**[1], V. PASCOLI[1], C. LÜSCHER[1,2];
[1]Neuroimaging Res., Univ. of Geneva, Geneva, Switzerland; [2]Dept. of Neurol., Univ. Hosp. of Geneva, Geneva, Switzerland

Abstract: Exposure to drugs of abuse, such as cocaine, induces characteristic forms of synaptic plasticity, for example a potentiation of glutamatergic inputs onto medium spiny neurons of the nucleus accumbens (NAc). One behavioral correlate of this plasticity is locomotor sensitization, a phenomenon in which repeated exposure to equivalent doses of cocaine induces progressive increases in locomotor activity. Deep brain stimulation (DBS) is a surgical therapy used primarily for movement disorders, in which electric current is passed through electrodes implanted into specific brain nuclei. We sought to reverse cocaine-evoked plasticity and behaviour using DBS applied to the fiber bundle of excitatory projections originating in the mPFC and targeting the NAc shell. We found that classical DBS protocols (high frequency: 130Hz, 100μA) effectively decreased the locomotor response to cocaine. However, this effect was transient and lasted less than four hours after the cessation of DBS. In line with these behavioral observations, the cocaine-induced enhancement of excitatory inputs onto MSNs was unchanged, as inferred by measuring the AMPA:NMDA ratio *ex vivo* 24 hours following the cessation of DBS. We then demonstrated that depotentiating the projection from the medial prefrontal cortex (mPFC) to the NAc using optogenetic stimulation delivered at 12 Hz *in vivo* restores normal synaptic transmission and abolished locomotor sensitization to cocaine, which we then attempted to mimic with DBS. However, given that the 12Hz protocol is dependent on mGluR activation, and that signaling through dopamine D1-receptors in MSNs opposes mGluR signaling, we hypothesized that D1 antagonism may be necessary to unmask a DBS-induced depotentiation onto MSNs. Indeed, when we administered the D1 antagonist SCH23390 (0.3mg/kg, i.p.) in conjunction with DBS, cocaine sensitization and cocaine-evoked plasticity were abolished. We have further confirmed that this combination of DBS and D1-antagonism reverses plasticity via an mGluR-dependent mechanism. Taken together, our results provide a proof of principle that combined with pharmacology, DBS may be used to reverse to cocaine-induced synaptic plasticity and drug-adaptive behavior, which may have important implications for the clinical application of DBS for the treatment of addictive disorders.

Title: Design, synthesis, and pharmacological characterization of selective serotonin (5-HT) 5-HT2C receptor positive allosteric modulators as potential small molecule therapeutics for psychostimulant use disorders

Authors: *C. WILD, C. DING, G. ZHANG, N. ANASTASIO, R. FOX, S. STUTZ, R. HARTLEY, K. CUNNINGHAM, J. ZHOU;
Pharmacol. and Toxicology, Univ. of Texas Med. Br., Galveston, TX

Abstract: Preclinical evidence suggests that dampened serotonin (5-HT) 5-HT2C receptor (5-HT2CR) signaling during withdrawal from psychostimulant use promotes relapse, a major hurdle of overcoming addiction. Therefore, restoration of 5-HT2CR signaling capacity via positive modulation of the receptor during withdrawal provides the conceptual framework for the development of pharmacotherapies that promote abstinence maintenance. While developing selective ligands for the 5-HT2CR remains a challenge, targeting the topologically distinct allosteric site - as opposed to the conserved orthosteric site - represents a promising drug design strategy. A series of new small molecules have been rationally designed, chemically synthesized, and pharmacologically characterized by using privileged fragments as templates, homology modeling and molecular docking techniques, as well as a battery of in-house *in vitro* (functional and radioligand binding studies) and *in vivo* (behavioral studies) assays to assess allosteric modulation of the 5-HT2CR. To date, several compounds have been identified to enhance 5-HT2CR-mediated Cai++ release and ERK1/2 activation induced by the endogenous ligand 5-HT or the selective 5-HT2CR agonist WAY 163909. Our drug development efforts open new avenues in probing 5-HT2CR function and the discovery of novel pharmacotherapeutics for cocaine addiction and other central nervous system disorders.

Abstract: Maternal drug addiction constitutes a major public health problem affecting children, with high rates of abuse, neglect, and foster care placement. However, little is known about the ways in which drug addiction alters brain function underlying maternal behavior. Prior studies have shown that infant cues and drugs of abuse similarly activate dopaminergically innervated brain reward circuits. Here, we report on an fMRI study documenting that mothers with addictions demonstrate reduced activation of reward regions when shown cues of their own infants. We further report on preliminary data suggesting that intranasal oxytocin may be effective in reversing the disrupted maternal brain responses in these mothers. Thirty-six mothers seeking treatment at an inpatient drug abuse facility underwent fMRI scanning at 6 months postpartum, while viewing happy and sad face images of their own infant, along with those of a matched unknown infant. Effects of intranasal oxytocin were examined as part of a randomized double-blinded crossover study, involving a subsample of 3 addicted mothers and an independent sample of 10 non-addicted mothers, who were given a nasal spray of oxytocin or placebo prior to one of two fMRI scanning sessions. When viewing happy face images of their own infant compared to those of an unknown infant, mothers with addictions showed a striking pattern of decreased activation in dopamine- and oxytocin-innervated brain reward regions, including the hypothalamus, ventral striatum, and ventromedial prefrontal cortex--regions in which increased activation has been observed in non-addicted mothers. Intranasal oxytocin, compared to placebo, was found to enhance activation in these brain reward regions, especially in mothers with addictions. Our results are the first to demonstrate that mothers with addictions show reduced activation in key reward regions of the brain in response to their own infant's face cues. Intranasal oxytocin may have the potential to improve altered brain reward responses in these mothers, and may prove useful as a novel treatment in this population.

Title: Transcranial direct current stimulation for the reduction of alcohol cravings

Authors: *D. RUDDER, C. TESCHE, P. COULOMBE;
Dept. of Psychology, Univ. of New Mexico, Albuquerque, NM

Abstract: Background: Craving is implicated the maintenance of alcohol abuse and dependence as well as relapse during attempts at recovery. A 2008 investigation by Boggio et al. (Drug &

Alcohol Dependence, 92, 55-60) demonstrated that transcranial direct current stimulation (tDCS) applied over dorsolateral prefrontal cortex (DLPFC) was effective in reducing craving among individuals with alcohol dependence. The present study is the first to continue to explore the potential of tDCS to manipulate craving in the context of alcohol use and abuse. Methods: The study design was a randomized, controlled crossover experiment utilizing repeated measures. Eleven adult participants completed assessments of alcohol abuse severity [Alcohol Use Disorders Identification Test (AUDIT)] as well as pre- and post-stimulation assessments of alcohol craving [Alcohol Urge Questionnaire (AUQ)] and mood [Quick Mood Scale (QMS)]. Subjects received active and sham stimulation delivered in two separate experimental sessions spaced 3 to 7 days apart. During active stimulation, 2mA was applied for 20 minutes through an anodal electrode placed over the left DLPFC and a cathodal electrode placed over the right DLPFC. Sham stimulation entailed applying 2mA of stimulation for only the first 15 seconds of the session. Results: Active stimulation produced a significant reduction in craving as measured by change in AUQ scores ($p = .03$), whereas sham did not ($p = .42$). A multilevel model for repeated measures demonstrated that, controlling for alcohol abuse severity (as measured by AUDIT scores), active stimulation produced a greater reduction in craving than did sham stimulation ($p = .03$). In addition, higher AUDIT scores were associated with a greater reduction in craving ($p < .001$), and this effect did not differ between the active and sham conditions. Overall, regardless of whether participants scored high or low on alcohol abuse severity, providing them with active stimulation led to greater reductions in craving relative to sham stimulation. There were no significant changes in mood as measured by the QMS for either condition. Conclusions: Our results lend further support for the potential of tDCS to modulate craving in individuals with alcohol use disorders who experience frequent or intense cravings. These results motivate additional studies on the utility of tDCS for alcohol abuse in clinical treatment settings. Future research utilizing larger sample sizes and targeting participants who meet the diagnostic criteria for alcohol abuse or dependence is recommended.

Title: "Analyzing the concentration and the effects of omega 3 on nicotine dependence"

Authors: *J. ZAPAROLI, E. K. SUGAWARA, A. A. L. SOUZA, S. TUFIK, J. F. GALDURÓZ;
UNIFESP - Univ. Federal De São Paulo, São Paulo, Brazil

Abstract: Abstract: Background: Free radicals present in cigarette play a role in several diseases associated with smoking. The omega 3 series present changes in concentration *in situ*ations of high oxidative stress, like contact with cigarette smoke. Since omega-3 play a role on dopaminergic neurotransmission and this is related to development and perpetuation of dependence. Therefore it is important to understand the levels and the effects of omega 3 on nicotine dependence. **Methods:** The first study consisted of a cross-sectional to compare levels of omega 3 between smokers and non-smokers in a sample of 171 individuals, matched by age, gender, height, weight, and BMI. The second was a clinical-trial, double-blind, randomized, placebo controlled, in which 60 smokers received daily treatment with capsules of fish (source of omega 3) or mineral oil (placebo), taken three times a day for 90 days. The outcome was evaluated by means of psychometric (Beck Anxiety and Depression Inventory; Fagerström Test for Nicotine Dependence; Questionnaire of Smoking Urges; and Richmond Test) and biological measures (percentage of carbon monoxide in the exhale breath and cotinine concentrations) as well as self-reports of tobacco use (smoking dairy). **Results:** The evaluation of omega-3 lipid profile showed that smokers present lower concentrations of docosahexaenoic acid (DHA). At the end of the clinical intervention we observed that the group treated with omega 3 showed a significant reduction in the levels of dependence, but no difference was observed on the other outcomes. **Interpretation:** Smokers showed lower peripheral levels of omega 3, which might interfere in the normal function of different systems, including the dopaminergic system. On the other hand, the treatment with omega-3/day brought about reduction in nicotine dependence without, however, resulting in quit cigarette consumption. Although this study presents limitations it is possible that higher dosage administered and prolonging the duration of the treatment may be helpful achieving better rates of success on the treatment of nicotine dependence.

Title: Results of a double-blind, placebo-controlled study of the safety and pharmacokinetics of noribogaine administered to healthy volunteers

Authors: L. FRIEDHOFF[1], M. LOCKHART[2], F. LAM[3], N. HUNG[3], C. T. HUNG[3], *P. GLUE[4];

Abstract: Background: The iboga alkaloikds have been reported to have striking efficacy for treatment of various addictions in case reports and case series reports. In spite of this long history of uncontrolled results, no blinded, placebo-controlled clinical trials of an iboga alkaloid have ever been conducted. Here we report the first placebo-controlled clinical trial of an iboga alkaloid, noribogaine hydrochloride. Aims: The objectives of this Phase I study were to assess the safety, tolerability, pharmacokinetic and pharmacodynamic profile of noribogaine. Methods: This was an ascending single-dose, placebo-controlled, randomised, double-blind, parallel-group study in 36 healthy drug-free male volunteers. Four cohorts (n=9) received oral doses of 3, 10, 30 or 60mg or matching placebo, with intensive safety and pharmacokinetic assessments out to 216h following dosing, along with pharmacodynamic assessments sensitive to the effects of mu-opioid agonists. Safety monitoring included: physical examinations, vital signs, serum chemistry, hematology, urinalysis, ECGs, oximetry and capnography. Results: Noribogaine was rapidly absorbed, with peak concentrations occurring 2-3 hours after oral dosing, and showed dose-linear increases of AUC and Cmax between 3-60mg. The drug was slowly eliminated, with mean half-life estimates of 27-40 hours across dose groups. The apparent volume of distribution was high.

No safety or tolerability issues were identified in any cohort. No mu-opioid agonist effects were noted in pupillometry or cold-pressor testing. Conclusions: Single oral doses of noribogaine 3-60mg were safe and well tolerated in healthy volunteers. There was no evidence of mu-agonist activity on pharmacodynamic testing up to 60mg.

Title: Serum exosomal microRNA-137 as biomarker for repeated cocaine exposure in mice

Authors: E. NAM, *H.-I. IM;
Ctr. for Neurosci., Korea Inst. of Sci. & Technol., Seoul, Korea, Republic of

Abstract: Diagnosis, prognosis and therapy in neuropsychiatric disorders including drug addiction have been very difficult as of now. The measurement of circulating microRNAs (miRNAs) is most recent effort to identify novel biomarkers in preclinical safety. An important fraction of miRNAs are circulated in plasma or serum either in free forms or within exosomes. Exosomes are small (40~100 nm) vesicles originating from within multi-vesicular bodies, which are secreted into the extracellular space and reflects the physiological and pathological status of the source cells. In this study, we examined whether exosomal miRNAs in the serum might reflect the changes of the brain in repeated cocaine exposure in mice. Firstly, we observed the expression of various miRNAs (miRNA-137, -9, and -132) in the whole serum and serum exosomes. The levels of miRNA-137 are robustly increased in serum and exosomes at 2hrs and 24hrs after the last exposure. Secondly, we examined whether exosomal miRNAs in serum are originated from brain tissue so that the changes of exosomal miRNAs are relevant to those of brain regions. To end this, we used the lenti-WPRE (Woodchuck Hepatitis Virus Posttranscriptional Regulatory Element) fragments injection, which are not existed in physiological conditions of mammalian, into striatum. We confirmed that not only the expressions of WPRE could be detected in serum exosomes but also those are getting decreased in the striatum over time (6hrs vs 6wks). Interestingly, the levels of miRNA-137 are significantly decreased in ventral striatum and lateral habenula in repeated cocaine exposure in mice, which is along with 'WPRE' experiments. Finally, we confirmed that the exosomal miRNAs including miRNA-137 would be a quite stable in various conditions such as extreme temperatures and chemical treatment compared to the free forms of miRNAs in serum. Taken together, the serum exosomal miRNA-137 may serve as diagnostically sensitive biomarker for drug addiction.

Title: Chronic oral nicotine consumption does not alter circulating estradiol levels but reduces cotinine in sera and urine of female rats

Authors: S. HALDER[1], J. M. LYNCH[2], *A. R. PEARCE[3];
[1]Mol. Biosci., Arkansas State Univ., State University, AR; [2]Psychology, [3]Arkansas State Univ., STATE UNIV, AR

Abstract: With the increasing awareness of complications in pregnancies or reduced fertility, many women who smoke turn to nicotine replacement products. Nicotine delivered orally is a route for nicotine replacement therapy, however, the risk and safety of oral nicotine have not been adequately assessed. Nicotine inhibits aromatase, an enzyme responsible for conversion of testosterone to estradiol, one of the principal female reproductive hormones; hence, it is important to investigate changes in estradiol levels linked to chronic oral nicotine consumption. Using an established multiple bottle approach and adult female Sprague-Dawley rats, animals were provided with 4 bottles of nicotine solution (30 µg/ml) and water, or water only. Nicotine dosages were determined across 14 days and sera and urine were collected following the first 24 hours, 7, or 14 days of nicotine intake. Estrous cycle stages were evaluated and sera from animals in proestrus were analyzed for estradiol by ELISA. Sera and urine were also analyzed by ELISA for cotinine, a major nicotine metabolite. Despite notable individual differences, overall daily nicotine intake patterns were comparable across exposure days. Circulating estradiol levels did not differ significantly between nicotine and control groups (6.30±3.96 pg/ml vs. 5.81±2.88 pg/ml, $p>0.05$). Consistent with previous pilot studies, there was intra-individual variation, yet trends showed a substantial amount of cotinine in serum following the first 24 hours of nicotine intake; however, cotinine concentrations decreased to negligible levels after 7 and 14 days. Cotinine in urine followed a similar pattern: concentrations diminished from approximately 93.55±33.85 ng/ml after 24 hours of nicotine intake, to 11.13±9.49 ng/ml on day 7, and 16.23±19.76 ng/ml on day 14. Findings suggest decreases in serum cotinine at 7 and 14 days were not due to a reduction in nicotine intake across exposure days, nor to increased cotinine clearance through urine. We contend that oral nicotine intake for the given concentration or duration may not alter circulating estradiol and the initial elevated yet later reduced cotinine levels in serum and urine may indicate an inhibition in the nicotine metabolic pathway. Considering cytochrome P4502B1 is the main nicotine metabolizing enzyme in rats, assessing its gene and protein expression as well as enzyme activity will likely elucidate cotinine's systemic reduction, and also provide information about the risk and safety of oral nicotine use in females.

Title: A preclinical electrophysiological biomarker of D3-receptor antagonism using the selective D3-receptor antagonist PF-04363467

Authors: *C. B. PURYEAR[1], D. P. NGUYEN[2], T. KISS[1], D. L. BUHL[1], A. MEAD[3]; [1]Neurosci. Res. Unit, [2]Dept. of Pharmacokinetics, Pharmacodynamics and Metabolism, Pfizer, Inc, Cambridge, MA; [3]Global Safety Pharmacol. Drug Safety R&D Statistics, Drug Safety Res. and Develop., Pfizer, Inc, Groton, CT

Abstract: Drug dependence is associated with marked changes in mesocorticolimbic dopaminergic circuitry of the brain. In addition to the extensive characterization of dopamine D1 and D2 receptors in the neurocircuitry of addiction, recent work suggests an important role of dopamine D3 receptors (D3Rs) in mediating drug-dependent states, especially given their unique spatial distribution in pathways involved in reward processing. In particular, upregulation of D3 receptors has been shown in key mesolimbic areas in rodent models of drug seeking. Furthermore, increased D3R binding potential has been demonstrated in a variety of human populations with experience of drug use, suggesting the role of D3Rs may overlap across different types of addiction. This body of evidence has led to a number of studies showing that selective D3R antagonists reduce drug seeking, intake, and relapse in preclinical rodent models. Given the efficacy of D3R antagonists in drug addiction models, we sought to develop a robust biomarker of D3 antagonism by utilizing electroencephalography (EEG) in freely behaving rats. Although effects of D1 and D2 antagonists on EEG activity have been described, the effects of D3 antagonists on neuronal oscillations remain unknown. We therefore investigated the effects of the selective D3 antagonist, PF-04363467, on EEG patterns in freely behaving rodents in order to determine whether a D3-mediated biomarker could be established. Male Sprague-Dawley rats (N=9) implanted with 3-channel telemeters (DSI, Int.) were used to enable continuous home-cage wireless recording of EEG and EMG for 24-48 hours. Rats received 3 doses of PF-04363467 (3.2, 10.0, 32.0 mg/kg) or vehicle using a crossover Latin square design, with 3 days between each dose. To detect any potential pharmacodynamic responses, we calculated broadband changes in EEG power for 4 hours post-dose relative to a 1-hour pre-dose baseline period. A dose-dependent decrease in theta (7-12 Hz) and alpha (12-14 Hz) power was observed concomitant with an increase in gamma (30-80 Hz) power that persisted for ~1 hour post-dose. In addition to quantitative EEG, we present a pharmacokinetic/pharmacodynamic model that describes the relationship between spectral power changes and unbound brain concentration of PF-04363467. The combination of the selective action at the D3 receptor and a dose-dependent pharmacodynamic response suggests that the spectral changes we observe may

serve as a translatable, non-invasive biomarker of D3R antagonism in human studies of addiction or other psychiatric disorders.

Title: Expression of c-Fos after GABA-A receptor agonist gaboxadol in mouse brain regions: link to aversion?

Authors: *E. R. KORPI[1,2], O. VEKOVISCHEVA[1], E. KANKURI[1], E. VASHCHINKINA[1]; [1]Univ. of Helsinki, Helsinki, Finland; [2]Dept. of Pharmacol., National University of Singapore, Singapore

Abstract: Previous studies have demonstrated that THIP (gaboxadol), a selective agonist of extrasynaptic GABA-A receptors, induces aversion in place conditioning in mice (Vashchinkina et al., J Neurosci 32: 5310-20, 2012), although it as a single dose induces neuroplasticity in glutamate synapses of VTA dopamine neurons similar to rewarding drugs of abuse. Here, we used c-Fos immunohistochemistry to measure neuronal activation in C57BL/6J, GABA-A receptor δ subunit-knockout (δ-KO) mice and wild-type controls 2 h after THIP (6 mg/kg, IP). Possible anxiety behavior as well as plasma corticosterone levels were also assessed. In wild-type mice, THIP treatment triggered an increase in the number of c-Fos-positive neurons in the oval part of the Bed Nuclei of Stria Terminalis (BNST). This effect was abolished in δ-KO mice.

Behavioral changes suggested negative withdrawal-type, anxiety-mimicking effects, such as increased latency in entering the center of an open field, in contacting with a new object, and in entering the lit compartment in light-dark box at 2 h after the THIP treatment. At 45 min after THIP treatment, a transient increase in plasma corticosterone level was observed in wild-type mice, but not in δ-KO mice. In summary, these data suggest that THIP treatment shifts the pattern of response of the oval BNST to an anxiogenic/aversive mode.

Title: Cocaine-related deficits in cognitive flexibility and inhibitory response control are attenuated by the alpha-2A adrenergic agonist guanfacine in a novel nose-poke based set-shifting task in rats

Authors: *P. M. CALLAHAN[1,2], L. VANDENHUERK[2], A. V. TERRY, Jr.[1,2];
[1]Dept. of Pharmacol. and Toxicology, [2]Small Animal Behavioral Core, Georgia Regents Univ., Augusta, GA

Abstract: Cognitive flexibility (task or rule switching) and the ability to inhibit inappropriate responses in a changing environment are key components of executive function that are often impaired in substance abuse disorders. Accordingly, it has been argued that targeting these behavioral alterations in drug addicted patients is a rational therapeutic strategy. There were 3 objectives of the experiments described here 1) to introduce a new, computer-automated set shifting task for rats that utilizes nose-poke based spatial location and visual discrimination strategies and allows for the assessment of cognitive flexibility as well as inhibitory response control, 2) to evaluate the effects of cocaine on cognitive flexibility and inhibitory response control in this new task, and 3) to evaluate the ability of the alpha-2A selective adrenergic agonist, guanfacine to attenuate cocaine-related alterations in task performance. Male Wistar rats were trained on a spatial response location (nose-poke center aperture) to visual-cue (nose-poke

steady vs. blinking light any aperture) discrimination; switching from spatial response to visual-cue required the subject to complete 10 consecutive correct responses; session terminated after subjects completed 10 consecutive correct responses on the visual-cue strategy or 90 min lapsed. Cognitive flexibility was assessed by evaluating the number trials to criterion associated with the spatial location and visual discrimination strategies and inhibitory response control was assessed by measuring the number of premature, perseverative, and timeout responses. Under vehicle conditions, subjects required fewer trials to reach criterion for the spatial vs. the visual-cue discrimination. Cocaine (2.5-15 mg/kg, ip) dose-dependently increased the number of trials to criterion as well as the number of premature and timeout responses during both discriminations. Co-administration of guanfacine (0.1-0.6 mg/kg, ip) with cocaine (15 mg/kg, ip) attenuated the cocaine-related deficits in cognitive flexibility and inhibitory response control. These animal studies support the argument that our new computer-automated set shifting task is sensitive to alterations of executive function that are induced by acute cocaine exposure. The studies also suggest that the alpha-2A selective adrenergic agonist guanfacine may have therapeutic potential for treating impairments of executive function that are associated with the abuse of cocaine.

Title: Methamphetamine-induced inhibition of perirhinal long-term depression underlies meth-induced deficits in novel object recognition memory

Authors: *M. D. SCOFIELD[1], H. L. TRANTHAM-DAVIDSON[2], M. SCHWENDT[3], J. PETERS[2], R. E. SEE[2], C. M. REICHEL[2];
[1]Neurosci., [2]Med. Univ. of South Carolina, Charleston, SC; [3]Univ. of Florida, Gainsville, FL

Abstract: Methamphetamine (meth) addiction is often characterized by cognitive impairment including episodic, verbal, and working memory deficits. In human meth addicts, the extent of memory dysfunction has been positively correlated with relapse probability. Consequently, the molecular mechanisms underlying meth-induced memory impairment are an important consideration for the development of pharmaceutical therapies designed to aid in the cessation of drug abuse. Recently, we demonstrated that 6-hour/day chronic meth self-administration (SA) results in novel object recognition (NOR) memory deficits in rats. Recognition of novelty is dependent upon intact perirhinal (pRh) cortex function, which is compromised by chronic meth SA. We have shown that pRh expression of GluN2B-containing NMDA receptors is downregulated following chronic meth SA. GluN2B-containing NMDA receptors mediate the induction of pRh long-term depression (LTD), which is one of the principle physiological processes underlying NOR memory. We hypothesized that the meth induced down regulation of pRh GluN2B receptors would contribute to a loss of pRh LTD. To test this hypothesis, male Sprague-Dawley rats self-administered meth (0.02 mg/infusion, i.v.) along an FR1 schedule of reinforcement or received yoked saline infusions. After 7 daily 1-hour sessions, rats were switched to 6-hour sessions for 14 days, followed by a period of abstinence. On day 7 of abstinence, rats were tested for NOR memory using a two-item object recognition task. Immediately after the test, rats were decapitated and tissue was used to measure LTD or surface expression of GluN2B in the pRh. Chronic meth SA decreased surface expression of the GluN2B NMDA receptor subunit and blocked the induction of pRh LTD. Further, pharmacological activation of pRh NMDA receptors with D-cycloserine (DCS) both reversed meth-induced NOR deficits and restored induction of LTD. Importantly, Ro 25-6981, a GluN2B-contiaing NMDA receptor antagonist, blocked restoration of pRh LTD by DCS. Taken together, our data indicate that GluN2B-containing NMDA receptors play a central role in the physiological processes that underlie novel object recognition memory, and may serve as a potential target for pharmacotherapies designed to treat meth-induced cognitive deficits.

Title: Activation of perirhinal mglur5 receptors reverses recognition memory deficits resulting from long-access methamphetamine self-administration in rats

Authors: J. PETERS, M. D. SCOFIELD, H. TRANTHAM-DAVIDSON, S. M. GHEE, *R. E. SEE, C. M. REICHEL;
Dept. of Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Previous work from our laboratory has indicated that long-access (LA), but not short-access (SA), methamphetamine self-administration leads to cognitive deficits in rats. In particular, performance in a novel object recognition task, which relies upon the perirhinal cortex, is impaired in LA rats. This seems to result, at least in part, from a downregulation in perirhinal mGluR5 protein expression and impaired long-term depression (LTD). We have previously shown that systemic administration of the positive allosteric modulator (PAM) 3-Cyano-N-(1,3-diphenyl-1H-pyrazol-5-yl)benzamide (CDPPB) reverses this memory deficit in LA rats. However, intracranial infusion studies to identify the brain site whereby these therapeutic systemic effects are elicited have to date been untenable, given the poor solubility of mGluR5 PAMS. The novel mGluR5 PAM, 1-(4-(2,4-difluorophenyl) piperazin-1-yl)-2-((4-fluorobenzyl)oxy)- ethanone, or DPFE, demonstrates greater solubility and selectivity relative to CDPPB, thus allowing us to test the hypothesis that mGluR5 activation restores object recognition memory in LA rats via action in the perirhinal cortex. Male, Sprague-Dawley rats self-administered meth (0.02 mg/infusion, i.v.) along an FR1 schedule of reinforcement. After 7 daily 1-h sessions, rats were switched to 6-h daily access sessions for 14 days, and then underwent drug abstinence. On abstinence days 7 and 8 (90 min and 24 hr tests, respectively), rats were tested for object recognition memory using a two-item object recognition task. Immediately after object familiarization, LA-meth rats were bilaterally infused with DPFE (0.5 µg/side) or vehicle (20% 2-hydroxypropyl-β-cyclodextrin) into the perirhinal cortex. Ninety min and 24-h later, they underwent a short-term and long-term memory test, respectively. Perirhinal mGluR5 activation restored object recognition memory at both time points, suggesting that DPFE rescued the ability to consolidate the memory in perirhinal cortex. Current experiments are underway to assess the ability of DPFE to restore perirhinal LTD, which we have recently shown to be the electrophysiological substrate of the recognition memory deficits in LA rats. These findings implicate mGluR5 activation as a promising pharmacological therapy for restoring cognitive function in methamphetamine addicts. Activation of mGluR5 may have therapeutic implications for relapse as well, particularly *in situ*ations where environmental novelty can be protective against competing meth-conditioned cues.

Title: Relapse involving choice between a novel cue and a methamphetamine-conditioned cue relies on perirhinal cortex

Authors: *J. PETERS, M. D. SCOFIELD, S. M. GHEE, C. M. REICHEL;
Dept. of Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Our lab has previously identified deficits in novel object recognition memory in rats that have self-administered methamphetamine under long-access (LA), but not short access (SA), conditions. This deficit results from neuroadaptations in perirhinal cortex, a brain region known to be critical for the detection of novelty. Novel cues are naturally rewarding, and animals will respond more to novel cues versus familiar ones. A methamphetamine-associated cue is a highly familiar cue to a LA meth rat and is also a conditioned cue that possesses the ability to drive expression of the conditioned response to seek meth. Here, we developed a novel test for relapse involving choice between a novel cue vs a conditioned-meth cue that reveals patterns of responding between SA and LA meth rats in cue preference. Male Sprague-Dawley rats self-administered meth (0.02 mg/infusion, i.v.) on an FR1 schedule of reinforcement. After 7 daily 1-h sessions, half the rats remained on 1 hr sessions and half were switched to 6-h daily access sessions for 14 days; then all rats underwent home cage abstinence. On abstinence day 7, rats were returned to the self-administration chamber and tested for a novel cue preference. During the test rats had access to the previously meth-associated cue and a novel cue. SA rats prefered novel cues, whereas LA rats prefered meth cues, measured by the number of lever presses for each cue. Furthermore, a priming injection of methamphetamine (1 mg/kg, i.p.) shifted this preference in SA rats to one resembling LA rats. Additionally, perirhinal microinfusion of 1-(4-(2,4-difluorophenyl) piperazin-1-yl)-2-((4-fluorobenzyl)oxy)- ethanone, or DPFE, an mGluR5 positive allosteric modulator, restored novelty preference in LA meth rats. Interestingly, this new type of relapse test can parse apart different components of a relapse episode: the effect of novelty competition was evident at the start of the session (within the first 15-min), and the effect of motivation to seek meth was evident on longer timescales (1-2 hours), the latter being more akin to traditional models of relapse. Importantly, the early-session novelty preference is consistent with meth-induced memory deficits found in a novel object recognition task. We

hypothesized that both tasks depend on perirhinal cortex function based on the ability of a memory-repairing compound (i.e. DPFE) to restore novelty preference in both of these tasks. These findings collectively underscore the importance of novelty as a protective agent against relapse.

Title: Effects of environmental enrichment on memory impairment induced by toluene

Authors: ***N. PAEZ-MARTINEZ**[1,2], R. C. SOLIS-GUILLEN[1], S. MONTES[3];
[1]Escuela Superior de Medicina. Inst. Politécnico Nacional, Mexico. D.F., Mexico;

[3]Neuroquímica, Inst. Nacional de Neurología y Neurocirugía Manuel Velasco Suarez, Mexico City, Mexico

Abstract: Inhalant abuse is a health problem worldwide and toluene is an organic solvent found in in the main commercial products misused with intoxication purposes. Memory impairment has been described as a medical consequence among inhalant abusers and this effect has been confirmed in different preclinical protocols of toluene exposure; however therapeutic alternatives that can counteract this effect are limited. Environmental enrichment is a preclinical approximation that has demonstrated to produce positive effects on memory in different animal models of central nervous system diseases. Altogether the aims of the present work were to model memory alterations after repeated toluene exposure and subsequently to evaluate the influence of environmental enrichment on these effects. Adolescent mice were exposed to toluene vapors from 1 to 4 weeks. Effects on memory were tested every week using the object recognition test. In the second part of the experiment, control animals and mice exposed to

toluene were housed on standard conditions or environmental enrichment during four additional weeks. Memory evaluation was conducted again after completing the housing treatment. Results showed that chronic toluene exposure impair memory from the first up to the last week of evaluation. Memory impairment was independent of the toluene concentration and the time of evaluation. On the other hand the result of environmental enrichment showed that this treatment was able to counteract toluene-induced memory alteration; while animals with history of toluene exposure and housed on standard conditions maintained memory impairment. Overall, the present study showed that environmental enrichment positively impacts some effects produced by repeated exposure to toluene.

Title: Redox-based epigenetic changes via the cysteine transporter EAAT3: A novel unifying mechanism for the actions of drugs of abuse

Authors: *M. S. TRIVEDI;
Neuro-Pharmacology, Northeastern Univ., Boston, MA

Abstract: Canonically, drugs of abuse can activate intracellular signaling cascades, leading to epigenetic changes, inducing long lasting alterations in gene expression, affecting learning, memory and behavior. Additionally, these drugs can also alter glutathione (GSH) levels and induce oxidative stress; however, the consequences are unclear. Building upon substantial preliminary data, we investigated the acute and long-term effects of selected drugs of abuse and their mechanism of influence on pathways of redox metabolism and DNA methylation (DNAMe) status in cultured neuronal cells. Drugs of abuse alter EAAT3 activity and subsequent changes were observed in the GSH as well as S-adenosylmethionine levels, which define the redox and methylation status of neuronal cells, respectively. As a prototype, we characterized the effects of morphine-induced methylation changes at CpG sites in LINE-1 retrotransposons, measured via MBD-sequencing and bisulfite sequencing, along with genome-wide changes in

transcription. qRT-PCR analysis of mRNA for enzymes and transporters involved in antioxidant and methylation pathways was also carried out. Lastly, redox and methylation responses were also investigated upon removal of drugs of abuse after a prolonged exposure (i.e. *in vitro* washout). Changes in cysteine uptake, cellular levels of GSH and cysteine and DNAMe were observed both acutely and upon washout of morphine. Taken together, these findings provide an improved understanding of the mechanism by which drugs of abuse can influence neuronal cell redox and methylation status, including DNAMe. Since epigenetic changes are also implicated in withdrawal phenomenon, we suggest a novel mechanism for addiction and the action of drugs of abuse.

Title: Amygdala-hippocampal phospholipase d (PLD) signaling: Identifying neural substrates for therapeutic disruption of cocaine-environment maladaptive long-term memories

Authors: *B. KRISHNAN;
Pharmacol. and Toxicology, Univ. of Texas Med. Br. At Galveston, Galveston, TX

Abstract: Long-term conditioned memory mechanisms are critical in recall of drug-environment associations and are key contributors in relapse to cocaine (and other drug) dependence. Recently, we reported an important role for rat amygdala phospholipase D (PLD) downstream to dopaminergic and glutamatergic systems in expression of cocaine-conditioned behavior. In the present study, we elucidate the role for PLD signaling downstream to serotonergic transmission in the expression of conditioned responses to cocaine in different drug-free states by studying the

limbic regions of the rat amygdala and hippocampus implicated in associative memory mechanisms. We observed conditioned hyperactivity in both early (Day-1) and (Day-14) withdrawal (drug-free states) following 7-day training. Increased phosphorylation of PLD isoforms in the amygdala crude synaptosomal fractions characterized the Day-1 drug-free state while overall increase of the total protein levels for PLD1 and PLD2 was additionally observed in the Day-14 drug-free state. Further, cellular studies confirmed that increased PLD phosphorylation states contribute to the signaling mechanism. Thus, the novel PLD signaling mechanisms associated with maladaptive long-term mechanisms can provide possible therapeutics targets in preventing relapse to cocaine use and other neuropsychiatric disorders.

Title: Prelimbic beta-adrenergic receptor blockade during trace fear memory retrieval reduces fear and prevents reinstatement following extinction

Authors: *D. MUELLER[1], J. M. OTIS[2], M. K. FITZGERALD[2], J. L. BURKARD[2], M. A. DRAKE[2];
[1]Dept. of Psychology, [2]Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Retrieval of aversive memories can drive fear in fear/anxiety disorders, whereas retrieval of drug-associated memories can induce drug seeking in addiction. Disruption of memory retrieval would therefore be beneficial for treatment of these disorders. Inhibition of beta-adrenergic receptor (beta-AR) activity within prelimbic medial prefrontal cortex (PL-mPFC) causes long-lasting impairments in contextual drug-associated memory retrieval (Otis et al, 2013), and these impairments provide protection against drug-induced reinstatement (Otis et al, 2011, 2014). Thus, PL-mPFC beta-AR activation maintains drug-associated memory retrieval, but whether this activity is a fundamental mechanism that maintains retrieval of

memories across paradigms is unclear. Here, we examined the effects of PL-mPFC beta-AR blockade on retrieval of recent and remote contextual and trace fear memories. For contextual fear conditioning, rats were trained to associate a training context with 4 presentations of a shock unconditioned stimulus (UCS; 1s, 0.8mA). Rats returned to the training context 1 or 30 days later, during which PL-mPFC microinfusions of the beta-AR antagonist nadolol were given. Nadolol reduced context-induced freezing during these tests, but not during subsequent nadolol-free extinction tests or during UCS-induced reinstatement. In the next experiment, rats were underwent trace fear conditioning, which is known to require PL-mPFC (Gilmartin et al, 2013). Conditioning consisted of 6 paired presentations of a tone conditioned stimulus (CS, 10s) and a shock UCS (1s, 1.0mA) separated by a 20s trace interval. Rats were then tested within an alternative testing context 1 or 30 days later, during which a single presentation of a tone CS was presented followed by a 120s stimulus free period. PL-mPFC microinfusions of nadolol reduced freezing during the stimulus free period for rats tested at 30 days but not 1 day following conditioning, suggesting that remote trace fear memory retrieval requires beta-AR activation. Although freezing returned to control levels during subsequent extinction tests, nadolol-treated rats expressed significantly less freezing during a UCS-induced reinstatement test following extinction. These data suggest that inhibition of beta-AR activity during remote trace fear memory retrieval may weaken the CS-UCS contingency, such that extinction is capable of persistently suppressing retrieval.

Title: Inhibition of PKA signaling in the prelimbic cortex persistently disrupts retrieval of a cocaine-associated memory and prevents subsequent reinstatement

Authors: *M. FITZGERALD, J. M. OTIS, M. A. DRAKE, J. L. BURKARD, D. MUELLER; Univ. of Wisconsin - Milwaukee, Milwaukee, WI

Abstract: Drug-associated cues trigger craving and relapse in addicts, and preventing retrieval of cue-evoked memories would reduce relapse susceptibility. Previously we found that retrieval of drug-associated memories can be blocked by β-adrenergic receptor (β-AR) inhibition in the prelimbic medial prefrontal cortex (PL-mPFC; Otis et al., 2013), but the β-AR signaling cascades underlying retrieval remains uncertain. β-AR activation is known to stimulate adenylyl cyclase increasing intracellular cAMP and activating protein kinase A (PKA; Mueller et al., 2008). Additionally, β-AR has been shown to stimulate a receptor tyrosine kinase ultimately leading to the activation of a MAPK signaling pathway (Meitzen et al., 2011). Therefore, using a cocaine-induced conditioned place preference (CPP) paradigm, we first determined whether retrieval required activation of MAPK or PKA signaling pathways in the PL-mPFC. We found that a bilateral PL-mPFC microinfusion of the MAPK inhibitor UO126 prior to the initial CPP test had no effect on expression of a CPP. In contrast, a single bilateral PL-mPFC microinfusion of a PKA inhibitor, Rp-2'-O-Monobutyryl-cAMPS, persistently disrupted expression of a CPP across trials and prevented reinstatement to a cocaine priming injection following extinction. Thus, cocaine-associated memory retrieval requires PKA signaling, but not MAPK signaling, in PL-mPFC. Previous work has shown β-AR activation and PKA signaling enhances the intrinsic excitability of neurons, an effect mediated by a reduction in the slow afterhyperpolarization (sAHP; Zhang et al., 2013). PKA phosphorylates calcium-activated potassium channels and blocks their activity, thereby reducing the sAHP (Neylon et al., 2006). Thus, we next determined whether PKA mediates retrieval by reducing the sAHP using co-infusion of the PKA inhibitor and a sAHP blocker, UCL2077, into the PL-mPFC prior to the initial CPP. We found that the co-infusion rescued CPP expression. These results suggest β-AR activation results in PKA activity which reduces sAHP resulting in enhanced neuronal excitability necessary for cocaine-associated memory retrieval and reinstatement. Thus, enhancing sAHP function could impair cocaine-associated memory retrieval, thereby preventing cue-induced drug seeking and relapse long after treatment.

Title: Infralimbic NR2A-containing NMDA receptors are necessary for the reconsolidation of cocaine self-administration memory

Authors: *M. HAFENBREIDEL, C. RAFA TODD, J. M. OTIS, R. C. TWINING, D. MUELLER;
Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Addiction is characterized by high susceptibility to relapse, which can be triggered by drug-associated cues. Cue presentation results in retrieval of the original drug-cue memory that becomes labile and must be reconsolidated back into long-term storage. Repeated unpaired cue presentation, however, induces extinction. Thus, cue-reactivity can be reduced by either blocking reconsolidation or facilitating extinction. Previous research revealed that systemic blockade of NMDA receptors (NMDArs) can disrupt reconsolidation of drug-cue associations in a modified self-administration paradigm (Milton et al., 2008) or extinction in a standard self-administration paradigm (Hafenbreidel et al., 2014). To further characterize these processes, we examined the effects of post-extinction injections of an NMDAr antagonist on drug seeking following self-administration. Rats acquired cocaine self-administration (0.25 mg/inf, i.v., 90 min/day) followed by extinction. Extinction consisted of four 45-min extinction sessions in which rats were administered the NMDAr antagonist CPP (10 mg/kg, i.p.) immediately after each session. Extinction retention was then tested during a subsequent 90-min session. CPP treatment decreased lever pressing during subsequent extinction sessions, suggesting either disrupted reconsolidation or facilitated extinction consolidation. We next targeted the infralimbic medial prefrontal cortex (IL-mPFC), a structure implicated in extinction (Quirk & Mueller, 2008). Using the same procedure, CPP infusions (36 μg/ 0.3 μL) before or after four brief extinction sessions resulted in a similar reduction in lever pressing across subsequent days. To determine the NMDAr subtype involved, we infused either the NR2A-selective antagonist NVP (1 μg/ 0.3 μL) or the NR2B-selective antagonist Ro25 (2 μg/ 0.3 μL) after four 45-min extinction sessions. Similar to the effects of nonspecific NMDAr blockade, blocking NR2A- but not NR2B-containing NMDArs reduced lever pressing across subsequent days. Finally, to dissociate if blocking NR2A-containing NMDArs disrupts reconsolidation or facilitates extinction consolidation, NVP was infused into the IL-mPFC after four 10-min reactivation trials or in the absence of behavioral testing. Memory retention was then tested during a subsequent 90-min session, revealing that blocking NR2A-containing NMDArs after memory reactivation results in reduced lever pressing. Overall, these results indicate that blocking NR2A-containing NMDArs

in the IL-mPFC disrupts reconsolidation following reactivation of the original drug-cue memory rather than facilitates extinction consolidation.

Title: Prelimbic neuronal excitability and synaptic potentiation underlie cocaine-associated memory retrieval and are reversible during retrieval

Authors: ***J. M. OTIS**[1], M. A. DRAKE[2], J. L. BURKARD[2], D. MUELLER[2]; [1]Psychology, Univ. Wisconsin-Milwaukee, Milwaukee, WI; [2]Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Retrieval of drug-associated memories promotes addictive behaviors, as presentation of drug-associated cues induces both drug seeking and relapse. The prelimbic medial prefrontal cortex (PL-mPFC) is critical for retrieval of cocaine-associated memories (Otis et al., 2013) and for reinstatement of drug seeking (see Peters et al., 2011). The plasticity mechanisms within PL-mPFC that maintain cocaine-associated memory retrieval and reinstatement, however, remain unclear. Thus, we examined intrinsic and synaptic changes in PL-mPFC using a model that requires contextual drug-associated memory retrieval, the conditioned place preference (CPP) paradigm. Following conditioning and two daily cocaine-free retrieval tests, rats were sacrificed for electrophysiological recordings. We first assessed the intrinsic neuronal excitability of layer V/VI PL-mPFC pyramidal neurons in cocaine-conditioned and naïve rats. Although conditioning did not modify overall intrinsic neuronal excitability, the excitability of PL-mPFC neurons was positively correlated with CPP scores ($r(5)=0.84$; $p=0.02$). Given that PL-mPFC excitability is regulated by beta-adrenergic receptors (beta-ARs; Otis et al., 2013), we examined the effects of propranolol, the beta-AR antagonist, on retrieval. Propranolol injections (10 mg/kg; i.p.) before

the first CPP test prevented retrieval during that test and during the following propranolol-free test (consistent with previous findings, Otis et al., 2011, 2013, 2014). Moreover, CPP scores from rats treated with propranolol did not correlate with intrinsic excitability of PL-mPFC neurons ($r(2)=-0.38$; $p=0.62$). Thus, intrinsic excitability of PL-mPFC neurons regulates CPP memory retrieval. Next, we characterized the effects of cocaine conditioning on the strength of synaptic inputs to layer V/VI PL-mPFC pyramidal neurons. Cocaine conditioning induced potentiation of PL-mPFC postsynaptic strength, as evidenced by an increase in AMPA-mediated currents as compared to NMDA-mediated currents (AMPA:NMDA ratio). Conditioning also modified presynaptic input, as evidenced by paired-pulse facilitation. Thus, synaptic plasticity in layer V/VI PL-mPFC pyramidal neurons may regulate cocaine CPP memory retrieval. In support of this, propranolol treatment reversed the increase in AMPA:NMDA ratio, indicating that beta-AR blockade induced synaptic depotentiation in PL-mPFC. Our data demonstrate that PL-mPFC intrinsic excitability and synaptic plasticity regulate drug-associated memory retrieval, and this plasticity is maintained by beta-AR activation during retrieval.

Title: Paternal cocaine exposure elicits transgenerational learning deficits

Authors: ***M. E. WIMMER**, L. A. BRIAND, C. P. CRAIGE, L. A. GUERCIO, A. C. ARREOLA, H. D. SCHMIDT, R. C. PIERCE;
Psychiatry, Univ. Pennsylvania, PHILADELPHIA, PA

Abstract: Cocaine addiction is associated with profound cognitive impairments, including deficiencies in memory function. In some cases, these memory deficits predict poor treatment retention and outcome. Additionally, growing evidence indicates that drug abuse can influence behavior and neurophysiology not only in adults, but also in offspring. We previously showed that paternal cocaine self-administration reduces the reinforcing efficacy of cocaine in offspring. Here, behavioral and electrophysiological techniques were combined to examine the influence of paternal cocaine self-administration on memory formation and synaptic plasticity in offspring. Object-based paradigms are ideally suited to evaluate memory traces because they circumvent potentially confounding alterations in motor function or stress response, and the underlying neural circuits have been well defined. Male rats self-administered cocaine daily for 60 days and controls received yoked saline infusions. Cocaine-experienced and saline-experienced sires were then bred to drug-naïve females and memory formation was assessed in the resulting adult (60 days and older) offspring. Paternal cocaine self-administration elicited short-term (30 minutes) spatial memory deficits in male, but not female, offspring (F1 generation) and grand-offspring (F2 generation). F1 and F2 animals showed normal novel object recognition in a hippocampus-independent version of this task. These findings indicate that paternal cocaine self-administration produces transgenerational spatial learning deficits and disrupts hippocampal function. Theta bursts-induced LTP, a cellular model of memory formation, was evaluated to directly test hippocampal plasticity in the descendants of cocaine-exposed sires. LTP induction was impaired in adult male F1 offspring, suggesting that NMDA receptor signaling was reduced. Consistent with this hypothesis, bath application of the endogenous NMDA receptor co-agonist D-serine restored LTP induction in hippocampal slices from F1 rats. Taken together, these findings indicate that the offspring and grand-offspring of cocaine-experienced rats show spatial learning deficits, which may be caused by reduced NMDA receptor signaling in the hippocampus.

Title: The interaction between NMDA receptor and CaMKII in prelimbic cortex modulates extinction of cocaine self-administration

Authors: Z.-Y. ZHANG[1], Y.-Z. ZHANG[2], S.-Q. CHEN[2], *H. SHEN[1];
[1]Natl. Inst. On Drug Dependence, Peking Univ., Beijing, China; [2]Inst. of Neurosci., Guangzhou Med. Univ., Guangzhou, China

Abstract: Vulnerability to relapse to drug seeking is the most important characteristic in drug addiction, which linked to activating prefrontal cortex (PFc) projections to the nucleus accumbens during the cue exposure. Pervious study have demonstrated that inactivation of PFc inhibited cue-induced or drug-primed reinstatement in drug self-administered animals. Furthermore, PFc is involved in extinction training of drug seeking which is considered as a learning process for disassociation of cue and reinforcement. In present study, we investigated whether that the interaction between NMDA receptor (NMDAR) and CaMKII in PFc contributes to extinction of cocaine self-administration. To disrupt the NMDAR/CaMKII complex, CN class of peptides were packaged in a lentiviral construct (LV-CN21) that interfere NMDAR binding to CaMKII. During abstinence from cocaine self-administration, LV-CN21 or LV-GFP was infused in prelimbic cortex (PL). Three weeks after microinjection, reinstatements were triggered by context and drug-associated cue, and consequent extinction training were conducted for further 2 weeks. We found that LV-CN21 failed to prevent the reinstatements, but decelerate the extinction procedure in the second week of extinction training. These data implies that NMDAR-mediated signaling in PL might underlie the molecular mechanism for extinction learning and would be a pharmacological target for addiction treatment.

Title: Short-term exposure to nicotine sensitizes the anxiety-producing effects of nicotine when later encountered

Authors: *R. C. BARNET, A. HOGENMILLER;
Col. William & Mary, Williamsburg, VA

Abstract: We previously reported that chronic (14-day) nicotine exposure can produce long-term alterations in hippocampus dependent context conditioning (Spaeth et al., 2010). Chronic nicotine exposure has also been shown to produce long-lasting changes in anxiety measured in Light Enhanced Startle (LES; Barnet et al., 2013). Effects of acute nicotine are more variable with anxiolytic or anxiogenic properties reported depending on species, task, and age, among other factors (e.g., Faraday et al., 2003; File et al., 1998; Picciotto et al., 2002). In our own laboratory, acute nicotine has been shown to be anxiogenic in both adults and younger animals when measured in the LES paradigm. In the present experiment we sought to examine nicotine's anxiogenic profile following limited, short term, nicotine preexposure. Adult rats were exposed to saline, 0.15 mg/kg, or 0.40 mg/kg nicotine (i.p.) for 4 consecutive days. Following this nicotine preexposure phase, all animals were exposed to a single acute 0.40 mg/kg nicotine injection and the effect of this acute nicotine exposure on anxiety was measured in LES. Nicotine's anxiogenic effect on LES was found to be significantly greater in nicotine preexposure groups compared to saline preexposure groups. The results suggest that even limited exposure to nicotine can sensitize the brain's response to nicotine's stress-inducing effects when nicotine is later encountered.

Title: The role of the dentate gyrus in morphine CPP: Adult-generated neurons regulate extinction of reward learning

Authors: *P. D. RIVERA, R. K. RAGHAVAN, S. YUN, M.-K. MCGOVERN, S. LATCHNEY, S. BIRNBAUM, A. J. EISCH;
Dept. of Psychiatry, UT Southwestern Med. Ctr., Dallas, TX

Abstract: The hippocampus, and dentate gyrus (DG) in particular, is involved in several aspects of addiction. For example, after conditioned place preference (CPP) for psychostimulants or opiates there is an increase in DG cellular activity (cFos+ cells). Interestingly, the adult DG gives rise to new neurons throughout life. These adult-generated neurons are thought to be important in hippocampal function and activated by spatial tasks, although prior work suggests they are not important in cocaine CPP acquisition or retention. Here we addressed two unanswered questions: Is DG activity actually induced by the retrieval of a morphine/context association? And are adult-generated neurons important in the retrieval, retention, and extinction of a morphine/context association? To determine cellular activity within the DG granule cell layer (GCL) after saline/saline and saline/morphine CPP training, respectively, C57BL/6J mice were sequestered into their non-drug paired context or drug paired context on test day. Quantification of cFos+ cells 90min post-test showed mice conditioned to a previously-learned drug context have ~30% more cFos+ GCL cells than controls. Thus, retrieval of a drug/context association reward memory appears to occur in the DG GCL. To examine if adult-generated neurons are important in the retrieval, retention, and extinction of a morphine/context association, C57BL/6J mice received sham irradiation (IRR) or image-guided X-Ray IRR (15Gy) 6 wks prior to morphine CPP training, and then assessed for acquisition, retention, and extinction. Similar to prior work with cocaine, IRR mice are able to retrieve and retain a morphine/context association similar to controls. However, while Sham mice extinguished preference ~8 days post-CPP, IRR mice surprisingly never extinguish, and by 20 days post-CPP still spend significantly more time (~200%) in the drug context compared to Sham. These data suggest cranial IRR abolishes the extinction of reward learning in morphine CPP. Taken together, these data clarify the role of the DG GCL in morphine CPP and the potential importance of adult-generated neurons in the extinction of reward learning. Ongoing studies are using DREADD technology to selectively activate/inactivate adult-generated neurons during extinction, and a conditional knock out strategy to ablate adult neurogenesis before and after morphine CPP training to dissect the role of adult-generated neurons in this hippocampal-dependent memory task.

Title: The effects of β-arrestin dependent signaling pathways on alcohol dependence and memory reconsolidation

Authors: *X. LIU, Y. TAO, L. MA, B. HUANG, L. MA;
The Inst. of Brain Science, Fudan Univ., Shanghai, China

Abstract: β-Arrestins, known as key regulators of GPCR signaling, are highly expressed in the central nervous systems. But their roles in brain functions remain largely unknown. Here we report that β-arrestin 2 expression can regulate preference and sensitivity for alcohol in mice. mGluR5 antagonist MPEP inhibited alcohol dependence in the chronic alcohol drinking mice. The chronically free consumption of alcohol increased the phosphorylation levels of Akt, a β-arrestin 2 binding partner, and GSK3β, in the dorsal striatum of wild type mice, but not β-arrestin 2 knockout mice. These data reveal that β-arrestin 2 is a negative regulator of striatal Akt/GSK3β pathway and a protective molecule to inhibit alcohol preference and dependence. The increased activation of AKT/GSK3β in the dorsal striatum induced by stable alcohol consumption was greatly suppressed by MPEP, while no significant changes were detected in signaling pathways such as ERK/CREB and S6K1/S6 in dorsal striatum after the chronic alcohol intake. The intracerebroventricular administration of either MPEP or wortmannin, the PI3K inhibitor, markedly reduced the voluntary alcohol intake in mice. What's more, our data suggest that memory reconsolidation is mediated by a β-arrestin-dependent β-adrenergic signaling pathway. Our study implicates that the β-arrestin mediated mGluR5 cascade in the dorsal striatum and β-adrenergic signaling in hippocampus formation may be individually involved in the development of alcohol dependence and memory reconsolidation, and reveals the theraputic potential for β-arrestin regulated signaling processes in treatment of alcohlism and memory related disorders.

Title: Unique molecular alterations in synapses following acute cocaine and novelty exposure

Authors: *V. SELVAM, F. C. CRUZ, R. M. LEAO, B. T. HOPE;
NIDA, Natinal Inst. On Drug Abuse - NIH, Baltimore, MD

Abstract: Learned associations between drug effects and stimuli in the drug environment play an important role in drug addiction. These associations are thought to be encoded by sparsely distributed patterns of neurons called neuronal ensembles that are selected by the drug-related stimuli. Alterations in dendritic spines of neuronal ensembles are thought to play an important role in learning addiction-related behaviors. Our goal is to identify synaptic alterations uniquely within synapses activated during drug-related behavior. We will determine the time course for cocaine and novelty-induced Arc, which will set the time constraints for using this molecules as a marker of activated synapses in future behavioral studies. We developed a procedure that uses flow cytometry to purify behaviorally activated synaptosomes (which contain the presynaptic terminal and attached post-synaptic density) to identify unique molecular and cellular alterations that are distinct from those in non-activated synapses. We injected rats with 20 mg/kg cocaine or saline vehicle and immediately placed them in a novel environment (bowls). Rats were decapitated 0, 60, 90 or 120 min following injections and the accumbens was dissected from 2 mm coronal slices. Synaptosomes were prepared and immunolabeled for PSD95 (to label all synapses) and Arc (to label activated synapses). For flow cytometry, we identified unique forward and side light-scattering characteristics of synaptosomes and assessed alterations in ARC protein levels over time in the PSD95 positive synaptosomes. Cocaine increased total Arc protein levels in synaptosomes at 60 min, suggesting that Arc translocation to the PSD of synaptosomes can be used as a marker of cocaine-activated synapses in flow cytometry. We conclude that Arc can be used as a marker of cocaine-activated synapses that make up the neuronal ensembles that encode learned associations between cocaine and the drug-associated context and play a role in context-induced reinstatement of cocaine seeking.

Title: Systemic inhibition of myosin II disrupts the storage of drug-associated memories

Authors: *E. J. YOUNG[1], A. M. BLOUIN[1], S. B. BRIGGS[1], G. RUMBAUGH[2], C. A. MILLER[1];
[1]Metabolism & Aging, Neurosci., [2]Neurosci., Scripps Res. Inst., Jupiter, FL

Abstract: Exposure to environmental cues associated with previous drug use can cause the involuntary retrieval of deeply engrained memories capable of redirecting behavior towards obtaining drugs. Our lab is focused on identifying mechanisms capable of disrupting these powerful, consolidated memories, with the goal of developing therapeutics. Regulators of synaptic dynamics are one particularly promising avenue, as emerging evidence indicates that memory formation depends on structural and functional plasticity of dendritic spines, for which actin polymerization is critical. Indeed we have found that, when performed days after training, home cage delivery of an actin depolymerizing agent to the amygdala (AMY) immediately and persistently prevents memory-induced drug seeking. This unexpected disruption of drug-associated memory storage had no impact on other types of amygdala-dependent memories, indicating that the actin dynamics supporting drug-associated memories remain uniquely active post-consolidation. While promising, the potential for actin polymerization inhibitors as therapeutics is limited, as they cannot be administered systemically because a multitude of peripheral processes rely on dynamic actin (e.g. cardiac function). For this reason, we have shifted our focus upstream of actin polymerization to identify mechanisms that could be safely manipulated from the periphery. We recently reported that myosin IIb, a non-muscle form of myosin, imparts a mechanical force that triggers spine actin polymerization in response to synaptic stimulation. To test the role of myosin II in the maintenance of drug-associated memories, we employed two models of context-induced drug seeking: conditioned place preference (CPP) and context-induced reinstatement of self-administration. Similar to an actin depolymerizing compound, pre-test inhibition of myosin IIb ATPase activity in the AMY produced a rapid and lasting disruption of drug-seeking behavior. We next determined the

potential therapeutic value of myosin II inhibition by establishing that systemic inhibition of myosin II successfully disrupted CPP to the same degree as direct intra-AMY delivery. Systemic inhibition of myosin II also reversed the drug-induced increase in AMY spine density but not in Area CA1 of the hippocampus. Consistent with this, inhibiting myosin II in Area CA1 failed to disrupt drug-associated memory, despite being a brain region necessary for this type of memory. Together, these findings indicate that myosin II represents a potential therapeutic target for disrupting these powerful, extinction-resistant memories capable of triggering relapse.

Title: Inoculation stress model of environmental enrichment

Authors: *E. J. CROFTON, Y. ZHANG, X. FAN, D. LI, T. A. GREEN;
Pharmacol. and Toxicology, Ctr. for Addiction Res., Univ. of Texas Med. Br., Galveston, TX

Abstract: Environmental enrichment is a non-drug, non-surgical manipulation that confers robust protective addiction and depression phenotypes in rats. In this paradigm, rats are housed for 30 days post-weaning in large cages with plastic children's toys that are changed and rearranged daily. Enriched rats are exposed to novelty, social contact and exercise and will self-administer less cocaine and amphetamine than isolated rats despite being more sensitive to the locomotor activating effects of the drugs. Additionally, enriched rats show decreased anhedonia-like behavior in the sucrose preference test, decreased social withdrawal shown by longer grooming time in the social contact test, and longer mobility time in the forced swim test. A major question in this field is how environmental enrichment can produce such robust behavioral differences in such a wide range of behavioral paradigms. Our hypothesis is that animals in the enriched environment undergo inoculation stress through living in a complex and dynamic environment, interacting non-aggressively with conspecifics, and exercising. Environment enrichment is a chronic mild stress environment that yields the animals less sensitive to future,

more severe perturbations, such as exposure to drugs of abuse or stress. Psychological stress is a major factor in the development and relapse to both addiction and depression in humans and determining the underlying molecular mechanism of the protection from addiction and depression could lead to efficacious treatments for both.

Title: Effect of chronic misused solvent exposure on adrenergic responses in isolated perfused rat heart

Authors: N. ALVARADO GÓMEZ[1,2], G. HERRERA LÓPEZ[3], L. ORTEGA VARELA[4], D. GODÍNEZ HERNÁNDEZ[2], *M. Y. GAUTHEREAU[1];
[1]Facultad de Ciencias Medicas y Biologicas Dr. Ignacio Chavez, [2]Inst. de Investigaciones Químico Biológicas, [3]Facultad de Químico Farmacobiología, [4]Escuela de Enfermería y Salud Pública, UMSNH, Morelia, Mexico

Abstract: The intentional inhalation of misused solvents to achieve intoxicating states is an important public health issue in Mexico. It has been reported that chronic administration of abused drugs in animal experimental models can produce tolerance, physical dependence and sensitization. Several reports indicate that inhaling solvents can lead to the occurrence of cardiac arrhythmias and a phenomenon known as sudden sniffing death, but the mechanisms by which these effects are produced are not completely understood. However, there are some reports indicating that cardiac arrhythmias due to sensitization of the heart to epinephrine are probably the most common cause of death. Based on this evidence, the purpose of this study was to investigate the effect of chronic exposure to 3 representative misused solvents (toluene, xylene and benzene) on the reactivity of the heart to epinephrine and on protein expression of the α_1 and

β_1-adrenergic receptors in aorta, atrium and ventricles. Male Wistar rats (250-300 g) were placed in a static exposure chamber and exposed to 6000 ppm of solvent (toluene, xylene, benzene) or air (control) during 30 minutes, twice a day for 30 days. On 31st day rats were anesthetized with sodium pentobarbital (50 mg/kg), and the hearts were isolated and perfused according to Langendorff method. Concentration-response curves to epinephrine (adrenergic agonist: 1 x 10^{-9}- 1 x 10^{-4} M) were made and parameters such as perfusion pressure, heart rate and strength of ventricular contraction were measured. The results showed that chronic solvent exposure produced a decrease in perfusion pressure; on the other hand, it was observed that repeated exposure to toluene, xylene or benzene produced an increase in the strength of ventricular contraction of isolated rat heart, i.e., there was a positive inotropic effect. Furthermore, in hearts of animals exposed to solvents, it was shown a decrease in the density of β_1 adrenergic receptors in ventricle. In conclusion, the results suggest that chronic solvent exposure can produce desensitization or tolerance to epinephrine effects on perfusion pressure and sensitization to solvent action on the strength of ventricular contraction; however, additional studies are required to elucidate the mechanisms involved in these effects.

Title: Comparison of conditioned place preference and progressive ratio operant conditioning to high fat/sugar foods: Correlation with nucleus accumbens c-Fos expression

Authors: *G. C. LOPEZ[1], M. L. NGBOKOLI[1], J. C. HONOHAN[1], R. H. MARKSON[1], L. CAMERON[1], K. S. BANTIS[1], E. LUNER[2], J. A. SCHROEDER[1];
[1]Connecticut Col., New London, CT; [2]Col. of William and Mary, Williamsburg, VA

Abstract: Obesity is a rapidly expanding epidemic that has serious health consequences and is the leading cause of preventable death in the United States. Psychostimulant and opioid addiction is a separate serious societal issue stemming from an individual's inability to control reward-seeking behavior. Cravings for drugs of abuse as well as highly palatable foods can be triggered simply by exposure to a reward-paired environment. Stimulation of the nucleus accumbens by

addictive substances, including high fat/sugar foods triggers expression of immediate early genes, the measurement of which can be used as an indicator of cellular activation. The current study employed an 8-day biased CPP paradigm to compare the rewarding properties of a high fat/sugar food (Oreo cookies) that is highly palatable to humans and rats to the rewarding properties of cocaine and morphine. Reward behavior was correlated with immunohistochemical measurement of nucleus accumbens c-Fos expression. In a on-going follow-up study, a progressive ratio operant condition paradigm was used to compare the break points in responding to regular rat food vs. chocolate flavored high fat/sugar pellets with the same nutritional content as Oreos. Results indicate that the reward behavior associated with consuming Oreos is equivalent to cocaine or morphine reward behavior. The magnitude of conditioned place preference to all three substances was positively correlated with nucleus accumbens c-Fos expression. These findings suggest that high fat/sugar foods and drugs of abuse trigger brain addictive processes to the same degree and lend support to the hypothesis that maladaptive eating behaviors contributing to obesity can be compared to drug addiction.

Title: Synaptic depotentation via mGluR5 activation and AMPAR internalization in the nucleus accumbens drives cocaine-primed reinstatement

Authors: *M. A. BENNEYWORTH, A. J. ASP, M. C. HEARING, C. E. SCHMIDT, S. R. EBNER, A. E. INGEBRETSON, M. J. THOMAS;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Relapse after periods of drug abstinence is a major obstacle to long-lasting recovery for many addicts. Understanding the neurobiological responses to drug-associated stimuli that incite drug craving and drive relapse has the potential to help target our efforts to treat addiction. The nucleus accumbens (NAc) serves as a critical interface of mesolimbic dopamine circuitry with excitatory cortical afferents in the regulation of motivation and drug seeking. Repeated *in vivo* cocaine exposure potentiates synaptic strength in the NAc medium spiny neurons (MSN), which is thought to promote addiction-related behavior. However, the present studies test the hypothesis that reversal of that augmented synaptic strength, or depotentiation, in the NAc shell may be a necessary factor in relapse. Metabotropic glutamate receptor subtype 5 (mGluR5) activation is one cellular mechanism known to promote synaptic depression. Therefore, we investigated whether cocaine-primed reinstatement of place preference in C57BL/6J mice is mGluR5-dependent and involves reductions in AMPA-type glutamate receptor signaling using conditioned place preference (CPP) behavior and *ex vivo* whole-cell electrophysiology. In support of our hypothesis, we observed that cocaine-primed reinstatement of CPP was disrupted by either intra-NAc shell infusion of the tat-GluA23Y "interference" peptide (inhibitor of activity-dependent AMPAR internalization; Ahmadian et al., 2004) or the mGluR5 antagonist MTEP (tat-GluA23Y:91.1% reduction in preference; MTEP: 63.6% reduction in preference). Importantly, preliminary data suggests that MTEP blocks NAc shell AMPAR depotentiation that would otherwise be induced by a cocaine-primed injection. Additionally, intra-NAc shell infusion of the mGluR5 agonist CHPG produced a dose-responsive reinstatement of CPP in extinguished mice (339.6 vs -6.97 CPP score in CHPG and control animals, respectively). Further experiments are being done to explore whether CHPG-induced reinstatement is also blocked by tat-GluA23Y. These findings support a model in which mGluR5-mediated functional reduction in GluA2-containing AMPARs in the NAc shell MSNs is a critical factor in the reinstatement of cocaine-primed behavior

Title: Increased BDNF in hippocampus of female rats after acute administration of methylphenidate and hormonal influence

Authors: *L. FREESE[1], Y. BOITA[2], N. D. COUTO-PEREIRA[4], G. AGNES[3], M. SOUZA[3], H. BARROS[5];
[1]Pharmacol., Univ. Federal De Ciências Da Saúde De Porto Alegre - UFCSPA, Porto Alegre, Brazil; [2]Pharmacosciences, [3]Univ. Federal de Ciências da Saúde de Porto Alegre, Porto Alegre, Brazil; [4]Univ. Federal do Rio Grande do Sul, Porto Alegre, Brazil; [5]Pharmacosciences, Univ. Federal de Ciências da saúde de Porto Alegre, Porto Alegre, Brazil

Abstract: Methylphenidate (MPH), commonly prescribed for attention deficit hyperactivity disorder, is used recreationally by adolescents or adults. Women represent a risk group for abuse of psychostimulants because they respond more intensely, probably due to sex hormones. BDNF is a neurotrophic factor that modulates several neuronal functions in the CNS and with important implications in memory. Studies show that female hormones, specially estrogen, influences neuroplasticity of the hippocampus. Objective: to evaluate the modulatory effects of female sex hormones in the mRNA levels of BDNF mRNA in the hippocampus of MPH sensitized rats. Female adult Wistar rats were assigned to the ovariectomized or intact groups and submitted to a sensitization protocol in subgroups: acute MPH (ACT), repeated MPH (RPT) and control (CTR). Two weeks after ovariectomy, for 5 consecutive days, RTP rats received MPH 2,5mg/Kg i.p. while ACTs and CTRs received 1mg/Kg saline. After a 7day washout, ACT and RPT rats received MPH 2,5mg/Kg as challenge. The horizontal activity was scored for 60 minutes. After the test, rats were euthanized by decapitation and the hippocampus were dissected for BDNF real-time PCR. Data analysis: 2v-ANOVA/Bonferroni post-hoc. As expected (Freese et al., 2012) RPT showed sensitized behavior. The intact group had a greater expression of BDNF (2.45 +0.40) in respect ovariectomized (0.139 +0.347), ($F(1,17) = 6.112$; $p=0.024$). ACT treatments presented higher levels of BDNF ($F(2,17) = 6.982$; $p=0.006$). ACT treatment induces higher levels of BDNF in intact females ($Fint(2,17) = 6.982$; $p=0.001$). All animals of the intact group were evenly distributed through the estrous cycles and castration was confirmed. It was observed that acute exposure to MPH induces significant increment in the expression of BDNF in the hippocampus, specially in females under physiologic estrous cycling. As also seen in GAD65 and GAD67, RPT treatment with MPH induced tolerance to the BDNF increase, in animals that are behaviorally sensitization. The neuronal adaptations reflected by normalized levels of GABA synthesis and of BDNF after repeated exposure to MPH may be a consequence of a mal-adaptation that may be associated to increased risk of a psychostimulant abuse.

Title: Integration of olfactory bulb glomeruli by the anterior olfactory nucleus

Authors: *B. E. SANCHEZ, N. E. SCHOPPA;
Physiol., Ucdenver Anschutz Med. Campus, Aurora, CO

Abstract: There is now strong consensus that the piriform cortex is a major locus where information about different molecular features of an odor are integrated, leading to perception of an olfactory object (Stettler and Axel, 2009; Apicella et al., 2010; Davison and Ehlers, 2011; Miyamichi et al., 2011). However, very little is known about such integration in the anterior olfactory nucleus (AON), which also receives direct input from the olfactory bulb. In addition, AON differs from piriform cortex in that much of its input is derived from tufted cells, which show quite distinct odor-evoked responses as compared to mitral cells (Igarashi et al., 2012). To examine the integrative capacity of AON, we measured pyramidal cell calcium responses to electrical stimulation of one or two glomeruli in the bulb in fura-2,AM-loaded brain slices from mouse. The slices often included the bulb, AON, and aPC so that responses could be compared between AON and aPC. To ensure that each electrode activated only one glomerulus, calcium responses of bulbar cells that surrounded glomeruli were closely monitored. Following electrical stimulation of single glomeruli (4 pulses at 5 Hz; 40-150 uA), we found that many pyramidal cells were activated in each structure, with no spatial ordering. When two glomeruli (≥240 μm-separation) were stimulated separately, 25±4% of AON cells (930 cells across 8 slices) and 35±5% of aPC cells (808 cells across 8 slices; $p = 0.046$, unpaired t-test) responded to stimulation of both glomeruli. Hence, different glomeruli appear to be less effective at driving cell activation in AON versus aPC. The fraction of cells that required simultaneous stimulation of both glomeruli to be activated was similar (13±3% of AON cells, 18±5% of aPC cells; $p = 0.31$). At least part of the difference between AON and aPC in their integrative capacity appeared to be due to intracortical mechanisms. Upon addition of the GABAB receptor agonist

baclofen (40 μM) to inhibit recurrent excitatory synapses, the fraction of cells that responded to separate stimulation of both glomeruli increased by 29±13% in AON (418 cells in 5 slices) but decreased by 22±10% in aPC (400 cells in 5 slices; $p = 0.015$ in unpaired t-test between AON versus aPC). These results suggest that different glomeruli in the bulb send convergent inputs onto single pyramidal cells in both AON and aPC, but that intracortical mechanisms, most likely inhibition, limits the ability of AON cells to respond to activation of different glomeruli.

Title: Role of basal forebrain cholinergic neurons in olfactory learning

Authors: A. NUNEZ-PARRA, *D. RESTREPO;
Cell Dev. Biol & Neurosci Prgm, Univ. Colorado Med. Sch., Aurora, CO

Abstract: The ability of the olfactory system to represent sensory cues is strongly influenced by neuromodulators released in response to a challenging and constantly changing external environment. Different processing stations throughout the olfactory pathway receive massive afferents from several brain regions that alter neuronal excitability and modify olfactory processing. Of particular interest is the neuromodulator acetylcholine (ACh), which has been linked in several brain regions with attention and cue detection. The olfactory bulb (OB) and piriform cortex (PC) receive abundant cholinergic innervation from the basal forebrain, specifically from the horizontal diagonal band of Broca (HDB) and mangocellular preoptic area (MCPO). It has been suggested that in these regions ACh promotes contrast enhancement among similar odorants and network synchronization to generate a more efficient olfactory coding, ultimately affecting olfactory learning and memory. Great efforts has been made to study the cellular effects of ACh in the olfactory pathway, yet how basal forebrain neurons are activated during active olfactory learning remains unknown. Here, we performed electrophysiological

recordings from the HDB/MCPO of awake and freely moving animals exposed to the associative learning paradigm go-no go. This task studies the capacity of a water-deprived rodent to actively and continuously discriminate between two odorants (a rewarded and a non-rewarded odor). Importantly, the electrophysiological and neurochemical properties of neurons in the basal forebrain are very diverse. Thus, the complex neuronal heterogeneity of the HDB/MCPO presents a challenge to study the exclusive contribution of cholinergic release to olfactory learning. To bypass this constraint we used selective optogenetic stimulation to identify cholinergic neurons of the HDB/MCPO. Specifically, we stereotactically inserted an optetrode (composed of an optical fiber and four tetrodes) into the HDB/MCPO of animals expressing channelrhodopsin (ChR) under the control of the choline acetyltransferase (ChAT) promoter (ChAT-ChR mice), an enzyme that is exclusively expressed in cholinergic neurons. Cholinergic neuron identification was performed by applying blue light directly into this region and by performing off-line spike sorting analysis.

Title: Structural basis for serotonergic regulation of neural circuits in the mouse olfactory bulb

Authors: Y. SUZUKI, *E. KIYOKAGE, K. TOIDA;
Kawasaki Med. Sch., Kurashiki, Japan

Abstract: Serotonin (5-HT), a monoamine neurotransmitter, originates from the dorsal and median raphe nucleus and distributes fibers throughout the forebrain. It also distributes the olfactory bulb (OB) and plays a crucial role in olfactory processing. Odor information processing

occurs in the OB and is regulated by bulbar interneurons and afferent neurons from other brain regions including 5-HT, noradrenalin, and acetylcholine. However, a detailed anatomical basis for the role of 5-HT in the OB remains to be understood. We thus focus on serotonergic regulation of OB function in the present study. We analyzed the projection pathway of 5-HT neurons from the dorsal raphe nucleus to the OB, and synapses between 5-HT axons and bulbar interneurons. We injected GFP-tagged sindbis viral vector into the dorsal raphe nucleus of mice and visualized the infected neurons. Infected neurons were identified as 5-HT immunoreactive by immunocytochemistry and reconstructed three dimensionally with Neurolucida. Confocal laser microscopy was performed to examine whether 5-HT axons contact with bulbar interneurons. Subsequently, pre-embedding immuno-electron microscopy for 5-HT and chemical markers of these interneurons was conducted to analyze the synapse. Moreover, we evaluated whether 5-HT neurons in the OB expressed vesicular glutamate transporter 3 (VGLUT3) or not. Our results demonstrate that 5-HT neurons project axons from dorsal raphe nucleus to the OB with bifurcations to other brain regions. 5-HT axons contacted several interneurons and formed asymmetrical synapses containing heterogeneous and dense-cored vesicles with these neurons in plural layers in the OB, suggesting that 5-HT neurons in the OB inhibit projection neurons in several ways and thus regulate the OB function at various steps. In addition, the 5-HT neurons in the OB were confirmed as VGLUT3 immunoreactive by co-localizing with VGLUT3 in electron microscopy. Our present study strongly indicates that afferent regulations from other brain regions contribute to elaborate mechanisms in olfactory processing and possibly coordinate or link olfactory encoding with other neural systems.

Title: Illuminating the role of inhibitory microcircuits in higher-order olfactory processing in zebrafish

Authors: *T. FRANK, R. W. FRIEDRICH;
Friedrich Miescher Inst., Basel, Switzerland

Abstract: The brain creates dynamic representations of the sensory environment by extracting stimulus features at early processing stages and synthesizing more abstract object representations in higher brain areas. We dissect the function of neuronal microcircuits in a higher olfactory brain area in order to identify elementary computations of basic cortical circuits and to analyze the underlying cellular mechanisms. To this end, we use a combination of genetic, electrophysiological and optical approaches to visualize and manipulate different types of interneurons (INs) in the posterior zone of the dorsal telencephalon (Dp) of adult zebrafish. This brain area is homologous to olfactory cortex in mammals and assumed to be involved in olfactory object representations and associative memory. We identified two types of INs that have similar electrophysiological properties but are differently connected to other neurons in Dp. Preliminary results suggest that optogenetic silencing of these IN types has different effects on odor-evoked activity patterns in Dp. Ongoing experiments further examine the influence of these interneurons on the processing of odor information in order to elucidate computations performed by different microcircuits in Dp. The results are expected to provide insights into canonical computations performed by basic cortical circuits.

Title: Modulation of amygdalar circuits important for chemosensory signal processing

Authors: L. BIGGS[1], *M. MEREDITH[2];
[2]Dept. Biol. Sci., [1]Florida State Univ., Tallahassee, FL

Abstract: The medial amygdala receives chemosensory information from the vomeronasal organ (VNO) and the main olfactory system and evaluates chemosignals used by many rodent species to convey social information. Medial amygdala (Me) responds differentially to conspecific and heterospecific chemosensory signals that convey different meanings and evoke different behavioral responses; and it may be responsible for routing information to hypothalamic and preoptic circuits involved in producing appropriate responses. The main intercalated nucleus (m-ICN), one of the GABA-ir intercalated cell groups dispersed throughout the amygdala, is located just lateral to posterior medial amygdala (MeP) and appears to be involved in the processing of chemosensory signals in Me. The role of m-ICN in chemosignal processing may be similar to the regulation of basolateral and central amygdala by adjacent paracapsular intercalated cell groups in the fear conditioning circuit. Previous research using immediate-early gene (IEG) expression has shown a negative correlation between m-ICN and MeP IEG responses to various types of chemosensory signals, however the circuitry has not been directly studied. Current research using whole cell patch-clamp electrophysiology in hamster coronal brain slices has shown a functional connection between m-ICN and MeP, e.g hyperpolarization of MeP neurons after localized field stimulation of m-ICN in a GABAa receptor dependent manner. Further, bath-applied dopamine significantly reduces the amplitude of the m-ICN induced IPSP seen in MeP neurons, with a return to baseline amplitude after DA washout. The effect of DA on m-ICN neurons directly has also been investigated using whole cell electrophysiology. Connections between anterior medial amygdala (MeA) and MeP, and potential connections between MeA and m-ICN are under study in horizontal brain slices including all 3 nuclei.

Title: Disinhibition mediated by VIP-interneurons in piriform cortex

Authors: A. M. LARGE, N. W. VOGLER, *A.-M. M. OSWALD;
Dept. of Neuroscience, Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, PITTSBURGH, PA

Abstract: Odor information is processed by the neural circuitry of the piriform cortex. Pyramidal cell (PC) responses to odor information are controlled by GABAergic inhibitory interneurons. Recent studies have characterized interneurons in piriform cortex (1) but little is known about the functions of distinct classes. Interneurons that express vasoactive intestinal peptide (VIP) are a major class of Layer 2 (L2) interneurons that have been proposed to inhibit L2/3 PCs. We used optogenetics to selectively activate VIP interneurons in brain slices from VIP-cre/lox-ChR2 mice while recording inhibitory postsynaptic currents (IPSCs) in VIP(-) interneurons and PCs in anterior piriform cortex (APC). Surprisingly, we found VIP cells inhibited only 20% of recorded PCs (n=2/10) but 75% of interneurons (n=14/19) and all neurons that received inhibition were in L3. Recipient interneurons could be divided into two classes based on inhibitory strength and input resistance (R_n) of the postsynaptic interneuron. Interneurons with low R_n (102 ± 5 MΩ) received significantly less inhibition from VIP cells (18 ± 3 pA) than high R_n interneurons (R_n: 183 ± 37 MΩ, IPSC: 94 ± 19 pA, $p<0.01$). Based on preliminary analysis of morphology, we putatively identified the low R_n interneurons as parvalbumin (PV) interneurons and high R_n neurons as somatostatin (SOM) interneurons. In other cortical areas, VIP interneurons mediate disinhibition of pyramidal cells through disynaptic circuits with PV or SOM interneurons (2,3). We have previously shown that the caudally-biased gradient of inhibition onto pyramidal cells in piriform cortex (4) may be due to disinhibition through are rostrally-biased gradient of inhibition onto interneurons. We investigated the spatial profile of VIP-mediated inhibition onto VIP(-) interneurons in APC slices from our VIP-cre/lox-ChR2 transgenic mice. We find a rostrally-biased gradient of inhibition ($p<0.05$) onto interneurons that is consistent with our previous findings using a VGAT-ChR2 mouse line. Taken together, our results suggest a potential mechanism by which VIP-interneuron to interneuron disinhibitory circuitry generates a rostro-caudal inhibitory gradient and regulates pyramidal cell activity. Ongoing studies are directed toward identifying the functional significance of VIP-mediated disinhibition for olfactory processing. 1) Suzuki and Bekkers (2010) Cerebral Cortex 20:2971-84 2) Pi et al. Title: Characterization of postsynaptic targets of M72 odorant receptor expressing olfactory sensory neurons via local electroporation

Authors: ***A. LIU**[1], M. GERAMITA[1], N. N. URBAN[2];
[1]Dept. of Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Dept. of Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: The organization of the olfactory system is distinct from that of other sensory systems that possess more intuitive topographic organization. Odorant molecules bind to receptors located on olfactory sensory neurons (OSNs), which send projections to the olfactory bulb. These projections are organized into glomeruli that each receive input from OSNs that express the same odorant receptor. Both local and global chemotopic patterns of glomerular activation exist, and these suggest that the glomerular circuitry also may show stereotyped spatial organization. Transgenic mice such as the M72-IRES line, in which all OSNs that express the odorant receptor M72 produce GFP, have allowed for detailed study of how axons of OSNs converge onto glomeruli. Alterations of receptor expression and of activity have been shown to modify olfactory sensory neuron targeting to the M72 glomerulus, suggesting that organization of the chemotopic map within the bulb is dependent upon or closely tied to receptor expression. Since M72 OSNs reliably converge onto glomeruli in the same spatial location across mice, we hypothesize that additional elements of the glomerular circuitry also will be stereotyped. Specifically, we aim to further the study of glomerular identity by analyzing the anatomical and morpohological properties of excitatory neurons, mitral and tufted cells, that are associated with the M72 glomerulus. Here, we use *in vivo* electroporation of the fluorescent dye Alexa 594 to label the mitral and tufted cells that project their dendrites to the M72 glomerulus in M72-IRES-GFP mice. Following a craniotomy created over the dorsolateral M72 glomerulus, glass electrodes containing dye were targeted to the M72 glomerulus using two-photon microscopy. Current pulses (750-1000 in number) were applied to perform the localized electroporation. Mice were subsequently perfused and sacrificed. The olfactory bulbs were sectioned, and confocal imaging was performed to visualize the labeled glomerulus and the cells having dendrites that entered the labeled glomerulus. The connected cells were quantified and described based on spatial location relative to the electroporated glomerulus. We demonstrate that local electroporation successfully labels postsynaptic targets of targeted glomeruli. These postsynaptic cells are located within 300 microns of the corresponding glomerulus. This analysis allows for a further description of M72 glomerulus characteristics, including the degree to which this glomerulus is stereotypical across animals, as well as future comparison of experience-dependent changes to the circuitry.

Title: BDNF increases apical spine density of olfactory bulb granule cells *in vivo*

Authors: B. MCDOLE, C. ISGOR, *K. M. GUTHRIE;
Dept Biomed Sci., Florida Atlantic Univ., BOCA RATON, FL

Abstract: The neurotrophin brain-derived neurotrophic factor (BDNF) promotes maturation and plasticity of dendritic spines, both during development and in adulthood. GABAergic granule cells in adult olfactory bulb mediate lateral inhibition of excitatory mitral/tufted cells via dendrodendritic synapses in the external plexiform layer (EPL). Granule cells express low levels of BDNF, and knockout of TrkB receptors in adult-born granule cells that migrate to the bulb from the subventricular zone alters their dendritic maturation. Apical dendritic spine density is reduced by this manipulation in cells that are 3 wks old and establishing synapses in the EPL. Suppression of BDNF/TrkB signaling therefore impairs normal spine formation and/or maintenance in this population of young neurons. To determine if increasing endogenous BDNF availability can promote dendritic spine formation/maintenance in the granule cell population overall, we examined bulbs from adult transgenic mice that chronically over-express BDNF throughout the granule cell layer. Elevations in bulbar BDNF mRNA and protein were quantified by *in situ* hybridization and Western blotting/ELISA, and Golgi-Cox staining was used to visualize olfactory granule cells in their entirety. Computer-based image analysis was performed using Neurolucida (Microbrightfield Inc.) to reconstruct dendritic arbors and quantify dendritic lengths, number of branches, and spine distribution, type and density. Comparison of measures from transgenic and wild-type mice showed that increased BDNF had no significant effect on total dendritic length or complexity of granule cell branching. However apical dendritic spine densities were significantly higher in the transgenic group (mean=0.37 spines/um +/- 0.03, SEM) compared to control mice (0.28 spines/um +/-0.02 SEM, p=0.012, unpaired t-test). This included an increased frequency of mushroom-type "headed" spines (0.25 spines/um +/- 0.02 SEM, vs 0.18 spines/um +/- 0.01 SEM, transgenic vs control respectively; p=0.018, t-test). Sholl analysis demonstrated that significant differences in spine density between genotypes emerged in distal

portions of apical dendrites beginning ~120-140um from the cell soma. These differences likely reflect autocrine/paracrine BDNF effects on granule cells and their synaptic partners, and provide insights into how endogenous BDNF may regulate dendritic morphology to shape bulb circuit organization.

Title: Role of oligophrenin 1 in circuit formation in the olfactory bulb of a mouse model of X-linked intellectual disability

Authors: N. REDOLFI[1], E. SAVOIA[1], I. ZAMPARO[2], *C. LODOVICHI[1,3];

Abstract: Among the X-linked forms of intellectual disability, oligophrenin 1 (OPHN1) encodes a Rho GTPase-activating protein. OPHN1 is thought to regulate several processes including dendritic morphology, axon outgrowth and cellular migration. To assess how this morphological alteration at the cellular level can affect circuit formation and function, we studied neural circuit in the olfactory bulb (OB), namely whether OPHN-1 can regulate the neurogenesis and the morphology of the newly generated granule cells (GCs). We quantified the number of newly generated GCs in the olfactory bulb in control and OPHN1 ko mice, using BrdU as a division marker. We found that 24 hours after BrdU injection (dpi), the number of new GCs in the subventricular zone (SVZ) was similar in control and OPHN1 mice. However at 15 dpi, the number of the new GCs was significantly lower in the OB of OPHN1 ko mice than in controls. At 50 dpi, new GCs were reduced by one-half in experimental animals as in controls. To examine the morphology of the new GCs, neuronal precursor were labelled in the SVZ with lentivirus expressing GFP. The morphology of the GCs was analyzed in the olfactory bulb, 30 days after the SVZ injection. We found that the length and the branching of dendrites was similar in control and experimental animals. However we found that the morphology of the spines was

significantly perturbed in OPHN1 ko mice. Our data indicate that in OPHN1 ko mice both the neurogenesis and the maturational process of the newly generated GCs in the OB are significantly perturbed.

Abstract: The anterior piriform cortex (APC) is the largest cortical area receiving direct inputs from the olfactory bulb (OB). Odorants are represented in APC by neural ensembles that are not organized in a topographic manner (horizontally). However, whether odor information is organized in a systematic manner across layers (vertically) is unclear. Recent data suggest that principal neurons in layer 2 are not homogeneous, but can be broadly classified into 2 subtypes: semilunar (SL) and superficial pyramidal (SP) cells. Here we investigated the axonal projections of these 2 subtypes using transgenic mice and viral-expression of fluorescent proteins. We found that CaMK2-Cre mouse can be used to label SP cells when paired with retrograde labeling using a Cre-dependent adeno-associated virus (AAV) from the OB. The axon collaterals of SP cells project to various olfactory cortical regions including the posterior piriform cortex, corroborating our previous results obtained by Retrobead labeling. We used a transgenic mouse line that allowed conditional expression of myristoylated-mCherry in SL cells to visualize their axonal projection. We found that SL cell axons project to similar olfactory cortical regions as SP cells,

but do not send collaterals to the OB. This suggests that feedback information received by the OB will be critically dependent on the signals represented by the SP cells. Ongoing efforts are aimed at mapping all axons emanating from these 2 cell types using CLARITY and whole brain imaging. Understanding the logic of axonal and synaptic connectivity of this first cortical relay has important implications for neural coding of olfactory information.

Title: Genome-scale analysis of main and accessory olfactory bulb spatial heterogeneity

Authors: *J. B. CASTRO[1], T. NOTO[2], S. J. TRIPATHY[3];
[1]Psychology, [2]Bates Col., Lewiston, ME; [3]Ctr. for High-Throughput Biol., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: It has long been known that peripheral inputs to the olfactory bulb are labeled, modular, and topographically organized. By contrast, we have comparatively little understanding of whether the bulb's intrinsic circuits show similar modularity. At one extreme, the bulb may consist of only a single canonical circuit providing uniform physiological 'readout' of segregated, parallel inputs. Alternatively, the bulb may be segregated into parallel channels that are physiologically and genetically distinct, allowing for input-specific readout. To investigate these and intermediate possibilities, have clustered spatially-registered genome-scale expression data from the Allen Brain Atlas (ABA; Lein et al, 2007), using non-negative matrix factorization (NMF). Applying NMF to ABA voxels corresponding to the accessory olfactory bulb (AOB), we observed a robust dichotomous clustering that recapitulated the well known division of the AOB into anterior and posterior divisions. Specifically, we found this division to be driven by genes [leading rank ordered genes for posterior and anterior: pcbp3 and fam108b, respectively] and gene categories corresponding to axonal guidance and dopaminergic synaptic transmission functional classes. That is, clustering expression data was sufficient to reveal genetically delineated, spatially contiguous regions of the bulb. In ongoing work, we are using this approach in an exploratory context to identify genetically defined subregions of the bulb that can then be

validated using targeted physiological recordings. In parallel, we are integrating axonal connectivity data from the Allen Mouse Brain Connectivity Atlas (Oh et al, 2014) to assess whether these genomically-defined bulbar subregions are recapitulated via afferent and efferent projections. Moreover, this suite of tools that we are developing can be applied to any brain structure to densely characterize neural heterogeneity. References: Lein et al (2007). Title: Neocortical markers in the olfactory cortex

Authors: *P. C. BRUNJES, S. K. OSTERBERG;
Dept Psychol, Univ. Virginia, CHARLOTTESVLE, VA

Abstract: Olfactory cortical regions such as the anterior olfactory nucleus (AON), piriform cortex (PC) and olfactory tubercle (OT) share many features with the neocortex such as clear lamination, an outer plexiform layer, pyramidal output neurons and similar interneuron types. How do their 2-3 layers compare with the six found in the neocortex? Substantial research has demonstrated that neocortical laminae can be described by a variety of developmental markers (e.g., Molyneaux et al, *Nature Rev, Neurosci.* 8, 2007). The present work examines the expression of some of these markers in three olfactory cortices: the anterior olfactory nucleus (AON), the anterior piriform cortex (APC) an olfactory tubercle (OT). Both coronal and horizontal sections were immunostained and confocal images gathered for 5 markers that span the neocortex. **CART**, which has been reported to label neocortical layer 2 (NL 2), was found to be absent from the AON, but densely labeled cells in Layer 2 of the PC and OT. **CUX1,** reported in NL 2-4, was found in all portions of the pars principalis of the AON, but differentially distributed within the structure. All of layer 2 in pars ventroposterior contained immunoreactive cells, but only the deep portion of layer 2 in pars lateralis and dorsalis. Profiles were very sparse

in pars medialis. In the PC only Layer 3 was labeled and in the OT the marker was absent. **TRB1**, a marker for NL 2356, was found throughout Layer 2 in the AON and in Layers 2 and 3 in the PC. It was absent from the OT. **Foxp2** (NL 6) was observed only in a line of cells just below the lateral olfactory tract in the AON. It was sparse in the PC but labeled Layer 2 in the OT. **Nurr1** (subplate) was absent from all regions. The findings indicate that the expression of these markers varies both within and between olfactory cortices, suggesting a) that understanding the developmental histories of the areas may yield important information about their similarities and differences and b) that the markers may be useful to distinguish between these higher olfactory system areas.

Title: Diversity and light adaptation of parallel processing streams in the retina

Authors: *J. PEARSON, D. KERSCHENSTEINER;
Ophthalmology, Washington Univ. In St. Louis, St Louis, MO

Abstract: The mammalian retina encodes different features of the visual world in the spike trains of approximately 20 retinal ganglion cell (RGC) types. These spike trains are the sole source of visual information to the brain. In spite of their fundamental importance to vision, the diversity of parallel processing streams from the retina is incompletely understood. A number of adaptive mechanisms in photoreceptors as well as downstream circuits enable to retina to support vision over a wide range of light levels. How light adaptation maps onto the diversity of parallel processing streams has not been explored in detail. Here, we perform large scale multielectrode

array recordings from mouse retinas and characterize and classify RGC responses to a broad set of stimuli. This allows us to reliable identify distinct functional RGC types. We then probe how visual encoding of RGC types changes across different light levels. In so doing, we find a surprising degree of diversity among light adaptation of different RGC types including changes in linearity/nonlinearity, spatial integration, temporal tuning and persistence or switch of trigger features.

Title: Blockade of pathological ganglion cell hyperactivity improves optogenetically evoked responses in a mouse model of retinitis pigmentosa

Authors: ***J. M. BARRETT**[1], L. BARCA[1], P. DEGENAAR[2], E. SERNAGOR[1];
[1]Inst. of Neurosci., [2]Sch. of Electrical & Electronic Engin., Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: Retinitis pigmentosa (RP) is a hereditary progressive retinal dystrophy that causes visual impairment and eventually blindness. Retinal prosthesis is the primary methodology providing hope for vision restoration. Presently, electrical prostheses restore only crude vision, but newer approaches based on optogenetics - genetic expression of light-sensitive proteins in neurons - may potentially offer higher-quality vision. However, alongside photoreceptor loss, retinal degeneration also involves significant inner retinal remodelling that leads to spontaneous, rhythmic bursting activity in retinal ganglion cells (RGCs). This source of biological noise is often overlooked in retinal prosthetic research. Recently, Toychiev et al (2013) were able to improve the signal-to-noise ratio of photoreceptor-mediated full-field stimulation and electrically-evoked responses by dampening this activity. We sought to extend these results to optogenetic stimulation and more sophisticated stimuli than full-field illumination. We crossed a

transgenic mouse line expressing the light-sensitive cation channel channelrhodopsin2 (ChR2) in RGCs with the rd1 model of retinal degeneration, creating a strain of mice with retinal degeneration and ChR2-expressing RGCs (ChR2rd1 mice). We recorded RGC activity from ex-vivo ChR2rd1 retinas using 60-channel ITO multielectrode arrays, while stimulating ChR2 using a 256-pixel Gallium Nitride microLED (μLED) array. The stimuli used included full-field flashes, bars moving in eight directions, and spots and annuli of different radii and thicknesses. We blocked spontaneous oscillations and bursting using either the gap junction blocker meclofenamic acid (MFA) or the Kv7 potassium channel opener flupirtine. Before application of the drugs, most recorded RGCs showed very strong bursting that made it difficult to discern responses to external stimuli. Both MFA (80uM) and flupirtine (100uM) greatly decreased the spontaneous firing rate, thus increasing the signal to noise ratio of responses to optogenetic stimulation and increasing the mutual information between the stimulus and the μLED-evoked responses. Our results show that spontaneous hyperactivity in the rd1 retina decreases the signal-to-noise ratio and information content of prosthetically-evoked responses and that these can be improved by reducing this activity. This may partially explain the poor quality of vision returned by current prosthetics and suggests that future retinal prosthetic research should explore methods of reducing or compensating for this pathological hyperactivity.

Title: Correlations between interneuron and output neuron populations of the retina

Authors: ***M. D. MENZ**, S. BACCUS;
Neurobio., Stanford Univ., STANFORD, CA

Abstract: Understanding the function of diverse neurons within a neural circuit has benefited from methods that record simultaneously from a neural population. In the retina, amacrine cells are inhibitory interneurons that shape the output of the retina as conveyed by retinal ganglion

cells. Both populations are diverse, but many of their specific functions are unknown. We recorded the visual responses from a population of amacrine cells optically using second harmonic generation (SHG) imaging, while simultaneously recording electrically from a population of retinal ganglion cells with a multielectrode array (MEA). From those recordings we analyzed correlations to infer the effect interneurons have on output cells, the location of noise sources, and connectivity. In the isolated salamander retina, we recorded amacrine and ganglion cell responses using a custom two-photon microscope that imaged the retina through a transparent MEA. We recorded the SHG signal generated by FM 4-64 applied to the bath from somas in the amacrine cell layer proximal to the inner plexiform layer. Ganglion cell spiking responses were recorded using an MEA. To measure correlations between the two populations, the visual stimulus was a moving dark bar against a light background. Population results were recorded from 122 ganglion cells, 365 amacrine cells, and nearly 5000 cell pairs were pooled across four retinas. By correlating many cell pairs for specific amacrine and ganglion cell types, we computed the average spatiotemporal pattern of activity of an amacrine cell population relative to the spike of a ganglion cell. These space-time plots show a wave of amacrine activity relative to ganglion cells as the bar moves across the retina, with different patterns for different amacrine cell types. Results indicated that in response to a moving edge, a significant fraction of the amacrine population was activated in advance of the ganglion cell, likely delivering retrograde inhibition. We further analyzed the noise correlations between amacrine and ganglion cell pairs by analyzing responses recorded on the same trial and on different trials. By averaging many cell pairs, we saw a strong average effect that nearby cell pairs with positive stimulus-driven correlations had negative noise correlations. This result was inconsistent with the dominant source of noise being in photoreceptors as has been previously suggested, and instead implies that for these cell pairs and stimulus, the dominant source of noise is in the inner retina. These results will be useful in understanding the contribution of specific amacrine populations, and in constraining models of how interneurons shape retinal output.

Title: A successful model for visual responses of alpha retinal ganglion cells to natural stimuli

Authors: *B. KRIEGER[1,2], M. QIAO[2], X. DUAN[2], J. R. SANES[2], M. MEISTER[1];
[1]Biol., Caltech, Pasadena, CA; [2]Harvard Univ., Cambridge, MA

Abstract: The retina sends many parallel channels of visual information to the brain through the axons of >20 retinal ganglion cell (RGC) populations. The purpose of these distinct circuits for vision remains an open question. Recent results suggest that each cell type responds selectively to a specific feature of the visual scene. These conclusions are derived primarily from experiments with artificial visual stimuli. It is unknown whether the insights gathered under such conditions extend to the natural environment in which the retina evolved. One can address this question by building a mathematical model of RGC responses to artificial stimuli and then testing how well that same model performs with natural visual input. For several RGC types this exercise has failed dramatically, indicating an imperfect understanding of their neural code. Here we focus on alpha RGCs, which possess large cell bodies, stout axons, and wide receptive fields. Three subtypes have been defined based on their responses to light steps: On, Off-sustained, and Off-transient. In the mouse, these alpha cells provide most of the input to layer 4 of the visual cortex and thus constitute an important pathway for cortical processing. The Off-transient type has been proposed as a looming detector involved in defense from predators. We targeted these RGCs for recording using a transgenic mouse line in which GFP is expressed in all three alpha subtypes. Using both artificial stimuli and natural movies, we measured the visual responses of the mouse alpha cells. We then constructed a simple cascade-style model to link the stimulus to the firing rate. The model includes an antagonistic center and surround, each with partial rectification. The center is further divided into nonlinear subunits. This model accounted very well for the visual responses of all three alpha RGC subtypes, correctly predicting about 70% of the variance in firing. The same model worked for both artificial stimuli (e.g. random flicker) and natural stimuli (mouse-cam and simulated-mouse movies). Across conditions there were only minor adjustments to parameters, as expected from adaptation processes. Under natural movie stimulation, the antagonistic surround of the receptive field played a relatively small role whereas the spatial subunit processing within the receptive field center made a larger contribution. This successful account of alpha cell function will be valuable as a retina model for understanding cortical vision in the behaving mouse.

Title: Exclusive cholinergic excitation of on-off ganglion cells in rat retina

Authors: S. SETHURAMANUJAM[1], *M. M. SLAUGHTER[2];
[1]Neurosci., [2]SUNY Buffalo Sch. Med., BUFFALO, NY

Abstract: The objective was to ascertain the role of cholinergic synaptic input to retinal ganglion cells (RGCs).. Acetylcholine is released only by starburst amacrine cells, which are stratify in two narrow bands in the inner plexiform layer. Most RGCs express functional nicotinic acetylcholine receptors (nAChRs), but their role in light-evoked spike activity is unclear. Experiments were performed in the whole-mount mature rat retina. RGCs were classified based on responses to a spot of light (500nm, 200µm diameter). We recorded from ON sustained (ONs), ON-OFF transient and OFF sustained (OFFs) cells. 100µM hexamethonium chloride, a nAChR antagonist, did not significantly affect the light-evoked spike activity of ONs and OFFs cells. However, in a sub-population of ON-OFF cells, hexamethonium completely blocked both the ON and OFF light-evoked spike activity. Similar effects were seen using 100µM D-tubocurarine. Whole cell recordings revealed that hexamethonium drastically reduced the voltage response and excitatory synaptic currents in both the ON and OFF responses. These results indicate that in a sub-population of ON-OFF cells are driven exclusively or predominantly by acetylcholine excitation and lack direct bipolar cell input under these stimulus conditions. The lack of glutamate excitation was unexpected. We tested if this was due to pre-synaptic inhibition. Picrotoxin, TPMPA, and strychnine were used to block GABAA, GABAC and glycine receptors in the retina. With inhibition blocked, glutamate synaptic currents dramatically increased, indicating that pre-synaptic inhibition can suppress bipolar cell input to these cells, regulating the acetylcholine/glutamate excitation ratio. It has been shown that mGluR2 receptors are co-expressed with starburst amacrine cells. DCG-IV (10µM, a mGluR2 agonist) increased the light evoked spike activity of hexamethonium sensitive RGCs. Interestingly, light evoked spike activity in DCG-IV was not completely blocked by hexamethonium indicating that DCG-IV increased the direct, bipolar cell glutamate input to these RGCs. In summary, we find that the glutamate excitation to some RGCs can be superseded by acetylcholine and can be modulated by pre-synaptic inhibition.

Title: Large-Scale recording of light-evoked responses in the retinal ganglion cell layer of the explanted retina: A new HD experimental platform

Authors: *S. DI MARCO[1], A. MACCIONE[1], G. HILGEN[2], S. PIRMORADIAN[3], T. NIEUS[1], M. HENNIG[3], E. SERNAGOR[2], L. BERDONDINI[1];

Abstract: Aims: We introduce an innovative setup to simultaneously evoke and record *in-vitro* extracellular visual responses from Retinal Ganglion Cells (RGCs) with micrometer/cellular resolution from a complete whole-mount mouse retina. We show the capabilities of this setup by investigating the effects of the extra-classical receptive field of RGCs. The applicability of this setup ranges from the study of a complete biological system, to optogenetic experiments that may benefit from the precise control of a light stimulus (structured or not) and from the ability to simultaneously record spikes from thousands of single cells. **Methods:** Two main parts constitute the setup: the optical stimulator and the recording system. The recording system is a customized version of the commercially available Biocam (www.3brain.com) adapted to fit the optical stimulator geometrical constraints. Briefly, the system is composed by a CMOS 4096-electrode array chip (electrode size 21 μm x 21 μm, inter-electrode separation 21 μm), mounted on hardware for real-time filtering and simultaneous recording of all the electrodes at a sampling rate of about 7KHz/channel. With an active area of 7.12 mm^2 the system allows pan retinal recording from mouse explanted retina. Since the chip is not transparent, visual stimuli are delivered from the top of the chip by means of a DLP-projector, with 3-axis of free-movement, aligned with a single-convex lens that focuses the image on the biological sample. A beam-splitter, positioned in the optic pathway, direct the reflected light to a camera allowing to precisely align the stimulus with the recording area. To precisely control and synchronize the timing of the photo-stimulation with the data acquisition, custom hardware and software tools

were developed. These also allow generation of complex photo-stimulation protocols, and to record the timestamp of the photo-stimulations with millisecond precision. **Results:** Here we show that a visual stimulus confined to a small region of the retina does affect the spontaneous activity in parts of the retina not exposed to the stimulus. In particular, spontaneous activity is reduced in the area not exposed to the stimulus for during stimulus presentation, and increases sharply and transiently at stimulus offset. **Conclusions:** Our integrated platform enables successful recording of a large number of RGCs in the mouse retina during photo stimulation. Our results show that such dense and large-scale recordings can reveal spatial processing mechanisms in the retina that are difficult to characterize using conventional technology.

Title: Characterising retinal population response with high density multielectrode arrays

Authors: *S. PIRMORADIAN[1], G. HILGEN[2], O. MUTHMANN[1,3], A. MACCIONE[4], U. BHALLA[3], L. BERDONDINI[4], E. SERNAGOR[2], M. HENNIG[1];

Abstract: Retinal ganglion cells are categorized according to a range of physiological criteria. So far, however, this classification largely relied on pooling data from multiple preparations due to limitations in the number of neurons that could be simultaneously recorded. Here, we present a new, efficient method for localizing ganglion cells recorded in the adult mouse retina during light stimulation with high density multielectrode arrays of 4096 channels. Recording channels were arranged on a 64x64 lattice and separated by 42 μm, enabling simultaneous sampling of activity at near cellular resolution of >800 units on a large patch of the retina. The method

exploited the fact that signals from the same cell were detectable on multiple neighboring channels. By averaging the signals of neighboring channels, we improved spike detection, which yielded more reliable and robust detection than is possible in single channels. The relative contributions of the different channels to each spike are then used to localize the signal source. Finally, spikes are iteratively clustered together by spatial proximity, thus identifying the activity of single units. A comparison with standard spike sorting techniques showed this method could substantially improve spike detection and correctly cluster spikes that would otherwise be assigned to different sources. We characterized the population response of single units, identified by the method, in a full field experiment (a sequence of dark/light stimuli) for comparison with previous work (Carcieri et al., J Neurophysiol, 2003). We observed that response latencies were broadly distributed from 50-950 ms, with faster responses in OFF cells. Distribution of the ratio of ON versus OFF responses were broad, with higher abundance of ON cells compared to OFF cells. The spatial distribution of ON and OFF cells in the dorsal retina was random. In summary, our results are a first step towards a comprehensive and statistically sound characterization of the activity of a large population of neurons without variability caused by combining data from multiple preparations.

Title: Expansion-selective ganglion cells in frog retina

Authors: *H. ISHIKANE[1,2,3], M. MATSUZAKI[1];
[1]Dept Psychol, Senshu Univ., Kanagawa, Japan; [2]Grad. Sch. of Letters, Senshu Univ., Kanagawa, Japan; [3]Ctr. for Psychological Science, Inst. for the Develop. of Social Intelligence, Senshu Univ., Kanagawa, Japan

Abstract: Mice engage in protective behaviors in response to a looming stimulus. It has been reported that a subtype of ganglion cells (PV-5 cells) in the mouse retina exhibits approach sensitivity and that the involvement of PV-5 cells may be necessary for triggering these protective behaviors. Similarly, frogs exhibit escape behavior, a form of protective behavior, in response to a looming stimulus. We have already demonstrated that synchronized oscillatory spikes among class-4 neurons (dimming detectors) encode visual information that is necessary to induce escape behavior in frogs. However, it is still unclear what kinds of retinal outputs are sufficient for eliciting escape behavior. To elucidate this issue, we recorded spikes that occurred in frog retinal ganglion cells in response to a looming stimulus (a dark expanding disc). The frog's behaviors in response to this visual stimulus were also recorded using a video camera under infrared illumination. When a dark expanding disc was presented to the retina, all subtypes of ganglion cells generated spikes. Synchronous oscillatory spikes were observed among class-4 neurons. Then, we presented a dark ring that gradually filled in toward the center to become a solid disk. When this stimulus was presented, synchronized oscillatory spikes were observed among class-4 neurons. However, frogs exhibited no escape behavior in response to this stimulus. This result suggested that encoding of expansion is essential for eliciting escape behaviors. Thus, expansion selectivity of all subtypes of retinal ganglion cells was investigated. When both a dark expanding square and a dark square that was gradually filled in toward the center were presented to frog retinas, only class-3 neurons showed expansion selectivity. These results suggest that expansion-selective class-3 neurons might encode information that is necessary for eliciting escape behaviors in frogs.

Title: Temporally modulated long-wavelength light radically slows eye growth in young tree shrews

Authors: *T. J. GAWNE, J. T. SIEGWART, A. H. WARD, T. T. NORTON;
Dept Vision Sci., Univ. Alabama Birmingham, Birmingham, AL

Abstract: A post-natal eye will normally adjust its growth to achieve sharp focus. The retina can detect the sign of the defocus (hyperopia-eye too short, myopia-eye too long). It could use longitudinal chromatic aberration and compare the relative sharpness of the long and short wavelength images as a guide for whether it should increase or decrease its elongation rate to achieve well-focused retinal images. However, the sparseness of short-wavelength photoreceptors would seem to make it impossible to tell if the short-wavelength image is in focus. We hypothesize that the retina uses the temporal abruptness of changes in light at different wavelengths as a proxy for image focus: when an image is in sharp focus a photoreceptor will experience rapid changes in illuminance as the animal moves around the world and produce sharp transients in bipolar and amacrine cell membrane potentials. An out-of-focus image at a specific wavelength would reduce the illuminance transients and neural responses. Abrupt temporal illuminance transients at long wavelengths should cause the retina to slow the rate axial elongation. We tested this hypothesis on developing tree shrews (dichromatic mammals closely related to primates) at an age when the eyes are elongating rapidly and refractions are decreasing from hyperopia toward emmetropia. From day 11 after eye opening to day 24, tree shrews (n=3) were housed on a 14 h ON/10 h OFF light cycle in long-wavelength light (620 nm peak, 10 nm width at half height, mean illuminance at cage floor 325 lux) that was pseudo-randomly modulated with rapid, sharp increases and decreases of intensity. This illuminance regime radically slowed the refractive decrease and axial elongation compared to animals in standard fluorescent colony lighting (see figure - however, one animal showed signs that this effect was ebbing near the end of the period, suggesting some form of habituation). We speculate that the retina uses abrupt long-wavelength transients in the absence of abrupt short-wavelength transients as a signal to a postnatal eye that it should stop elongating.

Title: Signal recombination in the inner retina

Authors: *N.-W. TIEN[1], J. DEMAS[2], D. KERSCHENSTEINER[1];
[1]Ophthalmology and Visual Sci., Washington Univ. in St. Louis, Saint Louis, MO; [2]Physics and Biol., St. Olaf Col., Northfield, MN

Abstract: In the mammalian retina, bipolar cells (BCs) relay signals from photoreceptors to ganglion cells (GCs), the output neurons of the eye. In cone-mediated vision, signals first diverge as each photoreceptor provides input to 10 types of BCs, and then are recombined in the inner retina to give rise to distinct spike trains of approximately 20 types of GCs. While it is known that BC types differ in their responses to photoreceptor input, how the output of individual BC types shapes spikes trains across GC types remains incompletely understood. This is in part, because in addition to providing direct excitation to GCs, BCs also drive specific sets of interneurons (amacrine, ACs) which in turn have varied influences on BCs, other ACs and GCs. To probe the logic and mechanisms of signal recombination in the inner retina, we generated mice in which a single BC type is removed. We then combine multielectrode array and patch clamp recordings to determine the influence of this processing stream from the outer retina on the spike trains of different GC types, and characterize the underlying mechanisms (direct excitation, indirect inhibition and indirect excitation). In addition to providing insights into visual processing in the retina, our findings may be relevant to other circuits in the nervous system that share architectural and computational features.

Title: Roles of retinal circuits in innate visual behaviors of mice

Authors: *M. YILMAZ[1,2], X. DUAN[2], J. SANES[2], M. MEISTER[1];
[1]Caltech, Pasadena, CA; [2]Harvard Univ., Cambridge, MA

Abstract: The mouse retina has >20 different types of retinal ganglion cell (RGC), each of which reports a specific feature of the visual scene. Despite anatomical and physiological characterization of many of these neural circuits, their behavioral roles are mostly unknown. A few RGC types are dedicated to specific visual behaviors, for example pupil constriction and light entrainment of circadian rhythms [1]. Here we explore whether distinct RGC types can also be linked to more elaborate visual behaviors, such as predator defense, cliff avoidance, and the optokinetic response. All these behaviors rely on the interpretation of image motion. We ablated two different retinal cell types, alpha ganglion cells and starburst amacrine cells, using genetically targeted expression of the diphtheria toxin receptor followed by intraocular injection of diphtheria toxin. Toxin was injected in adulthood to avoid developmental effects. Alpha cells constitute ~6% of mouse retinal ganglion cells, encompassing 3 recognized cell types. They have the largest cell bodies and receptive fields in the retina, respond sensitively to fast motion, but are not selective for motion direction. Starburst amacrine cells provide asymmetric inhibition to 7 recognized types of direction-selective (DS) cells in the retina, which altogether make up ~20% of mouse RGCs. Ablation of the starburst amacrine cells has been shown to abolish the direction-selectivity of DS cells as well as the optokinetic nystagmus [2]. We show that ablation of alpha RGCs selectively impairs the mouse's defensive responses to looming objects (freezing and fleeing), whereas it leaves the optokinetic reflex and pupil construction largely intact. On the other hand, ablation of starburst amacrine cells completely abolishes the optokinetic reflex, while leaving looming avoidance and pupil constriction intact. This double dissociation suggests that the targeted retinal circuits indeed contribute to distinct visual behaviors, supporting the neuroethological hypothesis that each circuit in the retina evolved in response to a specific behavioral need. 1.Chen S.K., Badea T.C., and Hattar S. (2011). Photoentrainment and pupillary

light reflex are mediated by distinct populations of ipRGCs. Nature. 476, 92-95. 2.Yoshida K., Watanabe D., Ishikane H., Tachibana M., Pastan I., and Nakanishi S. (2001). Title: Targeting channelrhodopsin-2 to ON-bipolar cells with vitreally administered AAV restores ON and OFF visual responses in blind mice

Authors: ***E. MACÉ**[1], R. CAPLETTE[1], O. MARRE[1], A. SENGUPTA[1], A. CHAFFIOL[1], P. BARBE[1], M. DESROSIERS[1], E. BAMBERG[2], B. ROSKA[3], J.-A. SAHEL[1], S. PICAUD[1], J. DUEBEL[1], D. DALKARA[1];

Abstract: Inherited retinal degenerative diseases are a clinically promising focus of adeno-associated virus (AAV)-mediated gene therapy. These diseases arise from degeneration of photoreceptors eventually leading to blindness. Optogenetic reactivation of surviving retinal neurons is a promising strategy to restore vision. However, targeting ganglion cells neglects the visual processing done by the inner retina. Targeting upstream neurons is more suited for preserving retinal processing but up to now could only be addressed by a subretinal injection, which may damage the fragile degenerated retina of patients. Here we used an engineered AAV variant that can target the bipolar cells of the retina after safe administration into the eye's easily accessible vitreous. This capsid variant called AAV2-7m8, in combination with a cell-type specific promoter allowed strong and specific expression of channelrhodopsin (ChR2/H134R) in ON bipolar cells. Our results show that, after viral delivery in blind mice (rd1), different types of

ON-bipolar cells express efficiently and specifically the opsin. Functional efficacy of our transfection was controlled with multielectrode array (MEA) recordings. On the MEA, ON responses were recorded when stimulating treated retinas with blue light and the responses withstand pharmacological block at the cone to ON-bipolar pathway. OFF responses were also observed and were suppressed by blocking inhibitory responses of amacrine cells. To assess whether the new retinal photo-responses are transmitted to higher brain centers, we performed extracellular recordings in the visual cortex. Both ON and OFF responses were restored in treated animals as seen on VEPs and, for the first time, on multiunit spiking activity. The shorter latency of ON responses was consistent with the bypass of photoreceptors. Finally, treated mice also retrieved light induced locomotory behaviour. Our results support the clinical relevance of a minimally invasive AAV-mediated optogenetic therapy for visual restoration. By targeting inner neurons, both ON and OFF pathways are reactivated; which is a promising avenue for restoring a vision as close to natural vision as possible.

Title: Electrophysiological characterization of cortical neuron subtypes in mouse visual cortex

Authors: *J. BERG, T. JARSKY, S. SORENSEN, C. ANASTASSIOU, A. OLDRE, A. BERNARD, C. KOCH, H. ZENG;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: The Allen Institute has initiated a 10-year program to take a systematic and comprehensive set of experimental and computational approaches to understand the circuitry involved in the mouse visual system. A foundational aspect of this project is to create a comprehensive classification scheme for neuronal classes within the mouse visual cortex and lateral geniculate nucleus, dorsal part (LGd). Part of this classification scheme is to understand how diverse neurons integrate synaptic input to generate output signals, a function of their intrinsic electrical properties. To characterize these cell classes electrophysiologically we will utilize the Institute's recently established *in vitro* slice electrophysiology platform to systematically record the intrinsic electrophysiological properties from individual neurons. For our initial data set, we will target layer-specific projection neuron Cre mouse lines as well as interneurons that span lamina. We will use a robust 'core' set of electrophysiology protocols designed to efficiently characterize the most salient electrophysiology properties of each neuron. This stimulus set focuses on: 1) subthreshold properties, including the linear range of a neuron's voltage response to current injection, 2) action potential threshold and kinetics, given both square and ramp pulse current injections, 3) spiking due to suprathreshold stimuli and the frequency to injected current relationship, and 4) subthreshold and suprathreshold response to derivative rich noisy stimuli. We will use custom software to extract relevant electrophysiological features and use principal component analysis to identify different classes of neurons. Together with complementary projects within the Allen Institute, these data will help us to understand the diversity of electrophysiological cell types within the cortex.

Title: Dynamics of neural activity in mouse cortex during visual behavior

Authors: *D. R. OLLERENSHAW, P. A. GROBLEWSKI, M. E. GARRETT, J. ZHUANG, J. WATERS, S. R. OLSEN;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: Behavior and cognition are the result of dynamic neural activity in the neocortex and interconnected subcortical structures. We are using the mouse visual system as a model to understand the mechanistic basis of these processes. We train mice to perform visual behavioral tasks using the linear foraging paradigm, and monitor/manipulate neural activity in the visual cortex during the task. In the foraging task, a head-fixed mouse runs on a circular treadmill, the motion of which is coupled to the movement of stimuli across the visual display (Olsen & Scanziani, 2013). The mouse is trained to approach and stop at target stimuli, whereupon it receives a water reward. The foraging task has features that simulate environmental interactions including optic flow, object approach behavior, and decisions to stay or go. Mice are capable of completing hundreds of trials per day, allowing rapid estimation of psychophysical thresholds. Using this task we have characterized the psychophysics of visual stimulus detection for a variety of stimulus parameters including grating contrast, spatial frequency, size, and location in the visual field. In addition, we have assessed the impact of distractor stimuli on target detection thresholds. In another task, we characterized the mouse's ability to perform orientation discrimination at multiple spatial locations in the visual field. In order to characterize the neural activity that underlies these behaviors, we monitor the activity of neuronal populations in the primary visual cortex and higher visual areas using wide-field fluorescence imaging and 2-photon imaging of genetically-encoded calcium sensors including GCaMP6. Finally, we use optogenetics to perturb activity in the visual cortex and find that visual behavior is impaired by this manipulation. Together, these techniques provide a powerful experimental system in which behavior can be mechanistically linked with the underlying neural code. Title: On spike detection and the development of quantitative measures for spike clustering using "ground truth" data: A computational and slice electrophysiology study

Authors: C. MITELUT[1], S. L. GRATIY[2], S. DURAND[2], K. MIZUSEKI[2], K. GODFREY[2], C. LEE[2], T. BLANCHE[2], N. SWINDALE[1], C. REID[2], M. HAWRYLYCZ[2], C. KOCH[2], *C. ANASTASSIOU[2];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Allen Inst. for Brain Sci., Seattle, WA

Abstract: The quantity and quality of neural recordings is the cornerstone for many experimental investigations of the brain. Specifically, extracellular spiking in the living brain is typically measured using metal electrodes either in the form of single or groups of wires (tetrodes, etc.) or, alternatively, through metal contacts on silicon probes. The basic algorithmic steps after data collection are spike detection, extraction of distinctive features from the extracellular spike waveform, and clustering of the spikes by these features. With regards to this process, two important questions arise: (1) what is the optimal electrode size, configuration and geometry to allow for maximal detection of proximal spiking given a particular cell type of specific morphological and electrical features and (2) based on the detected signals, what are the quantitative measures to compare the "goodness" of spike sorting across different methods [Hill et al, JNeurosci, 2011]? To address both questions we use morphologically and functionally detailed compartmental models of cortical and thalamic neurons to simulate extracellular spike waveforms [Gold et al, J Comput Neurosci, 2006]. We systematically characterize the impact of cell type, extracellular medium as well as electrode size and configuration to the yield and quality of extracellular measurements. In a subsequent step, we test several clustering algorithms including: Klustakwik (EM), K-means, SIGAC, template matching pursuit, Superparamagnetic and bagged clustering, using in silico benchmarks to generate quantitative measures of goodness among such algorithms. Finally, we perform a blind analysis of several spike sorting methods using a unique *in vitro* data set where intracellular and extracellular spikes were simultaneously recorded from rodent cortical slice in a cell type-specific manner [Anastassiou et al, SfN, 2013].

[1]Allen Inst. For Brain Sci., Seattle, WA; [2]Yale Univ., New Haven, CT

Abstract: The Mindscope project at the Allen Institute for Brain Science aims to elucidate mechanisms underlying cortical function in the mouse, with the primary focus on the visual system. This involves concerted efforts of a large team of scientists employing experimental, computational, and theoretical techniques to characterize cell types, connectivity, and neuronal activity in behaving animals. An integral part of these efforts is the construction of a detailed biophysical model of the cortical tissue. Here we present preliminary progress in building such a model, with current emphasis on the first step in transformation of sensory information by the cortex: namely, on the transformation of visual signals by layer 4 of primary visual cortex (area V1). The present biophysical model accounts for a significant portion of layer 4 in V1 and includes ~10,000 neurons (80% excitatory and 20% inhibitory), each consisting of hundreds of compartments representing morphologically realistic dendritic arbors. The current generation of the model relies on preliminary, but broad experimental characterization of layer 4, including both *in vitro* and *in vivo* data. Using this model, we have performed simulations of spiking behavior of layer 4 neurons in response to putative visual stimuli. Simulation results are compared to experimental data from *in vivo* patch-clamp intracellular recordings as well as extracellular microelectrode recordings. For example, the magnitude of the excitatory postsynaptic currents in layer 4 neurons and levels of cortical amplification are studied. Potential effects of the various connectivity modes, including preferential connectivity between co-tuned cells, on the neuronal dynamics are investigated. We also extensively characterize effects of optogenetic manipulations of neuronal populations within layer 4 and investigate the efficiency of such manipulations for a number of scenarios.

Allen Inst. For Brain Sci., Seattle, WA

Abstract: Sensory processing depends not only on sensory inputs, but also on the internal brain state of the animal. We aim to better understand the changes in cortical function with arousal and attention in awake, behaving mice. The neurotransmitter acetylcholine (ACh) is widely thought to be involved in arousal and attention and is released into neocortex primarily by cholinergic neurons from the basal forebrain. We used optogenetic techniques to manipulate the activity of cholinergic neurons in a mouse performing a visual discrimination task. We crossed the Chat-IRES-Cre mouse line (B6;129S6-Chattm2(cre)Lowl/J) to the floxed reporter line Ai35D to produce mice which express archaerhodopsin (Arch) in cholinergic neurons. We implanted a head restraint bar and guide cannula in mice at P40-90. The tip of the guide cannula was above posterior basal forebrain, 2 mm lateral, 0.5 mm posterior and 4.3 mm ventral to bregma. The mice were allowed a week of recovery prior to 1 week of handling and habituation to the training environment, followed by daily training (a single session of up to 1 hour per day) for 3-5 weeks. During behavioral sessions the mouse was head-restrained and ran on a disk while visual objects were presented to the right eye on a monitor centered 15 cm from the eye. The mouse was trained to discriminate between two 20-degree objects: a vertically-oriented stationary-grating target and a horizontally-oriented distractor, with only the vertically-oriented target being rewarded. Movement of the objects was yoked to running speed via the rate of rotation of the running disk, and the mouse collected a reward by slowing its running to select the target, while maintaining running speed to reject a distractor. The reward for successful target selection was 5-10 µL of water, with mice detecting 150-250 targets in a single session. To maintain motivation, mice were restricted to 1-1.5 mL of water per day. To test the role of cholinergic neurons, we used a 300 µm diameter optical fiber, inserted through the guide cannula to illuminate nucleus

basalis with 30 mW of 640 nm light. Illumination occurred on a randomized subset of 50 % of trials within a behavioral session, beginning immediately before the target appeared on screen and ending after the target left the screen. Consistent with a previous study (Pinto et al., Nature Neuroscience 16, 2013), optogenetic suppression of cholinergic activity decreased performance by impairing discrimination between the target and the distractor.

Title: *In vitro* single cell morphology in mouse V1 and LGN

Authors: *S. A. SORENSEN, H. PENG, J. BERG, S. SUNKIN, A. OLDRE, N. DEE, S. CALDEJON, Z. ZHOU, C. ANASTASSIOU, M. FISHER, K. JOINES, D. SANDMAN, A. M. HENRY, T. DESTA, W. WAKEMAN, C. KOCH, C. DANG, A. BERNARD, J. HOHMANN, J. W. PHILLIPS, H. ZENG;
Neurosci., Allen Inst., SEATTLE, WA

Abstract: The Allen Institute for Brain Science has initiated a large-scale effort to map and understand the mouse visual system. To begin addressing questions about the cell types present in the visual system, an *in vitro* single cell characterization platform has been established to systematically describe the intrinsic physiological and morphological properties of individual neurons in the primary visual cortex (V1) and lateral geniculate nucleus of the thalamus (LGN). Using layer-specific and interneuron-specific Cre driver mice crossed to tdTomato (tdT) reporter mice, we will march through the cortical layers recording from tdT+ and tdT- neurons in acute slices to survey the full complement of neurons in V1. When possible, a similar approach will be used in LGN. As part of each slice physiology experiment, neurons are filled with biocytin through the patch pipette. After staining, their detailed morphology is analyzed and used to study the presence of morphologically-defined cell types, and their relationship to physiologically- and genetically defined cell types. To capture morphological information, multi-tile, multi-plane digital images are acquired using a brightfield microscope. Images undergo customized enhancement, and an automated reconstruction is generated using the NeuronTracer tool in

Vaa3D (www.vaa3d.org). The reconstruction is then manually corrected to provide an accurate representation of the soma, dendritic and axonal tree. A spectrum of metrics can be extracted from these reconstructions, which can then be used to cluster neurons into putative classes or types. The functional significance of these findings can then be evaluated with respect to data from other modalities. This multi-modal data generation and classification approach will be used to create a taxonomy of cell types in mouse V1 and LGN.

Title: Simulating *in vivo* LFPs and intracellular [Ca2+] imaging data in mouse V1 using a detailed biophysical model of the cortical column

Authors: ***S. L. GRATIY**[1], A. GARNER[1], A. D. CHENG[1], S. DURAND[1], K. MIZUSEKI[1], J. BERG[1], S. SORENSEN[1], A. ARKHIPOV[1], M. L. HINES[2], A. SHAI[1,3], S. SUNKIN[1], J. W. PHILLIPS[1], H. ZENG[1], R. C. REID[1], M. HAWRYLYCZ[1], C. KOCH[1], C. A. ANASTASSIOU[1]; [1]Allen Inst. for Brain Sci., Seattle, WA; [2]Yale Univ., New Haven, CT; [3]Caltech, Pasadena, CA

Abstract: Despite recent progress in characterizing the properties of individual cells and their connections, the question of how these give rise to circuit processing and, eventually, computation remains largely unanswered [Koch, 1999; Oberlaender et al, *Cerebral Cortex*, 2012]. To understand how single-neuron activity and electrogenesis underlie brain function, one approach is to combine the available anatomical and physiological information within a biophysically realistic neuronal model and assess the extent to which it can replicate a host of experimental observations [Linden et al, *Neuron*, 2011; Anastassiou, Reimann et al, *Neuron*, 2013]. Eventually, a faithful and useful model must both emulate experimental observations and

make testable predictions regarding the role of cells and cell assemblies in circuit processing in a multitude of relevant spatiotemporal scales. We developed a large-scale, biophysically realistic model of a mouse V1 cortical column consisting of more than 10,000 neurons, utilizing reconstructed single cell morphologies, cell type-specific connectivity and active membrane conductances. The model is capable of simulating electrophysiological recordings such as unit activity and local field potentials [Buzsaki et al, *Nat Rev Neurosci*, 2012] and optical imaging of intracellular concentration of calcium ions $[Ca^{2+}]_i$ (e.g., via GCaMP6 monitoring [Chen et al, *Nature*, 2013]) as routinely recorded *in vivo*. Using this model we aim to (a) reproduce *in silico* stereotyped V1 activity as recorded electro-physiologically and optically *in vivo*, (b) deconstruct experimental recordings into their main constituents [Anastassiou, Reimann et al, *Neuron*, 2013], and (c) make experimentally testable predictions of whole-column cortical activity during visual processing. Which features of experimental recordings are captured by such a large-scale model? Which features remain unaccounted for and for what reason? Toward this end, we will provide quantitative comparisons between computational results and a host of experimental data.

Title: Characterization of cell-type specific role in circuit structure and function of mouse visual cortex *in vivo*

Authors: *L. LI, R. IYER, C. TEETER, S. DE VRIES, B. LONG, J. BERG, S. MIHALAS, L. MADISEN, H. PENG, C. KOCH, C. REID, H. ZENG;

Abstract: Cortical neurons display various morphological, physiological and genetic features and can be categorized into different ‘types,’ but how these types of neurons contribute to

cortical (micro)circuit construction and neural information processing remains largely unknown. The Allen Institute has recently begun its MindScope initiative: a multi-year project to understand how the mouse visual system functions. With the great support of transgenic mouse lines developed and acquired by the Allen Institute, we have set up a Mouse Cell Types program aimed at understanding morphological, physiological, genetic and connective properties of genetically defined cell types in the mouse visual system. In order to understand how different types of neurons are interconnected and assembled into microcircuits for neural information processing, we employ two-photon targeted whole-cell recording *in vivo* in transgenic mice in which individual types of neurons are fluorescently labeled. We characterize intrinsic membrane properties, spontaneous and visually evoked activities of neuronal types, and integrate these *in vivo* physiological data with gene expression patterns and morphology data. Since the Allen Institute also houses an initiative focusing on measuring intrinsic electrophysiological properties of neuronal types in brain slices, we can correlate our *in vivo* data with data generated from the *in vitro* pipeline, in order to obtain in-depth understanding of the construction and function of mouse visual circuits and how this leads to higher cognitive functions.

Title: The influence of long-range inputs on single-cell dendritic signaling

Authors: *A. SHAI[1,2], C. A. ANASSTASIOU[2], M. LARKUM[3], C. KOCH[2];
[1]Bioengineering, Caltech, Pasadena, CA; [2]Allen Inst. for Brain Sci., Seattle, WA; [3]Neurocure Cluster of Excellence, Berlin, Germany

Abstract: Here we explore the role of dendritic signaling in mouse primary visual cortex (V1) layer 5 (L5) pyramidal neurons during the integration of network inputs from the lateromedial (LM) higher order visual area. L5 pyramidal neuron dendrites extend along all six cortical layers

and receive inputs from both local and long-range axons and serve as a main output of columnar computation, making them one of the main integrators of cortical computation. We wish to understand how the anatomy of long-range connections relates to single neuron morphology and biophysics by focusing on axons that extend from LM to V1 L5 pyramidal neurons. First, we evaluate connectivity from LM to V1 using the method of subcellular channelrhodopsin assisted mapping (sCRACM) (Petreanu, Mao et al. 2009). We find that projections from LM synapse directly onto the tuft dendrites of V1 L5 pyramids, though these inputs seem to be substantially weaker than inputs onto their basal dendrites (Yang, Carrasquillo et al. 2013). However, due to limitations of the sCRACM method where tuft inputs might be underestimated and dendritic nonlinearities are left unaccounted for, we next tested the physiological influence these distal synapses might have. Continuing the optogenetic approach, we control the spatio-temporal pattern of inputs from LM onto L5 pyramidal neurons in V1 during somatic current injections using single photon laser stimulation in an *in vitro* prep. By monitoring the influence distal (in layers 1 and 2/3) LM inputs have on dendritic calcium-spiking (Larkum, Nevian et al. 2009), we show that these synapses do indeed play an important role in single-cell computation despite their substantial distance from the axon initial segment. In particular, we show that distal excitatory input from LM reduces the threshold for dendritic nonlinearities, ultimately allowing these long-range axons from LM to control burst-firing in L5 pyramidal neurons in V1. Larkum, M. E., T. Nevian, et al. (2009). "Synaptic integration in tuft dendrites of layer 5 pyramidal neurons: a new unifying principle." Science 325(5941): 756-760. Petreanu, L., T. Mao, et al. Title: Spiking responses in V1 are coupled to the phase of infragranular alpha LFP

Authors: *K. DOUGHERTY[1], M. A. COX[1], D. A. LEOPOLD[2], A. MAIER[1];
[1]Dept. of Psychology, Vanderbilt Univ., Nashville, TN; [2]Lab. of Neuropsychology, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Visual sensitivity varies considerably within and across experimental trials. Some of these fluctuations in visual task performance have been shown to correlate with cortical slow-wave activity in the alpha range (7-14 Hz), which has led to the hypothesis that visual sensitivity covaries with gradual changes in the excitability of cortex. In line with this hypothesis, recordings in primary visual cortex (V1) of monkeys revealed that the magnitude of the alpha-band local field potentials (LFP) in deep cortical layers couple with gamma-range (>30 Hz) amplitude within the same column. This finding is consistent with optogenetic work in rodents that demonstrates that infragranular neurons can control neural excitability in other layers. However, the laminar pattern of coupling between alpha-band LFP and spiking responses in primate V1 is largely uncharacterized. Here, we used a linear multielectrode array to simultaneously record LFP and multiunit spiking activity (MUA) across all layers of V1 of two macaque monkeys. Animals fixated while static grating stimuli were presented inside the neurons' receptive field. Congruent with previous reports, alpha-band LFP fluctuations were more prominent in infragranular layers relative to other layers. These fluctuations in the alpha range were not accompanied by overt changes in gaze position or microsaccade frequency. We found that within each trial the visually evoked MUA exhibited an increase in magnitude around amplitude peaks of alpha-band LFP. Circular statistics revealed that MUA responses in all cortical layers covaried with the phase of the infragranular alpha rhythm in both animals ($p < 0.05$). This robust interlaminar coupling of alpha-band LFP and MUA persisted for several hundred milliseconds while the stimulus remained on the screen. The slow modulation of columnar responses reported here is consistent with the notion of dynamic changes in cortical excitability during visual processing.

Title: Microcircuitry of agranular frontal and granular occipital cortex: Testing the generality of the canonical cortical microcircuit with cross-frequency phase-amplitude coupling during resting-state

Authors: *T. NINOMIYA, K. DOUGHERTY, D. C. GODLOVE, J. D. SCHALL, A. MAIER; Dept Psychol, Ctr. Integr & Cog Neuro, Vanderbilt Vision Res. Ctr., Vanderbilt Univ., Nashville, TN

Abstract: Diverse lines of research have been guided by the hypothesis that the cerebral cortex is comprised of a canonical laminar microcircuit. Evidence for such a circuit is based principally on anatomical observations of primary sensory cortex, especially early visual cortex. However, confidence in the generality of this hypothesis is weakened with recognition of the notable cytoarchitectural difference between granular sensory cortex and agranular frontal cortex. To test whether evidence for such a circuit is uniform across cortex, we used interlaminar cross-frequency phase-amplitude coupling as an assay of cortical circuitry. Using a linear microelectrode array, spontaneous local field potentials (LFPs) were recorded from all laminae of granular V1 and agranular supplementary eye field (SEF) while monkeys rested in darkness. We found substantial differences in the relationship between the amplitude of the gamma-band (>30 Hz) and the phase of alpha-band LFP (7-14 Hz) between these areas. In V1, gamma amplitudes in L2/3 and L5 were coupled with the alpha-band LFP phase in L5, as previously described. In contrast, SEF phase-amplitude coupling was most prominent within L3. These results suggest that laminar interactions in agranular frontal cortex are unlike those in granular V1. Thus, the canonical cortical microcircuit does not generalize across cortical areas.

Title: Dynamics of cortical correlation during vision

Authors: *N. WRIGHT, T. CROCKETT, J. POBST, R. WESSEL;
Physics, Washington Univ. In St. Louis, St Louis, MO

Abstract: Cortical circuits deal with time-varying sensory inputs via specific recurrent connections, from which coordinated and stochastic cortical population activity emerges dynamically. The stimulus-modulated population activity modifies circuit properties via adaptation mechanisms, which, in turn, reorganize the distribution of cortical correlations. Pairwise correlation is a measure of neuronal association that dwells at the core of how groups of neurons act in concert and how population coding might be optimized. Thus, understanding how visual stimulation impacts the co-varying activity among populations of neurons is a fundamental issue that remains to be fully addressed. To investigate the dynamics of cortical correlations during visual processing, we projected visual stimuli to the retina, recorded the local field potential (LFP) from the primary visual cortex of turtle using the *in vitro* eye-attached whole-brain preparation, and, simultaneously, monitored the membrane potential (V) from up to two cortical neurons via whole-cell recordings. We calculated normalized cross-correlation functions, C(d), with up to d = 500 ms lag from the band-pass filtered recordings (0.1 to 100 Hz) after trial averages had been subtracted. Our analysis of pairs of V-LFP and V-V recordings revealed four significant features of cortical correlation. First, cross-correlation functions, C(d), differed from pair to pair. These differences were not adequately reflected in the zero-lag cross-correlation coefficient, C(d=0). Cross-correlation functions reached extrema values of up to +/- 0.6. Second, for each pair tested, the cross-correlation function during visual stimulation differed from the C(d) at resting state. Third, resting state activity of small LFP amplitude was punctuated by distinct bursts of synaptic inputs accompanied by large LFP oscillations of up to 5 s duration, indicating a network state of high correlation. For a given pair, the cross-correlation function at resting state differed from the C(d) during bursts of LFP oscillations. Fourth, differences in C(d) from pair to pair or from small to large LFP amplitude network states were similar in magnitude to changes in C(d) evoked by visual stimulation, when compared to resting state. Together, these observations reveal a broad distribution of pair-wise correlations, with correlations for an individual pair changing under varying conditions. However, with the present data set, no obvious changes were detected for the distribution of correlations as a whole.

Title: Cortical pyramidal neuron subtype classification and visual response diversity

Authors: ***T. CROCKETT**[1], N. WRIGHT[1], S. THORNQUIST[2], M. ARIEL[3], R. WESSEL[1]; [1]Washington Univ. In St Louis, Saint Louis, MO; [2]Harvard Univ., Cambridge, MA; [3]St. Louis Univ., Saint Louis, MO

Abstract: A detailed inventory of the cortex's constituent pieces is essential to effectively understand the principles underlying cortical signal processing and computation. The classification of pyramidal neurons into functional subtypes remains a crucial part of this survey since the subtype-specific division of labor by the cortex provides manifold combinatorial possibilities, creating a rich substrate for computation. However, the extreme degree of integration of individual neurons into the collective cortex suggests that cellular individuality may represent a smaller component of computational role in the context of the larger network. This possibility raises an important question: is the computational function of a neuron determined by its individual type or by its circuit connections and network role? We investigate the problem of cellular organization using the ancestral model of the turtle primary visual cortex. The turtle's pyramidal neurons are arranged in a single layer in a three-layer visual cortex and are known to contain layer 4/input and layer 5/output homologs of the mammalian six-layer cortex. Electrophysiological profiles were created from measuring passive neuronal properties and responses to current injection using whole-cell patch-clamp recordings. These parameters were derived from the passive membrane properties, the shape of the action potential, the shape of the hyperpolarization, the time course of spike-rate adaptation, and the grouping of spikes. A blind clustering algorithm exercised on the data revealed the presence of two principle classes of neurons, presumably coinciding with L4/I- and L5/O-type neurons. To address functional profiles, we recorded visual responses of identified neurons to diffuse light flashes and applied a

cluster analysis to this data set. Visual responses consist of a smooth early response and a more dominant and fluctuating late response. These response epochs are hypothesized to correspond to thalamic and intracortical inputs, respectively. Based on the existing data set, we found that a cluster analysis of the dominant late response does not support evidence for subtypes. Our study shows that the answer to the posed question, whether cell type identity translates into functional identity when integrated into a network, appears to be both yes and no. Visual responses to whole-field flashes show likely cell-type specific inputs from the lateral geniculate nucleus, but late responses mediated by intracortical inputs are similar for both types.

Title: Characterization and proposed mechanisms of intermittent oscillations in cerebral cortex

Authors: ***M. HOSEINI**[1], J. POBST[1], W. CLAWSON[2], W. SHEW[2], R. WESSEL[1]; [1]Physics, Washington Univ. In St. Louis, Saint Louis, MO; [2]Physics, Univ. of Arkansas, Fayetteville, AR

Abstract: Rhythmic oscillations are ubiquitous in cerebral cortex and their potential functional roles continue to excite the imagination of neuroscientists. These oscillations are (i) intermittent, are (ii) of variable durations and frequencies, and (iii) typically are accompanied by sparse and irregular single neuron spiking. To our knowledge, no one spiking model has succeeded in capturing these three characteristics of cortical oscillations. What combination of neuronal and network properties mediates the characteristic features of observed cortical oscillations? To address this question, we recorded spontaneous and evoked neuronal oscillations in the visual cortex of turtle. This preparation was chosen because the local field potential (LFP) oscillations generated in this cortex are sufficiently large to allow single-trial analysis of characteristic

features without the need for averaging. We determined the frequency profiles for LFP oscillations, as well as the variability in the amplitude and the frequency of oscillations across trials, recording sites, and visual stimuli. Importantly, we designed a network of spiking model neurons with the objective to investigate model parameter values such that the network reproduces the observed features of cortical oscillations. The primary results of this study are that (a) visually-evoked activity often exhibits very large power increases with peaks in multiple narrow frequency bands, (b) from trial to trial, these peaks in relative power occur among different sets of frequencies within the 0.7 - 100 Hz range, and (c) for individual trials, spectral peaks are often shared among groups of electrodes across the electrode array, but these electrode groups may vary across trials and by frequency. The intermittent oscillations of variable duration and frequencies, accompanied by sparse and irregular spiking were reproduced with a model network consisting of excitatory neurons, and fast and slow inhibitory neurons. Model neurons with spike-rate adaptation were connected randomly to form a sparse network. Our model results indicate that fast interneurons help to keep the balance between excitation and inhibition, while slow interneurons play a critical role in turning off oscillations and causing intermittency. Adding dendritic non-linearity to the model allows for intermittency over a broader range of network parameters and makes the system more robust to noise. Our investigation demonstrates the possibility of generating intermittent and variable gamma-band oscillations in a network with realistic parameters and irregular and sparse single-neuron spiking.

Title: Scale-free cortical resting state activity *in vivo* at single-cell resolution

Authors: *Y. KARIMIPANAH[1], A. C. KWAN[2], Y. DAN[3], R. WESSEL[1];
[1]Washington Univ. In St.Louis, University City, MO; [2]Yale Sch. of Med., New Haven, CT;
[3]Univ. of California, Berkeley, Berkeley, CA

Abstract: Mounting evidence from fMRI, EEG, and LFP recordings of resting state activity *in vivo* reveals a high level of coordination among the neuronal populations at the recording sites and specifically indicates a lack of a characteristic scale in the spatiotemporal patterns of activities. This scale-free nature of cortical activity suggests the attractive hypothesis that the cortex operates near a critical state between order (large-scale activity) and disorder (small-scale activity), which, on theoretical grounds, has long been suggested to be optimized for computation. The coarse spatial resolution (>100 μm) of the fMRI, EEG, and LFP recording methods, raises the question whether the scale-free nature of cortical activity extends to a small cortical volume consisting of some 40 neurons. To address this question, we labeled layer 2/3 cells in the primary visual cortex of urethane-anaesthetized adult mouse by bolus injection of the calcium indicator dye Oregon Green 488 BAPTA-1 AM, used two-photon calcium imaging to monitor ensemble activity, and inferred spikes as described previously (Kwan, Dan 2012). We thus obtained the inferred spike trains of several minutes duration from up to 40 simultaneously recorded neurons in primary visual cortex from 42 mice. Recordings of ongoing cortical L2/3 activity at single-cell resolution revealed pronounced coordinated activity among the population of some 40 closely-spaced neurons. First, temporal correlations for both single neuron and network activity were exposed using the Detrended Fluctuation Analysis, which showed a linear trend for a long range of time windows, indicating the existence of long-term memory. Second, the cross-correlation coefficients among the spike trains of pairs of neurons were generally small with a skewed non-Gaussian distribution dominated by a long tail. Third, correlations in time and among neurons were further revealed using the neuronal avalanche concept. The avalanche size and duration distributions were best fit by a power law function (both truncated and with exponential cutoff), compared to other commonly tested functions (e.g., exponential, lognormal, etc). Fourth, consistent with the properties of a dynamical critical state, the avalanche sizes scaled with avalanche duration. Fifth, a critical model network with synaptic depression qualitatively reproduced the four observed hall marks of coordinated activity. Taken together, the data and model investigations support the hypothesis that the mouse primary visual cortex operates near a critical state including at the cortical microcircuit level.

Abstract: Changes in behavioral or cognitive state have been shown to dynamically modulate the responsiveness of cortical neurons to sensory stimuli *in vivo*. In the mouse primary visual cortex (V1), simple motor behaviors such as locomotion are correlated with increases in visually-evoked firing rates. Recordings of cortical local field potentials (LFP), a measure of population activity, also show alterations in power at certain frequency bands during different states. Under periods of quiet rest or sleep delta oscillations (1 - 4 Hz) are prominent, whereas periods of attentive locomotion are associated with increases in gamma-band (30 - 80 Hz) power. These observations suggest changes in the way information is processed across different states. To investigate the mechanisms underlying these changes we compared the activity patterns of mouse V1 pyramidal cells and parvalbumin-positive (PV+) interneurons, cells characterized by differences in their membrane physiology, during rest and locomotion. Using extracellular laminar recordings and optogenetic tagging we identified PV+ cells and pyramids throughout all layers of V1. Spiking activity and LFPs were simultaneously recorded during periods of quiet rest or locomotion in the absence of visual stimuli. Spectral analysis of the LFPs showed an increase in gamma and decrease in delta power during periods of locomotion across lamina. During locomotion we found a significant increase in firing rate for both cell types across all layers, which was especially pronounced for PV+ neurons. Using pairwise phase consistency we quantified the phase locking of action potentials from each cell type. During locomotion, PV+ cells showed decreased phase consistency at low frequencies and increased phase consistency in the gamma-band. Pyramidal cells showed a weak trend to reduce phase consistency at low frequencies during locomotion, but no changes were significant at any frequency. PV+ cells had significantly more phase consistency in the gamma-band than pyramidal cells during both locomotion and rest. These findings suggest that the phase locking of PV+ neurons may play a

critical role in mediating changes in visual cortical state during locomotion. We are currently addressing the impact of visual stimulation on phase locking behavior.

Title: Locomotion-induced changes in noise correlations in mouse primary visual cortex

Authors: ***B. J. HANSEN**, A. E. CASALE, J. F. MITCHELL, J. H. REYNOLDS, E. M. CALLAWAY;
Systems Neurobio. Lab., The Salk Inst., La Jolla, CA

Abstract: A fundamental question is how changes in behavioral state alter sensory processing in populations of neurons and what individual circuit elements mediate such changes in processing. Work in primates have employed spatial cueing paradigms to show improved signal-to-noise ratios when attention is directed to a stimulus, much of which is due to reductions in noise correlation, reflected in reductions of low frequency power in the local field potential (LFP). In addition, high frequency synchronization has been observed to increase, potentially leading to increases in the gain for downstream neurons. Despite their importance, the mechanisms that generate these changes remain unknown and the tools presently available for use in primates do not provide a means of modulating the activity of neuronal types thought to be involved. In contrast, the set of molecular and genetic tools available in the mouse are revolutionizing the study of neural circuits. Published studies show that locomotion in mice modulates visual processing: when mice are running, there is an increase in gain and changes in the LFP. These changes in processing may reflect improved sensory processing under active conditions, and be similar to the kinds of changes mediated by spatial attention in primates. But it is unknown whether locomotion also affects noise correlations. We tested the functional significance of

locomotion-induced changes in brain state in the mouse primary visual cortex (V1). We investigated whether and how locomotion-induced changes in brain state influence the accuracy of the population code via changes in the structure of correlations across networks in mouse V1. Head fixed mice ran freely on a wheel, while multi-contact laminar probes recorded extracellular activity of visually responsive neurons and LFPs. Cortical layers were identified by measuring the evoked-response potential and computing the current-source density. Visual stimuli consisted of drifting sine-wave gratings for 1.5 s. We examined the state-dependent changes in correlation structure by calculating spike count correlations (rsc) between pairs of neurons during trials when mice were running or stationary. In stationary mice noise correlations were high (rsc= 0.24 ± 0.03; mean ± SEM), similar to values in primates that are not attending a visual stimulus. During running, noise correlations decreased significantly (rsc= 0.07 ± 0.12) similar to the reduction induced by attention in primates. These results, confirmed across our population of 21 neuron pairs, show a remarkable property of decorrelation amongst neurons during a particular brain state, which is likely to strongly impact information coding.

Title: Intermodulation between broad- and narrow-band visual stimuli in visually evoked potential

Authors: *C.-C. CHEN;
Psychology, Natl. Taiwan Univ., Taipei, Taiwan

Abstract: The visibility of a periodic pattern (target) deteriorates when the pattern is embedded in white noise (mask). The conventional interpretation of such noise masking effect is that the external noise perturbs the internal response and thus makes it more difficult for the visual system to separate the target from the noise. Recently, it is also suggested that the noise mask is to suppress the internal response to the target. We investigated the mechanisms underlying noise

masking by observing event related potential evoked by various combination of periodic targets and noise masks. The target was a vertical Gabor patch (1.3cyc/d). The mask consisted of random dots (4'x4' pixel size) whose luminance drew from a uniform distribution. The contrast of the target or the mask was either 0, 6%, 12%, 25% or 50%. There were, thus, 36 target-mask combinations. Each combination was repeated 40 or 80 times for each participant. In each trial, the target and the mask appeared simultaneously for 300ms, followed by a blank period of variable length (mean=2s, sd=.25s). The participants performed an irrelevant attention task by indicating the change of color of the fixation dot (0.1 chance at stimulus onset, 300ms duration). The event-related potential (ERP) was acquired with an EGI 256-channel recorder at 500Hz sampling rate. The waveform was sorted and time locked at the stimulus onset and was band-pass filtered between 0.1 and 50Hz. Our data analysis focused on the P1 (85-115ms after stimulus onset) and P2 (180-220ms) components of the waveforms from the occipital electrodes. A standard equal-variance test failed to find a significant difference between the variances of the amplitude from different conditions. Hence, the hypothetic response perturbation by external noise was not manifested in ERP. The ERP amplitude increased with both target and mask contrasts. However, the target contrast effect decreased with mask contrast, suggesting a suppression of the response to the target by the mask. In P2, the mask contrast effect increased with target contrast, suggesting a lack of suppression on the response to the mask by the narrow-band target. In sum, our result is consistent with the notion that noise masking is due a suppression of the target response mechanism by the noise mask through a broadband contrast normalization process.

Title: The scaling of contrast discrimination under temporal constraints

Authors: *J. R. FLYNN[1], H. SHOUVAL[2];
[1]Neuroscience, Biology, and Anat., Univ. of Texas, Houston, Houston, TX; [2]UT Med. Sch. at Houston, Houston, TX

Abstract: Weber's law is a well-established phenomenon in the field of psychophysics. It states that the smallest detectable change in the intensity of a stimulus is proportional to the original intensity of the stimulus. This level of change is called the Just-Noticeable-Difference, or JND, and the ratio of the JND to the intensity of the stimuli is called the Weber Fraction. What is striking about Weber's law is that it holds for many, if not most, sensory modalities. This near universal feature across the senses suggests that there may be an unknown physiological basis for Weber's law. One model for this physiological mechanism is that innate noise in the firing rates of sensory system neurons may give rise to this linear scaling in perceptual errors. This model can also be adapted to non-linear scaling in pertinent systems. A useful aspect of this model is that, using experimentally determined spike count statistics of the relevant cortical neurons, it makes a very specific prediction on how the Weber Fraction will increase when the presentation time of the stimuli is reduced. It is this aspect of the model that we are testing here. We have chosen to perform the experiment in the contrast domain using sinusoidal gratings, because cortical neurons respond strongly to such stimuli. To determine the contrast JND for a subject, a reference contrast grating is shown, followed by test grating that has a slightly different contrast level. The subject is forced to decide if the test grating has a higher or lower contrast level. This is repeated multiple times, and a Bayesian based adaptive algorithm is used to adjust the difference between the test and reference grating in order to quickly find the JND. Black and white checkerboard masks are placed between the gratings in order to mask after images. Presentation times of the gratings are varied - the stimuli is left on the screen for 50, 75, 100, 125, 150, or 300 ms. We find that, for most subjects, a presentation time of at least 75 ms is necessary for performing above chance. As the presentation time increases further, the Weber fraction decreases until around 200 ms. Presentation times longer than this do not show any further decreases in subjects' Weber Fraction. While this result qualitatively corresponds to the theory being tested, the quantitative relationship between the Weber Fraction and the presentation time was not in line with our theoretical predictions. We suggest several alternative models that are in better agreement with the data.

Title: Population encoding and decoding of visual motion in primary visual cortex from naturalistic visual scenes

Authors: *G. B. STANLEY[1], S. T. KELLY[1], J. KREMKOW[2], J. JIN[2], Y. WANG[2], S. J. KOMBAN[2], J.-M. ALONSO[2];

Abstract: Although the large majority of what we currently know about the functional properties of neurons in the early visual pathway has been learned through the use of highly simplified, artificial visual stimuli, there is a growing body of complementary work involving natural visual scenes. However, the relationship between the classical tuning properties and natural scene responses is far from clear. Specifically, although artificial stimuli such as sinusoidal gratings are a fast and accurate way to capture the response of such neurons to particular single and highly controlled features such as orientation or spatial frequency, even in the simplest of real-world conditions these features strongly co-vary. Ultimately it is unclear how natural scenes, and more importantly the motion within them, are encoded by neuronal populations and how this encoding is transmitted between different brain regions. Using modern computer animation tools, we have created a novel stimulus that mixes natural scene properties (perspective and motion boundaries) with efficient artificial properties (sinusoidal gratings) to capture some of the complexities of the natural visual environment, while still maintaining some simplicity of the classical stimuli. These stimuli were presented to the visual pathway of the paralyzed, anesthetized cat, while recording single- and multi-unit activity in V1 using a multi-electrode array. Through a controlled sequence of navigation of the camera within the synthesized visual environment, we directly assess to what extent neuronal responses are predicted from classical tuning properties in this rich environment. Preliminary results indicate that while some V1 neuron responses are well predicted from classical tuning properties, a large portion are not. The data suggest that one key element is the proximity of the neuron's receptive field to motion boundaries, where there are potentially conflicting inputs to the neuron. The responses of these populations of neurons are, however, predictive of the motion in the scene, when utilized in a population decoding framework. Taken together, the results here suggest that V1 neurons do collectively capture the gross motion in the visual scene, but even simple extensions of traditional stimuli challenge notions of encoding.

Title: Exploring 200-1000 Hz field potentials with microelectrodes, ecog and meg

Authors: *B. F. HANDEL[1], C. A. BOSMAN[2], T. WOMELSDORF[3], P. FRIES[1];
[1]Ernst Strüngmann Inst. (ESI) For Neurosci. In Cooperation With Max Planck, Frankfurt, Germany; [2]Swammerdam Inst. for Life Sci., Univ. of Amsterdam, Amsterdam, Netherlands; [3]Dept. of Biology, Ctr. for Vision Res., York Univ., Toronto, ON, Canada

Abstract: Magnetoencephalography (MEG) has primarily been used to record event related fields or ongoing brain rhythms, both reflecting neuronal population activity, specifically, synchronized post-synaptic potentials (PSPs). This PSP synchrony generates signal power primarily in the classical EEG frequency bands below 200 Hz. By contrast, the individual post-synaptic potential contains power in a broad frequency band, reaching substantially beyond 200 Hz. Interestingly, microelectrode recordings and human electrocorticography (ECoG) recordings show activation-dependent increases in broadband high-frequency (BHF, 200-1000 Hz) power, reminiscent of the PSP spectrum. We explored whether we could trace such BHF power increases from microelectrode and ECoG recordings in monkeys to human MEG recordings. Both monkey and human subjects fixated and monitored a moving grating stimulus while recordings were obtained from visual cortex. Microelectrode recordings in V1 showed stimulus-driven sustained increases in firing rates, narrow gamma-band power and BHF power. The peak BHF power showed trial-by-trial correlations to peak firing rate increases (R=0.48, P=0.1^-10). When signals were first averaged in the time domain and then spectrally analyzed, the BHF component persisted and showed a post-stimulus peak around 100 ms with a similar correlation to firing rates. ECoG recordings showed stimulus-driven sustained increases in narrow gamma-band power and BHF power as well. The signal showed BHF power peaking at a similar latency as the microelectrode data. The ECoG grid covered large parts of the left hemisphere. The topography of BHF power increases was specific to the early visual system. MEG recordings showed stimulus-driven increases in narrow gamma-band power, but only very weak increases in

BHF power. However, when signals were first averaged in the time domain and then spectrally analyzed, there was a BHF power increase with a similar latency as in the microelectrode data and a topography suggesting a focus in the visual system. The BHF component was lateralized showing a higher power contralateral to the visually stimulated hemifield. The fact that the BHF response was visible in the MEG power only after time-domain averaging suggests limitations in MEG signal resolution. Yet, the comparison across the three approaches strongly suggests that MEG reflects in principle neuronal signals up to over 1000 Hz. This BHF signal strongly correlated with spike count and might prove useful in interpreting non-invasive electrophysiological data serving as proxy for spiking activity in the MEG.

Title: Visual stimulation triggers temporally-structured cortical cell assemblies in awake mice

Authors: ***L. CARRILLO**, J.-E. KANG MILLER, J. JACKSON, R. YUSTE;
Biol. Sci., Columbia Univ., New York, NY

Abstract: Although primary visual cortex has been intensely studied in the context of development and experience dependent plasticity, little is known about multineuronal sequential activity patterns during spontaneous network activity that could encode natural visual responses. We used *in vivo* two-photon calcium imaging to record simultaneous activity of hundreds of neurons with single cell resolution in mouse visual cortex. Sequential presentation of natural stimuli defined different network states depicting closed cycles of activity. Network dynamics reliably described the neural correlate of visual stimuli. Without sensory stimulation we observed endogenous generated network dynamics, displaying temporally structured sequential activity patterns showing cell assembly signatures. Cell assemblies have recurrent activity over long

timescales and persist after network perturbations indicating robust neural circuits as the substrate of visual responses. Our results point out that sequential representation of visual percepts use spatiotemporal attributes of imprinted neural circuits opening the possibility to understand the emergent encoding of visual information in a multidimensional cortical space. The connections, modulation and pathological states of these emergent patterns deserve further study since they may reveal general properties of neural networks.

Title: Improved perceptual performance and coding accuracy following optical stimulation of V1 populations

Authors: *A. R. ANDREI, S. POJOGA, R. JANZ, V. DRAGOI;
Neurobio. & Anat., Univ. of Texas Hlth. Sci. Ctr. At Houston, Houston, TX

Abstract: The detection of subtle changes in the environment can challenge the limits of the organism's sensory systems. Studying neural activity and behavior at this sensory limit allows us to titrate out the contributions of unique cellular subpopulations to the formation of sensory percepts. In this study, we used optogenetic methods to investigate how the population activity of glutamatergic neurons in primary visual cortex (V1) impacts an animal's ability to detect near-threshold visual stimuli. We delivered the ChR2 gene to multiple sites in V1 using a lentivirus vector with a CaMKII promoter in two monkeys (macaca mulatta). Starting 4 weeks after the injection, single and multi-unit activity were recorded using laminar electrodes and a custom built laser positioned 0.5mm from the nearest recording site. Monkeys performed a visual detection task - while maintaining fixation, oriented gratings with differing contrast levels were presented parafoveally over the receptive fields of the neurons of interest for 1300 ms. The monkey signaled the presence or absence of a stimulus by releasing or holding a response bar. Half of the trials were paired with simultaneous optical stimulation (20-50Hz, for ~300ms). We recorded a total of 36 sessions, and a total of 473 light-responsive single and multi-units. 22/36

sessions activated neuronal populations closely tuned to the stimulus orientation, while 14/36 sessions activated distally-tuned populations. We found that optical stimulation of populations of excitatory neurons tuned to the visual stimulus resulted in an 8.0% ± 2.2 SEM improvement in behavioral detection of near-threshold stimuli (P=0.0022, Wilcoxon signed rank test). In contrast, optical stimulation of neurons unresponsive to the visual stimuli resulted in no change in task performance. At the neuronal level, while both session types showed robust firing rate augmentation and increases in signal to noise ratio, pairs of neurons from stimulus tuned sessions also showed a significant decrease in noise correlations (P<0.0001, Wilcoxon signed rank test, n=2436 pairs) and increase in coding accuracy following optical stimulation. These effects are unlikely to be caused by phosphenes elicited by optical stimulation as we did not observe changes in the false alarm rates or the percentage of aborted trials due to broken fixations. Our results suggest that the distinction between relevant and irrelevant information used in behavioral decisions is made at an early stage of visual processing and is reflected in differences in stimulus coding at the local network level.

Title: Hidden spatial selectivity of receptive fields in turtle visual cortex

Authors: *J. FOURNIER, C. M. MUELLER, G. LAURENT;
Max Planck Inst. For Brain Res., Frankfurt-am-Main, Germany

Abstract: As the primary cortical recipient of geniculate afferents, the three-layered dorsal cortex (DC) of turtles can be considered analogous to the primary visual cortex of mammals (V1). At a functional level however, this primary sensory area seems to process visual information in a very different way compared to mammalian V1. When stimulated with single flashes of light, DC neurons show wide receptive fields (RFs), generally covering most of the

contralateral visual field with no clear spatial preference. Moreover, thalamic axons projecting to dorsal cortex seem to lack the localized retinotopic arrangement of mammalian thalamo-cortical projections (Mulligan & Ulinski, J.Comp.Neurol. 296: 531, 1990), arguing for a distributed representation of the visual space across the entire dorsal cortex. Here we re-investigated the issue of spatial selectivity of DC neuron receptive fields using white noise analysis. Single units were recorded extracellularly in the dorsal cortex of anesthetized (0.5-1% isoflurane) and paralyzed turtles (Trachemys scripta) and their RFs were mapped with a two-dimensional white noise covering most of the contralateral visual field. Receptive fields were decomposed into 3 different components: a spatially non-selective component, contributing to the evoked response irrespective of the spatial pattern of the stimulus; a linear component, selective to the position and the polarity of contrast changes; and a nonlinear component, also spatially selective but independent of the polarity of the stimulus. Although the spatially non-selective component often dominates over the selective ones, we found localized and spatially structured linear and nonlinear RF components in a substantial fraction of neurons. Some of those RF components revealed alternating ON and OFF sub-regions, reminiscent of the spatial organization of V1 simple RFs, though considerably larger. These spatially selective components of the RF generally extend over large parts of the visual field and their locations can greatly differ between neurons recorded at the same cortical location. These results show that, despite the apparent absence of spatially tuned responses when mapped with single flashes of light, the RFs of turtle visual cortex neurons reveal spatial selectivity once the spatially non-selective component of their response is subtracted. This indicates that spatial information is indeed encoded across the DC neuron population although it is not mapped across dorsal cortex, consistent with the lack of hard-wired retinotopy of the thalamo-cortical afferent projections.

Title: Locomotion and arousal regulate activity patterns and visual encoding in V1

Authors: *M. VINCK, U. KNOBLICH, R. BATISTA-BRITO, J. CARDIN;
Yale Univ., New Haven, CT

Abstract: Neural function depends critically on behavioral state, such as sleep, wakefulness, arousal and focused attention. Previous work in rodents has found that the gain of cortical, but not thalamic, visual responses is strongly modulated by locomotion state (sitting vs. running), and that locomotion enhances area V1 gamma-band synchronization while reducing low-frequency synchronization. It remains unclear whether these changes in cortical state are driven entirely by locomotion or if concurrent changes in arousal contribute to state-dependent shifts in V1 activity. To investigate this, we recorded isolated single units and local field potentials (LFPs) from multiple sites throughout layers 2-6 of V1 in awake mice. Mice were head-fixed and mounted on a wheel apparatus. Visual stimuli of varying contrast were presented, interspersed with baseline periods without visual stimulation. Simultaneous measurement of pupil diameter allowed for a continuous assessment of global arousal levels. Fast-spiking (FS) and regular-spiking (RS) cells were identified based on extracellular waveforms and firing characteristics. Using the statistical method of change-point analysis, we identified transitions between quiet and active behavioral states with high temporal resolution. We found increases in firing rates of both FS and RS cells during locomotion, both in the absence and presence of visual stimulation. Locomotion especially increased the firing rate of cells that were also significantly activated by visual stimulation. Visual stimulation and locomotion caused enhancements of gamma-band synchronization in the same frequency range (~50 Hz). To assay the contribution of arousal to these changes in cortical activity, we studied the temporal trajectories of firing rate statistics and oscillatory dynamics around behavioral state transitions. Overall, we found a tight relationship between locomotion and pupil diameter. However, we also identified an additional behavioral state characterized by high levels of arousal in the absence of locomotion. Arousal-only periods were accompanied by spectral signatures similar to those observed during the locomotion state. We find that arousal explains a substantial amount of variation in firing rate statistics and oscillatory dynamics beyond locomotion state (quiet vs. active), while only a small fraction of the variance in firing rates is explained by locomotion parameters such as speed and acceleration. Our findings suggest that the changes in visual cortical activity associated with locomotion may reflect the combined influence of signals related to arousal and movement.

Title: Effects of locomotion on somatostatin- expressing interneurons in mouse visual cortex

Authors: *M. DIPOPPA, A. RANSON, M. CARANDINI, K. D. HARRIS;
Univ. Col. London, London, United Kingdom

Abstract: An outstanding question in neuroscience concerns how processing in sensory cortex is modulated by multisensory and nonsensory information. In mouse primary visual cortex (V1) locomotion increases visual responses (Niell and Stryker, 2011), and decreases the suppression that cells receive from regions surrounding their receptive fields (Ayaz et al., 2013). Surround suppression has been ascribed to interneurons expressing Somatostatin (SOM, Adesnik et al., 2012), but it is unclear whether locomotion causes their activity to increase (Polack et al., 2013) or decrease (Fu et al., 2014). We asked how the responses of SOM neurons to stimuli of different size are modulated by locomotion. We used 2-photon imaging to record from superficial-layer neurons in V1 of head-fixed mice. Mice were free to run on a spherical treadmill in front of a screen showing drifting gratings within disks of different diameters. Viral expression of GCaMP6 revealed the calcium activity of all labelled neurons in the injection area. To identify SOM interneurons among these, we injected a flex-tdTomato virus into SOM-Cre mice. Cells not expressing tdTomato were unclassified, presumably consisting mostly of pyramidal neurons. Consistent with previous reports (Adesnik et al. 2012), SOM cells integrated over a larger region of space than unclassified cells (preferred size of 30 ± 20 s.d. vs. 22 ± 16 s.d. deg, , N = 24 and 87). Locomotion increased the stimulus-driven activity of all cells (both SOM and unclassified) in response to visual stimuli of optimal size (SOM: +46%, uncl.: +32%). It increased responses of unclassified cells and SOM cells by an approximately equal factor, which depended on stimulus size. Finally, consistent with previous results (Ayaz et al., 2013), locomotion decreased surround suppression in both SOM and unclassified cells. These results indicate that locomotion

enhances the activity of SOM cells. Because SOM cells provide both inhibition and disinhibition to pyramidal cells (Pfeffer et al., 2013), the ultimate effect of this enhancement is yet to be determined. Finally, these results suggest an intriguing hypothesis, that while active behavior affects the firing of different neuronal classes in sensory cortex, the ratio between their activity levels still remains constant.

Title: Stimulus feature selectivity for ultraviolet light in mouse primary visual cortex

Authors: ***Z. TAN**, W. SUN, T.-W. CHEN, D. KIM, N. JI;
Janelia Farm Res. Campus, Ashburn, VA

Abstract: The mouse has become an important model for understanding the neural basis of visual perception. Although it has long been known that mouse retina cones express two types of opsins, with ultraviolet (UV) and visible peak sensitivity, the vast majority of work on mouse visual processing uses visible light stimuli. Consequently, little is known about how UV visual information is processed in mouse brain. Using a custom UV stimulation system and *in vivo* calcium imaging, we characterized the feature selectivity of layer 2/3 neurons in mouse primary visual cortex. In young mice (immediately post-eye-opening), a minority of layer 2/3 neurons respond to UV stimuli, compared to visible stimuli. In adult mice, a comparable percentage of the neuronal population responds to UV and visible stimuli, with similar pattern selectivity and receptive field properties, indicating that UV sensitivity provides an important pathway for mouse vision.

Title: Mapping RFs from chronically recorded low-SNR signals in monkey visual cortex

Authors: E. DREBITZ[1], B. SCHLEDDE[1], D. WEGENER[1], *A. KREITER[2];
[1]Brain Res. Inst., Univ. of Bremen, Bremen, Germany; [2]Univ. Bremen, FB2, Bremen, Germany

Abstract: Chronic recordings with multiple electrodes implanted over extended periods of time are an increasingly important prerequisite for understanding the dynamic mechanisms of distributed parallel processing in multiple brain structures. The same requirement arises for high performance brain computer interfaces resting on detailed information from local sets of neurons with defined response properties. A common problem for such chronic recordings of neuronal responses in higher mammals is the relatively weak signal-to-noise ratio of spiking activity in comparison to conventional recordings with electrodes inserted in each recording session anew. Often, considerable numbers of electrodes show no discernable, or much smaller, spikes than the typical well isolated single unit action potential acquired from an acutely and individually positioned electrode. This raises the question whether other signals than spike trains isolated by thresholding or spike-sorting approaches can be derived from such chronically implanted electrodes and how they compare to characteristic properties of well isolated single or multi-unit spike trains. Here we investigate a signal taking the entire high frequency activity into account [Gail et al. 2000, Cerebral Cortex 10:840-850] instead of individually selected action potentials. We recorded neuronal signals with chronically implanted lacquer-insulated tungsten microelectrodes, utilizing our recently developed miniature microdrives that allow for day-by-day depth adjustment. V1 recordings were carried out in two rhesus monkeys performing a fixation task, using automated mapping procedures to characterize receptive filed (RF) size, orientation selectivity, and direction selectivity. RF properties were investigated for thresholded single- and multi-unit spiking activity, the gamma-band LFP, and the rectified and low-pass

filtered high frequency activity between 350 Hz and 12.5 kHz (RLPF). We found that based on the RLPF-signal, receptive fields could be estimated at many recording sites for which this was not possible based on spiking activity. Day to day comparisons revealed a high reliability and good reproducibility of this signal. Orientation and direction selectivity estimates were in good agreement with the spike signals. In addition, we observed similar results for the RLPF-signal for recordings in areas V4 and MT with acutely inserted electrodes. These findings indicates that the RLPF-signal, which reflects the spiking activity of the population of neurons close to the electrode tip, could be a particularly useful signal in chronic multi-electrode recordings.

Title: Shift and gain of color-tuning in V4 neurons is modulated by hue distribution in natural scenes

Authors: ***P. RAMKUMAR**[1], H. L. FERNANDES[2], M. A. SMITH[3], K. P. KORDING[2]; [1]Physical Med. & Rehabil. and Neurobio., Northwestern Univ., Chicago, IL; [2]Rehabil. Inst. of Chicago and Northwestern Univ., Chicago, IL; [3]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Neurons in macaque area V4 are known to respond selectively to color, but their tuning properties have only been characterized using artificial stimuli. Here, we present a method to characterize their hue-tuning properties from neural activity during the free viewing of natural scenes. Within independently characterized spatial receptive fields (RF) we assume cosine-tuning to hue and orientation, allowing us to fit a generalized linear model (GLM) to spike trains as a function of hue, saturation, luminance (HSL color space representation), and orientation. For each feature, we compare our full model that allows for temporal modulation by that feature as well as a generic response to saccade onset, against a simpler model that only captures the generic saccade response. This approach allows us to identify neurons tuned to each feature. For hue-tuned neurons, we found that both preferred hue and gain were modulated by the local hue distribution (within-RF variance of hue). These results suggest that the tuning curve is not a stationary attribute of a hue-tuned neuron, but is in fact modulated by the statistics of natural scenes during active vision. Our methods allow the characterization of neural tuning properties

under a wide range of conditions, paving the way for a richer understanding of how colors are perceived in natural scenes.

Title: Electrophysiological modulation in an effort to complete illusory figures

Authors: ***M. GIRELLI**[1], T. POSCOLIERO[2];
[2]Neurolog. and Vision Sci., [1]Univ. Verona Dept. Neurolog. and Vision Sci., Verona, Italy

Abstract: Visual completion is a mandatory effortful cognitive operation when we attempt to discriminate illusory figures that miss some substantial parts of their contours. In this cognitive operation a crucial role is played by the Support Ratio (SR): The proportion of the real contour with respect to the total length of the contour of the figure; thus low SRs mean large gaps between successive real parts of the contour. ERPs in humans have revealed that the early negative component N1 (140-190 ms post-stimulus) might represent the cognitive operation leading to the emerging illusory figure by visual completion of the illusory contours. The N1 component has a lateral-ventral-occipital localization in the human brain which reminds a well known area involved in general object recognition i.e. the lateral occipital complex (LOC) encompassing the lateral occipital gyrus and the posterior fusiform gyrus. In this study the SR was systematically varied, across trials, in a discrimination task between illusory figures and figureless percepts in two different experimental conditions. Physical stimulation was kept constant throughout the different SRs in order to elicit the same visual evoked potential in the different experimental conditions allowing to emphasize only the effect of the cognitive operation leading to visual completion of the illusory contours. Behavioral performance of human observers showed that in the low SR trials the reaction times were slow and very similar in the two experimental conditions as if it was very difficult to discriminate the illusory figure from the figureless percept. On the other hand, Medium and high SRs trials showed a significant

difference between the illusory figure and the figureless percept favoring the highest SR trials where the RTs were faster than in the medium and low SR trials. The ERP results were inversely correlated to behavioral results in that the N1 component showed the largest amplitude difference between the illusory figure and the figureless percept in the lowest SR trials with respect to medium and high SR trials, likely representing an effortful cognitive operation. Peak voltages in current source density as well as voltage maps onto the difference waveforms between the ERPs elicited by the illusory figure with respect to the figureless percept in the N1 latency (140-190 ms), were localized in the lateral-ventral-occipital regions of the brain which is perfectly compatible with the LOC localization. Visual completion of an illusory figure, therefore, requires an effortful cognitive operation taking place in the visual system as early as 140-190 ms post-stimulus and likely represented in the LOC of the human brain.

Title: Dual representations of a visual perceptual space

Authors: *J. D. VICTOR, S. M. RIZVI, M. M. CONTE;
Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY

Abstract: A perceptual space is a representation of a sensory domain that serves as a substrate for discrimination, classification, and working memory. Color is a classic visual perceptual space; other well-known examples include visual texture and faces. Representing a perceptual space within biological constraints is challenging, primarily because the number of dimensions needed to describe the space can be very large. Thus, a brute-force approach, in which each region of the perceptual space is independently represented at the neuronal level, leads to a dimensional explosion: the resources required to represent a space grow exponentially with the number of dimensions. Two broad classes of alternative strategies can surmount the dimensional explosion: representations via projections onto coordinates, and distributed representations via broadly-tuned neurons. Here, using the perceptual space of local image statistics as a model, we

present psychophysical studies that imply that both of these strategies are used in parallel. We worked within a perceptual space of black-and-white visual textures, parameterized by their local statistics. Each image statistic (each parameter of the space) corresponded to a type of correlation within 2x2 neighborhoods of pixels. The texture space had 10 such independent coordinates, large enough to make a brute-force representation implausible. Moreover, the space captures many of the informative statistics of natural scenes, as well as the complex interactions of contrast, edge, and corner. In one experiment, we measured the perceptual distances between well-separated points in the space via a boundary salience paradigm (4-alternative forced choice, 4 subjects). We found that along some axes, distant points that were on opposite sides of the origin were perceived as similar. This behavior cannot occur in a coordinate-based representation, but is readily explained by a distributed representation whose resources are concentrated near the origin of the space. In a second experiment, we measured perceptual distances between nearby points in the space via a segmentation paradigm (also 4-AFC, same subjects). We found that thresholds in the space's periphery and near the space's origin were similar. This is inconsistent with the above distributed representation, but is readily explained by a representation based on coordinate projections. In sum, similarity judgments in a visual perceptual space reveal the parallel operation of two representation strategies: a coordinate-based strategy that supports near-threshold judgments and a distributed one that supports suprathreshold comparisons.

Title: Reference frame of the tilt aftereffect measured by Pavlovian differential conditioning

Authors: *Y. NAKASHIMA[1], T. IIJIMA[1], K. TOHYAMA[2], Y. SUGITA[1];
[1]Dept Psychol. Waseda Univ., Tokyo, Japan; [2]Lab. Nano-Neuroanatomy, Iwate Med. Univ., Morioka, Japan

Abstract: It has been reported that tilt aftereffect (TAE) occurs in spatiotopic frame of reference. However, it was claimed that TAE is not spatiotopic but retinotopic. We investigated the reference frame of TAE, employing differential eyelid conditioning paradigm. In conditioning

trials, a vertical or horizontal gabor patch was first presented for 3 s. 500 ms later, a patch tilted clockwise or counterclockwise was presented for 200 ms, one of which (CS+) was always followed by an airpuff, whereas the other (CS-) was not. In test trials, a patch tilted clockwise or counterclockwise was presented for 3 s as an adaptation stimulus. After 500 to 1000 ms inter-stimulus interval (ISI), a vertical test patch was presented for 200 ms. In a full adaptation condition where the adaptation and the test patches were presented in the same position, eye blink responses were observed for the test patch, when the adaptation patch was tilted in the opposite direction to the CS+. The differential responses were also observed in a retinotopic adaptation condition, where the adaptation and the test patches were presented in the same retinal but different screen position. In a spatiotopic condition where the adaptation and the test patches were presented in the same screen but different retinal position, the response was very weak and decayed as increasing ISI. These results indicate that TAE is not only retinotopic but spatiotopic, but the spatiotopic effect is very weak and decays rapidly.

Title: An anisotropic gain control model replicates the orientation anisotropy of overlay masking

Authors: *B. RICHARD[1], A. P. JOHNSON[1], B. HANSEN[2];
[1]Psychology, Concordia Univ., Montreal, QC, Canada; [2]Dept. of Psychology and Neurosci. Program, Colgate Univ., Hamilton, NY

Abstract: The suppressive effect of a broadband, in spatial frequency, mask in overlay masking is anisotropic (Kim, Haun, & Essock, 2010). Suppression is greatest at horizontal, while smallest at oblique orientations. The horizontal anisotropy when the input stimulus is broadband is typically attributed to a cortical anisotropic gain pool that stems from the overrepresentation of horizontally tuned neurons in the striate cortex (Hansen, Haun, & Essock, 2008). Under higher

levels of activity (e.g., broadband input), greater gain adjustments are applied to horizontally tuned neurons than to neurons tuned to other orientations, which results in a reduced sensitivity to horizontal content. A cortical anisotropic gain pool may also explain the horizontal anisotropy witnessed in overlay masking. We developed a network of integrate-and-fire conductance based neurons with properties similar to those of simple cells in the striate cortex, and added an anisotropic gain control mechanism to recreate the horizontal anisotropy found in overlay masking. The network contained a total of 1890 (20% inhibitory) neurons separated into three independent spatial frequency layers (tuned to the same frequency as the target stimulus, plus an octave above and an octave below). Each spatial frequency layer (630 neurons) contained 12 orientations columns (0 - 165°) with an anisotropic population density - with more neurons tuned to horizontal (0°), followed by vertical (90°), while oblique (45°) tuned neurons were least populous. Excitatory synapses between neurons were short-range (+/- 11.5°) while inhibitory synapses were long-range (+/- 45°). Gain adjustments to a high-contrast stimulus within our network involved a feedback inhibitory pool from nearby neurons (+/- 45°), modelled as a shunt conductance, in addition to background synaptic activity (noise). The combination of a shunt and noise has a divisive effect on the slope of firing rates at increasing stimulation intensities, a trademark of gain modulation. External input to the network was a sinusoidal grating, and overlay narrowband or broadband mask, oriented at either 0°, 45° or 90°. The ability of the model to detect a target stimulus was inferred from the firing rate of neurons for mask alone or target plus mask trials. Suppressive anisotropies occurred both under narrowband and broadband masks. Under narrowband masks, accuracy was highest at horizontal and lowest at oblique, the inverse occurred with broadband masks. We found that an anisotropic population density and concordant gain pool can generate suppressive anisotropies, which renders it a likely contributor to the horizontal anisotropy of overlay suppression.

Title: A hierarchical sparse-coding model of natural images explains shape tuning properties in V2 and V4

Authors: *H. HOSOYA[1], A. HYVÄRINEN[2];
[1]ATR Inst., Kyoto, Japan; [2]Computer Sci., Univ. of Helsinki, Helsinki, Finland

Abstract: In light of the tremendously high dimensionality of sensory inputs, a sensible hypothesis is that the sensory cortex might employ a coding strategy that is optimized to the input statistics stemming from the natural environment. Sparse coding and independent component analysis (ICA) are well-known statistical learning models that have successfully explained various properties of V1. However, it is not clear whether this line of modeling can be extended to extrastriate areas and, in particular, direct quantitative comparisons to neurophysiological experiments are rare. Here, we extend existing learning models and investigate the connection to experimental findings on V2 and V4. We trained a four-layer model consisting of a stack of ICA modules, with image patches extracted from natural movies of various types including wild and urban life, sport, documentary, film, etc. After learning, the upper two layers in the model exhibited response properties qualitatively and quantitatively compatible with several major neurophysiological results: 1) Third layer represented subfield orientation integration with a distribution biased to smaller orientation differences consistent with a V2 study by Anzai et al. 2) Third layer further exhibited tuning to angles with response specificity to one componential orientation as in a V2 study by Ito and Komatsu. 3) Fourth layer exhibited tuning properties to position-specific curvatures with a distribution biased to acute convexities as in a V4 study by Pasupathy and Connor. However, inspection of the internal representations revealed that units of these two layers did not quite represent angles or curvatures per se. Rather, the prominent structures of most units were fairly regular, combining local orientations in co-linear or parallel ways, and thus elicited strong responses to rather straight contours or artificial textures. Many units, however, also had quite complicated structure in the detail, combining slightly or largely different local orientations, which often contributed in explaining the angle or curvature selectivities. Taken together, our results offer alternative interpretations to the existing experimental data on shape tuning in the intermediate visual areas.

Title: Lateral interactions in an anisotropic population code for color predict human color induction effects

Authors: *C. KELLNER[1,2], T. WACHTLER[1,2,3];
[1]Biol. II, [2]Grad. Sch. of Systemic Neurosciences, Ludwig-Maximilians-Universität München, Planegg-Martinsried, Germany; [3]Bernstein Ctr. for Computat. Neurosci., München, Germany

Abstract: The perceived color of an object depends not only on the spectral composition of the light reflected from its surface, but also on the visual context such as illumination and background color. Such contextual interactions are thought to underlie perceptual phenomena like color constancy. A possible neuronal basis may be lateral interactions which manifest in contextual influence on the tuning of color-selective neurons in the visual cortex (Wachtler et al., 2003). Here we present a model of cortical color processing that predicts color shifts induced by chromatic backgrounds as observed in psychophysical studies. The model assumes that stimulus hue is encoded by a population of neurons with Gaussian tuning curves and preferences distributed in color space, corresponding to the finding of distributed color preferences in primary visual cortex (Lennie et al 1990). Lateral inhibitory interactions between neurons sharing the same color preferences are modeled by a Difference-of-Gaussian interaction kernel. No interactions between color channels are assumed. Due to the contextual modulation the readout of the population response showed systematic shifts in the encoded stimulus hue when stimuli were presented on colored backgrounds. The induced shifts depended on the distance between stimulus and background hues in colorspace, but were always directed away from the hue of the background. The specific shapes of the resulting induction effects strongly depended on the configuration of the population code, like the density distribution and widths of the tuning curves. Specifically, anisotropic distribution of tuning curves resulted in dependencies of the induction strength and distribution on the location in color space, in line with effects observed in psychophysical studies. The results indicate that important computations in color vision that lead to perceptual hue shifts can be realized using simple neural mechanisms when color is represented by a distributed code. Title: Comparison of spikes versus local field potential (LFP) and its implication on brain computer interfacing applications

Authors: *S. T. KANTH, S. RAY;
Ctr. for Neuroscience, IISc, Indian Inst. of Sci., Bangalore, India

Abstract: Neurons in the primary visual cortex respond preferentially to particular features of the visual stimulus, which allows us to infer the properties of the external world by observing the spiking activity. Because spiking activity is stochastic (often following Poisson statistics), the inference is incomplete when observing a single neuron, but can be improved by pooling the responses of a population of neurons. Previous studies have shown that like spiking activity, the local field potential (LFP) is also feature selective, and therefore the properties of the stimulus can be inferred using the LFP as well. However, single trial estimate of LFP power is extremely variable because of inherent limitations of spectral estimators, which limits its use for detection or discrimination of a stimulus on a particular trial. However, variability can be reduced by averaging the power over multiple frequencies. The overall performance is expected to depend on both the choice of spectral estimator and the frequency band to average. We recorded multiunit activity and LFP from microelectrode arrays implanted in the primary visual cortex of monkeys while presenting a stimulus of variable contrast, explored the choice of spectral estimator and frequency band that can maximize the detectability of the stimulus, and compared the performance of LFPs versus spiking activity. We found that when the stimulus contrast was high (above ~25%) and a salient gamma rhythm was generated, the performance was best when only the gamma range (30-60 Hz) was used for analysis, and this outperformed the spiking activity. At lower contrasts, gamma was weak or absent and did not reveal the presence of a stimulus; best performance was obtained by using the low frequency (<20 Hz) component of the LFP instead. Overall, our results suggest that LFP power in certain frequency bands could be a useful measure for inferring the properties of the external stimulus, which in some cases can outperform the discriminability of spiking activity. These make LFPs a suitable candidate for

brain machine interfacing applications, where changes in signal power due to changes in external stimuli or behavioural state can be used to control a device.

Title: Functional organization of colors, places and faces in alert macaque frontal cortex

Authors: ***M. C. ROMERO**, K. S. BOHON, R. LAFER-SOUSA, B. R. CONWAY; Neurosci., Wellesley Col., Wellesley, MA

Abstract: Both single-unit and fMRI evidence in macaque monkeys shows that frontal cortex contains domains that are biased for face processing. But it is not known whether the analysis of faces represents a special case, or whether frontal cortex is carved up with functional subdomains showing relative specialization for other kinds of visual computations. Such local specialization appears to be found within inferior temporal cortex (IT), a region of extrastriate cortex that plays an important role in high-level visual object perception. Anatomical evidence shows that frontal cortex receives input from diverse subcortical and cortical regions, including a strong projection from inferior temporal cortex. Cumulative evidence suggests that IT comprises a parallel multi-

staged processing network including regions that are functionally biased for faces, along with other regions biased for colors, and other regions biased for places. We sought to address the extent to which the architecture observed in IT extends to frontal cortex. We measured the fMRI response to color gratings, images of familiar scenes, and faces in four passively fixating rhesus macaque monkeys. Stimuli were presented in standard block design; animals were given an intravenous iron contrast agent to boost the fMRI signal. Three different color-biased regions were observed: an anterior patch located in area 12r (found in 7/8 hemispheres tested), a ventral region on the border of areas 12r and 47 (5/8 hemispheres) and a posterior patch in area 8Av in all four monkeys (8/8 hemispheres). These color-biased regions were adjacent and non-overlapping with the previously reported face-responsive frontal patches called PO, PA, and PL. In addition, we found a place-biased region dorsal to the posterior color patches, and not overlapping with the face patches (8/8 hemispheres). The most posterior color-biased, face-biased and place-biased regions were near and may partially overlap with the frontal eye fields. Preliminary results confirm the functional bias within each of the regions defined by an independent data set. These results suggest that the frontal cortex comprises a more precise functional organization than previously recognized.

Title: The cat's curious computation of contrast adaptation and normalization

Authors: ***A. J. KELLER**[1], N. M. DA COSTA[2], K. A. C. MARTIN[1];
[1]Inst. of Neuroinformatics, Zurich, Switzerland; [2]Allen Inst. for Brain Sci., Seattle, WA

Abstract: Sensory neurons encode stimulus intensity in their spike rate and adjust their sensitivity by adaptation. In the visual cortex, adaptation is crucial because the dynamic range of

individual neurons is far narrower than the range of contrasts encountered in natural scenes. The dynamic range is shaped by normalization, which assumes that the output of a large number of excitatory neurons is pooled to provide drive for recurrent divisive inhibition. The normalization model, however, does not explain the slow adaptation, which shifts the contrast response function (CRF) over seconds according to average contrast in the scene. Here we use two-photon calcium imaging of a local network in cat primary visual cortex and found that the neurons exhibit a wide range of CRFs. This effectively extends their collective dynamic range without further adaptation. In addition, however, we discovered that the parvalbumin-expressing neurons and the neurons in the most superficial sites, about half of which were GABAergic, paradoxically increase their activity during contrast adaptation. These neurons may be critical components in the circuits that provide the slower adaptation.

Title: Unfilled hole in the V1 representation of a pure color surface

Authors: *S. ZWEIG[1], R. M. SHAPLEY[2], H. SLOVIN[1];
[1]Bar Ilan University, The Gonda Multidisciplinary Brain Res. Ctr., Ramat-Gan, Israel; [2]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: The perceived color and brightness of a uniform surface can be influenced by its surrounding background. This perceptual phenomenon suggests an interaction between the edges of the surface and its interior. We asked what are the interactions between edges and center responses of chromatic surfaces in the primary visual cortex (V1) and how does it compare with achromatic surfaces responses. To investigate edge vs. center responses, we presented two fixating monkeys with square patches of different sizes. The patches were either chromatic squares (CS) equal in luminance to the surrounding gray background or black and white

achromatic squares (AS) with equivalent contrast to the CS. Using voltage-sensitive dyes in V1, we imaged the evoked neuronal population response at high spatial and temporal resolution. Early responses (within 40-100 ms) evoked by CS and AS were similar and had a "rectangle" like spatial pattern in the imaged cortical area. The responses to the edges of the square were high while weaker responses were observed in its center. However, responses to CS and AS, at later times were different. The population response to the center of the AS showed a slow response increase. Its amplitude at late times (>150ms) was close to the edge response amplitude. Additional analysis suggested that the late AS-response increase progressed from edges to center as if there were a neural filling-in effect. The time required for the center to fill-in increased with the square size. The CS-response in the center, however, did not fill-in; it was edge-dominated at all times for all square sizes. In summary, during early times the spatial patterns of V1 population responses evoked by both CS and AS surfaces were edge dominated. However while the center of AS gradually filled-in later, the responses to CS were maximal at the edge-projections throughout. That is, we observed no color filling-in in V1. We conclude that while chromatic and achromatic surfaces processing in V1 may have different underlying mechanisms, both are sending to higher levels of the visual pathway figures that are edge-dominated.

Title: Characterization of the effects of stimulus size and contrast on the initial afferent response in human primary visual cortex

Authors: *N. GEBODH, M. I. VANEGAS-ARROYAVE, A. BLANGERO, S. P. KELLY; Dept. of Biomed. Engin., The City Col. of New York, New York, NY

Abstract: The early visual system, particularly primary visual cortex (V1), is the most widely characterized part of the cerebral cortex owing to intracranial recordings in animals. In human visual evoked potentials (VEP), the initial “C1” (70-100 ms) component is thought to originate from V1. The latter is based on a line of studies starting with Jeffreys and Axford (1972),

characterizing the systematic shifts in topography with visual stimulus location, which together formed what came to be known as the Cruciform model. Despite this work, the C1 is famously elusive. Due to the anatomy of V1 and the individual differences in the folding of the calcarine sulcus, certain locations of the visual field might not elicit a detectable C1 at all for a given individual, because of the orientation of the portion of V1 that it activates. The location of stimuli in the visual field is therefore critical to be able to elicit and measure the C1. As a result of such signal reliability issues, the sensitivity of the initial afferent V1 response to elementary stimulus parameters such as contrast and size have not been characterized on a level anywhere near as fine as in animal intracranial work. Our aim was to achieve such a characterization by using individualized mapping for robust C1 measurements. We first identified the optimal individual location in the visual field that elicited the largest midline posterior C1 using multifocal, pattern-pulse mapping with m-sequence stimuli at 32 polar angles around the visual field. In a follow-up session, observers maintained fixation at the center of the screen while attending to Gabor stimuli that were presented at the optimal location derived from the multifocal mapping. The subjects' task was to keep track of the number of vertically or horizontally oriented stimuli and report which was the more numerous at the end of each trial. We tested 6 contrasts ranging logarithmically from 3.13% to 100%, and 4 sizes from 1 to 4 degrees of visual angle in diameter. Preliminary data show that monotonic scaling of both the amplitude and latency of the early C1 component as a function of both the contrast and size of Gabor stimuli can be observed robustly on the single-subject basis. Remarkably, for contrasts as low as 3.13% we are able to elicit a reliable C1 based on as few as 100 trials. Beyond the purposes of fundamental characterization, a practical implication of this is that once stimuli are placed so that they project to a cortical locus within the calcarine bank, very low contrasts close to perceptual thresholds can be used to elicit robust C1s just by increasing the size of the stimulus, opening new possibilities for principled studies of early visual perception and attention.

Title: Human contrast sensitivity in naturalistic conditions and the effects of saccadic eye movements

Authors: *O. RUIZ[1], T. R. LII[2], M. A. PARADISO[2];
[1]VCL, Salk Inst. For Biol. Studies, La Jolla, CA; [2]Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: Visual contrast sensitivity is usually studied by flashing simple patterns on blank backgrounds or by having subjects examine charts displaying gratings or optotypes. The use of simplified stimuli without visual context and the possible neglect of normal saccadic eye movements make standard procedures different from natural vision. We investigated whether a more naturalistic test paradigm may yield measurements of contrast sensitivity more reflective of natural vision. This study was motivated by previous data from our laboratory, obtained in macaque primary visual cortex (V1), which showed that V1 responses are lower after saccades across complex scenes compared to responses elicited during steady fixation (vcl.salk.edu/~oruiz). Here, we tested the prediction that the complex scenes and eye movements of natural vision may reduce human contrast sensitivity. We found that human contrast sensitivity is indeed reduced after saccades on complex backgrounds. This post-saccadic suppression occurred in peripheral vision when tested with short-duration stimuli, and extended to foveal vision using exposure times typical of natural fixations. The decrease in contrast sensitivity depended on the visual scale of the test pattern: suppression was larger at low to mid spatial frequencies (1 to 2 cycles/deg) than at higher frequencies (4 to 8 cycles/deg). The post-saccadic reduction of contrast sensitivity was found for both short-duration stimuli and, surprisingly, stimuli presented for 300 ms (a typical fixation duration). Evidently the initial post-saccadic response is critical for the visual system and prolonged fixation cannot compensate for an early response altered by a saccade. We speculate that the initial visual response at the start of a fixation is critical for contrast sensitivity and possibly other aspects of visual perception. Our results suggest that, during natural saccadic exploration, a scene is perceptually high-pass filtered, presumably increasing the salience of foveated details. The basis of post-saccadic suppression appears to be a unique combination of adaptation and surround suppression that depends critically on natural visual input and timing. Our findings suggest a modified form of contrast sensitivity measurement that would be better at predicting real-world visual performance.

Title: Effect of reference scheme on power and phase of the local field potential

Authors: *A. BORTHAKUR, V. SHIRHATTI, S. RAY;
Ctr. for Neurosci., Indian Inst. of Sci., Bangalore, India

Abstract: Spectral domain analyses are powerful tools to interpret brain signals and deduce information about the underlying neuronal networks. These analyses typically estimate the power and phase at different frequencies of the signal. The slope of the power spectral density (PSD) can indicate the noise and filtering properties of the network. Similarly, the phase alignment between two brain areas at particular frequencies has been implicated in neuronal communication. Electrophysiological signals are typically recorded with respect to a reference electrode, which is placed at a location away from the region of interest. However, if this reference wire picks up any activity, the signals recorded from other electrodes may get corrupted. Several different referencing schemes have been proposed to address this issue, such as average reference (where the reference signal is the average of all the electrodes), bipolar reference (the reference electrode is one of the neighboring electrode) and current source density (CSD; for a 2-D array the reference signal is the average of the four neighboring electrodes). For proper interpretation of the spectral measures such as PSD slopes and phase differences/consistency, it is essential to inspect their dependence on the reference scheme. We recorded Local Field Potential (LFP) signals from a 2-D array of microelectrodes chronically implanted in the primary visual cortex of monkeys. After referencing the signals using four reference schemes - single-wire, average, bipolar and CSD, we computed PSD slopes, coherence and phase difference between LFPs as a function of frequency and inter-electrode distances. We found that PSD varied with respect to reference scheme at low frequencies (<100 Hz), but remained unaffected by the scheme at high frequencies. Surprisingly, the mean phase difference between sites were found to be reference dependent and yielded contradictory results for the different schemes: 0º for single-wire, 180º for average reference, and 90º for bipolar and CSD. Analyses of the coherence profile across sites and properties of the spectral estimator explained these results. Our results show that PSD slopes and phase differences are sensitive to different reference schemes, necessitating careful interpretation of these spectral measures to gain insights into the network properties.

Title: New insights from large-scale analysis of colored-sequence synesthesia

Authors: *D. M. EAGLEMAN;
Neurosci., Baylor Col. of Med., HOUSTON, TX

Abstract: Synesthesia is a perceptual condition in which stimulation of one modality triggers anomalous experiences in another modality. For example, synesthetes may experience colors in response to overlearned sequences such as letters, numbers, weekdays and months -- a form we term colored-sequence synesthesia. We here analyzed the data from 6,588 colored-sequence synesthetes rigorously verified using the Synesthesia Battery. We found that even while the colors in an individual's alphabet may be random, there are patterns in the relationship of the colors to one another within the alphabet. For example, while letters later in the alphabet are sometimes reported as having no color, early letters (e.g., A, B, and C) are almost always colored, with colors at the farthest points away from one another in color space. This suggests that synesthesia arises in part as a mnemonic device (perhaps unconscious) that is invested in the initial challenge of learning of sequences. Second, we found that several letter groupings tend to have the same colors (irrespective of what that color is) -- for example, B, P and 8; or E,F, and 3; or H, N, and Z; or L, 7 and T. These color similarities strongly suggest an influence of shape on the color of the letter, possibly belying a clustering of similar shapes on the cortical surface, and a corresponding connectivity of that region to a particular color. Finally, we verified a common observation that the letters I and O, as well as the numbers 1 and 0, tend to be uncolored or white. Is this because 0 and 1 form the beginning of a sequence, or instead because I, O, 1, 0 are natural shapes seen by children well before they learn the meaning of an alphabet? We found that the probability of a letter-color synesthete having uncolored I and O was the same whether or not s/he also had colored numbers -- thus supporting the natural shape hypothesis. We discuss implications for different theories of the neural basis of synesthesia, introducing a new anatomical hypothesis from our neuroimaging of areas involved in overlearned sequences, as well as new data about the heritability of synesthesia in twins. The capacity to perform large-scale analysis of the colors of verified synesthetes is made possible by our laboratory's advances in large-scale, online psychophysical testing.

Title: Orientation anisotropies in human early visual cortex depend on contrast

Authors: *R. T. MALONEY, C. W. G. CLIFFORD;
Sch. of Psychology, UNSW Australia, Sydney, Australia

Abstract: Mechanisms of orientation processing in mammalian visual cortex appear matched to the environment, such that larger populations of cells are tuned to the cardinal orientations (horizontal/vertical) than oblique orientations. Perceptually, this property appears to be manifested in poorer sensitivity to oblique compared to cardinal orientations in a variety of tasks: the so-called *oblique effect*. Some recent functional magnetic resonance imaging (fMRI) studies have however revealed an opposite pattern of anisotropy - namely, an increased response to the oblique orientations over the cardinals: the *inverse oblique* effect. This might reflect efficient coding strategies optimised to the particular diet of orientations encountered during natural viewing. Accordingly, it might be expected that the anisotropies would change as the quality/strength of the oriented stimulation changes. In two experiments, the fMRI blood oxygenation level dependent (BOLD) signal at 3T was measured in functionally-defined visual cortex (n=5 human subjects) as a function of the orientation of a sinusoidal grating, across different stimulus contrasts (10, 30 & 100% contrast in Experiment 1; 3 & 100% contrast in Experiment 2). The results revealed a shift from the previously observed inverse oblique effect at high contrast to an oblique effect at low contrast. In Experiment 1, a significant orientation by contrast interaction was evident only in primary visual cortex. There was a similar pattern in Experiment 2 that extended to subsequent visual areas. The qualitative change in the orientation

anisotropies as a function of contrast is consistent with the idea that early visual cortex adaptively changes its coding strategy as a function of stimulus signal-to-noise ratio.

Title: Slow activity fluctuations alter the decoding strategies of an ideal observer

Authors: ***X. CHEN**[1], M. SANAYEI[1], D. CHICHARRO[2], S. PANZERI[2], A. THIELE[1]; [1]Newcastle Univ., Newcastle Upon Tyne, United Kingdom; [2]Ctr. for Neurosci. and Cognitive Systems, Italian Inst. of Technol., Rovereto, Italy

Abstract: The area under the receiver operating characteristic curve (AUROC) is a widely used measure of the discriminability of neuronal responses to a range of stimuli. It typically involves estimating distributions of activity levels by pooling across multiple trials for each stimulus, yielding an AUROC value which indicates the degree of overlap between these distributions of activity. However, for task paradigms in which the stimuli to be discriminated are presented within the same trial, this pooling process discards valuable trial-wise information which may be used in stimulus discrimination. In this report, we present a novel method of analysis, termed DICAF ('DIfferentiation of Correlated Activity Fluctuations'), which remains robust to inter-trial fluctuations in activity and offers superior discriminability capabilities over the AUROC technique. The DICAF approach is based on a comparison of within-trial activity and a simple calculation of the proportion of trials in which the response elicited by a particular stimulus was higher than that elicited by the other stimulus. We demonstrate that it can be used to extract stimulus-related information from spiking and multiunit data during a contrast discrimination task, and we show how it relates mathematically to the AUROC measure. Neuronal recordings were taken from chronically implanted multielectrode arrays in macaque V1 and V4 while subjects were presented with stimuli of various contrast levels, at peripheral and parafoveal

visual field locations. The DICAF method outperformed the AUROC technique at both the single channel and at the population level. Furthermore, the pooling of data across an ascending number of simultaneously recorded channels was accompanied by a corresponding improvement in signal discriminability.

Title: Encoding of prediction error by complex spikes of the cerebellum

Authors: *D. J. HERZFELD[1], Y. KOJIMA[2,3], R. SOETEDJO[2,3], R. SHADMEHR[1]; [1]Dept. of Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [2]Physiol. and Biophysics, Univ. of Washington, Seattle, WA; [3]Washington Natl. Primate Ctr., Seattle, WA

Abstract: An important hypothesis is that learning in the cerebellum is driven by prediction errors that are communicated via climbing fibers to Purkinje (P) cells, resulting in complex spikes (CSs). However, numerous experiments have found that the probability of CSs does not change as would be predicted by this simple hypothesis. What is encoded by complex spikes? Monkeys were trained to produce saccades to targets in exchange for an applesauce reward. Stainless steel recording chambers placed over oculomotor vermis (OMV) were implanted and single-unit P-cell activity was recorded. In every trial, monkeys made saccades to a target, however in some trials, we shifted the target backwards, producing a prediction error (difference

between actual eye position at saccade end and current target position). Recent work has shown that P-cells in OMV are tuned for the error direction in foveal coordinates. We confirmed these results by observing the probability of CSs in the 200ms following the primary saccade across error direction. Indeed, we found that P-cells (n=20) were highly tuned for error direction, with a tuning width of 74.5+/-7.9° (half width at half maximum height, mean±SEM). Therefore, complex spikes strongly coded the direction of the vector representing prediction error. We tested whether the presence of a CS affected learning from error. In addition, we hypothesized that CSs might signal the appropriate direction of adaptation. To test this hypothesis, we divided our data into the two sets: pairs of trials in which two consecutive primary saccades were in the same direction, or in opposite directions. When two trials were in the same direction, the presence of a CS increased the magnitude of the learning compared to the condition in which a CS was not present (paired t-test, $p < 0.05$). That is, the monkey learned more from the error when CS was present. We noted the opposite trend when the primary saccades in two consecutive trials were in the opposing direction: presence of a CS decreased learning from error ($p < 0.05$). To confirm these results, we compared the probability of CSs across error directions for trials in which adaptation was larger or smaller than the mean adaptation. When adaptation in the P-cell's preferred error direction was larger, so was the probability of CSs. Therefore, at the level of a single P-cell, probability of CS encodes direction of the prediction error vector. When a CS occurs, it drives learning in the direction of the preferred error vector, regardless of the direction of saccade. Learning from error, measured as trial to trial change in behavior, can be predicted as the population coding of this error vector.

Title: Mechanistic underpinnings in the primate saccadic adaptation: A cerebellar standpoint

Authors: M. NEGRELLO[1], G. TESTA-SILVA[1,2], M. JUNKER[3], A. SMILGIN[3], S. HONG[4], E. AVILA[1], P. ROELFSEMA[2], P. THIER[3], E. DE SCHUTTER[4], *C. DEZEEUW[1,2];

Abstract: The cerebellum has crucial roles in adaptation and learning of motor function, and in addition to these roles, its efferents project massively to the spinal cord, basal ganglia, thalamus, midbrain and cortex. These outputs are relayed by Purkinje cells, whose variations in firing rate take the shape of either smooth modulations, or event-like perturbations to its efferent targets. Event like changes are due to pauses in purkinje cell activity, which originate from inhibitory interneurons, complex spike calcium transients or indirectly through glutamate spillover. In motor function, many of the correlates of online behavior have not yet been charted. In particular, a wide body of literature has observed that pauses, seen as reductions of firing rate in peristimulus time histograms will provoke coordinated disinhibition of selected cerebellar nuclear cells, and the contribution of such events are likely to be felt by the cerebellar multiple targets. Furthermore, reductions of firing, and pauses, have since long been observed as the concomitants of motor behavior. In addition, it has also been noted that the onset of pauses is closely linked with onset of behavior. However, the end of pauses, that is, resumption of inhibition of the cerebellar nucleus, has not been thus far linked to motor function, and thus the relevance of pauses to the system have not yet been fully elucidated. While most studies show pauses at the beginning or right before the onset of motion, we are not aware of any study that demonstrated a correlation between the duration of pauses and a specific motion. We have determined that, in primates, the end of pauses in purkinje neurons correlates with the end of the saccadic eye motion (the smooth period between the end of the saccade and the fixation, denominated glissade) which can last for hundreds of milliseconds. We have shown in Vermis lobule VIc and VII, that the end of glissades (when fixation resumes) are a tight correlate of pauses. During saccadic adaptation with an intra-saccadic step, we have verified that the otherwise highly stereotypical saccades are more variable, and that this variability mainly happens at the tail of the saccade. In addition to variations in peak velocity, we have observed substantial alterations of the end of the saccadic profile, the glissadic tail. We have thus set to test the hypothesis that pauses of firing underly motor adaptation in the cerebellum of the primate. Experiments were carried out to (1) verify whether the pause-glissade correlation exists during adaptation; and (2) measure the change of glissade parameters during adaptation.

Title: Transcranial direct current stimulation of the dorsal cerebellum affects saccadic adaptation

Authors: *M. PANOUILLERES[1], C. MIALL[2], N. JENKINSON[3];
[1]Nuffield Dept. of Clin. Neurosci., Univ. of Oxford, Oxford, United Kingdom; [2]Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom; [3]Nuffield Dept. of Clin. Neuroscience, Univ. of Oxford, Oxford, United Kingdom

Abstract: Reactive saccades are fast and highly precise ballistic eye movements that allow us to rapidly redirect our line-of-sight. Sensory-motor adaptation is critical to maintain saccadic accuracy in a dynamic world. Depending of the direction of the error signal, saccadic adaptation can increase or decrease saccades amplitude. Several studies in human and non-human primate have demonstrated that these two processes may be underpinned by different mechanisms, probably relying on partially distinct neural substrates. One area of the brain known to be heavily involved in saccadic adaptation is the cerebellum. Interestingly, a recent patient study has proposed separate cerebellar substrates in the adaptive control of saccade amplitude increase and decrease. The aim of the present study was to assess the role of the oculomotor vermis in saccadic adaptation in healthy human by using transcranial direct current stimulation (TDCS). In different sessions, subjects' saccades were adaptively increase or decrease using the double-step target paradigm. This paradigm consists in jumping the saccadic target to a new location while the eyes are in flight. The consequence of this target step is that at the end of the saccade, there is a discrepancy between the eyes' position and the target position. By repeating this error for about hundreds of trials, the amplitude of the saccades will be progressively lengthened or shortened, depending of the target's jump direction, allowing the eyes to land closer to the new target location. Concurrently with the adaptation paradigm, anodal, cathodal or sham TDCS was applied to the scalp over the dorsal cerebellum. In control sessions, anodal or cathodal stimulation was applied in non-adaptation session, to assess whether TDCS over the dorsal cerebellum in the absence of adaptation could change saccades metrics. Preliminary results showed that anodal or cathodal TDCS over the dorsal cerebellum does not modify saccadic accuracy. However, anodal TDCS tended to slow down both adaptive processes, while cathodal TDCS seemed to boost mainly the adaptive process increasing saccade amplitude. These preliminary results suggest that the dorsal cerebellum could play a similar role in the adaptive lengthening and shortening of saccades.

Title: Contribution of the cerebellar dentate nucleus to the generation of anti-saccades

Authors: *J. KUNIMATSU, T. SUZUKI, M. TANAKA;
Physiol., Hokkaido Univ. Sch. Med., Sapporo, Japan

Abstract: The anti-saccade task has been used to investigate the neural mechanisms of volitional oculomotor control. In this task, subjects suppress saccades to the sudden appearance of visual stimuli (pro-saccade) and make a saccade in the opposite direction. Previous studies have shown that many cortical and subcortical regions play roles in the generation of anti-saccades, including the frontoparietal cortices (Schlag-Rey et al., 1997; Gottlieb & Goldberg, 1999; Condy et al., 2007; Johnston et al., 2014), the basal ganglia (Yoshida & Tanaka, 2009; Watanabe & Munoz, 2009, Phillips & Everling, 2013) and the motor thalamus (Kunimatsu & Tanaka, 2010). The cerebellum is also interconnected with these regions, and in fact, recent imaging studies have revealed the enhanced activity in the cerebellum during anti-saccades (Tu et al., 2006; Jamadar et al., 2013). However, its role in anti-saccades remains unclear. Here, we recorded from single neurons in the cerebellar dentate nucleus in monkeys performing anti-saccades, and examined the effects of local inactivation. Among 28 task-related neurons, more than one third showed greater activity during anti-saccades than during pro-saccades. In the population as a whole, neuronal activity in the dentate nucleus was significantly greater during anti-saccades. In addition to the transient activity associated with saccades, more than half of dentate neurons also exhibited a gradual buildup of activity prior to the target onset. In the population, these preparatory activities were also greater during anti- than pro-saccades. Because the enhanced activity disappeared in erroneous anti-saccade trials, these signals might play a role in suppressing reflexive saccades to the visual stimulus. To examine the causal role, the recording sites were locally inactivated by injecting a small amount of muscimol (5μg in 1μl) in separate experiments. For all 3 sites tested so far, the number of erroneous pro-saccades increased significantly in the anti-saccade trials in either or both directions. Furthermore, the latency of saccades was also altered during inactivation; one site delayed, while the other two sites

shortened anti-saccade latency. Our results show that signals in the cerebellar dentate nucleus do play roles in the generation of anti-saccades. These signals may be sent to the prefrontal cortex or to the basal ganglia via the thalamus. The neuronal processes in the lateral cerebellum through the dentate nucleus to the frontal cortices might be essential for the proactive control of volitional eye movements.

Title: GABAergic innervation of the monkey ciliary ganglion - an electron microscopy study

Authors: M. BARNERSSOI[1], P. MAY[2], *A. K. HORN-BOCHTLER[1];
[1]Inst. of Anat. and Cell Biol. I, LMU, Munich, Germany; [2]Neurobiological and Anatomal Sci., Univ. Mississippi Med. Ctr., Jackson, MS

Abstract: The ciliary ganglion (CG) of vertebrates contains postganglionic, cholinergic neurons that are known to be involved in pathways mediating pupillary constriction and lens accommodation by activation of the sphincter pupillae and ciliary muscle, respectively. CG neurons are controlled by cholinergic and peptidergic afferents that originate from preganglionic motoneurons of the Edinger-Westphal nucleus (EWpg). Recent immunocytochemical studies in avian, rat and monkey ganglia applying antibodies against the GABA synthetizing enzyme, glutamate decarboxylase (GAD) revealed a dense supply of GAD-positive nerve endings targeting a subpopulation of postganglionic neurons. From double-immunofluorescence staining for choline acetyltransferase (ChAT) and GAD there is evidence that these markers co-localize in many afferent terminals within the CG. To extend these findings, we examined the CG of 3 macaque monkeys by using electron microscopy techniques on paraformaldehyde/glutaraldehyde fixed tissue. After embedding in Durcupan, ultrathin sections were processed for GABA post-embedding using immunogold labelling with an antibody to glutaraldehyde fixed GABA.

Ultrastructural analysis revealed numerous GABA-positive terminals present in the CG. Most GABA-positive terminals were observed contacting dendrites in the perisomatic neuropil. A smaller number contacted dendrites in neuropil not associated with specific cells, and a few directly contacted somata. Most somata displayed nearly exclusively GABA-positive or GABA-negative contacts on their membranes or in the perisomatic neuropil. In fact, among these GABA recipient CG neurons, less than 1% of associated nerve endings did not show immunolabeling. Those with GABA-positive contacts represented approximately 25% of all CG cell bodies. Preganglionic terminals were generally large, were filled with clear, spherical vesicles, had occasional dense-cored vesicles, and displayed asymmetric synaptic terminals. The vesicles of GABA-positive terminals appeared somewhat more pleomorphic and the synaptic densities appeared less prominent. A quantitative analysis resulted in 5.1 terminals on average associated with one CG neuron in a given section. In conclusion, a direct synaptic input from GABAergic nerve endings to a subpopulation of postganglionic neurons in the CG is confirmed in primates. This points to the presence of heterogeneity within postganglionic cell population, as only a subpopulation would be modified by the GABA co-transmitter. The function of the GABAergic innervation of the CG remains to be clarified, and the presence and action of GABA-receptors needs to be verified.

Title: Corollary discharge of head motor commands mediates primate gaze control and eye-head coordination

Authors: ***W. ZHOU**[1,2], J. HUANG[1,4], Y. XU[1], I. SIMPSON[1], W. WEI[1], K. KOSEK[3], H. ZHU[1];
[1]Dept. of Otolaryngology and Communicative Sci., Univ. of Mississippi Med. Ctr., JACKSON, MS; [2]Neurol. and Neurobio. and Anatom. Sci., Univ. of Mississippi Med. Ctr., Jackson, MS; [3]Dept. of Ophthalmology, Univ. of Mississippi Med. Ctr., JACKSON, MS; [4]Dept. of Neurophysiol., Sch. of Life Sciences, Univ. of Sci. and Technol. of China, Heifei, Anhui, China

Abstract: Corollary discharge (CD) of central commands is essential for internal models of motor control. However, neural mechanisms utilizing CD remain to be elucidated. Here we show evidence in primate vestibular-oculomotor system that CD of head motor commands supersede vestibular sensory signals for active gaze stabilization (AGS), which is superior to and independent of the vestibulo-ocular reflex (VOR). First, we showed that AGS generates compensatory eye movement that is temporally synchronized with active head rotations with virtually no latency. Since the VOR lags head rotation by ~7ms, AGS is not initiated by vestibular sensory signals, but by the corollary discharge of head motor commands. Second, motor learning experiments showed that the VOR can be independently modified without affecting AGS, indicating that AGS supersedes the VOR, rather than supplement it as presently believed. Third, extraocular motoneurons exhibit different discharge patterns during AGS and VOR, suggesting that motoneurons receive different premotor inputs in the two conditions. Furthermore, we identified a group of neurons near the nucleus prepositus hypoglossi (NPH) that encode active head rotation signals and meet the criteria of mediating AGS. Since all current gaze control models treat the VOR as the sole gaze stabilization mechanism that interacts with saccade system during combined eye-head gaze shifts, these behavioral and neuronal results call for constructing new gaze control models that take AGS into consideration in order to understand the neural mechanisms underlying eye-head coordination in natural conditions (e.g., head unrestrained).

Title: Calretinin-positive neurons within the macaque oculomotor C-group may represent cell bodies of palisade endings for medial and inferior rectus muscles

Authors: *K. LIENBACHER[1], M. MUSTARI[2], S. ONO[2], A. K. E. HORN[1];
[1]Inst. of Anat., Munich, Germany; [2]Dept. of Ophthalmology, Washington Natl. Primate Res. Center, Univ. of Washington, Seattle, WA

Abstract: Extraocular muscles (EOM) are composed of two major muscle fiber types based on their innervation pattern: singly-innervated twitch fibers (SIF) and multiply-innervated non-twitch fibers (MIF). SIFs are controlled by motoneurons within the motonuclei proper, whereas MIFs are supplied from neurons in the periphery of the motonuclei. This population may also house the cell bodies of palisade endings (PE). PEs are associated with MIFs at the EOM myotendinous junction and both are suggested to play an important role in gaze stabilization and eye alignment. Currently, it is unclear, whether the peripheral neurons represent a homogeneous group that give rise to PEs and the multiple endings or whether they represent two groups, MIF motoneurons and PE cell bodies. The C-group at the dorsomedial border of the oculomotor nucleus houses the MIF motoneurons of inferior rectus (IR) and medial rectus muscle (MR). Our discovery that in monkey PEs of the MR and IR express a selective immunoreactivity for the calcium-binding protein calretinin (CR) initiated a systematic study of the C-group for the identification of CR-positive putative PE cell bodies. Macaque monkeys received tracer injections (choleratoxin subunit B or wheatgerm agglutinin) either in the muscle belly or distal myotendinous junction of the MR or IR. Double-immunofluorescence methods were used to identify retrogradely labelled neurons in the C-group and CR expression. After a distal MR injection a considerable number of tracer-labelled CR-positive neurons (up to 45%) was found in the C-group, and only few after a distal IR injection. In general, much less tracer-labelled CR-positive neurons were found in the C-group after a belly injection of IR or MR. No topographical arrangement was found, instead CR-positive and CR-negative tracer-labelled neurons were intermingled with each other at all caudo-rostral planes. The absence of CR in SIF motoneurons goes along with the lack of CR in the central “en-plaque” endings in the SIFs. In conclusion, our study indicates that two different neuron populations are present within the C-group for IR and MR, respectively. CR- positive neurons may represent PE cell bodies and CR-negative MIF motoneurons, respectively. It cannot be ruled out that some CR-positive neurons give rise to PE and multiple endings. The confinement of the CR-expression to PEs of the MR and IR indicate the need for a specific calcium buffer system in these muscles that may contribute to vergence. Malfunction of this system may play a role in strabismus or nystagmus.

Title: Precise control of microsaccades by cerebellar purkinje cells

Authors: *M. A. JUNKER, D. ARNSTEIN, A. SMILGIN, P. W. DICKE, P. THIER;
Hertie Inst. For Clin. Brain Res., Tübingen, Germany

Abstract: Microsaccades, the small saccades made when we try to maintain fixed gaze, were once believed to be inconsequential for vision. However, recent studies suggest that the preferred fixation locus is an order of magnitude smaller than the fovea, and just as macrosaccades serve to bring objects of interest to the fovea, microsaccades bring task-relevant visual targets to the preferred subregion of the fovea (Putnam et al., 2005, J. Vis., Vol. 5; Ko et al., 2010, Nat. Neurosci., Vol. 13; Poletti et al., 2013, Curr. Bio., Vol. 23). It is known that the cerebellum is necessary for precise macrosaccades, so we investigated whether microsaccades may also exploit this neural machinery in order to precisely relocate gaze. We recorded the simple spike discharge of vermal Purkinke cells (PCs) while monkeys made macrosaccades (>1° saccades) and microsaccades (<1° saccades made during attempted fixation). The vast majority increased or decreased their spike rate during macrosaccades compared to the pre-saccade baseline (126/146, 86%). Surprisingly, almost as many PCs modulated their spike rate during microsaccades (119/146, 82%). The simple spike modulation during macrosaccades was systematically related to the modulation during microsaccades. Neurons with a burst (spike rate increase) during macrosaccades usually also responded with a burst for microsaccades, and neurons with a pause (spike rate decrease) during macrosaccades usually also responded with a pause for microsaccades. The timing and direction-selectivity of the discharge were also correlated

between macro- and microsaccades. Many PCs were selective for saccade amplitude, but the preferred amplitudes ranged from the smallest microsaccades to the largest macrosaccades, and the tuning curves indicated a continuous representation of amplitude. Finally, the population average spike rate correlated well with saccade duration across both the macro- and microsaccadic domains. In sum, the oculomotor vermis of the cerebellum is involved in the control of microsaccades in addition to macrosaccades. Recent behavioral studies have shown that microsaccades are not simple "busy work" but are rather directed purposefully in order to scrutinize the fine details of a visual scene. Our findings complement these behavioral studies by uncovering the neural basis of microsaccadic precision.

Title: Neurophysiological and modeling evidence that strabismus is associated with cross-axis oculomotor signals in brainstem

Authors: *M. M. WALTON[1], S. ONO[2], M. MUSTARI[2];
[1]WanPRC, Univ. of Washington, Seattle, WA; [2]Washington Natl. Primate Res. Ctr., Seattle, WA

Abstract: Pattern strabismus is characterized by horizontal and vertical eye misalignments that are correlated with eye position along the orthogonal axis. This is typically considered to be, and treated as, abnormal action of oblique muscles but we do not know whether or how this might be related to disordered brainstem oculomotor commands. A number of studies have reported that saccades are notably disconjugate in both humans and monkeys with strabismus. Postsaccadic

drifts have also been consistently reported. Interestingly, we have found that, for our strabismic monkeys, the horizontal and vertical disconjugacies were correlated with the amplitude of the orthogonal component, suggesting the possibility that this phenomenon might share a common mechanism with “A” and “V” patterns of static fixation. In an attempt to investigate this, we have recorded single units in PPRF (n=60) and nucleus prepositus hypoglossi (NPH, n=10) while strabismic monkeys (one esotrope and one exotrope) made saccades to targets presented on a tangent screen. For both animals, the PPRF recordings revealed an abnormally broad distribution of preferred directions on one side of the brain. An unexpectedly large percentage (20%) of units modulated their activity most strongly in association with the vertical component of the saccade. Preliminary data from NPH suggest that the integration of these disordered saccade velocity commands may cause horizontal eye position signals to become “contaminated” by vertical signals. For 6/10 neurons, the tonic firing rate was significantly correlated with both horizontal and vertical eye position. It has been suggested that the neural integrators in NPH and interstitial nucleus of Cajal (INC) are shared by various oculomotor systems. We suggest, therefore, that pattern strabismus may result from the integration of cross-axis eye movement commands in brainstem. As a predictive guide for future experiments, we constructed a Simulink model by making the following modifications of the Becker and Jurgens (1990) model: 1) the horizontal and vertical burst generator gains differ for the two eyes, 2) the population drive from PPRF and riMLF differ for the two eyes, carrying differently biased cross-axis signals and 3) the neural integrators are partially separate for the two eyes. The model replicated the known aspects of saccade disconjugacy in strabismus, including amplitude and directional disconjugacies (Walton et al., 2014), post-saccadic drifts and a pattern strabismus for static fixation. If this model is correct, future recordings from INC, NPH, and riMLF will reveal cross-axis eye position and velocity signals in strabismic monkeys.

Title: Activity of neurons in brainstem nucleus reticularis gigantocellularis during head-unrestrained pursuit and gaze shifts

Authors: *A. PALLUS[1], M. M. G. WALTON[2], E. G. FREEDMAN[1];
[1]Neurobio. and Anat., Univ. of Rochester Med. Ctr., Rochester, NY; [2]Washington Natl. Primate Res. Ctr., Univ. of Washington, Seattle, WA

Abstract: The nucleus reticularis gigantocellularis (NRG) has been shown in cats to contain neurons with activity related to head movements made during gaze shifts (Isa and Naito 1995). Although recordings from individual neurons in primates have not been reported, microstimulation of the NRG in rhesus monkeys has been shown to produce a variety head movements (Cowie and Robinson 1994). The rostral portion of the NRG (rNRG), in particular, produces horizontal head rotation ipsilaterally when stimulated (Quessy and Freedman 2004), and likely participates in generating head movements during gaze shifts (Freedman and Quessy 2004). When the head is not restrained, monkeys make head movements that contribute to both saccadic gaze shifts and smooth pursuit, yet these behaviors are controlled by separate neural circuitry. It is unknown whether individual neurons in the NRG drive head movements associated with these very different eye movements. The purpose of this experiment, therefore, was to investigate the activity of single units in the rNRG of rhesus monkeys during horizontal head movements contributing to these different behaviors. We recorded from neurons in the rNRG in two rhesus monkeys while they performed both horizontal delayed gaze shift and head-unrestrained pursuit tasks during each recording session. Neurons with task-related activity were chosen for further analysis. Most of these were observed to have greater firing rates during movements in one horizontal direction (the preferred direction). By controlling the initial positions of the eyes in the orbits, we were able to observe a wide range of head movements associated with identical gaze movements, allowing us to dissociate gaze, eye and head kinematics. We determined that the observed task-related activity was best correlated with head velocity. The correlation between firing rate and head movement was observed during both behavioral tasks. Despite this, small but statistically significant differences were observed in this correlation between movement types. In addition to head velocity-related activity, some neurons also showed activity related to eye position, which was especially evident when gaze was stationary.

Title: Structure/function of precerebellar eye-velocity sensitive neurons in the caudal hindbrain of larval zebrafish

Authors: *C. L. GROVE[1], M. LEE[2], R. BAKER[1], E. AKSAY[2];
[1]Physiol. and Neurosci., Physiol. and Neurosci., NYU Sch. of Med., New York, NY; [2]Inst. for Computat. Biomedicine and the Dept. of Physiol. and Biophysics, Weill Cornell Med. Col., New York, NY

Abstract: Adaptations enabling precision in oculomotor behavior depend upon interactions between Purkinje cells and premotor neurons that provide mossy fiber inputs to the cerebellum. In *hoxb4a:yfp* zebrafish, a prominent mossy fiber projection arises from rhombomeres 7 and 8 in the caudal hindbrain. Here we examined the structure/function relationships in this brain region associated with a group of cells, termed eye-velocity sensitive neurons (VSNs), which are believed to be involved in generating (and perhaps storing) appropriate slow-phase eye-velocity command signals from visual and vestibular inputs (Beck et al., 2006). VSNs were identified using two-photon calcium imaging in 5-9 day post fertilization *vglut:dsRed* zebrafish. As previously observed for VSNs of adult goldfish, neuronal activity correlated with changes eye velocity, but showed little sensitivity to position, fast phase responses, and spontaneous saccades. The majority of VSNs were dsRed positive and mapped to the portion of the glutamatergic scaffold associated with *alx* (~33%) and *dbx1b*(~48%) transcription factors. Subsequent electroporation of VSNs revealed at least two distinct morphologies. Cells along the *alx* domain projected ipsilaterally, whereas those along the *dbx1b* domain projected across the midline. In both cases, cells projected to the cerebellum, consistent with an excitatory mossy fiber identity. These data help specify links between the molecular, genetic, structural, and functional properties of VSNs, a prominent precerebellar neuronal group that may play an important role in velocity storage and oculomotor plasticity.
