Title: The organization of extraocular muscle motoneuronal pools in the mouse

Authors: *M. O. BOHLEN[1], S. WARREN[2], R. BLUMER[3], J. F. STAHL[4], P. J. MAY[2]; [1]Psychiatry and Human Behavior, Program In Neurosci., Jackson, MS; [2]Dept. of Neurobio. & Anatom. Sci., Univ. of Mississippi Med. Ctr., Jackson, MS; [3]Ctr. for Anat. & Cell Biology, Integrative Morphology Group, Med. Univ. of Vienna, Vienna, Austria; [4]Neurol. Division, Cleveland Dept. of Veterans Affairs Med. Ctr. & Dept. of Neurol., Case Western Reserve Univ., Cleveland, OH

Abstract: While frontal-eyed animals, particularly monkeys, have been the model of choice for oculomotor research, recent advances in the use of genetic manipulations in the mouse has increased the importance of this rodent model for vision-related research. To undergird this approach, it is necessary to define the basic parameters of the mouse oculomotor system and plant. Towards this end, we have investigated the distribution of motoneurons supplying the extraocular muscles using two mouse strains: C57BL/6 (n=5) and 129S1/Svlm (n=7) by intramuscular injections of WGA-HRP. Histologically, the abducens nucleus (VI) is represented by a cluster of neurons ventromedial to the facial nerve, and the trochlear nucleus (IV) lies in a depression in the medial longitudinal fasciculus (MLF), immediately caudolateral to the oculomotor nucleus (III). While III maintains its relationship with the MLF, it sits as separate nuclei, with small non-motoneurons lying between the two sides. Injections of the lateral rectus muscle labeled cells within the confines of ipsilateral VI. Injections of the superior oblique muscle labeled cells in contralateral IV. Injections of the inferior oblique muscle labeled cells in ipsilateral III, located predominantly rostrally. The pool forms a comma shaped cap on III rostrally, but hooks medially as the column extends caudally, so that it occupies most of the medial edge of the nucleus. The labeled inferior rectus motoneurons were most common in the middle of the rostrocaudal extent of ipsilateral III. Labeled medial rectus motoneurons were found predominantly rostrally in ipsilateral III. They filled the rostral pole of the nucleus, and

extended ventrolaterally, adjacent to and sometimes within the MLF. Labeled superior rectus motoneurons were predominantly located caudally in contralateral III. They filled the mediolateral extent of III, and also extended into the MLF. A few labeled cells were found on the opposite side for many of the muscle injections. This general pattern of muscle-related motoneuronal pools is broadly similar to that observed in other mammals. The areas of the multipolar labeled motoneurons ranged in size from 75 to 490 square μm, with a mean of 243. Examination of the muscles themselves, using anti-neurofilament protein for nerve fibers and anti-synaptophysin for contacts, reveals that mice lack palisade endings at the muscle-tendon interface. However, they do display both multiply and singly innervating forms of motor axons. In light of the large range of cell sizes and the presence of two axon types, further investigation is needed to determine whether two morphologically distinct populations of motoneurons are present.

Title: Independent active contractile mechanical behavior of bovine extraocular muscle(EOM) compartments

Authors: *A. SHIN, L. YOO, J. DEMER*;
UCLA / JSEI, Los Angeles, CA

Abstract: Intramuscular innervation of horizontal rectus EOMs is segregated into superior & inferior (transverse), compartments while all EOMs are also divided into global (GL) & orbital (OL) layers with scleral & pulley insertions, respectively. Mechanical independence between both types of EOM compartments has been demonstrated during passive tensile loading (Shin et al., Invest. Ophthalmol. Vis. Sci. 53: 8414-23, 2012.) We examined coupling between EOM

compartments during active, *ex vivo* contraction. Specimens of the 6 anatomic EOMs were removed from fresh adult bovine orbits, and parts of the tendon end of each EOM were attached to two independent Grass strain gauges. EOMs were immersed in 50 mM CaCl2 labeled with sodium fluorescein dye and warmed to 37°C. One compartment was coated with hydrophobic petrolatum to avoid permeation, and contraction was induced by CaCl2 in the other compartment while tensions in both channels were monitored. Control experiments omitted petrolatum, so that the entire EOM contracted. After physiologic experiments, EOMs were sectioned transversely to demonstrate specificity of CaCl2 permeation by yellow dye fluorescence excited by blue light. In control experiments without petrolatum, both transverse and GL/OL compartments contracted similarly. Contraction forces by 300 s were typically 6 gm in both transverse compartments, and 2.5 gm in GL and 1.5 gm in OL (GL is larger than OL). Selective petrolatum coating caused markedly independent compartmental contraction whether measured at the OL vs. GL insertions, or for transverse compartments at the scleral insertion. In the first 100 s, force decreased in the petrolatum-coated compartment, while increasing in the other compartment. While some CaCl2 spread occurred after 100 s, force coupling for 5 specimens still averaged only 10.5±3.3% and 6.0±1.5% in GL/OL and transverse compartment experiments, respectively. Typical contraction forces were 250 & 30 mg in GL & OL compartments, and 320 & 18 mg in superior & inferior compartments with coated OL and inferior compartments. Fluorescein penetration confirmed selective CaCl2 permeation. This experiment confirms findings of mechanical independence of EOM compartments, and extends results to active contraction. EOMs behave actively as if composed of mechanically independent parallel fiber bundles that have different insertional targets, and so differing mechanical actions, endowing each EOM with potential for separately controllable actions as proposed in the active pulley & transverse compartmental hypotheses.

Title: Synchrony in the macaque brainstem: Oculomotor system

Authors: ***A. DALE**, K. E. CULLEN;
Physiol., McGill Univ., Montreal, QC, Canada

Abstract: The brain employs a variety of strategies for encoding signals in an ensemble of neurons, and this can be observed by investigating the collective output of a population. For example, burst-tonic neurons in the nucleus prepositus integrate burst inputs encoding eye velocity to provide abducens motoneurons with an eye position signal. The generation of this signal occurs within the nucleus prepositus itself, and is likely accomplished through local feedback loops as suggested by single-unit characterizations (Delgado-Garcia et al. 1989) and labeling studies (Escudero et al. 1992). If this is the case, then the ensemble of burst-tonic neurons should exhibit correlated activity. To obtain direct electrophysiological evidence of local connections between neurons, we simultaneously recorded pairs (n=29) of burst-tonic neurons in the nucleus prepositus of rhesus macaque monkeys using 8-channel linear microelectrode arrays. We then computed cross correlations between their spike trains during fixations at different eye positions. We found that cross correlations between burst-tonic neurons corresponded to increased coincident firing during ipsilateral fixations, which reflects the eye position sensitivity of the neurons. By accounting for the expected chance level of correlations between the two neurons in a pair, however, we found that burst-tonic neurons also exhibited positive excess synchrony, and that this excess synchrony displayed a decreasing trend with increasing eye position. These results suggest that burst-tonic neurons receive common, synchronizing input and that there is a functional change in that input during the encoding of different eye positions. Interestingly, we lastly found that the magnitude of positive excess synchrony also decayed exponentially with increasing distance between neurons (inter-channel spacing), which provides insight into the anatomical range of projections within the nucleus prepositus. When we performed the same analyses on pairs of vestibular nuclei neurons or of their afferent inputs, we found no excess synchrony between any pairs either during spiking at their resting rates or during vestibular stimulation at various frequencies and with different behavioral goals. We interpret these findings to suggest that higher-order processing of self-motion signals is achieved by pooling the independent outputs of multiple neurons. Together, our results reveal contrasting strategies - synchrony in the oculomotor system and independence in the vestibular system - by which ensembles of neurons achieve accurate downstream function.

Title: High poisson ratio of contracting human superior rectus muscle indicates reverse compressibility

Authors: *L. H. YOO, R. CLARK, A. SHIN, J. L. DEMER;
Ophthalmology, UCLA, Los Angeles, CA

Abstract: A fundamental parameter describing the mechanical behavior of any material is the PR, the ratio of transverse to axial strain, i.e., the ratio of change in cross sectional area to change length during uniaxial loading. Measurement of the PR requires accurate 3-D determination of specimen dimensions, typically by quantitative imaging during changes in mechanical loading. During passive, *ex vivo* tensile elongation, computed x-ray tomography showed the PR of bovine extraocular muscle to be ~0.45 (Kim et al., BioMed. Res. International, 2013), but optical coherence tomography demonstrated the PR of extraocular tendon to slightly exceed the ideal incompressible value of 0.5 (Shin et al, ARVO, 2013). A remarkably high PR of 2.88 has been reported for sheep flexor tendon (Lynch et al., J Biomech Eng, 2003). Since the PR of contracting extraocular muscle (EOM) is unknown, we used magnetic resonance imaging (MRI) to determine the PR of the living human SR whose axial dimension changes physiologically during vertical gaze change. Surface coil MRI of 8 orbits of 4 normal adults was performed in ~20 deg target-controlled up and down gaze positions to obtain sets of 20 contiguous images 2 mm thick in quasi-coronal planes perpendicular to the long orbital axis of each orbit at 312 micron resolution. SR length change from computed up to down gaze positions were obtained from reconstructed sagittal images. The SR was outlined in each coronal image plane to obtain the area centroid, and the cross sectional area, and areal strain by Green's theorem. To correct for path curvature, centroids were sequentially aligned to straighten the SR for analysis. EOMs were then discretized into elements 10-20 microns long. Changes in longitudinal thickness of each element were determined to calculate strain. Mean SR volume significantly increased by 24% from down to up gaze ($P<0.005$). The mean PR from discretized 3-D models for every microscopic element in the 8 SRs was 0.76±0.06 (SD), markedly exceeding the incompressibility criterion of 0.5. A material having a PR <0.5 is said to be compressible. However, the much higher PR value for the SR muscle implies that its total volume in the active contraction significantly exceeds that in relaxation, a behavior termed reverse compressibility. Heretofore demonstrated for tendons, reverse compressibility of EOMs would strongly impact accuracy of finite element analysis simulations of EOM cooperative biomechanics and also provides a strong rationale for use of EOM volume metrics as functional indices of contractility.

Title: Magnetic resonance imaging (MRI) demonstrates differential compartmental function in the superior oblique (SO) muscle during vertical fusional vergence (VFV)

Authors: *J. L. DEMER[1], R. A. CLARK[2];
[1]Jules Stein Eye Inst., Jules Stein Eye Inst., LOS ANGELES, CA; [2]Ophthalmoloyg, Univ. of California Los Angeles, Los Angeles, CA

Abstract: Slight vertical binocular misalignment is normally compensated by VFV. In light of recent findings suggesting potential for differential control of SO neuromuscular compartments preferential for infraduction vs. incycloduction based upon scleral insertion site, we employed MRI to clarify the SO contribution to VFV induced by a 1° base up prism before one eye of 6 normal young adult subjects binocularly fusing an accommodative target 20 cm distant. Viewing through such a prism requires 1° infraduction, without eye rotation by the aligned fellow. Scans were repeated without prism, and with prism shifted to the opposite eye. Contractility, indicated by change in extraocular muscle (EOM) posterior partial volume, was separately analyzed in the medial (equatorial insertion, torsion) and lateral (posterior insertion, vertical) SO halves, and the superior vs. inferior horizontal rectus EOM halves. Notwithstanding anatomical evidence against compartmentalized intramuscular innervation in vertical rectus EOMs, the medial and lateral halves were separately analyzed as a control. In the infraducting eye that viewed through prism, the medial (torsional) SO half significantly relaxed by 7.4±2.1% (SEM, $P<0.005$), while the lateral (vertical) half did not change. In the aligned eye, the lateral (vertical) SO half contracted significantly but paradoxically by 7.2±2.7% ($P<0.025$), while the medial (torsional) half did not change. The vertical component of VFV was implemented mainly by the inferior rectus (IR), whose medial and lateral halves contracted similarly ($P>0.3$) by 3.3±0.9% in the infraducting eye, but paradoxically relaxed by 2.1±1.0% in the aligned eye; the interocular difference was significant ($P<0.0001$). There was no significant contractility either the medial or lateral halves of the superior rectus in either the infraducting or aligned eye ($P>0.4$). There was also no significant contractility of the inferior or superior halves of the medial rectus in either the infraducting or aligned eye ($P>0.5$). However, there was similar ($P>0.1$) contraction in both the superior and inferior lateral rectus (LR) halves that was significantly greater in the infraducting

(4.9±0.2%) than aligned eyes (-0.9±2.0%, P<0.01). We conclude that VFV is associated with striking differential SO compartmental activity: relaxation limited to the medial SO of the infraducting eye would promote excycloduction, but contraction limited to the lateral SO of the aligned eye would promote infraduction without cycloduction appropriate to balance supraduction from IR relaxation. This pattern suggests that the SO overrides balanced binocular vertical vergence commands to the IR.

Title: Preferential expressions of specific nicotinic receptor subtypes are different in neurons exhibiting distinct neurotransmitter phenotypes in the medial vestibular and prepositus hypoglossi nuclei

Authors: ***Y. ZHANG**, Y. YANAGAWA, Y. SAITO;
Genet. and Behavioral Neurosci., Gunma Univ. Grad. Sch. of Med., Maebashi, Gunma, Japan

Abstract: Neurons in the medial vestibular nucleus (MVN) and prepositus hypoglossi nucleus (PHN) receive cholinergic inputs from the pontomesencephalic reticular formation. Such inputs are thought to play important roles in horizontal eye movements. In our previous studies, we found that cholinergic responses mediated via nicotinic ACh receptors (nAChRs) were larger than those mediated via muscarinic ACh receptors (mAChRs) in cholinergic neurons that projected to the cerebellum. In this study, we clarified whether the expression patterns of ACh receptors are different in neurons exhibiting distinct neurotransmitter phenotypes. Individual neuron types such as cholinergic, GABA/glycinergic, and putative glutamatergic neurons were identified using specific transgenic rats and cholinergic responses to the puff application of ACh in these three neuron types were investigated using whole-cell recordings in brainstem slices. We

found that the nAChR-mediated currents were also larger than mAChR-mediated currents in all these three types of neurons. To focus on the nAChR-mediated currents, we isolated the currents from mAChR-mediated currents by the application of atropine. We detected three types of nAChR-mediated current responses that exhibited the distinct activation and desensitization kinetics and therefore designated them as fast, slow, and fast & slow types. The fast type was found to be a preferred response in both MVN and PHN GABA/glycinergic neurons, while the slow type was a preferential response in both MVN and PHN glutamatergic neurons. The cholinergic neurons showed no preferred response type. Pharmacological analyses revealed that the fast, slow, and fast & slow types were mainly mediated by α7, non-α7, and both α7 and non-α7 nicotinic receptors, respectively. These findings suggest that MVN and PHN neurons express nAChRs predominantly and show three distinct current responses dependent on the expressions of α7 and/or non-α7 receptors. Furthermore, the preferential expression pattern of the nAChR subtypes may be different in the neuron types.

Title: Activities of premotor extraocular neurons during rapid eye movement (REM) sleep

Authors: *M. ESCUDERO, L. C. CERVANTES, A. SANCHEZ-LOPEZ;
Univ. of Seville, Seville, Spain

Abstract: REM sleep is mainly defined by rapid eye movements, high frequency and low amplitude EEG waves and a decrease or absence of muscular tonus interrupted by twitches. We recently showed that rapid eye movements mainly occur in the abducting direction of the horizontal plane and are generated by the activity of abducens motoneurons. Although it is now know that abducens motoneurons display a tonic inhibition interrupted by phasic activities timely

associated with ponto-geniculo-occipital (PGO) waves, the source of their premotor activities remains unknown. Now we characterized the activity of premotor extraocular neurons. Six cats were prepared for chronic recording of eye movements and unitary activities. Eye movements were recorded by the scleral search coil technique. Premotor neurons were identified by its localization with respect to the abducens nucleus, its activity during wakefulness and/or its antidromic activation from the abducens nucleus. We recorded burst neurons from the reticular formation related to the generation of saccadic eye velocity; and, from the medial vestibular and prepositus hypoglossi nuclei related to the generation of eye position signals. Burst neurons showed coherent activities with the phasic events during REM sleep. Vestibular neurons showed a decrease in their mean tonic discharge but remained active during REM sleep. Prepositus hypoglossi neurons displayed phasic and tonic discharge patterns during REM sleep similar to that showed during wakefulness. Almost all neurons showed phasic inhibitions or activations in association with PGO waves. As conclusion, the premotor extraocular system seems to be not inhibited during REM sleep but its activity is not conveyed to the eye due to the inhibition of the extraocular motoneurons. Although the inhibition of the motor output during REM sleep prevents the interpretation of the oculomotor activities, the study of premotor extraocular neurons could be used as a tool to analyze dreams imagery.

Title: Central neural processes in mouse vestibular system

Authors: ***N. SHIMIZU**[1], S. WOOD[2], A. PERACHIO[1], R. COOK[1], T. MAKISHIMA[1]; [1]Univ. of Texas Med. Br., Galveston, TX; [2]Azusa Pacific Univ., Azusa, CA

Abstract: Background The central vestibular system plays an important role in higher neural functions responsible for self-motion perception and spatial orientation. The velocity storage mechanism (VSM) is one such function used to store head angular velocity. For more than three decades, VSM has been thoroughly investigated across a wide range of species. Although

numerous studies on VSM has been done in other mammalian species, very little known is known regarding that of mice. One of the reasons why the mouse is understudied is because the mouse lacks optokinetic after-nystagmus or a dominant time constant of vestibulo-ocular reflex under traditional rotational paradigms, which are frequently used to evaluate VSM. Therefore, we sought to establish new stimulus paradigms to examine the eye movements related to VSM and to verify its characteristics in mice. Methods Wild type C57BL/6J mice were used. We used a novel stimulus paradigm, pseudo off-vertical axis rotation (pOVAR), which consists of dual yaw axis rotations to generate a similar rotating gravity vector as a traditional off-vertical axis rotation (OVAR) but with a larger resultant gravito-inertial force (1 g). In pOVAR, the semicircular canals do not respond to the ongoing constant rotation, while the otolith organs are activated by the rotating vector around the subject. To study the relationship between the induced eye movements during pOVAR and the central neural processes, we further investigated the effect of baclofen, a GABA B receptor agonist, which is known to reduce the central activities of the oculomotor and the vestibular systems. Results Similar to previously reported OVAR experiments, there were two components in the steady state eye movement during pOVAR: 1) a bias component, and 2) a modulation component. During OVAR, each response is considered to be generated by two different mechanisms; for the bias component, the VSM is responsible, whereas modulation components arise predominantly through linear VOR orientation mechanisms. Baclofen significantly reduced the bias component indicating that the drug affected the central neural processes. Conclusions We revealed the dynamic characteristics of mouse eye movements during pOVAR. The findings suggest the mouse also has a process in the central vestibular system working as the primitive VSM, similar to that of other mammalian species.

Title: Connectivity underlying persistent firing in zebrafish

Authors: *A. VISHWANATHAN[1], K. DAIE[2], A. RAMIREZ[2], A. SHOWLER[2], E. AKSAY[2], S. SEUNG[3];
[1]BCS, MIT, Cambridge, MA; [2]Dept. of Physiol. and Biophysics, Weill Cornell Med. Col., New York, NY; [3]Princeton Neurosci. Inst., Princeton, NJ

Abstract: The ability to hold one's eyes at a particular location requires a command signal to hold the eye at a desired position, the effort of will according to von Helmoltz. This signal is generated by the oculomotor neural integrator, which temporally integrates upstream eye-velocity signals to eye-position commands. Previous work has led to the hypothesis that recurrent interactions between integrator neurons are essential for generating persistent firing and that this persistent neural activity encodes the eye position. However, little is known about the precise patterns of connectivity mediating temporal integration in this system. To better understand the connectivity of this circuit, we performed two-photon calcium imaging of the larval zebrafish integrator during spontaneous eye movements followed by serial electron microscopy in the same animal. To date, we have imaged at a nominal resolution of 5 nm in x-y and 45 nm in z a volume of the caudal hindbrain that includes ~1/4 of the integrator population and a motorneuron subgroups to which they project. Preliminary reconstructions of functionally-identified integrator cells reveal two morphological classes, one cell type with an ipsilaterally-projecting axon and widely- ramifying dendritic arbor, and a second cell type with a contralaterally-projecting axon and relatively compact dendritic arbor. Additionally, we observe somatic gap junctions, numerous axo-dendritic synapses, and notable heterogeneity in the sizes of presynaptic vesicles. Detailed reconstruction and annotation of this data set promises insights into the microcircuitry underlying temporal integration.

Title: Modeling of network neuronal processing in the central vestibular nuclei

Authors: *D. OGORODNIKOV[1,2], C. C. D. SANTINA[3], J. N. ERON[4];
[1]Mount Sinai Sch. Med., NEW YORK, NY; [2]FNND LLC, Elmwood Park, NJ; [3]2Department Otolaryngology Head-Neck Surgery, Johns Hopkins Sch. of Med., Baltimore, MD; [4]3Inst. of Higher Nervous Activity and Neurophysiol. of RAS, Moscow, Russian Federation

Abstract: The neural network underlying the vestibulo-ocular reflex (VOR) is considered to include a *fast* component (mediated by a *direct pathway* including second order eye movement related neurons in the vestibular nuclei (VN)) and a *slow* component (mediated by an *indirect pathway* via vestibular-only (VO) neurons in VN). While the neural basis of fast/direct component VOR is well understood, neuronal mechanisms underlying the slow/indirect component, which involve neural circuits mediating the velocity storage mechanism, remain unclear. Recent evidence suggests that the efferent vestibular system may be involved in changing excitatory influences to central vestibular neurons that encode the slow component of VOR. In the present study, we analyzed the VOR slow component of horizontal eye movements tested in five monkeys (three *Macaca fascicularis* and two *Macaca mulatta*) and nine mice (six C57BL6 wild-type vs. three $\alpha 9^{-/-}$ mutant mice) to estimate network neuronal processing in the vestibular nuclei. Measured time constants of horizontal VOR responses and neuronal activities of central vestibular neurons during constant velocity step rotations (30-250°/s) about an Earth-vertical axis in the darkness were used for model predictions of mechanisms of neural circuits. Our model includes the following components: 1) the number of active vestibular cells in neuronal circuits; 2) unilateral and bilateral activation of neuronal circuits; 3) inhibitory inputs from vestibular-cerebellum; and 4) modulated interactions of efferent vestibular neurons to neurons in VN. Our model results suggest that (1) positive feedback is a major mechanism contributing to the "neural integrator" and (2) the value of the VOR time constant during constant velocity step rotations is predominantly determined by the weight of activated cells in both hemispheres. ***Supported by NIDCD R01-DC2390, RFFI Grant 13-04-01736***

Research to Prevent Blindness

Title: Compartmental innervation scheme for the mammalian superior oblique (SO) and inferior oblique (IO) muscles

Authors: *A. LE, J. L. DEMER, V. POUKENS;
Ophthalmology, UCLA, Los Angeles, CA

Abstract: Innervation of horizontal rectus muscles in human, monkey, and non-primate mammals divides into superior and inferior non-overlapping zones. We sought evidence for a similar innervation scheme in SO and IO muscles. Whole orbits were obtained from 4 humans: two adults, a 17 mos old toddler, and a 33 wk fetus; 2 rhesus monkeys; 1 rabbit, and 1 cow. Each orbit was formalin fixed, embedded in paraffin, coronally sectioned at 10 μm thickness, and stained with Masson trichrome. Muscle fibers and trochlear (CN4) & oculomotor nerve (CN3) branches were traced in digitally imaged serial sections using Adobe Photoshop and projected using ImageJ to reconstruct intramuscular innervation in 3-D. After en bloc excision from fresh bovine & human orbits, SO tendons removed in continuity with muscles were unrolled to trace fiber continuity topographically from innervation zone to scleral insertion. In all 4 species, CN4 bifurcates prior to entering the SO muscle. In postnatal humans, CN4 arborizes in non-overlapping superomedial & inferolateral muscle fiber zones. Fetal CN4 exhibited 4 major branches with some overlap. Monkey and bovine orbits display bifurcation of intramuscular CN4 with minimal overlap between resulting zones of innervated fibers. Gross dissection shows that the superior bovine SO compartment inserts posteriorly on the sclera for mainly vertical action, while the inferior portion inserts anteriorly for mainly torsional action. The lateral human SO belly is in continuity with the posterior scleral insertion for mainly vertical action, while the medial belly is in continuity with the anterior insertion for mainly torsional action. The rabbit SO muscle has two heads, each innervated by separate CN4 branches whose branches remain non-overlapping more anteriorly where the two heads have fused. The nerve to the monkey IO bifurcates external to the muscle innervating non-overlapping anterior and posterior zones. Compartmental innervation exists for the mammalian IO and SO. CN4 arborizes into superomedial & inferolateral branches apparently specialized for torsional vs. vertical actions, while the IO motor nerve arborizes into anterior & posterior branches whose potential specializations remain unknown. Since there is little mechanical sheer coupling between adjacent parallel muscle fibers, bifurcation of the motor nerves of the horizontal rectus and oblique muscles allows independent mechanical actions of each of their compartments.

Title: Decreased susceptibility to pilocarpine in Rac-GAP α-chimaerin deficient mice

Authors: *A. KATOH[1], E. TAKEUCHI[1], T. HATANAKA[1], E. SASAGAWA[2], T. IWASATO[3], S. ITOHARA[4];

Abstract: α-chimaerin (α-chimerin), a Rac-specific GTPase activating protein, plays a key role to wire neurons precisely in the brain. Indeed, $miffy$ mice, α-chimaerin spontaneous null mutant mice, have abnormal midline crossing of corticospinal tract axons and abnormal spinal central pattern generators, resulting in exhibiting a rabbit hopping gait (Iwasato, 2007). A more recent study reported that when α2-chimaerin, one of two major isoforms of α-chimaerin and known as a gene causing Duane Retraction Syndrome, was knocked-down in neurons in oculomotor nuclei, its axon guidance was impaired in zebrafish (Clark, 2013). Here we found that $miffy$ mice were significantly less sensitive to pilocarpine which induces myosis. Instillation of 1% pilocarpine hydrochloride into the eye shrank the pupil by 80% in wild-type mice, whereas $miffy$ mice exhibited less than 40% shrinking of the pupil. The pupillary response to light occurred in $miffy$ mice but the time course of the size change of the pupil was altered compared to wild-type mice. In addition, the effect of atropine to induce mydriasis seemed more profound in $miffy$ mice than in wild-type mice. Myosis is controlled by parasympathetic nerves innervating to sphincter muscles of the pupil, originated from oculomotor nuclei through ciliary ganglion, and mydriasis is controlled by sympathetic nerves. Our current results suggest that lacking of α-chimaerin altered mechanisms balanced by sympathetic and parasympathetic nerves to regulate the pupil size.

Title: Fixational-saccade related and periodic activity of the pedunculopontine tegmental nucleus neurons in behaving monkeys

Authors: *Y. KOBAYASHI[1,3,2], K.-I. OKADA[1];
[2]Res. Ctr. for Behavioral Econ., [1]Osaka Univ., Suita, Japan; [3]Ctr. for Information and Neural Networks, Natl. Inst. of Information and Communications Technol., Suita, Japan

Abstract: The pedunculopontine tegmental nucleus (PPTN) is the major source of excitatory projections to the midbrain and thalamus. Classical literature emphasizes that the activity of PPTN neurons plays an important role for regulating cognitive states during behavior control. However, it remains unclear how do PPTN neurons fire phasically or tonically during various behaving conditions, including saccades and reward seeking. For the phasic response we analyzed saccade-related neuronal activity (including microsaccades) of the PPTN, and for the tonic response we analyzed dynamics of task-related tonic neuronal activity of PPTN. Fixational microsaccades are small, involuntary eye movements that occur during attempted visual fixation and are affected by several cognitive process. We recorded the activity of PPTN neurons in behaving monkeys during a reward-biased visually guided saccade task, and analyzed neuronal activity for small fixational saccades during visual fixation and compared it with the activity for large visually guided targeting saccades. A population of PPTN neurons exhibited a fixational saccade-related phasic increase or decrease in activity, and many of them also showed activity modulation with large targeting-saccades and showed tonic modulation with task execution and reward expectation. Thus, fixational microsaccade-related signals of PPTN neurons share information with large-targeting saccade signal and the tonic reward expectation signal, and

might contribute to the cognitive modulation of fixational saccades. The dynamics of the tonic response of PPTN neurons might be influenced by local property of the PPTN and reverberate large-scale circuit including the PPTN. To explore dynamical modulation of the tonic firing of PPTN, we analyzed their firing regularity and periodicity for each neuron. A population of PPTN neurons exhibited a tonic regular firing pattern in that the coefficient of variation of inter-spike intervals was lower than that of theoretical random and irregular spike trains. Furthermore, a group of PPTN neurons exhibited a clear periodicity of firing. Many of these neurons exhibited the tonic regular-periodic firing pattern during highly active states, either during the task execution or resting period. The periodic firing neurons exhibited longer action potential durations and were also mainly distributed in the caudal part of the PPTN, consistent with the reported feature of cholinergic neurons. These task context-related changes in tonic and periodic discharge of PPTN neurons might regulate the monkey's motivational and arousal level to perform the cognitive task.

Title: Lumbosacral ganglia in female rats

Authors: N. MIRTO-AGUILAR[1], *Y. CRUZ[2];
[1]Doctorado en Investigaciones Cerebrales, Univ. Veracruzana, Xalapa, Mexico; [2]Univ. Autonoma Tlaxcala, Tlaxcala, Mexico

Abstract: Afferent neurons are critical in supplying the central nervous system information about sensory events that occur in the periphery. Their cell body reside in the dorsal root ganglia (DRG), alongside the spinal cord. The aim of this study was to characterize the L3-S1 lumbosacral ganglia in female rats. Eight adult female Wistar rats were euthanized and the L3-S1

ganglia localized and measured. In 3 animals the ganglia were collected and fixed for histological study. The tissue was sectioned at 5 μm thickness and stained with Masson's trichrome stain. The number and distribution of neurons, as well as the area of neurons were determined. The results showed that L3-S1 DRGs differ in sizes, with L4 and L5 being longer ($p<0.01$), wider ($p<0.01$) and thicker ($p<0.05$) than L6 and S1. With exception of L6 (triangular shape), L3-S1 DRGs have an elliptical shape. The histology showed that the ventral root axons ran medial to the DRG neurons. Each ganglion had large (>30 μm in diameter) and small neurons (10 μm in diameter), most of the large neurons were located near the ventral root. The ganglion with more neurons was L5 (10678±839.8), and the ganglion with less neurons was S1 (3379±556.7). Around 60% of L3, L4, L5 neurons, and more than 80% of L6 and S1, are in a range of 101-500 μm^2. The described lumbosacral DRGs neurons are related to the innervation of reproductive and excretory organs (pelvic viscera and perigenital skin), as well as to the hind limbs. The detailed knowledge in DRG neuronal organization will allow to design experiments to determine neural circuits, effect of specific sensory neuronal damage and/or regeneration in future studies.

Title: Effects of vibratory feedback on efficient muscle use during a redundant, one-dimensional myocontrol task

Authors: *S. A. LIYANAGAMAGE[1], M. BERTUCCO[1], N. H. BHANPURI[1], T. D. SANGER[1,2,3];
[1]Biomed. Engin., [2]Neurology, Biokinesiology & Physical Therapy, USC, Los Angeles, CA; [3]Children's Hosp. of Los Angeles, Los Angeles, CA

Abstract: Application of vibratory feedback to a muscle, proportional to its level of activity, has been shown to significantly improve the motor function of children with cerebral palsy and upper extremity motor deficits, such as in dystonia. Understanding how vibration characteristics affect improvement is important for identifying possible mechanisms of action and optimizing feedback characteristics. To this end, we studied the effects of proportionally-scaled and constant modes of vibration on target muscle use. We conducted a redundant, one-dimensional myocontrol experiment on a group of children with dystonia and age-matched controls. Using Fitts' law, we designed a task combining target widths and movement amplitudes, which resulted in 5 different Indexes of Difficulty (IDs). Subjects were instructed to flex both their right and left biceps simultaneously to move a cursor on a computer screen, and reach each of the targets as quickly as possible. The experiment was designed in a manner that allowed for multiple solutions, of which, only a subset was energetically efficient. The vibration was delivered to the more dystonic arm in children with dystonia, and the non-dominant arm in controls. Vibration was provided at a frequency either scaled in proportion to measured EMG ("scaled") or fixed at a constant level of 50 Hz ("constant"). Results show that vibration leads to increased use of the vibrated arm across all groups. Scaled vibration helps subjects reach a more energetically favorable solution to the task, while constant vibration does not. These results were consistent across all IDs. Furthermore, Fitts' Law analysis showed no significant change in the index of performance (inverse of linear regression slope of movement time vs. ID) due to vibration. In other words, vibrational feedback can be employed to help people discover different, more efficient solutions without a reduction in performance. Thus, it is possible that scaled vibration provides an additional mode of salient sensory information, while constant vibration simply enhances attention to a specific muscle. These experiments are useful for understanding the underlying mechanisms of vibratory feedback as an adjunct therapy for childhood dystonia. We plan to conduct further experiments using other modes and frequencies of vibration in order to gain a better understanding of how vibration affects muscle use in children with dystonia.

Title: Selective optogenetic activation of ChAT-Cre/channelrhodopsin-expressing primary afferents

Authors: *I. A. SPEIGEL, S. HOCHMAN;
Emory Univ., Atlanta, GA

Abstract: Somatosensory inflow to the central nervous system is complexly regulated at the primary afferent synaptic relay to the spinal cord dorsal horn. Presynaptic nicotinic acetylcholine receptors (nAChRs) modulate synaptic transmission and are abundantly distributed on primary afferent terminals. Possible sources for cholinergic modulation of these nAChRs include dorsal horn islet-like interneurons, rostral ventrolateral medulla, and primary afferent fibers expressing a choline acetyltransferase (ChAT) splice-form specific to peripheral neurons (peripheral or pChAT). GM24-Gsat/ChAT-Cre mice (GENSAT) express Cre recombinase from the initiation site of the first coding exon shared by both ChAT/pChAT. We previously demonstrated reporter-based expression in known spinal cholinergic neurons as well as in a subpopulation of primary afferents that span the rostrocaudal neuraxis and includes cutaneous mechanoreceptors (Speigel et al. Society for Neuroscience 2013). Here, ChAT-Cre mice were crossed with the channel channelrhodopsin (ChR2) expressing Ai32D Cre-dependent line to examine the spinal actions of selectively recruited ChAT expressing primary afferents. We first show ChR2 trafficked to dorsal root ganglia (DRG), dorsal root axons, spinal projections and peripheral nerve fibers, enabling further studies on possible optical excitability. We then used the isolated hemicord to assess optical excitability in juvenile ChAT::ChR2 mice. In P7-10 preparations with attached hindlimbs, blue laser-diode light delivered through optical fibers positioned onto peripheral nerves evoked compound action potentials in recordings from sciatic nerve or lumbar dorsal roots. When recording from the thoracic or lumbar dorsal root entry zone of juvenile ChAT::ChR2 isolated hemicords, optical activation of afferents in DRG or dorsal roots elicited dorsal root potentials consistent with primary afferent depolarization, a form of presynaptic inhibition. We conclude that ChAT expressing primary afferents modulate spinal somatosensory transmission, and ongoing studies will determine whether evoked responses include activation of nAChRs. Title: Cutaneous silent period characteristics are dependent on the organization of upper limb muscles

Authors: ***N. R. ECKERT**[1], A. W. MEEK[2], K. SMITH[2], J. C. WILLIAMS[2], Z. A. RILEY[2]; [1]Sch. of Physical Educ. and Tourism, Conventions and Event Mgmt., Indiana Univ., Indianapolis, IN; [2]Indiana Univ. Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: Cutaneous silent periods (CSPs) are inhibitory spinal reflexes mediated by small diameter A-δ fibers, serving to protect the body from harmful stimuli (Leis et al., 1992; Kofler, 2003). Previously, CSPs were believed to only inhibit the extensor muscles of the upper limb to impede motions such as reaching; while other spinal circuits simultaneously excite flexor muscles to withdraw the limb. The present study sought to determine if CSPs could be evoked in both extensor and flexor muscles throughout the upper limb, thereby providing further insight into the organization of the spinal circuitry associated with this reflex. 22 subjects performed isometric contractions with each of the following upper limb muscles: abductor pollicis brevis (APB), flexor carpi radialis (FCR), extensor carpi radialis (ECR), biceps brachii long head (BIC), triceps brachii lateral head (TRI), anterior deltoid (AD), and posterior deltoid (PD). Subjects were electrically stimulated (10x perceptual threshold) with 20 individual pulses delivered to digit II (radial nerve), digit V (ulnar nerve), and paired digit II+III (digit III at perceptual threshold 100ms preceding digit II) of the right hand during each contraction, while muscle activity was recorded with electromyography. Distal muscles presented with the earliest onset times for the CSP ($F[6,21] = 15.42$), longest duration of inhibition ($F[6,21] = 65.25$), least amount of inhibition ($F[6,21] = 91$), and greatest amount of post-inhibitory rebound ($F[6,21] = 14.8$), though there were no specific differences noted for flexor-extensor muscle pairs. Furthermore, there were no significant differences across the three stimulation conditions. Linear regressions depicted that the distance a muscle is from the spinal cord can serve as a significant predictor of CSP duration (digit II $r2 = 0.43$; digit V $r2 = 0.46$; digit II+III $r2 = 0.36$, all $p < 0.001$) and the amount of inhibition (digit II $r2 = -0.51$; digit V $r2 = -0.48$; digit II+III $r2 = -0.48$, all $p < 0.001$). These results demonstrate evidence of the CSP in both flexor and extensor muscles of the upper limb, with the greatest effect taking place within the distal muscles. We hypothesize that this distal_proximal organization of cutaneous inhibitory reflexes may be influenced by the number of direct cortico-motoneuronal connections within the corticospinal tract. Thus, the cutaneous feedback plays a larger role in modulating direct descending input in distal muscles involved in grasping and manipulation, versus proximal muscles coordinating reaching.

Title: Congenital foot deformation altered the topographic organization in the primate somatosensory system

Authors: *C.-C. LIAO, H.-X. QI, J. L. REED, D. J. MILLER, J. H. KAAS;
Dept. of Psychology, Vanderbilt Univ., Nashville, TN

Abstract: For various reasons, part of a limb may fail to develop during early fetal stages. Here we describe the organization of the somatosensory system in a 6 years old monkey (Macaca radiata) that was born with a deformed left foot with toes 1, 3, and 5 missing, but with the most proximal parts of toes 2 and 4 present. We characterized the patterns of peripheral afferent inputs to the brainstem, thalamocortical connections, and somatotopic organizations in the primary somatosensory area 3b on both sides. Comparisons were made with results obtained from a normal monkey (Macaca fascicularis). Injections of cholera toxin subunit B (CTB) conjugated with horseradish peroxidase (B-HRP) into the matching locations of the two feet revealed the plantar representations in the lumbar spinal cord and gracile nucleus (GrN) of the brainstem. We mapped the area 3b of both hemispheres using multiunit recordings. Injections of wheat germ agglutinin horseradish peroxidase (WGA-HRP) and CTB made into the representations of toes and plantar foot of area 3b revealed the cortical projecting neurons in the ventroposterior lateral nucleus (VPL) of the thalamus. Contrary to the orderly-arranged foot representations throughout the lemniscal pathway in the normal monkey, the plantar representations of the deformed foot were significantly expanded and intruded into the expected representations of toes in the spinal cord, GrN, VPL, and area 3b. We also observed abnormal representations of toes and plantar pad in area 3b contralateral to the intact foot. Our results demonstrated that the congenital malformation greatly influences the development of topographic organization in the somatosensory system. Alteration not only involves the ipsilateral spinal cord and GrN, and the contralateral thalamus and cortex that represent the deformed foot, but also the cortex that represents the intact foot.

Title: fMRI characterization of central vagal projection sites via external ear stimulation

Authors: *B. R. KOMISARUK[1], E. FRANGOS[1], N. WISE[1], W. BIRBANO[1], K. ALLEN[1], J. ELLRICH[2];
[1]Dept Psychology, Rutgers, The State Univ. of New Jersey, NEWARK, NJ; [2]Hlth. Sci. and Technol., Aalborg Univ., Aalborg, Denmark

Abstract: Neuroanatomical and functional studies provide different views of the organization of the nucleus of the solitary tract (NTS). Evidence of viscerotopic organization of the NTS is based on stimulation of different parts of the alimentary tract, with esophagus, stomach, and intestines activating NTS regions in sequence along the length of the NTS in rats (Altschuler et al, 1992). By contrast, HRP injected into the cymba conchae of the external ear, which receives afferent innervation via the auricular branch of the vagus nerve, resulted in widespread labeling of the subnuclei of the NTS in cats (Nomura & Mizuno, 1984). In the present study using fMRI, mild electrical stimulation of the cymba conchae activated the NTS along its entire length in humans rather than in a somato- or viscerotopically-related region. Furthermore, this stimulation activated the conventional projection sites of the NTS, as demonstrated by "effective connectivity" analysis. This analysis also demonstrated the persistence of activation of the vagus projection sites for 4+ min after cessation of the stimulation. The location of the NTS was estimated with reference to the brainstem atlas of Duvernoy (Naidich et al, 2009); functionally, the NTS was "triangulated" with reference to activation of its surrounding localizers, e.g., nucleus cuneatus (finger tap), and principal trigeminal nucleus (face tap), and conjunction

analysis using a gustatory stimulus (sweet, sour, bitter, salty mixture) as a localizer that showed congruence of activation of NTS by cymba conchae stimulation. It is noteworthy that marked activation of the paracentral lobule resulted from the cymba conchae stimulation. This is consistent with our previous findings (Komisaruk et al, 2011) that vaginal and cervical self-stimulation activated the same region of the paracentral lobule in able-bodied women, and that vaginal and cervical self-stimulation in women with complete spinal cord interruption at T10 and above activated NTS, indicating a genital sensory role for the vagus nerve (Komisaruk et al, 2004). The ability to access and modulate the activity of the projections of the vagus nerve non-invasively via stimulation of the external ear could have significant therapeutic potential.

Title: Effect of cutaneous silent period on cortical output in proximal-distal muscles in the upper limb

Authors: ***A. W. MEEK**[1], N. R. ECKERT[2], K. SMITH[1], J. C. WILLIAMS[1], Z. A. RILEY[1]; [1]PETM Dept., Indiana Univ. Purdue Univ. Indianapolis, Indianapolis, IN; [2]Indiana Univ., Bloomington, IN

Abstract: A single pulse of high intensity electrical current delivered to the digits of the hand produces a period of decreased electromyographic (EMG) activity, or a cutaneous silent period (CSP), in muscles of the upper limb (e.g. thenar, triceps brachii) during voluntary contractions (Caccia and Violini 1973; Uncini et al. 1991; Inghilleri et al. 1997). Pairing transcranial magnetic stimulation (TMS) with digit stimulation results in motor evoked potentials (MEPs)

with reduced amplitudes in a thenar muscle (Kofler, 2008), suggesting a direct inhibitory influence on the descending drive from supraspinal centers through noxious cutaneous stimulation. However, it is not known whether this occurs only in hand muscles where there are a greater number of direct cortico-motoneuronal connections, or whether similar behavior can be observed in more proximal upper limb muscles. The current study investigated the inhibitory influence of the CSP on the descending drive for several muscles throughout the upper limb. 14 subjects performed isometric contractions, while EMG was recorded, with the following muscles: abductor pollicis brevis (APB), flexor carpi radialis (FCR), extensor carpi radialis (ECR), biceps brachii (BIC), triceps brachii (TRI), anterior deltoid (AD), and posterior deltoid (PD). During the isometric contractions, subjects experienced three different stimulation conditions: electrical stimulation of digit II (10x perceptual threshold) only (CSP), transcranial magnetic stimulation (TMS), and a pairing of digit II stimulation and TMS (TMS+). 10 individual pulses were completed for each stimulation condition, in random order, resulting in 40 total stimulations for each of the seven muscles. Comparisons of the MEP size showed significant differences ($p< 0.05$) between the TMS and TMS+ conditions. Specifically, the TMS MEP was significantly greater than the TMS+ MEP for APB ($p <0.001$), FCR ($p =0.006$), and BIC ($p <0.049$) muscles, though the opposite relationship was seen within the PD ($p <0.047$) muscle. An ANOVA test of normalized MEP values (TMS+/TMS) compared across muscles showed significant differences in APB vs TRI ($p = 0.004$) and PD ($p = 0.003$), and in FCR vs TRI ($p = 0.046$) and PD ($p = 0.037$) muscles. The results suggest that the CSP plays a differential role in modulating descending drive resulting in suppressed MEP amplitudes within distal muscles while facilitating MEP amplitudes within more proximal muscles. We hypothesize that this differential response may be due to the number of direct cortico-motoneuronal connections to distal muscles versus proximal muscles and could help to coordinate grasp (distal) versus reach (proximal) motor control.

Title: Zona incerta regulates communication between superior colliculus and POm

Authors: *G. D. WATSON, J. B. SMITH, K. D. ALLOWAY;
Ctr. for Neural Engin., Penn State Univ., University Park, PA

Abstract: The zona incerta is known for receiving dense projections from the superior colliculus and for sending inhibitory projections to the medial posterior thalamic nucleus (POm). To delineate the anatomical and functional specificity of the tectoincertal projections, different anterograde tracers were separately injected into visual-sensitive and whisker-sensitive parts of the superior colliculus. We found that the superior colliculus projects to the zona incerta, but not to a neighboring structure, the subthalamic nucleus. A crossing pattern was also observed in which visual-sensitive neurons in the medial superior colliculus project to the lateral zona incerta, whereas projections from whisker-sensitive collicular neurons terminate in more medial sectors of the zona incerta. In separate tracing experiments, we found that whisker-sensitive regions in POm receive projections mainly from the lateral sector of the zona incerta. Collectively, these anatomical findings implicate the zona incerta with a role in mediating communication between the superior colliculus and POm. To address this hypothesis, we have begun a series of experiments in which the responses of neurons in superior colliculus, ZI, and POm are recorded during sensory stimulation. In our initial study, we have recorded whisker-sensitive neurons in superior colliculus and POm simultaneously. The results indicate that neurons in both superior colliculus and POm respond to low frequency whisker deflections. During continuous whisker stimulation at 8 Hz, however, neurons in superior colliculus show significant adaptation whereas neurons in POm become more responsive.

Title: Analysis of proprioceptive endings in the mouse soleus muscle using a transgenic mouse model

Authors: M. J. SONNER, *D. R. LADLE;
Neurosci, Cell Bio, Physiol, Wright State Univ., DAYTON, OH

Abstract: Muscle spindles and Golgi tendon organs (GTOs) are encapsulated, stretch-activated sensory receptors housed within skeletal muscles, yet their functional contributions to proprioceptive monitoring of limb movements are quite different. For example, muscle spindles are responsible for detecting stretch of muscle fibers, and GTOs provide feedback regarding muscle tension during contraction. Peripheral axons extending from proprioceptive sensory neurons in the dorsal root ganglia supply muscle spindles and GTOs. Muscle spindles are innervated by Group Ia and II sensory fiber endings, while GTOs are innervated by a single Group Ib sensory fiber. The developmental process guiding axons from these neurons to their targets and ultimate functional identities in skeletal muscle, however, remains to be elucidated. To study these proprioceptive sensory neurons and their peripheral endings more closely, we took advantage of existing transgenic mouse models using cre-lox recombination technology in which all proprioceptive afferents are labeled with red fluorescent protein (Parvalbumin-Cre/+; Rosa-CAG-LSL-tdTomato-WPRE). Here we present results of confocal microscopy analysis of proprioceptive endings from whole-mount neonatal mouse soleus muscle preparations. From our survey of the right soleus muscle of 19 mice at postnatal ages 3 to 7 days, we found the soleus muscle to contain 10.8 ± 0.3 (mean ± SEM) muscle spindles and 5.2 ± 0.2 GTOs. We then analyzed a subset of proprioceptive endings at higher magnification and observed that GTOs were consistently innervated by a single proprioceptive axon (n = 20 GTOs). Numbers of proprioceptive axons innervating muscle spindles were variable, ranging from 1 to 5 (2.3 ± 0.2, n = 39 spindles). A consistent characteristic of innervation of the soleus muscle is the presence of thin and thick branches of the common soleus nerve, which diverge prior to muscle entry. The thin branch only supplies sensory endings housed within the proximal compartment of the muscle, while the thick branch provides both sensory and motor innervation to the remainder of the muscle. Our analysis revealed 4 to 9 proprioceptive axons are found within the thin branch (6.0 ± 1.1, n = 4 muscles). Invariably, the thin branch contained axons terminating in GTOs. The number of thin branch spindle afferents was more variable, ranging from 0 to 7. Our preliminary analysis suggests the thin branch often contains a mix of Ia and/or II spindle afferents, but occasionally contains muscle spindle afferents of only one type. This model may provide a useful tool in analysis of muscle spindle and GTO maturation during embryonic and early postnatal development.

Title: Barreloid-like structures in the ventroposterior medial subnucleus of the somatosensory thalamus in prosimian galagos

Authors: *E. K. SAWYER[1], C.-C. LIAO[1], H. QI[1], P. BALARAM[1], D. MATROV[2], J. H. KAAS[1];
[1]Vanderbilt Univ., Nashville, TN; [2]Intl. Inst. of Neurosci. at Natal, Natal, Brazil

Abstract: Galagos (Otolemur garnetti) are prosimian primates that appear to more closely resemble ancestral primates than any of the present-day anthropoids. As in many other mammals, facial whiskers of galagos are distributed across the upper and lower jaws and above the eye. In rats and mice, the mystacial macrovibrissae are famously represented throughout the ascending trigeminal lemniscal pathway as arrays of cytoarchitecturally distinct modules with each module having a one-to-one relation with a specific facial whisker. The macrovibrissa representations are termed barrelettes, barreloids, and barrels in the trigeminal somatosensory brainstem, the ventroposterior medial subnucleus of the thalamus, and primary somatosensory cortex, respectively. Despite the presence of facial whiskers in all non-human primates, similar barrel structures have not been reported in primates. Using cytochrome oxidase, Nissl stains and immunohistochemistry for vesicular glutamate transporters, we show a distinct array of barreloid-like modules in the ventroposterior nucleus of galagos. Labeled thalamocortical and corticothalamic connections demonstrate that barreloid-like modules are located in an area of the somatosensory thalamus that is topographically consistent with a role in facial touch. The presence of barreloid-like modules in galagos suggests the existence of broad similarities in the processing of sensory information in rodents and primates.

Title: VGLUT1 and VGLUT2 identify driving (class 1) and modulatory (class 2) glutamatergic projections in the somatosensory system of prosimian, New World, and Old World primates

Authors: *P. BALARAM, E. K. SAWYER, J. H. KAAS;
Psychology, Vanderbilt Univ., Nashville, TN

Abstract: Vesicular glutamate transporters (VGLUTs) regulate the uptake and release of glutamate from presynaptic vesicles of glutamatergic neurons in the central nervous system. Two VGLUT isoforms, VGLUT1 and VGLUT2, are differentially expressed in subsets of glutamatergic projections across the mammalian brain and appear to confer distinct properties of glutamate release to their host neurons. Previous studies of VGLUT1 and VGLUT2 expression in the primate visual system suggest that glutamatergic projections involving VGLUT2 correspond to Class 1 projections, which are capable of driving the activity of their post-synaptic targets. In contrast, glutamatergic projections involving VGLUT1 correspond to Class 2 projections, which primarily modulate the activity of postsynaptic cells. In order to determine whether VGLUT1 and VGLUT2 identify similar functional segregations of glutamatergic circuits in other primate sensory systems, we examined the distribution patterns of VGLUT1 and VGLUT2 across major subcortical nuclei and cortical areas of the dorsal column and trigeminal pathways in prosimian galagos, New World monkeys, and Old World monkeys. From the spinal cord to the cortex, these pathways contain a multitude of functionally distinct glutamatergic projections that have been shown to utilize VGLUT1, VGLUT2, or both VGLUT1 and VGLUT2 in nonprimate species. Thus, we examined the expression patterns of VGLUT1 and VGLUT2 mRNA and protein in the cuneate, gracile, and principal trigeminal nuclei of the brainstem, the ventroposterior nucleus of the thalamus, and areas 3b and 1 of somatosensory cortex. Similar to glutamatergic visual projections, driving somatosensory projections primarily utilize VGLUT2 while modulatory somatosensory projections primarily utilize VGLUT1. In addition, somatosensory nuclei of the thalamus appear to express both VGLUT1 and VGLUT2 in overlapping populations of glutamatergic projections, similar to thalamic visual projections in primates and thalamic somatosensory projections in rodents. Glutamatergic projections from somatosensory cortex predominantly utilize VGLUT1, but some subsets of cortical projections appear to utilize VGLUT2, similar to findings in the primate visual system and the rodent somatosensory system. These findings demonstrate that VGLUT1 and VGLUT2 differentiate between driving and modulatory glutamatergic projections across primate and nonprimate sensory systems.

Title: The precuneus is involved in the detection of incongruency between tactile and visual texture information: A functional MRI study

Authors: *R. KITADA[1], A. T. SASAKI[2], Y. OKAMOTO[3], T. KOCHIYAMA[4], N. SADATO[1]; [1]Div. of Cerebral Integration, Natl. Inst. For Physiological Sci., Okazaki, Japan; [2]RIKEN Ctr. for Life Sci. Abstract: Visual information can lead to incorrect conclusions regarding the physical substance of manufactured objects. For example, a plastic ring can look like a real gold ring. However, we can avoid misidentifying an object's substance by comparing visual and tactile information. As compared to the spatial properties of an object (e.g., orientation), little information regarding physical object properties (material properties) is shared between vision and touch. How can such different kinds of information be compared in the brain? One possibility is that visuo-tactile comparison of material information is mediated by associative memories previously learned between the two modalities. Previous studies suggested that a cortical network involving the medial temporal lobe, lateral prefrontal cortex and precuneus plays a critical role in the retrieval of information in associative memory. Here, we conducted a functional MRI study to test if these brain regions are involved in the visuo-tactile comparison of material properties. Stimuli consisted of surfaces in which an oriented plastic bar was placed on a background texture. Twenty-two healthy subjects determined whether the orientations of visually- and tactually-

presented bar stimuli were congruent in the orientation conditions, and whether visually- and tactually-presented background textures were congruent in the texture conditions. The texture conditions revealed greater activation of the fusiform gyrus, medial temporal lobe and lateral prefrontal cortex compared with the orientation conditions. In the texture conditions, the precuneus showed greater response to incongruent stimuli than to congruent stimuli. This incongruency effect was greater for the texture conditions than for the orientation conditions. These results suggest that the precuneus detects incongruency between tactile and visual texture information via the medial temporal lobe and lateral prefrontal cortex. Our findings highlight the contribution of the cross-modal association to the visuo-tactile texture comparison.

Title: Short-term use-dependent remapping of digit topography in human primary somatosensory cortex

Authors: ***J. KOLASINSKI**, T. MAKIN, S. JBABDI, C. STAGG, H. JOHANSEN-BERG; Univ. of Oxford, Oxford, United Kingdom

Abstract: The regions comprising primary somatosensory cortex (SI) are organized somatotopically, forming multiple sensory body map representations. The cortical representations of the digits are much exaggerated relative to their actual size, reflecting their dense sensory innervation and their potential role in the tactile acuity required for complex dexterous tasks. Electrophysiological studies in non-human primates have demonstrated the potential for use-dependent remapping of these representations in response to altered sensory inputs over the course of months. In this study we considered the potential for use-dependent plasticity in SI digit representations in human subjects, induced by a manipulation in which digit 2 (index) and digit 3 (middle) of the right hand are glued together. To map SI sensory representations of individual digits in human participants we applied BOLD fMRI at 7 tesla with

an isotropic resolution of 1.2mm using a self-administered phase-encoding paradigm. This approach produced robust and reproducible maps of SI digit topography (Fig. 1A) with high inter-session reliability. We further collapsed the digit maps along the axis of the central sulcus, producing a profile plot of the digit representations and their overlap for each session (Fig. 1B). Digit topography was mapped in nine participants before and after a 24-hour control period, and a 24-hour glued period using a repeated measures (RM) counterbalanced design. The gluing manipulation induced a reduction in the overlap of digits 3 (middle) and 4 (ring), and an increase in the overlap of digits 4 (ring) and 5 (little). These changes were not identified in an equivalent 24-hour control period (RM ANOVA: Significant interaction between condition and digit overlap, $F(4,32)=7.96$, $p<0.001$). This remapping provides a fundamental insight into the nature of plasticity in the human brain, demonstrating the potential for use-dependent reorganisation in digit representations not directly involved in the glued manipulation, and the propensity for such changes over a period as short as 24 hours.

Title: Transition to orgasm/ejaculation and to the refractory period in men: fMRI evidence

Authors: *K. ALLEN, N. WISE, E. FRANGOS, P. LAKSHMIN, W. BIRBANO, B. R. KOMISARUK;
Dept. of Psychology, Rutgers Univ., Newark, NJ

Abstract: After ejaculation, most men experience a "refractory period" during which they find it difficult or impossible to stimulate a subsequent orgasm. The neural processes underlying this period are still unknown. In the present study, we compared neural activity during orgasm to the activity during the post-orgasm refractory period. Functional Magnetic Resonance Imaging (fMRI) data were collected using a Siemens Trio 3T head-only scanner with each participant immobilized with a custom-fitted, thermoplastic whole-head stabilization mask. During genital self-stimulation to orgasm, subjects used a button-press to indicate the start of orgasm/ejaculation, the end of orgasm, and the end of any residual post-orgasmic feelings. The end of these residual feelings was the criterion we used to identify the onset of the refractory period. Neural responses to the first 6 seconds (3 TRs) of the refractory period were modeled and compared to the first 6 seconds of orgasm (preprocessing and analysis completed using AFNI). The brain regions found to have significantly different activations (cluster-corrected $p < 0.05$) during orgasm/ejaculation versus during the refractory period included the frontal cortex, temporal lobe, lentiform nucleus, hippocampus, septum, operculum (SII), anterior and posterior cingulate cortex, precuneus, pons, and cerebellum. Neural activity during the first 6 seconds of orgasm was also compared to the 6 seconds immediately preceding orgasm. A significant difference was observed in pons. The present findings provide evidence of distinctly different regional brain activity correlated with the physiological and subjective differences that distinguish between orgasm/ejaculation, the moments immediately prior to orgasm/ejaculation, and the refractory period following orgasm/ejaculation.

Title: Brain regional activation upon transition to self- and partner-induced orgasm in women: An FMRI analysis

Authors: *N. J. WISE, E. FRANGOS, K. ALLEN, W. BIRBANO, P. LAKSHMIN, B. R. KOMISARUK;
Psychology, Rutgers Univ., Newark, NJ

Abstract: The present study analyzed differences in regional brain activity occurring during self-induced and partner-induced orgasm in women (Ns=5). Functional Magnetic Resonance Imaging (fMRI) data were collected using a Siemens Trio 3T head-only scanner with custom-fitted, thermoplastic whole-head stabilization masks. Preprocessing and analysis were performed using FSL. In order to sample equivalent time points across the participants' variable durations of stimulation and orgasm, the first 10sec of orgasm was compared to the 10sec of genital stimulation immediately preceding orgasm. No significant deactivations in frontal cortical or other brain regions were noted for either the self-induced or partner-induced orgasm group. When the two groups were combined to assess the common activity during the first 10sec of orgasm compared to the global baseline, widespread activations (cluster corrected, $p < 0.05$) were noted, including the paracentral lobule (genital sensory cortex), primary sensory cortex (face and viscera regions), secondary sensory cortex, precuneus, supplementary motor areas, primary motor cortex, frontal pole, anterior and posterior cingulate, insula, nucleus accumbens, hypothalamus, hippocampus, amygdala, ventral tegmentum, corpus callosum, cerebellum, and pons. Comparison of the first 10sec of orgasm with the 10sec immediately preceding orgasm for the combined group (N=10) indicated that the activity of many of these regions increased significantly upon the onset of orgasm. These findings provide evidence that the activity of multiple brain regions, including primary sensory, motor, sensory- integration, and reward regions reach peak activity at orgasm.

Title: Changes in whisking behaviour during object exploration in cortically altered mice

Authors: *R. A. GRANT[1], N. H. GAMBLES[1], T. J. PRESCOTT[2];
[1]Manchester Metropolitan Univ., Manchester, United Kingdom; [2]Univ. of Sheffield, Sheffield, United Kingdom

Abstract: Rodents rhythmically sweep their whiskers back and forwards in a behaviour termed 'whisking'. During surface exploration, rodents employ active control strategies, which increases the information acquired from an object. The emergence of these behaviours in neonates coincides with the development of upstream cortical regions; however, limited studies have specifically examined the role of the cortex in active vibrissal sensing. This study examines the effect of cortical alterations on inquisitive whisker behaviours in three different transgenic mice: Barreless, RIM-DKO-sert and a Robo3 Knockout. Vibrissae movements were tracked in video recordings during contact and non-contact episodes and whisker kinematics were measured including; frequency, amplitude, asymmetry, retraction, offset and spread. All strains of mice showed behaviours that differed from controls during object contact. In particular, the RIM-DKO-sert mice showed a reduction in exploratory behaviour during active touch exploration. These findings suggest that the cortical regions of the brain are involved in whisking behaviours during object exploration, and, in particular, the thalamocortical circuits effect inquisitive, exploratory whisker movements.

Title: Topographical precision in the thalamocortical projection mediated by cannabinoid receptor in the developing barrel cortex

Authors: C. ITAMI[1,2,3], J.-Y. HUANG[2,3], H.-C. LU[2,3], *F. KIMURA[4];
[1]Dept. of Physiol., Fac. Med., Saitama Med. Univ., Moroyama, Japan; [2]The Cain Fndn. Lab, Jan and Dan Duncan Neurolog. Res. Inst. Texas Children Hosp., Houston, TX; [3]Pediatrics, Baylor Col. of Med., Houston, TX; [4]Grad. Sch. Med., Osaka Univ., Suita, Japan

Abstract: Cannabinoids, the major psychoactive component of marijuana, have involved with human lives for more than thousands of years, but how they affect neuronal circuit formation is not well understood. Here, we provide evidence that cannabinoid plays a major role in the development of precise formation of thalamocortical projection. We previously reported that before P14, thalamocortical terminals to L2/3 cells express cannabinoid receptor (CB1R), and these synapses exhibit CB1R-mediated spike timing-dependent LTD (STDP-LTD, or tLTD). In addition, L4-L2/3 synapses, which are undergoing massive synaptogenesis at this age, exhibit spike timing-dependent LTP (tLTP) (Itami, 2012, J. Neurosci.), Thus, two STDPs with opposite directions converge onto L2/3 cells from L4 and thalamus, and we showed evidence that these STDPs interact each other, shaping the precise thalamocortical projection. To explore whether CB1R-tLTD is the underlying cellular mechanism, pharmacological studies were conducted. Consistent with our hypothesis, neonatal treatment with WIN (CB1R agonist) strongly suppressed the thalamocortical projection. In contrast, blocking CB1R signaling with AM281 (CB1R antagonist) reversed the suppression of thalamocortical projection. To obtain further evidence and quantification, we examined the morphology of individual thalamocortical axons of CB1R-KOs at P12 using DiI-labeling technique. In wild type littermate controls, each thalamocortical axons were well-confined within L4 barrels, as consistent with previous studies. In CB1R heterozygotes and KO mice, however, significant increase in the number of thalamocortical axons were found in L2/3. Moreover, those axons were often beyond the barrel boundary, too. Taken together, these results provide evidence that cannabinoid signaling plays an important role in wiring neural circuits in the primary somatosensory cortex during early postnatal development.

Title: Multivariate tactile processing in children and adolescents with obsessive-compulsive disorder

Authors: ***B. GUCLU**[1], C. TANIDIR[2], E. CANAYAZ[1], B. GUNER[1], H. IPEK TOZ[2], O. UNERI[2], M. TOMMERDAHL[3];
[1]Biomed. Engin. Inst., Bogazici Univ., Istanbul, Turkey; [2]Child and Adolescent Psychiatry Clin., Bakırköy Mazhar Osman Hosp., Istanbul, Turkey; [3]Dept. of Biomed. Engin., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Obsessive-compulsive disorder (OCD) is considered to be associated with basal ganglia dysfunction, and was previously shown to reduce sensory gating in cortical areas. We tested whether OCD may alter tactile processing in the somatosensory cortex by using a battery of psychophysical experiments which applied mechanical vibrations on the skin. 32 patients with OCD (age range: 7-18, 11 male, 21 female) and 32 sex- and age-matched healthy controls participated in the study. The tactile stimuli were mechanical vibrations (25 Hz) generated by a portable device (CM-4, Cortical Metrics). The stimuli were applied to the fingertips and the participants responded based on a two-site forced-choice task. The test battery consisted of the following experiments: simple/choice reaction time (stimulus amplitude: 300 μm, duration: 40 ms), dynamic detection threshold (amplitude ramp: 2 μm/s), amplitude discrimination (standard: 200 μm, duration: 0.5 s), and amplitude discrimination with single-site adaptation (adapting stimulus: 200 μm, duration: 1 s). OCD participants performed similarly to controls except in the amplitude discrimination experiments. Specifically, OCD participants had significantly higher (one-tailed t-test, $p = 0.012$) discrimination limens (113 μm) than those from the controls (84 μm). Adaptation caused a significant increase of the discrimination limen for both groups (paired t-test, both p's < 0.002), but this increase was almost identical (72 μm for OCD, 78 μm for controls). We did not find any sex-based differences except that the females had worse discrimination than males after adaptation in the control group (one-tailed t-test, $p = 0.006$). Preliminary multivariate analyses based on Mahalanobis distances and jackknife classification showed that 79% of the OCD participants could be allocated to the correct group (classification sensitivity). On the other hand, 43% of the controls were classified as normal (specificity). The psychophysical results are consistent with the reduced sensory gating hypothesis and suggest cortical hyperexcitability at suprathreshold tactile inputs in OCD. However, in order to achieve normal Weber fractions internally, the lower level (i.e. standard) stimulus should be weighed more than the comparison stimulus during amplitude discrimination. We are currently working to improve multivariate classification test by including clinical data.

Title: Bottom-up sensory adaptation shifts the balance of thalamic burst/tonic firing

Authors: *C. SHEPHARD[1], C. WAIBLINGER[2,3], C. SCHWARZ[2,3], G. STANLEY[1]; [1]Wallace H Coulter Dept. of Biomedial Engin., Georgia Tech/Emory, Atlanta, GA; [2]Systems Neurophysiol., Werner Reichardt Ctr. for Integrative Neurosci., Tübingen, Germany; [3]Dept. of Cognitive Neurol., Hertie Inst. for Clin. Brain Research, Univ. of Tübingen, Tübingen, Germany

Abstract: Beyond acting as a simple relay from the periphery to cortex, the thalamus acts as a "gate" for the peripheral signals, controlling what does and does not get transmitted to cortex. Furthermore, this gating is dynamic, and can be influenced through both bottom-up sensory influence, and top-down mechanisms related to wakefulness and attention. In this work, we explored the bottom-up effect of stimulus adaptation on the encoding of features in the whisker thalamocortical circuit of the fentanyl-cocktail anesthetized rat using a classic signal-in-noise paradigm. Previous work has demonstrated that adaptation can lead to enhanced discriminability paired with reduced detectability, but the underlying mechanism is unknown. We hypothesize that bottom-up sensory adaptation shifts the gating of the thalamus from a burst encoding mechanism to a tonic encoding mechanism through depolarization of the thalamic membrane potential. In the context of the signal-in-noise paradigm, the level of the background stimulus "noise" adapts the pathway, effectively shifting thalamic neurons from burst to tonic firing for conveying information related to the embedded "signal". Preliminary experimental results suggest that thalamic cells (n=12) fire more burst spikes in response to "signals" presented in isolation than in noise and that this leads to a higher detectability, but a lower discriminability, as assessed using an ideal observer analysis of the thalamic unit spiking activity. We developed an integrate and fire neuron with an incorporated burst mechanism to systematically explore the

mechanisms underlying this shift from a burst to a tonic encoding scheme with increasing stimulus "noise" amplitudes. Consistent with the experimental findings, the model suggests that the "noise" is depolarizing the membrane potential of the simulated cell. Furthermore, a simple depolarization of the neuron will induce this shift and lead to a switch in the coding scheme suggesting that the depolarization of the thalamic neurons is one mechanism to alter information flow in the thalamocortical pathway. These experimental and computational findings are supported by previous results from our lab that suggest discrimination is enhanced in response to adapting stimulus contexts whereas detection is enhanced when information is presented in isolation.

Abstract: It is well known that muscle weakness and atrophy is induced by disuse (e.g., by cast immobilization), but little is known about neural adaptation in sensorimotor cortex caused by limb immobilization. We employ transcranial magnetic stimulation (TMS) and somatosensory evoked potentials (SEPs) to investigate sensorimotor cortex excitability induced by 10-hour arm immobilization. Nineteen healthy right-handed subjects were separated into two experimental groups (TMS, 10 subjects; SEP, 9 subjects). In the TMS group, we used single-pulse TMS to study resting motor threshold (RMT) and motor evoked potentials (MEPs), and paired-pulse TMS to study short-interval intracortical inhibition (SICI) and intracortical facilitation (ICF). MEPs were recorded from the left and right first dorsal interosseous muscles. In the SEP group, SEPs were obtained by electrical stimulation of the median nerve and recorded bilaterally from

Fz, on sensory areas for the hands, on the C7 spinous process, and on Erb's point. In the TMS group, following single-pulse TMS, RMT significantly increased and MEP amplitude significantly decreased on the immobilized side, but no significant changes were observed contralateral to the immobilized side. Paired-pulse TMS caused no significant changes in SICI and ICF on either side. In the SEP group, the amplitude potential of the N30 component recorded from Fz upon stimulation of the constrained hand increased significantly, whereas no significant changes were observed for the other potentials. Ten hours of arm immobilization can lead to modulation of cortical processing of motor output and sensory input. Decreased primary motor cortex (M1) excitability occurred without changes in SICI and ICF, and increased N30 amplitude thought to derive from the supplementary motor area (SMA) reflected activated SMA. We assume that this phenomenon is regulated by cortico–basal ganglia circuits. However, the details remain unclear, and further study is required.

Title: Rapid thalamocortical signal transfer through linear dendritic integration in layer 4 cortical neurons *in vivo*

Authors: *H. JIA, Z. VARGA, B. SAKMANN, A. KONNERTH;
Inst. For Neuroscience, Tech. Univ. Munich, Munich, Germany

Abstract: Mammalian cortical neurons compute sensory information that arrives through numerous synaptic inputs located on dendritic spines. A highly effective method to study

individual spine signaling and dendritic integration is two-photon Ca^{2+} imaging. However, due to technical difficulties in the imaging accessibility under *in vivo* conditions, Ca^{2+} imaging studies of dendritic spines had been largely restricted to superficial layers of the cortex, as well as the superficial dendritic compartments of deep-layer cortical neurons. Here we introduce an approach that allowed us to directly monitor single spine Ca^{2+} signals in layer 4 (L4) spiny stellate cells of the vibrissal mouse cortex *in vivo*, which allowed recordings of sensory stimulation-evoked Ca^{2+} transients in dendritic spines of L4 barrel cortical neurons at depths of up to 520 μm under the cortical surface. With the help of two-photon imaging guided navigation, we loaded single neurons in L4 with the Ca^{2+}-sensitive fluorescent indicator OGB1 by means of single-cell electroporation. Recordings were targeted in a subregion of the mouse vibrissal cortex corresponding to the C2 whisker, which was identified by intrinsic optical imaging. A LOTOS (low power temporal oversampling) method of two-photon Ca^{2+} imaging (Chen et al., Nature 2011; Varga et al., PNAS 2011; Hill et al., PNAS 2013) of dendritic spines was performed in depths ranging from 310 μm to 520 μm. Loose cell-attached recordings were also performed in combination with Ca^{2+} imaging of dendritic spines. By analyzing NMDA receptor-mediated Ca^{2+} signaling in spiny dendrites, we found that whisker stimulation produced large responses in spines but not in the parent dendrites. We identified stimulation-activated spines with short response latencies of about 10 ms, representing predominantly thalamo-cortical input sites. These short-latency responsive spines were denser at proximal dendritic regions comparing to distal regions. The amplitude of sensory-evoked spine Ca^{2+} transients was independent of the activity of neighboring spines, without evidence for cooperativity. Furthermore, we found that spine Ca^{2+} transients evoked by back-propagating APs (bAPs) summed linearly with sensory-evoked synaptic Ca^{2+} signals. Finally, the amplitudes of Ca^{2+} transients in both dendritic shafts and whisker-responsive spines increased linearly with respect to the number of APs evoked by whisker stimulation. Thus, taken together, our results identify in sensory information-receiving L4 cortical neurons a linear mode of dendritic integration that underlies the rapid and reliable transfer of peripheral signals to the cortical network.

Title: The corticothalamic switch: controlling the thalamus with dynamic synapses

Authors: *S. R. CRANDALL, S. J. CRUIKSHANK, B. W. CONNORS;
Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: Layer 6 corticothalamic cells provide massive excitatory input to thalamus. This "top-down" projection is thought to influence thalamic throughput of sensory signals by modulating the excitability and firing state of thalamic cells. Corticothalamic neurons monosynaptically excite thalamocortical cells, but also indirectly inhibit them by driving inhibitory cells of the thalamic reticular nucleus. Whether the overall impact of corticothalamic activity is to suppress or excite thalamic relay neurons remains unclear. Here we show that the influence of layer 6 on thalamic excitability is dynamic, with the excitatory-inhibitory balance shifting in an activity-dependent fashion. During low-frequency activity corticothalamic effects are mainly suppressive, whereas higher frequency activity (even short gamma-frequency bouts) converts the corticothalamic influence to enhancement. This shift depends upon the interactions of excitatory and inhibitory synaptic components of the CT circuit that have distinct forms of short-term synaptic plasticity. Clarifying these dynamic network mechanisms provides a fresh framework for interpreting the powerful but varied effects of corticothalamic activity on sensory processing.

Title: Roles of GABAA and GABAB receptors in regulating thalamic activity by the zona incerta: A computational study

Authors: *A. PARK[1], K. HOFFMAN[2], A. KELLER[1];
[1]Anat. & Neurobio., Univ. of Maryland, Baltimore, Baltimore, MD; [2]Mathematics and Statistics, Univ. of Maryland, Baltimore County, Baltimore, MD

Abstract: The posterior thalamic nucleus (PO) is a higher order nucleus heavily implicated in the processing of somatosensory information. We have previously shown in rodent models that activity in PO is tightly regulated by inhibitory inputs from a GABAergic nucleus known as the zona incerta (ZI). The level of ZI inhibition varies under both physiological and pathological conditions, leading to concomitant changes in PO activity. These changes are causally linked to a variety of phenomena from altered sensory perception to pathological pain. ZI regulation of PO is mediated by GABAA and GABAB receptors (GABAAR and GABABR) that differ in their binding kinetics and their electrophysiological properties, suggesting that each may have distinct roles in incerto-thalamic regulation. Thus, we developed a computational model to test this hypothesis. We created a two-cell Hodgkin-Huxley model representing PO and ZI with kinetically realistic GABAAR and GABABR mediated synapses. We simulated spontaneous and peripherally evoked firing in PO, and observed how these activities were affected by inhibition mediated by each receptor type. We show that spontaneous PO activity is preferentially regulated by GABABR mediated mechanisms, while evoked activity is preferentially regulated by GABAAR. We also show that modulation of ZI firing rate and synaptic GABA concentrations are effective means to regulate the incerto-thalamic circuit. Differential regulation of peripherally evoked and spontaneous activity by GABAAR and GABABR, respectively, represents an opportunity for the development of therapeutics, as different aspects of incerto-thalamic regulation and thus, thalamic function, can be targeted through manipulation of a specific class of GABAergic receptors. Thus, these findings may help provide interventions for pathologies of sensory processing such as altered states of arousal and chronic pain.

Title: Cortical amplification dynamics of thalamic inputs in the barrel cortex

Authors: *K. COHEN-KASHI, B. MOHAR, Y. KATZ, I. LAMPL;
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Anatomical and electrophysiological studies have shown that thalamic inputs to layer 4 (L4) of sensory systems constitute only a small fraction of the total number of excitatory synaptic connections in this layer. Indeed, optogenetic inactivation of cortical firing demonstrated recently that only about a third of the sensory evoked excitatory current in L4 of the visual and auditory cortices can be accounted as thalamic input. In the barrel cortex, whisker stimulation evokes an early (50ms) excitatory response followed by a complete return to baseline and a delayed slow excitatory response that lasts up to few hundreds of milliseconds. The later response was hypothesized as having a role in the perception of the stimulus in behaving mice. Here, we evaluated the time course of cortical amplification of excitatory L4 cells response in the barrel cortex following whisker stimulation. To that end, we optogenetically silenced the cortex of lightly anesthetized GAD-ChR2 transgenic mice while intracellularly recording excitatory currents. While optogenetic silencing of cortical firing reduced the total early excitatory response to a single deflection of the primary whisker (PW) by ~53%, the late response was eliminated almost completely (~87%), indicating that it depends on cortical amplification. Furthermore, the fact that the excitatory current returned to baseline after the termination of the early component suggests the involvement of other layers or other cortical regions in the generation of the late response phase. The late response evoked by stimulation of adjacent whiskers (AW) was smaller compared to that evoked by the PW, indicating that cortical amplification is mostly column specific. Finally, we measured the contribution of thalamic versus intracortical inputs during repetitive whisker stimulation (10 stimuli, 20Hz). In a subset of cells (n = 10) which demonstrated repetitive response, cortical amplification increases during adaptation (relative thalamic input of 49.2±9.4% vs. 36.6±7.4% first vs. last five stimuli respectively), probably reflecting the contribution of the late cortical response. In summary, whisker stimulation evokes a fast early excitatory response followed later by a much slower excitatory response that reflects locally confined reverberating cortical activity. The late response may play an important function in amplifying thalamic inputs during adaptation and thereby increasing the throughput of information to the cortex.

Title: Coding of active and passive whisker touches in mouse somatosensory thalamus

Authors: A. L. SUMSER, R. A. MEASE, B. SAKMANN, *A. GROH;
Sakmann Lab., Inst. For Neurosciences, TU München, Munich, Germany

Abstract: As somatosensory specialists, rats and mice rely on touch signals from their whiskers to sample the environment. Whisker touches can either be caused 1) actively, when rhythmically whisking against objects, or 2) passively, when whiskers are touched during non-whisking periods. While these touch modes activate the cortex differently [1], it is not well understood which neuronal mechanisms and circuits allow this discrimination. The somatosensory thalamus is a hub for the integration of ascending sensory pathways with corticothalamic inputs [2]. We hypothesized that passive versus active touch discrimination is performed the in thalamus, involving top-down cortical circuits referencing sensory inputs to behavior. To test this, we recorded spikes from location-recovered neurons in the ventral posterior medial (VPM) and posterior medial (POm) nuclei of the thalamus, regions which both receive massive cortical input. We compared spike responses in awake, head-fixed mice during 1) passive touches, induced by focal air puffs to the stationary whisker and 2) active touches, caused by the animal actively whisking against an object. Barrel cortex local field potentials (LFP were recorded to determine cortical activity states. In comparison to quiescence, spike rates increased approximately two-fold during free whisking and touch periods. In both VPM and POm, we found cells that responded to passive touches (air puffs) with short latencies (<10 ms). However, individual neurons responded very differently to active touches. In parallel, cortical state differed strongly between passive and active modes: Pronounced delta (1-4Hz) oscillations were only present during passive state [3], while during whisking, higher frequencies dominated, indicating the desynchronized brain state characteristic of sensory processing. While active and passive

touch may lead to the same receptor activation, our data suggest that thalamic responses encode these events differently and pass these differences on to the cortex. Whether this thalamic property arises from Top-Down cortical input is currently being investigated. [1] Sachidhanandam, S., Sreenivasan, V., Kyriakatos, A., Kremer, Y., & Petersen, C. C. H. (2013). Title: *In vivo* dissection of L1 inputs in the Barrel cortex

Authors: *W. ZHANG[1], R. BRUNO[1,2];
[1]Neurobio. and Behavior, [2]Kavli Inst. for Brain Sci., Columbia Univ., New York, NY

Abstract: Layer 1 of the cerebral cortex is a largely acellular layer that consists mainly of long-range projection axons and apical dendrites of deeper pyramidal neurons. In the rodent barrel cortex, layer (L) 1 contains axons from both higher motor and sensory areas of the brain. Despite the abundance of synapses in L1 their actual contribution to sensory processing remains unknown. We investigated the impact of activating long-range axons on BC L2/3 pyramidal neurons. We focused on three main sources of BC-projecting synapses: the posterior medial nucleus of the thalamus (POm, the secondary somatosensory nucleus), the primary motor cortex (M1), and the secondary somatosensory cortex (S2). In each animal, we delivered the gene for channelrhodopsin (ChR2) to one of these three regions, and then photostimulated the ChR2-

positive axons in BC L1 while recording whole-cell recording from L2/3 cells *in vivo*. We found that while activation of POm axons elicits strong EPSPs in all recorded L2/3 cells, activation of M1 or S2 axons elicited small or no detectable responses. Only POM activation boosted sensory responses in L2/3 pyramidal neurons. We also found that under sedated and awake conditions, POM activation not only elicited a strong fast-onset EPSP in L2/3 neurons, but also a delayed persistent response. Pharmacological inactivation of POM abolished this persistent response but not the initial synaptic volley to L2/3. We conclude that the persistent response requires intrathalamic or thalamocortical circuits and cannot be mediated by specialized synaptic terminals or intracortical circuitry. This persistent activity may play a role in sensory processing.

Title: Electrical microstimulation of hindpaw representation in rat SI cortex yields better detection probability compared to vibrotactile stimulation of the glabrous skin during operant conditioning

Authors: *I. DEVECIOGLU[1,2], B. GUCLU[1];
[1]Inst. of Biomed. Engin., Bogazici Univ., Istanbul, Turkey; [2]Biomed. Engin. Dept., Namik Kemal Univ., Tekirdag, Turkey

Abstract: We previously showed that rats usually can achieve accuracies >70% for detecting vibrotactile stimuli applied on the glabrous skin of the hindpaws. In this study we applied intracortical microstimulation (ICMS) within the hindpaw representation of SI cortices of three female Wistar albino rats which had performed poorly in a tactile detection task. Similar to the tactile detection task, the ICMS task required right/left lever press for detecting or not detecting the presence of ICMS. The tactile detection task involved sinusoidal displacement bursts with amplitude 120 μm, duration 0.5 s, and frequency 40 Hz. ICMS consisted of biphasic pulse pairs

(cathodic phase first, phase duration: 200 µs, amplitude: 300 µA, interpulse interval: 500 µs) delivered at 40 Hz with a duration of 0.5 s. Custom-made tungsten microelectrodes were implanted in SI (hind paw representation) and AgL (vibrissae representation in motor cortex). Multiunit receptive fields were mapped with von Frey hairs and by inducing muscle twitches. Electrical stimulation through SI electrode did not generate a muscle twitch; tactile stimulation of the skin did not elicit activity in AgL electrode. After implantation and mapping, rats recovered for 1-2 weeks. Each rat started the same training schedule and reached >90% accuracy in the visually-guided side-lever-press task. However, they performed at chance level (~50%) in the tactile detection task, even after 10-50 sessions (~100 trials/session). When tested with ICMS, two rats achieved >90% accuracy. The third rat did not want to perform the task with ICMS, i.e. did not press the trial-start lever. These results suggest that electrical microstimulation improve conditioning to neural activity elicited in cortical networks processing tactile information. This will be further studied in associative learning models with varying salience.

Title: The role of retinoid-related orphan receptor beta in mouse primary somatosensory cortex barrel development and maintenance

Authors: ***T. D. LAUER**[1,2], Q. ZHANG[1,2], M. RUTLIN[3], S. NELSON[1,2];
[1]Biol., Brandeis Univ., Waltham, MA; [2]Natl. Ctr. for Behavioral Genomics, Waltham, MA;
[3]Columbia Univ., New York, NY

Abstract: The mouse whisker-barrel system has been used as a model for studying mammalian somatosensory circuit development and function for more than 40 years. Many genes and pathways have been shown to be important for formation of cortical barrels, yet relatively little is known about genetic control of barrel maintenance. We found that deletion of the nuclear

receptor Retinoid-related Orphan Receptor beta (RORb) causes progressive deterioration of barrels. In RORb knockouts (KOs), barrels are seen at P7, but have subtly reduced thalamocortical afferent (TCA) segregation, cortical neuronal clustering and cytochrome oxidase (CO) activity. This initial map degrades over time, and individual barrel structures are hardly distinguishable in adult RORb KOs. Transcriptional profiling from RORb+ cells in the barrel field was done to identify RORb-regulated genes that may control barrel formation and maintenance. RNAseq was performed on RORb-eGFP+ Layer 4 (L4) neurons sorted from KO and heterozygous animals (4 replicates). The initial analysis revealed 1246 differentially expressed genes with a false discovery rate (FDR) of 5%. Expression of receptors and signaling molecules previously found to be required for barrel formation were not significantly affected. However, mRNA levels of transcription factors (TFs) important for barrel formation were altered. Lmo4 had 56% increased expression (P=0.03), implying compensatory up-regulation. BTBD3, a TF needed for barrel cell dendritic polarization, was reduced by 29% but was not significant (P=0.06). A corresponding trend of reduced L4 dendritic asymmetry was evident from Golgi-Cox staining, but was also not significant (P=0.08, Kolmogorov-Smirnov test). Current efforts are underway that will determine which RORb-regulated genes are contributing the maintenance deficit in the RORb-loss of function animals. Additionally, RORa, RORb's closest paralog appears to be up-regulated at the protein level in the barrel field, suggesting RORa could be compensating for RORb loss of function. We are currently testing this hypothesis by generating double KO mice.

Title: Thalamo-cortical synchronization during sensory information processing in the vibrissal motor cortex in rats

Authors: ***A. MÚNERA**[1], M. NAVA-MESA[2], J. RAMÍREZ-LATORRE[2];
[1]Univ. Nacional De Colombia, Bogotá, Colombia; [2]Univ. del Rosario, Bogotá, Colombia

Abstract: The vibrissal sensorymotor system enables rodents to extract precise information about three-dimensional configurations in their immediate environment, generating motor

commands based on sensory input instantaneous changes; this mechanism requires continuous interactions between vibrissal motor cortex (vM1) and somatosensory thalamic nuclei (posteromedial, POM and ventroposteromedial, VPM). Bipolar stimulating whisker pad electrodes and vM1 and POM or VPM recording electrodes were implanted to anesthetized Wistar rats to evaluate these interactions. Single and paired whisker pad stimuli were administered while cortical and thalamic field potentials were recorded. Following single whisker pad stimuli, short-latency population spikes occurred simultaneously in vM1, POM, and VPM. Such spikes were followed by low frequency oscillations associated with long-lasting epochs of enhanced thalamo-cortical coherence. Following paired whisker pad stimulation population spikes became facilitated, while low frequency oscillations became depressed. Taken together such findings suggest strong thalamo-cortical coupling, as well as sustained intracortical inhibition, in vM1 during somatosensory information processing and motor command generation.

Title: Thalamocortical feedforward inhibition by infragranular somatostatin-containing interneurons

Authors: *A. AGMON[1], H. HU[2];
[1]Dept Neurobiol & Anat, West Virginia Univ. Hlth. Sci. Ctr., Morgantown, WV; [2]West Virginia Univ., Morgantown, WV

Abstract: Inhibitory cortical interneurons are strongly activated by thalamocortical inputs and mediate disynaptic feedforward inhibition onto neighboring excitatory neurons, thereby curtailing their direct thalamocortical excitation and reducing spike dispersion. Most previous studies emphasize the role of parvalbumin (PV)-containing, fast-spiking (FS) interneurons in mediating feedforward thalamocortical inhibition. We previously reported (Tan et al 2008) that somatostatin-containing (SOM) interneurons may also be involved in feedforward inhibition, and

demonstrated that in response to high-frequency thalamocortical stimulation, infragranular FS interneurons are activated early but transiently due to depression of their thalamocortical EPSPs, while infragranular SOM interneurons are activated later but in a sustained fashion, due to facilitation of their EPSPs. Here we tested directly the relative contributions of FS and SOM interneurons to feedforward inhibition in infragranular excitatory (E) neurons, by recording their responses to trains of 10 thalamocortical stimuli at 10-40 Hz while suppressing firing of either SOM or FS interneurons optogenetically. Illuminating SOM interneurons in SOM-halorhodopsin mice hyperpolarized them by 8-25 mV and reduced their total spike count to 7-30% of control; illuminating FS interneurons in PV-archaerhodopsin mice hyperpolarized them by 4-7 mV and reduced their total spike count to ~60% of control. In E-neuron, thalamocortical stimulation elicited trains of either pure IPSPs or EPSP-IPSP sequences. Optogenetic suppression of FS interneuron reduced the first, and occasionally the second IPSP in the train, without significantly affecting later IPSPs. Total spike count in E cells, during and 1000 ms after the train, was increased by 1.6-fold at 40 Hz stimulation. In contrast, optogenetic SOM suppression most often left the first and second IPSPs unchanged, but strongly reduced, blocked or even reversed the later IPSPs in the train. In many E neurons as well as in some FS interneurons, SOM (but not FS) suppression elicited a slow depolarization during and following the train, triggering spikes and occasional “up states”. On average, SOM suppression increased the total spike count in E cells by 8-fold at 40 Hz stimulation. We conclude that SOM interneurons make a major contribution to feedforward inhibition of excitatory infragranular neurons during high-frequency thalamocortical volleys, and are critical for preventing over-excitation of infragranular excitatory neurons during sustained thalamocortical activity, such as may arise during exploratory behavior.

Title: Functional organization of the motor reticulothlamic input to VA/VL and CL neurons

Authors: ***Y.-W. LAM**[1], D. RHEE[2], S. SHERMAN[2];
[2]Neurobio., [1]Univ. of Chicago, CHICAGO, IL

Abstract: Most of our understanding of the organization of thalamus is based on studies of the sensory thalamic relays. To extend this, we investigated aspects of organization of other nuclei with a focus on the projection in mice from the GABAergic thalamic reticular nucleus (TRN) to the motor relays, the ventral lateral and ventral anterior nuclei (VA/VL), as well as the central lateral nuclei (CL). We used a slice preparation that preserves the connectivity between TRN and the thalamic nuclei of interest noted above. We used whole cell recordings in these nuclei and investigated the topography of their TRN input using laser scanning photostimulation. The pattern of these inputs was very similar to those described for the somatosensory thalamus. That is, TRN input to VA/VL neurons were spatially limited and topographically organized. Overall, the input zones, or footprints, were somewhat larger than those to the first order somatosensory nuclei, the ventral posterior lateral and ventral posterior medial (VPL and VPM), and in many cases, consisted of two separated footprints; in this respect, the pattern was more similar to the TRN input footprints to the higher order posterior medial nucleus (POm). The TRN input to CL was organized in a similar specific and topographic manner and interestingly, the TRN inputs of VA/VL and CL neurons were located in overlapping areas. As TRN is reported to be organized into functionally related segments, this result suggests that either CL neurons have motor related functions or the "motor" TRN in mice may actually consists of neurons with different functions. Overall, we conclude that the pattern of TRN inputs to these other thalamic nuclei, VA/VL and CL, is very similar to that described for sensory thalamic nuclei.

Title: Layer 4 in area 4: Characteristic input-output connectivity of pyramidal neurons at the layer 3/5A border in the lateral agranular region of mouse motor cortex

Authors: *K. E. BORGES, N. YAMAWAKI, B. A. SUTER, X. LI, G. M. G. SHEPHERD; Physiology, Feinberg Sch. of Med., Northwestern Univ., Chicago, IL

Abstract: An enduring enigma about the functional organization of agranular cortical areas such as primary motor cortex (M1; area 4) is the absence of a distinct layer 4 (L4) and how this relates to the local and long-range synaptic circuits. We investigated the possibility that M1 possesses the hodological equivalent of L4 in the form of excitatory neurons at the L3/5A border with characteristic input-output circuits similar to those of L4 in sensory areas. Consistent with this idea, putative L4 neurons in M1 received excitatory input from both motor (VA/VL) and sensory (PO) thalamus, and sent excitatory output to L4 and L2/3 neurons, but received relatively little local input from L2/3. M1 L4 neurons were electrophysiologically diverse, but morphologically fairly uniform, with pyramidal-type apical and basal dendritic arbors and locally ramifying axons with branches extending into L2/3. Thus, M1 L4 neurons largely resemble their counterparts in sensory cortical areas in possessing a core set of characteristic local and long-range input and output connections. However, they differ from sensory L4 neurons in that they receive weak or no input from L6 neurons, and lack spiny stellate morphology. These results thus decrypt the circuit connections of L4 neurons in the lateral agranular area of M1, demonstrating a basic input-output organization resembling that of L4 neurons in other cortical areas.

Title: Thalamic encoding of kinematic whisker slips in the awake behaving rat

Authors: *C. WAIBLINGER[1,2], C. SCHWARZ[1,2], C. J. SHEPHARD[3], G. B. STANLEY[3]; [1]Werner Reichardt Ctr. for Integrative Neurosci., Tübingen, Germany; [2]Hertie Inst. for Clin. Brain Res., Tübingen, Germany; [3]Wallace H Coulter Dept. of Biomed. Engineering, Georgia Tech. and Emory, Atlanta, GA

Abstract: The rodent whisker-related somatosensory thalamus (VPm) controls and modifies ascending tactile signals destined for the barrel cortex. We set out to investigate which aspects of the signal is transmitted by VPm and used to generate the animal's percept. Further, we tested

whether this transmission is adaptive, i.e. is influenced by presenting different sensory environments. Our starting point was previous work on rodent vibrissae biomechanics and perception that strongly suggest that fast kinematic signatures (so called ‘slip-events’ lasting for ca. 10 ms) which change in number and waveform depending on the touched texture are preferentially used to generate the subject's tactile percept. Here, we trained head-fixed rats to detect precise whisker stimuli that mimic these natural signatures (tagged 'slip-like events') embedded in broadband noise. Analyzing reaction times we found that rats extract whisker slips of different shape and direction based on the amplitude relative to the background noise but largely ignore slip frequency. VPm multi units respond to the broadband noise but additionally extracted slip-like events by brisk bursts of spikes. When subjecting rats with slip-like events that switch direction at one point during the session, we observed that VPm multi units change their response properties on a times scale of tens of seconds or minutes - possibly relating to an adaptation process brought about by the changed sensory conditions. A more detailed investigation of single unit receptive field properties and information transmission using the broadband noise stimuli is under way. Our results so far, confirm and further elaborate the hypothesis that instantaneous events are decisive coding elements for whisker-related tactile perception.

Title: The organization of the human thalamus estimated by large network functional connectivity

Authors: B. PASCUAL[1], M. HOLLENBECK[1], *J. C. MASDEU[2,1];
[1]Dept. of Neurol., Houston Methodist Hosp., Houston, TX; [2]Section on Integrative Neuroimaging, NIH, Washington, DC

Abstract: Introduction. The thalamus, a complex array of different nuclei, plays a major role in cortical activation. Data from non-human primates and from lesion studies suggest that the thalamus projects to the cortex in a highly organized fashion. However, the human thalamus is

highly evolved from non-human primates and lesion studies are limited by chance. Functional connectivity provides a novel approach to study the organization of the different thalamic nuclear groups. In order to clarify the functional connectivity of the left thalamus, we sought concordance between the resting-state BOLD signal in small nuclei of the left thalamus with a similar signal in the rest of the brain. We hypothesized that (1) different nuclei of the thalamus would be predominantly connected to different cortical and subcortical areas; and (2) from the pattern of cortical connectivity we could derive information on the functional relevance of each thalamic nuclear group. Methods. Using seed-based resting-state functional MRI data from 198 young adults, we examined cortico-subcortical correlations by means of a functional connectivity analysis. Fifty-seven seed regions of interest were projected along the anterior to posterior thalamus. Intrinsic functional connectivity MRI was used to extract low-frequency spontaneous BOLD fluctuations within those regions to calculate functional correlation maps. The topographical similarity of the resulting maps was calculated. Using these values, clustering analysis was performed to better understand the grouping of thalamo-cortical functional architecture within the thalamus. Results. Functional connectivity of the thalamus defined five major thalamic clusters: (1) Medial and anterior thalamic nuclear groups, which were positively correlated with the “limbic” and frontal lobes; (2) Ventral lateral nuclear group, correlated with basal ganglia and with precentral cortex; (3) Ventro-posterior and basal, which were correlated with postcentral structures, mostly in parietal lobe. (4) Dorsolateral and posterior nuclear groups, particularly the pulvinar, which were correlated with the precuneus; (5) Geniculate bodies, medial correlated with auditory cortex and lateral correlated with visual cortex. Many regions had cerebellar correlations, often larger with the contralateral cerebellar hemisphere. Conclusions. The functional connectivity of the thalamus is concordant with its known anatomic connectivity from studies in the monkey and from human lesion data. Refinement of this technique may render it even more useful to map the functional brain networks anchored in the thalamus

Title: Bilateral symmetries in an inherently asymmetric motor pattern

Authors: *A. WENNING[1], B. J. NORRIS[2], R. L. CALABRESE[1];
[1]Biol., Emory Univ., ATLANTA, GA; [2]California State Univ., San Marcos, CA

Abstract: Bilateral symmetry is common to all vertebrates and many invertebrates, yet underlying asymmetries abound both in the body plan and in the nervous system. We were curious to what extent bilaterally organized central pattern generators (CPGs), the motor patterns they control, and the corresponding motor outputs were symmetric. We chose a system dedicated to one task to ask how side-to-side variations within one animal compared to the variations seen across animals. We chose leech heartbeat in which each CPG (one on each side) controls an ipsilateral ensemble of heart (HE) motor neurons, which in turn entrain the segmental sections of the ipsilateral heart tube. Though the layout is bilaterally symmetric, patterns are not. At any given time, the beat pattern, the motor pattern, and the temporal pattern of the premotor (HN) heart interneurons display a left/right asymmetry. Intersegmental coordination is rear-to-front on one side and synchronous on the other with switches between sides every 20 to 40 heartbeat cycles. Thus, both CPGs control, and both sides execute, both coordination modes – albeit not at the same time – and leech heartbeat switches between two patterns: left synchronous/right peristaltic and *vice versa*. We compared the side-to-side variations of the beat patterns, the motor pattern, the temporal pattern of the HN interneurons, and their synaptic weight to the HE neurons within one animal and across preparations. We focused on midbody segments 7 to 14 where the same HN interneurons control the HE motor neurons. In isolated ganglia chains we examined the intersegmental phase differences of these HN interneurons and their synaptic weights to the HE motor neurons. In intact (imaged) animals we quantified the heart constriction patterns. We found that the intersegmental phase differences of the HN interneurons, their synaptic weights in the HE neurons, and the heart constriction patterns differ on the two sides. While there was no preference for body side regarding synaptic weights and the temporal pattern of the CPG, the heartbeat pattern showed lateralization in the peristaltic mode. Within one animal, side-to-side variability in the parameters examined so far was similar to the variability seen across animals.

Title: Do synaptic or intrinsic properties govern animal-to-animal variability in motor patterns?

Authors: *C. GUNAY[1], D. G. LAMB[2], R. L. CALABRESE[1];
[1]Biol., Emory Univ., ATLANTA, GA; [2]Neurol., Univ. of Florida, Gainesville, FL

Abstract: Motor patterns are essential for life, and they are known to be robustly expressed even in the presence of large animal-to-animal variations in both synaptic and intrinsic properties of the neurons that produce them. This suggests that underlying mechanisms exist to preserve functional output motor patterns. Studying these mechanisms is more difficult in the complex motor networks of vertebrates. In invertebrates like the leech (Hirudo sp.), a complete network of premotor and motor neurons can be mapped and recorded. The well-studied leech heartbeat central pattern generator network is appropriate for studying correlates of animal-to-animal variability. Here we used recordings from 6 leeches of a complete input-output network composed of firing patterns from all premotor inhibitory interneurons, strengths of their synapses that impinge onto two bilateral pairs of output motor neurons, and those motor neurons' output firing patterns (Wright and Calabrese, J Neurosci, 31(48):17555-17571, 2011). Each individual leech had variations in input and output motor patterns and in synaptic strengths. Here, we are asking what motor neuron intrinsic properties are necessary to produce the target output patterns given the recorded input patterns and synaptic strengths. To answer this question, we have previously conducted an evolutionary parameter search to find the intrinsic properties represented by ion channel maximal conductance parameters of a Hodgkin-Huxley type, muticompartmental model of heart (HE) motor neurons leech ganglia 8 and 12 (Lamb and Calabrese, PLoS ONE 8(11): e79267, 2013). As a result of this search, we have found candidate models that can reproduce target output motor patterns of HE(8) and HE(12) motor neurons, or both (431 model instances) for one given input pattern. In the present work, we simulated these successful instances with inputs recorded from other leeches: premotor temporal pattern and corresponding synaptic weights. Because these synaptic weights have been recorded as relative values in isolation, they must be scaled by a coefficient to be used in a model motor network. We were able to find such coefficients for some of the 431 HE model instances to produce target output phases for 4 out of the 6 individual motor patterns. The question that remains is whether any synaptic configuration exists that can produce these remaining 2 output patterns. Furthermore, are there any general mechanisms that affect intrinsic properties that can allow a set of instances to match all 6 input patterns? These questions can be addressed by conducting further parameter searches of this model motor network and mining the results.

Title: How can either stimulation or inhibition of the Na+/K+ pump current decrease the period of a central pattern generator?

Authors: *W. H. BARNETT[1], D. KUEH[2], R. L. CALABRESE[2], G. S. CYMBALYUK[1]; [1]Neurosci. Inst., Georgia State Univ., ATLANTA, GA; [2]Biol. Dept., Emory Univ., Atlanta, GA

Abstract: Growing evidence implicates the importance of Na+/K+ pump in central pattern generators (CPGs), which control rhythmic behavior such as locomotion [1]. The Na+/K+ pump has been shown to be a target for neuromodulation. In the leech heartbeat CPG, the neuropeptide myomodulin speeds up the period of the bursting pattern by increasing h-current and decreasing the Na+/K+ pump current in the heart interneurons (HNs) [2]. A role of the Na+/K+ pump current in the dynamics of HN neurons was indicated by experiments using the H+/Na+ antiporter monensin, which stimulates the pump by diffusively increasing the intracellular Na+ concentration. Interestingly, application of monensin decreases the period of a leech heartbeat half-center oscillator (HCO) in the presence of h-current. These results appear to be counterintuitive. How can either stimulation or inhibition of the Na+/K+ pump current decrease the period of a central pattern generator and what role does h-current play in this phenomenon? We developed a model of the HN neuron including intracellular Na+ concentration dynamics and the Na+/K+ pump current. We considered HCO and isolated HN neurons with and without h-current. HN neurons were isolated with bicuculline, and the h-current was blocked with Cs+. The model reproduced the key experimental results under all 12 experimental conditions. These results emphasize the role of the Na+/K+ pump current in the dynamics of the CPG neurons. The Na+/K+ pump dynamics directly affect HN neuron and HN-HCO bursting activity. Pump modulation provides an effective means for period control. The pump contributes to burst termination mechanism and governs interburst interval. Interaction between the pump current and the h-current creates a dynamic mechanism effectively controlling the interburst interval. References 1. Zhang HY, Sillar KT. Title: Sensitivity of period to variations of maximal conductances in an HCO model

Authors: *A. DOLOC-MIHU, R. L. CALABRESE;
Dept. of Biol., Emory Univ., ATLANTA, GA

Abstract: Robustness in response to developmental and environmental challenges is essential to the central pattern-generating networks (CPGs) that program rhythmic behaviors on all animals. Here, we used a half-center oscillator (HCO) (two mutually inhibitory neurons) model [1] that replicates the electrical activity (rhythmic alternating bursting of mutually inhibitory interneurons) of the leech heartbeat CPG under a variety of experimental conditions to determine the role of conductances in the robust maintenance of functional bursting activity. Precisely, we focused on the role of those parameters' changes which correspond to known neuromodulations such as the modulation of h current by myomodulin [2]. In our previous work [3], we had built a relational database (named HCO-db) of Hill's HCO [1] model instances. In the HCO model, an individual leech heart interneuron was represented as a single isopotential electrical compartment with Hodgkin and Huxley type intrinsic membrane and synaptic conductances. The HCO model has eight currents with voltage-dependent conductances including two types of inhibitory synaptic currents, spike mediated and graded. By varying a set of 8 key parameters (the leak reversal potential and maximal conductances of synaptic and several membrane currents) in all combinations possible (brute-force approach), we systematically explored the parameter space of this HCO model and analyzed more than 10 million of its simulated instances. We analyzed and classified within a group the simulated instances showing similar electrical activity, and we identified these groups which include instances showing burst characteristics (period and spike

frequency) similar to the animal. There were: 1,202,139 HCO instances; 99,066 realistic HCOs; 424 bursters, and 307 realistic bursters. Experimental studies have shown that period is a key attribute influenced by modulatory inputs variations in leech heart interneurons [2]. By querying our HCO-db database, we explored the sensitivity of period to changes in maximal conductance of the h current ($\bar{g}h$) for the above groups of instances. When $\bar{g}h$ was set to zero, no isolated neuron instances produced rhythmic burstss bur many instances of realistic HCO were observed. We also found that increasing the amount of $\bar{g}h$ monotonically decreases the period of the realistic HCOs, which confirms Hill's [1] results stated for a more restricted parametric space. Title: Stimulation of the Na^+/K^+ pump can accelerate rhythmic bursting in CPG neurons but requires the h-current

Authors: *D. KUEH[1], G. S. CYMBALYUK[2], R. L. CALABRESE[1];
[1]Dept. of Biol., Emory Univ., Atlanta, GA; [2]Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: The dynamics of various membrane and synaptic currents together shape the electrical activity of CPG neurons and networks that program motor output. Modulation of these currents can then regulate burst characteristics, e.g., period. The outward current generated by an electrogenic Na^+/K^+ pump is not often considered when exploring the bursting of CPG neurons, but can represent a target of modulation. To determine the effects of stimulating the Na^+/K^+ pump on bursting activity, we made simultaneous bilateral extracellular recordings from paired heart (HN) interneurons that form half-center oscillators in the leech heartbeat CPG. When the

pump activity of HN half-center oscillators was stimulated with monensin, a Na^+-H^+ antiporter, their burst period decreased significantly. This effect of monensin was not observed when the h-current was blocked by external Cs^+. To determine the effects of stimulated pump activity on single neurons, we pharmacologically isolated the HN neurons with bicuculline. When isolated in this way, the burst period decreased significantly. Application of monensin further decreased the burst period of these isolated HN neurons. Blocking the h-current in isolated HN neurons with Cs^+ increased their burst period dramatically, and subsequent application of monensin had no effect on burst period. However, monensin did eventually block all activity under these conditions and bursting could be restored after removal of Cs^+. Finally, inhibition of pump activity by the removal of external K^+, led to an initial decrease in burst period, but bursting was gradually and reversibly suppressed over time. Taken together, the stimulation of Na^+/K^+ pump activity in an HN half-center oscillator or in isolated HN neurons decreases the burst period, and this effect requires the presence of the h-current. Moreover, inhibition of pump activity initially speeds up rhythmic bursting activity as well, only to suppress all activity over time. Thus, the interaction of the electrogenic activity of the Na^+/K^+ pump with the h-current appears to play a significant role in the dynamics of bursting in the leech heartbeat CPG and perhaps in other rhythmically bursting neuronal networks as well.

Title: The effects of CsCl in the gastric and pyloric neurons in the stomatogastric ganglion of the lobster, Homarus americanus

Authors: *L. ZHU, A. I. SELVERSTON, J. AYERS;
Marine Sci. Ctr., Northeastern Univ., Nahant, MA

Abstract: Hyperpolarization-activated inward current (*Ih*) is an important pacemaker current that is known to regulate cellular excitability, post inhibitory rebound, and synaptic strength in the pyloric network in the stomatogastric ganglion (STG) in *Cancer borealis* and *Panulirus interruptus*. Schulz and Marder's research groups have profiled the ionic channel mRNAs in the STG in *Cancer borealis*, in which they've shown that the *Ih* channel mRNA (IH) is also

expressed in the gastric neurons, including GM, LG and LPG neurons. However, little is known about the role of *Ih* in gastric neurons in the STG. In our study, we investigated the role of *Ih* in rhythmic activity and cellular excitability in both gastric neurons (GM, MG, LG, LPG) and pyloric neurons (PD, VD, PY, LP) in *Homarus americanus.* Through determination of a dose response curve between 0.5mM and 500mM based on the rhythmic activities obtained from extracellular and whole cell current recordings, we found a dose of 100mM CsCl is necessary to achieve the strongest effects in blocking *Ih* in *Homarus*. At 100mM, the rhythmic activities of gastric neurons were abolished; the rhythmic activities of pyloric neurons were abolished or greatly reduced. Similarly, 300μM ZD7288 blocked gastric activity and most of pyloric activity. At 30mM CsCl, the slow oscillations (plateau potential) on all investigated gastric neurons were abolished, while the slow oscillations on all investigated pyloric neurons remained, indicating *Ih* concentration has differential effects on slow oscillations in the gastric and pyloric neurons examined. In addition, gastric neurons (GM, LPG) continued their spiking activities when the slow oscillations were abolished; however, pyloric neurons (VD, LP) lost spiking activities before the elimination of the slow oscillations. This indicates that the spiking activities are less sensitive to *Ih* concentration than the slow wave oscillations in the GM and LPG neurons, while the opposite relation applies to the VD and LP neurons. We are in the process of refining the differential sensitivities to *Ih* in different STG neurons. We performed an analysis of the changes in rhythmic properties at 30mM CsCl, including burst period, burst duration, and spikes per burst. Our results have shown that 1) Unblocking *Ih* induced temporary increase in the duty cycle of gastric neurons (GM, MG, LG) when compared to control levels (before the block), which indicates that *Ih* can increase the excitability of gastric neurons. 2) Blocking *Ih* increased the duty cycle of PY neurons, and reduced the spiking activities of VD neuron.

Title: Three different methods to identify transmitters of coordinating neurons in the crayfish swimmeret system

Authors: *A. C. SCHNEIDER[1], H. SEICHTER[1], S. NEUPERT[2], C. R. SMARANDACHE-WELLMANN[1];
[1]Zoological Institute, Animal Physiology, Emmy Noether Group, [2]Zoological Inst., Univ. of Cologne, Cologne, Germany

Abstract: Neural oscillators coordinated to produce meaningful behavior exist in a huge variety of animals, ranging from swimming and flying to walking and brain oscillations. We use the crayfish swimmeret system as a model to study coordination of neural oscillators because the mechanisms of coordinated motor output, especially neurons of the coordinating circuit, are identified on cellular level. Movement of the four pairs of swimmerets progresses in a metachronal wave from posterior to anterior with a stable phase lag of 25% between segments. Each swimmeret is controlled by one central pattern generator (CPG) located in each hemiganglion. The coordination of the CPGs is achieved by a coordinating circuit of exactly three neurons per hemiganglion: One ascending (ASC_E) and one descending (DSC) coordinating neuron, as well as one non-spiking Commissural Interneuron 1 (ComInt 1). The coordinating neurons ASC_E and DSC encode information about the activity state of their home ganglion and send it to the ComInt 1s of the other three ganglia, where the information, arriving with a gradient of synaptic strength, is decoded and integrated into the CPG. Each action potential of ASC_E and DSC causes a distinct and fast excitatory postsynaptic potential (EPSP) in ComInt 1. In our attempt to characterize the coordinating neurons we want to identify their putative transmitters. Because of the EPSP characteristics the transmitters of the coordinating neurons are supposedly of low molecular weight, like acetylcholine (ACh), serotonin (5-HT), or glutamate. For characterization we used (1) electrophysiological, (2) immunohistochemical, and (3) mass spectrometrical methods on an isolated preparation of the abdominal nerve cord. (1) In split-bath experiments we recorded intracellularly from ComInt 1 and perfused GABA and glutamate antagonists. As they did not block EPSPs in ComInt 1, we ruled them out as transmitters for ASC_E and DSC. (2) For the immunohistochemical experiments we stained ASC_E and DSC with intracellular dye injection and used antibodies against 5-HT in the respective ganglion. Results showed no colocalization of 5-HT immunoreactivity and the dye-filled coordinating neurons, also excluding this transmitter. (3) For the matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF), the coordinating neurons were dye injected and the thus visible soma or area of dendritic arborization isolated for analysis. We could identify ACh as putative transmitter of the coordinating neurons, present in samples of both the soma and area of dendritic arborization. Results further confirmed the absence of 5-HT in these neurons.

Title: Modeling encoding in identified coordinating neurons

Authors: *T. M. WRIGHT, JR, M. S. GOLDMAN, B. MULLONEY;
Neurobiology, Physiol. and Behavior, Univ. of California, Davis, Davis, CA

Abstract: Crayfish swim using four pairs of swimmerets on their abdomen that move in a periodic coordinated sequence. Each swimmeret is controlled by a local neural microcircuit that produces the patterned motor output that drives these movements. At each level of excitation, microcircuits in different segments have the same period but differ in phase. Although period changes in response to changes in excitation, these intersegmental phase differences do not change. Information required to coordinate these distributed microcircuits is encoded as bursts of spikes in identified coordinating neurons. A pair of coordinating neurons that project to targets in other segments originate in each microcircuit. Bursts of spikes in these neurons affect the phase and strength of motor output from the other microcircuits to which they project. As excitation changes, the periods and durations of bursts in these coordinating neurons change proportionately, but the numbers of spikes per burst do not change significantly. This invariance of intersegmental phase and spikes per burst suggests that encoding and decoding of coordinating information is modulated by changes in excitation that act either on synaptic currents, or on the neurons' intrinsic properties, or both. To describe the coordinating neurons' intrinsic encoding properties, we identified individual coordinating neurons in isolated ventral nerve cord preparations. We recorded their response to pairs of triangular ramp-currents whose periods and durations approximated the periodic synaptic currents these neurons receive in active preparations. Coordinating neurons exhibited two components of adaptation: a short-term

adaptation that causes spike hysteresis within a burst, and a longer-lasting adaptation that affects the second burst of the pair. To model these responses quantitatively, we constructed a mathematical model that captures the intrinsic excitability of these neurons. We tuned the model to capture the numbers and timing of spikes in response to different current durations and amplitudes, and also the intraburst and interburst components of adaptation. We show that the excitability of the model neuron can be tuned effectively by two parameters, and use the model to perform virtual experiments that show how excitability of coordinating neurons might be tuned by changing excitation.

Title: Robustness of coordination to temperature perturbation in a chain of microcircuits

Authors: *C. R. SMARANDACHE-WELLMANN, F. BLUMENTHAL;
Zoological Institute, Animal Physiology, Emmy Noether Group, Univ. of Cologne, Cologne, Germany

Abstract: Swimmerets are four pairs of limbs attached to the abdomen of crayfish, and are used for forward swimming. They are controlled and innervated by four of six abdominal ganglia. In each hemiganglion a neuronal circuit drives motor neurons which activate the limbs in alternating cycles of power-stroke (PS) and return-stroke movement. An identified coordinating circuit synchronizes these central pattern generators, so that a metachronal wave is present where the last segment starts the PS and the anterior modules follow with a latency of 0.25 phase. This synchronization is independent of the frequency of the rhythm and of sensory feedback. A different coordinating pattern was never observed in these crayfish. Here we wanted to test if temperature can change coordination. In normal conditions signal crayfish, Pacifastacus leniusculus, live in rivers where temperature ranges from 5°C (in wintertime) to 25°C (during

summertime). Therefore we used a similar temperature range to perturb the system. For these experiments we used animals which were kept at normal temperature (14°C, middle) and two sets of crayfish which were acclimated at extreme conditions: cold (4°C) and warm (25°C) for at least 6 weeks. All experiments were done on the isolated nervous system with extracellular recordings of all motor nerves responsible for swimmeret movements. We treated the nerve cord with saline having temperatures between 4 to 35°C. Here we tested if the nervous system's activity is stable towards temperature perturbations and if animals kept at extreme conditions reacted differently to sudden temperature changes. In all experiments, where the swimmeret rhythm was active, the coordinating pattern with a phase lag of 0.25 between PS bursts remained stable. On the other hand period, burst duration and PS burst strength decreased with increased temperatures. When we compared the different acclimated animals we observed very distinct effects. The coordinated rhythm of cold acclimated animals became unstable at around 15°C and broke down at high temperatures. In contrast warm acclimated crayfish had very slow or uncoordinated rhythms at low temperatures, which became stable at temperatures between 18°C to 30°C. Middle acclimated animals produced well coordinated rhythmic activity over a larger temperature range (4 to 25°C) than animals acclimated under extreme (cold or warm) conditions. When motor neurons were recorded intracellularly at the same time, their membrane potentials hyperpolarized during warm and depolarized in cold states. This change in membrane potential is probably due to a change in potassium flow according to Q10.

Title: Excitatory Hb9 interneurons involved in locomotor rhythm generation

Authors: *V. R. CALDEIRA, O. KIEHN, K. J. DOUGHERTY;
Neurosci., Karolinska Inst., Stockholm, Sweden

Abstract: Rhythm generating neurons are ventrally-located, ipsilaterally-projecting, excitatory neurons in the thoracolumbar spinal cord. There is no known marker of rhythm generating neurons, making it difficult to identify and target them. However, recently, a subset of Shox2 interneurons was found to make up a fraction of the rhythm generating population (Dougherty et al., 2013). In searching for other rhythm generating neurons, we are focusing on the excitatory subsets of mixed-transmitter, known populations. One such population is the Hb9 interneurons (Hb9 INs). Although the homeobox gene Hb9 was initially characterized as a motor neuron (MN) marker (Thaler et al., 1999; Arber et al., 1999), the generation of an Hb9::GFP mouse line (Wichterle et al., 2002) revealed that, in addition to MNs, GFP is also expressed in both excitatory and inhibitory interneurons. A small population of excitatory Hb9 INs that retains Hb9 protein expression postnatally has undergone extensive electrophysiological characterization and has been postulated to be candidate for rhythm generating neurons in the mammalian spinal cord (Hinckley et al., 2005; Wilson et al., 2005). Nevertheless, the involvement of Hb9 INs in rhythm generation has never been directly tested. Here we show that Hb9::Cre leads to recombination in a mixed population of interneurons throughout the spinal cord. Transmitter phenotype and overlap with developmental markers was evaluated in Hb9::Cre; Rosa26::XFP cords using crosses with various Transmitter::XFP mice and antibody stainings. To target the glutamatergic Hb9 INs, we resorted to an intersectional genetics approach to selectively delete Vglut2 specifically from Hb9 neurons. In the resulting mutant mice (Hb9Cre-Vglut2Δ/Δ), glutamate is not released from Hb9 INs, thereby synaptically silencing the excitatory Hb9 population. Locomotor-like activity was evoked in *in vitro* spinal cords from these mice at P0 with combination of NMDA and 5-HT. We did not observe any difference in left-right and/or flexor-extensor phasing between mutants and controls, suggesting that excitatory Hb9 INs do not affect pattern generation. In controls, the mean locomotor frequencies increased with increasing NMDA concentrations. The frequencies of locomotor activity in the Hb9Cre-Vglut2Δ/Δ cords also increased with increasing NMDA concentration but were significantly lower than in controls. Thus, the blockage of synaptic output from glutamatergic Hb9 neurons results in a lower locomotor frequency and thereby suggests these interneurons play a role in rhythm generation.

Title: A cell-type catalog of the neurons in the stomatogastric ganglion of the Jonah crab Cancer borealis

Authors: *M.-L. GOERITZ, T. BROOKINGS, R. Z. YANG, A. C. SUTTON, E. MARDER; Biol., Brandeis Univ., WALTHAM, MA

Abstract: The networks in the stomatogastric ganglion (STG) of the Jonah crab *Cancer borealis* have been extensively studied as a model system for central pattern generation. The physiology of the underlying cells has been described in detail, but surprisingly few studies have addressed the morphology of these cells in this species. As we continue to learn about the intrinsic properties of STG neurons and their variance across animals, a systematic documentation and comparison of their morphology is needed. We assembled a morphological catalog of the 14 different cell types in the STG, using dye-fills and high-resolution confocal microscopy. We found cell type specific differences in overall appearance, branching pattern and branching complexity. We compared the architecture of the C. borealis STG with that of its distant relative, the Maine lobster *Homarus americanus*. The two species separated in the Paleozoic, but the stomatogastric neurons have largely retained their physiological identities. The overall shape of the STG in C borealis is flattened and the neuron somata are organized laterally around a shared neuropil in the center of the STG. This is different from the STG in the lobster, in which the somata are dispersed over the dorsal surface of the spindle-shaped ganglion. Despite these differences in appearance, we found several salient features conserved between the two species. Among these is the overall organization of the neurons, which consist of a large soma at the periphery of the ganglion, and a wide primary neurite that gives rise to several secondary branches or varying complexity, and one (or several) axons that leave the STG and connect to the musculature. In both species, neurons can exhibit dramatic changes in diameter at branch points, and both have hand-like structures of branch points with multiple offspring branches (Bucher et al 2007). However, we also found features that were specific to *C. borealis* STG neurons, such as a more circular cross-section of the processes, and elongated varicosities in small diameter processes, for example in the lateral gastric (LG) neuron. Title: Endocannabinoids supplement a hardwired circuit to promote behavioral selection by switching between motoneuron pools in adult zebrafish

Authors: *J. SONG[1], K. AMPATZIS[2], J. AUSBORN[2], A. EL MANIRA[2];
[1]Karolinska Inst., Stockholm, Sweden; [2]Karolinska Institutet, Stockholm, Sweden

Abstract: Animals constantly make behavioral choices to move efficiently through the environment. When faced with a threat, animals make decisions in the midst of other ongoing behaviors through a context-dependent integration of sensory stimuli. The mechanisms underlying these behavioral selections in vertebrates are not well understood. In this study, we examine the neural underpinnings of the context-dependent priority of escape behavior over swimming by recapitulating these two motor behaviors and their interactions in an *in vitro* preparation of adult zebrafish. We show that the selection of escape over swimming is mediated by switching between fast and slow motoneuron pools. The fast motoneuron pool underlying escape is engaged via monosynaptic excitation. In contrast, the slow pool underlying swimming is disengaged via indirect inhibition that decouples these slow motoneurons from the premotor swim circuit. The onset of the escape and the associated inhibition of swimming activity are determined by a hardwired fast circuit. However, the threshold for initiation of escape and the extent of inhibition of swimming relies on endocannabinoid retrograde signaling. Thus, our results reveal a novel mechanism involving a hardwired circuit supplemented with endocannabinoid modulation that shifts between slow and fast motoneuron pools and hence mediates behavioral selection in vertebrates.

Title: Functional organization and patterning of the V0 interneurons in adult zebrafish

Authors: R. BJÖRNFORS, J. AUSBORN, *A. EL MANIRA;
Karolinska Inst., Stockholm, Sweden

Abstract: Vertebrate locomotion is generated by spinal circuits consisting of ipsilateral interneurons that provide the excitatory drive and commissural interneurons underlying the mid-cycle inhibition. The identity of the different neuronal populations in terms of transcription factors is preserved across vertebrate species. In addition, these neuronal populations appear to play similar roles from fish to mammals. In adult zebrafish, it has been shown that the motor neurons and the V2a excitatory interneurons form three discrete microcircuits: slow, intermediate and fast with preferential connectivity and recruitment frequencies matching the muscle type they innervate. However, the pattern of organization and functional subdivision of the commissural V0 interneurons remains unclear. We sought to determine if the V0 population of spinal commissural interneurons conforms to a frequency dependent circuitry division or not. Our findings show that both glutamatergic and glycinergic V0 interneurons, can indeed be divided into three modules that are recruited at slow, intermediate and fast swimming frequencies. The slow neurons fire action potentials on every cycle throughout the swim episode. The intermediate neurons are recruited only at intermediate and high frequencies, but are silent at low locomotor frequencies. Neurons belonging to the slow and the intermediate modules have slightly more depolarized resting membrane potentials, lower rheobase, and generally higher phasic fluctuations in membrane potential during swimming. Upon current pulse injection, these neurons generally display either a tonic or bursting firing pattern of action potentials. The neurons of the fast module never fire action potentials during slow to intermediate locomotion but receive synaptic input in the form of membrane potential oscillations in phase with the

swimming frequency. They tend to have a more hyperpolarized membrane potential, higher rheobase and lower phasic membrane fluctuations during swimming. These neurons show a tonic or adaptive firing pattern of action potentials, although adaptive firing is prevalent. In summary, the V0 interneurons are divided into three functional modules that display specific synaptic and intrinsic properties that set their recruitment order during swimming. This modular division is in accordance with that of the motor neurons and the V2a interneurons.

Title: Mechanisms of emergent bursting activity in small neuronal networks

Authors: *J. F. CANNON[1], O. BURYLKO[2], W. H. BARNETT[2], G. S. CYMBALYUK[2]; [1]Biol., Georgia State Univ. Biol. Dept, Atlanta, GA; [2]Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Bursting is the key regime of oscillatory networks controlling motor behaviors, Central Pattern Generators (CPGs). The endogenous dynamics of isolated CPG neurons are frequently found to be silent or spiking. We address an open question in neuroscience: how does bursting activity emerge in networks of non-bursting neurons? We present two mechanisms describing the emergence of bursting activity, one in a network of endogenously silent neurons and the other in a network of endogenously spiking neurons. The temporal properties of the transient responses of isolated silent and spiking neurons are organized by the cornerstone bifurcation. The networks presented here are constructed of neurons described by a 3D Hodgkin-Huxley style model which exhibits the cornerstone bifurcation. This bifurcation satisfies the criteria for both the Shilnikov blue sky catastrophe and the saddle-node bifurcation on invariant circle. The cornerstone bifurcation not only controls the burst duration (BD) and interburst interval (IBI) in bursting neurons but also determines the stereotypical transient responses of silent and spiking neurons. The mechanisms presented here are based on these responses. The first mechanism describes a half-center oscillator (HCO) consisting of two intrinsically silent,

mutually inhibitory neurons. The biophysical parameters of these two neurons were close to the critical values for the cornerstone bifurcation. This HCO showed anti-phase bursting activity. We found that if the half-activation voltage of a non-inactivating potassium current was systematically shifted towards the bifurcation value for the saddle-node bifurcation of periodic orbits, the BDs of both neurons increased in accordance with the inverse-square-root law and linearly depended on the spike number per burst. This new mechanism is different from release and escape. The second mechanism described the bursting activity of two intrinsically spiking, mutually excitatory neurons. The parameters of the neurons were also in vicinity of the cornerstone bifurcation. This network exhibited synchronized bursting. When the half-activation voltage of a hyperpolarization-activated current was systematically shifted to the bifurcation value for the saddle-node bifurcation of stationary states, IBIs of both neurons increased in accordance with the inverse-square-root law. The BDs of both neurons are controlled by the blue sky catastrophe bifurcation parameter which is the conductance of synaptic current. These mechanisms are generic and could govern the bursting regimes in rhythmic neuronal network such as central pattern generators.

Title: The modulation of transmission in the trigeminal nuclei and jaw opening reflex responses during superior laryngeal nerve stimulation

Authors: ***S. SAKAI**, K. TSUJI, J. MAGARA, T. TSUJIMURA, M. INOUE;
Dysphagia Rehabil., Niigata Univ., Niigata City/Niigata, Japan

Abstract: Introduction: The aim of the present study was to investigate the possible neuronal mechanisms for the modulation of jaw opening reflex (JOR) responses during superior laryngeal nerve stimulation (SLN) in anesthetized animals. Materials and Methods: Experiments were carried out on anesthetized rabbits with urethane. The inferior alveolar nerve (IAN) was stimulated to evoke the JOR in the digastric muscle. Current intensity was determined as 1.5 times (T) the threshold for evoking the JOR. In addition, single neurons responding to the IAN

stimulation were recorded in the trigeminal nuclei. To evoke the swallowing reflex, SLN was stimulated. Current intensity was determined as 1 to 4 T the threshold for evoking the swallowing reflex in 10 seconds. Peak to peak amplitude of JOR responses and activity of single neurons were compared between with and without SLN stimulation. Finally, the recording site in the brain stem was histologically identified. Results & Conclusion: 1. JOR was inhibited during SLN stimulation. 2. Responses of most neurons were inhibited during 2 or 4 T SLN stimulation. 3. Recording sites of the neurons were identified in the main sensory trigeminal nucleus and subnucleus oralis of the spinal trigeminal tract. 4. Current results suggest that low threshold evoked JOR is inhibited at the level of trigeminal interneurons in the JOR pathway during SLN stimulation. References: •Takako Fukuhara et al., 2011. Title: Quantitative TRP mRNA expression in single Dbx1 neurons in the preBötzinger Complex of neonatal mice

Authors: *M. D. PICARDO, C. A. DEL NEGRO;
Applied Sci., Col. of William and Mary, Williamsburg, VA

Abstract: Inspiratory-related rhythm generated in the pre-Bötzinger complex (preBötC) of the medulla is carried out by a substantial subset of rhythmogenic neurons derived from a single genetic line expressing the transcription factor Dbx1. Electrophysiological characterization of the Dbx1-derived population shows that these neurons highly express Ca2+-activated non-selective cationic current (ICAN), which is hypothesized to generate the inspiratory drive potential.

However, the molecular identity of the channels that generate the inspiratory bursts have not been identified. Non-selective cation channels of the transient receptor potential (TRP) family are likely candidates to give rise to ICAN in the preBötC based on evidence from previous findings, but the molecular identity of the TRP channel(s) involved has not been ascertained. TRPM4, TRPM5,TRPC3, and TRPC7 mRNA have each been shown to be present in the preBötC. Whole cell recordings of preBötC neurons also show TRP-like physiology. In addition, TRPM4 and TRPM5 mRNA were detected in the preBötC. However, expression of TRP channels has not been documented in rhythmogenic preBötC neurons. Here we used quantitative polymerase chain reaction (qPCR) to investigate the expression of TRPM4, TRPM5, TRPC3 and TRPC7 mRNA in single Dbx1 neurons in the preBötC. mRNA extraction, cDNA synthesis and pre-amplification, and subsequent qPCR were performed on individual Dbx1 neurons that were isolated from newborn transgenic mouse slice preparations. TRP mRNA levels in the preBötC Dbx1 neurons were compared with those in preBötC non-Dbx1 neurons, as well as with the Dbx1 neurons in the amygdala. Data show that TRPM4 mRNA was detected in all preBötC Dbx1 neurons, whereas TRPM5 mRNA was expressed in ~15% of the samples only. Both TRPC3 and TRPC7 were detected in about half of the sampled preBötC Dbx1 neurons. Dbx1 neurons isolated from the amygdala did not express TRPM5 mRNA, and had significantly lower mRNA expression of the other TRP channels, compared to the preBötC Dbx1 neurons. Although mRNA levels do not always indicate that these TRP channels are present or functionally important, these qPCR data provide a valuable comparison of expression at the mRNA level. The consistent expression of TRPM4 mRNA in the rhythmogenic Dbx1 neurons could imply involvement of the TRPM4 channel in giving rise to ICAN and generating the inspiratory drive potential. These qPCR data may provide insight in understanding the ionic basis of inspiratory burst generation in Dbx1 neurons in the preBötC.

Title: Quantification of morphological differences from reconstructions of multiple types of stomatogastric neurons

Authors: *A. C. SUTTON[1,2], T. BROOKINGS[2], M. L. GOERITZ[2], E. MARDER[2];
[2]Volen Ctr. for Complex Systems, [1]Brandeis Univ., Waltham, MA

Abstract: Central pattern generators robustly maintain target output activity despite wide variations in molecular parameters such as mRNA expression and ion channel conductance. However, neuronal structure can also vary widely between animals, and the effects of these changes have not been examined in conjunction with physiology. The stomatogastric ganglion (STG) of the Jonah crab C. borealis is a central pattern generator that consists largely of motor neurons controlling rhythmic activity of stomach muscles. STG neurons have been shown to tune their mRNA levels of ion channels to achieve targeted activity (Turrigiano et al., 1994). It is possible that certain aspects of a neuron's morphology can serve as 'free parameters' for the neuron to reach its goal. However, it is not known which morphological features are variable candidates and which are not. To this end, we sought to quantitatively identify morphological characteristics of STG neurons to determine common or 'fixed' aspects of neurons, which should be similar in all neurons of a given type. Previously, qualitative examinations of morphology have suggested differences between certain STG neuronal subtypes. We imaged dye-filled STG neurons with a confocal microscope and used reconstructions to extract morphological features of the soma, dendritic arbor and dendritic field. Basic features of the soma such as volume, surface area and major axis were examined; similar aspects of the dendritic field were also examined, including volume and orientation in relation to soma. The dendritic tree was also studied, and among the analyses were branching behavior, bifurcation asymmetry, tortuosity, Sholl analysis and path length.

Title: Homeostatic maintenance of network synchrony: Compensatory mechanisms underlying restoration of synchronized bursting in variable motor neurons

Authors: *B. J. LANE, J. L. RANSDELL, S. S. NAIR, D. J. SCHULZ;
Univ. of Missouri - Columbia, Columbia, MO

Abstract: The electrically coupled Large Cell (LC) motor neurons in the Cardiac Ganglion (CG) of the crab *C. borealis* display synchronized rhythmic bursting during normal network output *in vitro*, even though the individual LCs have variable underlying electrical properties. We exposed LCs to treatments with either TEA or serotonin to change membrane conductances, and found that in both cases LCs desynchronize and then recover synchrony over time. Pharmacological blockade with TEA increases the number of spikes per burst and the duration of bursts, but these propertiesrevert towards baseline levels as synchrony is restored. Neuromodulation with 5-HT increases the number of spikes per burst and spike frequency, yet these outputs remain elevated as synchrony is restored. To determine the mechanism of restored synchrony in these conditions, we investigated two hypotheses: 1) Homeostatic changes in intrinsic excitability in each LC independently adjust output and converge on synchronous activity, and 2) Network-level properties such as electrical coupling are altered to restore synchrony. To test whether intrinsic excitability is altered in response to desynchronized activity, we performed two-electrode voltage clamps to determine how individual LC conductances are affected by each treatment, and how conductances change during the process of re-synchronization. When the K^+ current I_{HTK} is blocked with TEA, the K^+ current I_A increases, a potential mechanism for restored output. We found that serotonin increases the magnitude of the K^+ current I_A by approximately 30%, and are examining whether similar compensation occurs in other currents. To test whether increased electrical coupling is a potential mechanism to resynchronize LC bursting, we isolated pairs of LCs, induced disparate output with TEA, and applied dynamic clamp to add an artificial coupling conductance. We found that dynamic clamp was able to artificially re-synchronize LCs within a biologically realistic conductance range. We will determine whether a functional increase in coupling occurs between cells as they resynchronize, by desynchronizing LCs and measuring coupling coefficients between LCs during the process of re-synchronization. Our data so far suggest that both intrinsic excitability and electrical coupling strength are potential targets for homeostatic compensation that restores network synchrony in response to challenges such as neuromodulation.

Title: Mechanisms of network synchrony arising from variable individual motor neurons of the crustacean cardiac ganglion

Authors: *S. S. NAIR[1], P. SAMARTH[1], B. LANE[2], D. J. SCHULZ[2];
[1]Electrical & Computer Engin., [2]Biol. Sci., Univ. Missouri-Columbia, COLUMBIA, MO

Abstract: The crab cardiac ganglion (CG) has five large motor cells (LCs) driven to burst by four small endogenous pacemaker cells (SCs). The CG is responsible for controlling the rhythmic contractions of the single-muscled crab heart. Our goal was to examine mechanisms of synchronization among the five LC motor neurons of the crab CG. We created a pool of model LCs using the biological current data and performed a sampling rejection technique to determine parameter sets that generated appropriate LC output characteristics. To be included in the model cell data set, a given LC model had to have passive properties within biological bounds and appropriate output responses to multiple current injection protocols consistent with experimental traces. Parameter sets obtained in this fashion were used to select model LCs for the network studies. A prediction using the single LC model was that the calcium current ICAN and the calcium-activated potassium current ISKKCa have to be in the ratio 1:0.83 for proper termination of the driver potential observed experimentally in isolated LC's in presence of tetraethylammonium (TEA). Also, the parameter set for model LCs revealed two strong inverse correlations: between leak and KA currents (r2=0.81) and between Nap and CaL currents (r2=0.69). We then developed a computational network model including the5 LCs and 4 SCs. This model was used to investigate the role of network parameters in maintaining synchronous output at both cellular and network levels. Biological results demonstrate that the variable properties of the individual motor neurons lead to loss of synchrony under conditions of neuromodulation and pharmacological blockade with channel blockers such as TEA. However, synchrony is dynamically restored following prolonged modulator exposure. Our goal was to use the model CG network to determine potential mechanisms underlying the loss, and restoration of, synchrony. We examined changes in intrinsic properties, synaptic drive, and electrical coupling to determine whether plasticity in these features could restore synchrony following model applications of neuromodulation and TEA.

Abstract: We investigate the function of GABAergic cerebrospinal fluid contacting neurons (CSF-cNs) in the spinal cord. These cells line the central canal and extend a brush of microvilli into the lumen but lack any obvious dendrites. They are conserved across many vertebrates and their atypical morphology makes them interesting candidates for sensory cells. The project aims to investigate the sensory roles and physiological recruitment of CSF-cNs. We use genetically encoded calcium sensors (GCaMP6f) to probe their activation in paralyzed and moving zebrafish larvae. Calcium imaging in paralyzed larvae revealed that CSF-cNs, unlike most other cells in the spinal cord, are not coordinately activated during fictive locomotion where no actual movement occurs. CSF-cNs express the ion channel Pkd2l1, which is suggested to be involved in responses to variations of pH and osmolarity. Accordingly, we show by combining two-photon calcium imaging and proton uncaging in the central canal that CSF-cNs respond to short exposures of acidic pH *in vivo*. We are currently testing other chemical cues that activate these cells. All together our work describes the physiological inputs of CSF-cNs suggesting that they can constitute a sensory feedback loop in the spinal cord. The role of Pkd2l1 in the responses of CSF-cNs to variation of pH is currently under investigation.

Title: Synaptic depression influences inspiratory burst termination and post-inspiratory activity in the preBötzinger complex

Authors: *A. KOTTICK, C. A. DEL NEGRO;
Applied Sci., Col. of William and Mary, Williamsburg, VA

Abstract: The preBötzinger Complex (preBötC) of the ventrolateral medulla generates the inspiratory rhythm that drives breathing behavior. Recurrent synaptic excitation initiates inspiratory bursts, but whether excitatory synaptic mechanisms also play a role in burst termination and recovery during post-inspiration is not well understood. Using a neonatal mouse medullary slice preparation that spontaneously generates inspiratory activity and motor output, we tested the hypothesis that short-term synaptic depression influences inspiratory burst termination and post inspiratory activity. We used an excitatory light-gated ion channel, channelrhodopsin, to rapidly stimulate the preBötC throughout the respiratory cycle. We performed whole-cell recordings in the preBötC and measured a refractory period of ~2 seconds after endogenous inspiratory bursts that precluded optically evoked activity. We found no change in the amplitude distribution of spontaneous EPSPs before or after endogenous inspiratory bursts, suggesting that there is no postsynaptic modulation of synaptic transmission after endogenous inspiratory bursts. However, the duration of the refractory period was liable to extracellular calcium concentration, which is consistent with presynaptic modulation. These results provide the first experimental evidence that short-term synaptic depression in the preBötC influences inspiratory burst termination and post-inspiratory activity, which contrasts previous models that ascribed these functions to extrinsic sources of synaptic inhibition.

Title: Substitution of extracellular Ca2+ by Sr2+ prolongs inspiratory burst in preBötzinger Complex (preBötC) neurons. Implications for burst termination mechanisms

Authors: *C. MORGADO-VALLE[1], J. FERNANDEZ-RUIZ[2], L. LOPEZ-MERAZ[1], L. BELTRAN-PARRAZAL[1];
[1]Ctr. de Investigaciones Cerebrales, Univ. Veracruzana, Xalapa, Mexico; [2]Facultad de Medicina, Univ. Nacional Autonoma de Mexico, Mexico, DF, Mexico

Abstract: The role of Ca^{2+} in the mechanisms underlying the initiation and termination of the inspiratory burst in preBötC neurons is a matter of intense debate (Pace *et al*., 2007; Morgado-Valle *et al*., 2008; Mironov 2008; Del Negro et al., 2011; Beltran-Parrazal *et al*., 2012; Rybak *et al*., 2014). We aimed to test the effects of removing extracellular Ca^{2+} without affecting neurotransmission on burst initiation and termination. In a brainstem rhythmic slice we current-clamped preBötC neurons (V_m-60 mV) and bath applied ACSF with no Ca^{2+} and either 1.5 mM or 2.5 mM Sr^{2+} while recording integrated hypoglossal nerve (∫XIIn) activity as motor output. Substitution of extracellular Ca^{2+} by Sr^{2+} significantly increased the duration of inspiratory burst (from 653 ± 31 ms in control conditions to 982 ± 78 ms and 2048 ± 448 ms in 1.5 and 2.5 mM Sr^{2+} respectively); increased the decay time (by 60% and 290% for 1.5 and 2.5 mM Sr^{2+} respectively) and area (by 65% and 200% for 1.5 and 2.5 mM Sr^{2+} respectively) with respect to control conditions. At the systems level, substitution of extracellular Ca^{2+} by Sr^{2+} significantly increased ∫XIIn burst duration (by 30% for 1.5 or 2.5 mM Sr^{2+}), decreased ∫XIIn period (by 40% and 25% for 1.5 and 2.5 mM Sr^{2+} respectively) and had not effect on burst irregularity score. Substitution of Ca^{2+} by Sr^{2+} is the first reported ionic manipulation that significantly increases the duration of inspiratory burst. Sr^{2+} substitution of Ca^{2+} is a well-established method to desynchronize neurotransmitter release. Our findings suggest that the increase of inspiratory burst duration is determined by a presynaptic mechanism involving desynchronization of glutamate release within the network. We suggest that termination of inspiratory drive depends

on a presynaptic mechanism rather than in a postsynaptic mechanism involving extracellular Ca^{2+} for which Sr^{2+} cannot substitute.

Abstract: Central pattern generators (CPGs) are neuronal networks controlling rhythmic motor behaviors such as flying, breathing, and walking. CPGs can produce characteristic rhythmic patterns even when deprived of sensory feedback. It is likely that CPGs can share neurons, forming multifunctional CPGs. It has been shown in several species that the same interneuron can be active during multiple behaviors [1]. Sensory information and modulatory tone would determine which pattern of activity and therefore, which behavior is produced. Here, we explore the idea that one set of neurons in a single multifunctional CPG could be intrinsically capable of producing multiple regimes of activity without changes in biophysical properties of its neurons and inter-neuronal connections. Such a multi-stable CPG would only require a transient

perturbation to switch between regimes. Multistability of a CPG arising from synaptic dynamics has been demonstrated in models of neuronal networks with depressing synapses [2]. We investigated whether two rhythmic cat behaviors, walking and paw shake, could be controlled by a single half-center oscillator (HCO) composed of two mutually inhibitory neurons. Is it possible for cellular dynamics to underlie multistability in a CPG? We have created a parsimonious HCO model with neurons containing two slow inward currents: a Na+ current (INaS), and a Ca++ current (ICaS) which inactivates slower and at more negative voltages than INaS. Two regimes of activity coexist in this model: a fast, 10 Hz paw shake regime with low spike frequency and high ICaS inactivation, and a slow 2 Hz walking regime, with high spike frequency and low ICaS inactivation. It is possible to switch between regimes with pulses of excitatory or inhibitory conductance. We also demonstrate that changes of certain conductances can lead to hysteresis of regimes, elucidating a role for neuromodulation in pattern switching. The multifunctional CPG model is also incorporated into a neuromechanical model of the cat hindlimbs in the AnimatLab environment [3] that reproduces realistic walking and paw-shake response. Title: Local spinal circuits dictate locomotor output in caudal stimuli-elicited startles of larval zebrafish

Authors: *Y.-C. LIU, M. E. HALE;
Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: The startle response of zebrafish and goldfish has long been used as a model for understanding fundamentals of neural circuit organization and function. A major focus of study

has been on how variation in behavior arises at a circuit level. We've previously shown in larval zebrafish that stimulus direction can induce variations in axial bending behavior. Stimuli to the head result in an escape response called the C-start while a distinctly different S-start response may be triggered when the stimuli is directed at the tail. The most striking kinematic difference between these behaviors is that the body forms a "C" shaped bend during the C-start while during the S-start the body forms an "S" shaped bend. Neurons responsible for generating startles include a pair of Mauthner (M-) cells in the hindbrain that when fired initiates the behavior. When the left M-cell fires, it activates motoneurons in the spinal cord on the right side causing unilateral muscle contractions. It also excites commissural local (CoLo) neurons on the right side, which inhibits neuronal activity on the left side. While this model can explain the rapid C-shaped bend in C-starts, it does not allow for the caudal counter bend that is characteristic of the S-start. We have previously shown that in response to tail stimuli, both M-cells always fire during S-starts, while either one or both M-cells fire during C-starts. Involvement of M-cells in both caudal C- and S-starts suggest local variations in the spinal cord. We have found that primary motoneurons in the caudal spinal cord are often inhibited before the first burst of activity during tail-elicited startles, while rostral motoneurons are not, and this inhibition appears before the Mauthner spike. CoLo activity coincides with early motoneuron inhibition. These data taken together show that local inhibition caused by CoLos in the caudal spinal cord act as a switch that predetermines whether the M-cell command signal ultimately generates a C- or S-start to caudal stimulation. To investigate sensory inputs to the caudal spinal cord that may activate local CoLos, we conducted paired recordings between CoLos and Rohon-Beard (RB) cells. Preliminary data show RBs firing immediately after caudal stimuli, coincident with initial activity of CoLos in the same segment. Suprathreshold current injections in RBs result in PSPs in CoLos and may sometimes elicit spikes. These data suggest it is likely that RBs are the sensory cells responsible for local activation of inhibitory CoLos in the caudal cord that results in the counter bend of the S-start.

Title: Phase maintenance requires precise matching of synaptic inputs and intrinsic properties

Authors: *H. ANWAR[1], F. NADIM[1,2];
[1]Biol. Sci., NJIT, Newark, NJ; [2]Rutgers-Newark, Newark, NJ

Abstract: Rhythmic motor activity often requires precisely timed output from each of the neurons in the underlying neural network. The generation of phasic patterns of neuronal activity arises from the synaptic interaction of the network neurons. Therefore, the relationship between intrinsic properties and the strength and dynamics of synaptic inputs must be maintained for the robust output. It is known that, in oscillatory networks, both ionic current levels and synaptic strength vary in the same cell type, yet, the phase relations of neurons are maintained. We examine the hypothesis that the strength and dynamics of synaptic inputs are tuned in each neuron to be the "best" input match for the intrinsic properties, and therefore to maintain constant activity phase across preparations. This hypothesis predicts that, across preparation, in a neuron type that produces a constant activity phase, 1) synaptic inputs are not correlated with the activity phase, 2) if synaptically isolated, different inputs would be required to produce a constant activity phase, and 3) the same input would produce different activity phases. We test this hypothesis in the pyloric network of the crab stomatogastric ganglion. The follower LP neuron receives synaptic input from the pyloric pacemakers which allows it to produce stable bursting activity. We measured synaptic currents in LP neurons across different preparations during ongoing pyloric oscillations and measured the parameters (rise, fall, amplitude, etc.) of the synaptic current with the bursting features (onset and end phase, ISI, etc.) of LP neurons across preparations. We found that both the synaptic parameters and the bursting features widely varied, but appeared to be uncorrelated, across preparations. We then blocked the synapses to isolate the LP neuron, which switched from bursting to tonic activity. We injected O-U noise current in the LP neurons with an expectation that certain levels of inputs would induce different kinds of bursts in each LP neuron. The burst-triggered-average of injected noise currents for different burst types (defined by # spikes/burst) showed that the same burst type in LP corresponded to different input types in different preparations. These results confirm the first two predictions of our hypothesis. We are currently examining whether the dynamic clamp injection of the same synaptic input into synaptically isolated LP neurons would produce different activity phases in different preparations. Together, these results would show that synaptic inputs in each preparation are tuned to match intrinsic properties and therefore maintain phase relationship of neurons across different preparations.

Title: The dorsal striatum is under diurnal control; an electrophysiological study comparing time of day and the effectiveness of a D2 antagonist

Authors: *A. FREDERICK, J. BOURGET-MURRAY, C. A. CHAPMAN, S. AMIR, R. COURTEMANCHE;
CSBN, Concordia Univ., Montreal, QC, Canada

Abstract: The circadian system influences both changes in behavior and alterations in physiology throughout the day. However, little is known about how the circadian system influences neural activity. Experiments in the dorsal striatum show robust circadian gene rhythms in medium spiny neurons and fluctuations in extracellular dopamine levels that peak later in the dark period, suggesting that basal ganglia function may be regulated in a diurnal manner. In order to explore this, we recorded local field potentials from pairs of electrodes in the medial and lateral dorsal striatum of urethane-anesthetized rats at four different times of day (1, 7, 13 and 19 hours after lights on in a 12h:12h light-dark cycle). Strength of oscillations and coherence were compared at baseline and after i.p. injection of the D2 antagonist raclopride. An inverse relationship in the presence of oscillations between 0-3 Hz and 3-8 Hz was observed at baseline, where the presence of 0-3 Hz activity decreased from around 95% of the time at one hour after lights on, to around 50% of the time at one hour after lights off. Furthermore, raclopride had the greatest effects one hour after lights off, where it decreased the occurrence of 3-8 Hz activity and increased 0-3 Hz activity by about 20%. 0-3 Hz coherence followed a similar trend as the oscillatory activity. Both comparisons within electrode pairs and between electrodes placed medially and laterally in the dorsal striatum showed decreased 0-3 Hz coherence at one hour after lights turned off that increased after raclopride administration. Comparisons with electrodes placed in the cerebellum demonstrated a similar modulation at 0-3 Hz, suggesting that the diurnal mechanisms that alter the drive of these oscillations under urethane anesthesia may be centrally located. From these results, we conclude that neural activity in the dorsal striatum is influenced diurnally. Since the peak time in raclopride response does not correspond to when extracellular dopamine is peaking, we propose that alterations in postsynaptic targets, such as changes in neurotransmitter receptors, are diurnally modulated and partially contribute to this modulation. This could have clinical implications in explaining why Parkinson’s disease patients experience diurnal fluctuations in motor symptoms and response to L-DOPA.

Title: Functional MRI reveals paradoxical cerebral blood volume decreases in striatum during optogenetic stimulation of the striatonigral "direct" pathway

Authors: *D. ALBAUGH, G. STUBER, I. SHIH;
Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: Introduction. The striatonigral “direct” pathway of the basal ganglia is well-known for its role in the facilitation of movement, and recent work suggests that stimulation of this pathway is therapeutic in Parkinson’s disease. However, the broader neural networks modulated by direct pathway stimulation remain to be described, which may potentially uncover novel therapeutic stimulation targets for movement disorders. Here, we discuss our preliminary investigations using optogenetic stimulation coupled with a functional magnetic resonance imaging (fMRI) readout to evaluate the global brain response profile to selective direct pathway stimulation. Methods. Wild-type rats received ChannelRhodopsin-2 viral infusions (AAV5, CamKIIa promotor) targeting the dorsolateral striatum, and optical fibers for stimulation of direct pathway projections were placed directly above the substantia nigra pars reticulata. This approach allows us to specifically stimulate the direct pathway without requiring opsin expression selectivity in striatal cell bodies. Following a period of at least 8 weeks to allow for sufficient opsin expression, rats were sedated for fMRI using a 9.4T Bruker system. Changes in cerebral blood volume (CBV) were measured in response to direct pathway optical stimulation at multiple frequencies (10, 20,30, and 40Hz) and compared to within-scan baseline measurements. Results. Direct pathway stimulation resulted in robust, time-locked CBV decreases in the striatum. These responses were frequency-dependent, with the largest CBV decreases occurring at 40Hz. No CBV responses were noted in the substantia nigra pars reticulata or any other region examined. Discussion. It is not readily apparent why direct pathway stimulation would result in striatal CBV decreases, which are traditionally associated with regional silencing in brain activity. However, our group has previously shown that increases in striatal activity can result in

paradoxical BOLD or CBV signal decreases. Thus, we hypothesize that the obtained CBV response reflects antidromic stimulation of direct pathway striatal neurons. Future work will determine behavioral and whole-brain functional connectivity correlates of striatonigral pathway stimulation.

Title: Excessive synchronization in basal ganglia-thalamocortical circuits in the hemiparkinsonian rat during bradykinesia and dyskinesia

Authors: ***K. B. DUPRE**, A. J. MCCOY, E. BRAZHNIK, C. DELAVILLE, A. V. CRUZ, N. NOVIKOV, C. P. DODGE, C. M. GERBER, C. HATCH, M. A. COHEN, D. S. KURUP, J. R. WALTERS;

Abstract: The hemiparkinsonian rat is commonly used as a model for Parkinson's disease (PD). However, in addition to being relevant to PD, this preparation provides the opportunity to explore the properties of brain circuits as they become recruited into a sustained, excessively synchronized and oscillatory state. Synchronized activity associated with bradykinesia emerges in the dopamine (DA) cell-lesioned hemisphere over the first week after unilateral injection of 6-hydroxydopamine into the medial forebrain bundle. Chronic recordings in the motor cortex (MCx), striatum, globus pallidus, subthalamic nucleus (STN), substantia nigra pars reticulata (SNpr) and ventral medial thalamus (VM) have shown sustained alterations in LFP spectral peaks with increased power and coherence in the 30-35 Hz range during walking on a circular treadmill. Interestingly, the levels of spiking entrainment to the 30-35 Hz LFP activity varies widely across these nuclei, with respect to the proportion of cells with significant spike-LFP phase-locking and its relative increase following DA cell lesion. Increases in phase-locking were greater in the STN, SNpr, and VM and lowest in the striatum. The sequence of spike timing in the MCx, STN, SNpr, and VM nuclei was assessed by comparing the phase relationship of each

spike train to a common oscillation, in this case the MCx LFP. The temporal relationships between the phase-locked spikes support a sequential entrainment of activity from MCx-STN/SNpr-VM-MCx, consistent with the anatomical connections within this circuit. A different synchronized state can also be seen during L-dopa-induced dyskinesia. Synchronized activity, referred to as 'finely tuned gamma,' with varying dominant frequencies in the 70-120 Hz range, is present in LFPs recorded from the MCx, VM and striatum. This activity is not prominent in the STN and SNpr power spectra, however significant coherence in this range is observed between these structures and the MCx. Notably, the peak frequency of this band varies with rat strain, with a lower peak frequency occurring in Sprague Dawley compared to Long-Evans rats. Surprisingly, spike-LFP phase-locking in the MCx significantly decreases as high gamma oscillations increase in LFP power. Collectively, these results highlight the fact that LFP is not necessarily a reliable marker for synchronized spiking or spike timing in a given brain area, as prominent spectral LFP peaks may not be accompanied by spike-LFP phase-locking. It remains to be determined whether highly synchronized LFP oscillatory activity in a given circuit may disrupt information flow in ways other than through local synchronization of spiking activity.

Title: Dopaminergic modulation of 45-55 Hz low gamma power in the medial prefrontal cortex and the subthalamic nucleus in a behaving rat model of Parkinson's disease

Authors: *C. DELAVILLE, A. J. MCCOY, J. R. WALTERS;
NIH NINDS, Bethesda, MD

Abstract: The role of dopamine (DA) in modulating activity in motor cortex (mCx) and associated subcortical circuits has been a subject of recent interest. Studies have shown dramatic changes in oscillatory activity in these circuits in animal models of Parkinson's disease (PD) and

PD patients. These changes are particularly evident in the hemiparkinsonian rat during treadmill walking (Delaville et al., 2014). On the other hand, dysfunction of the medial prefrontal cortex (mPFC) and the subthalamic nucleus (STN) is thought to lead to non-motor symptoms such as anxiety, attention, depression and other cognitive impairments often observed in PD. Here, we focused on neuronal activity in the mPFC and its relationship with STN activity in normal and hemiparkinsonian rats during rest and treadmill walking. Simultaneous recordings of spike and LFP data were obtained from electrode bundles implanted in mPFC, STN, and mCx before and over a 3 week period after unilateral 6-hydroxydopamine-induced DA cell lesion, mimicking severe PD. In control rats, spectral power in the 45-55 Hz frequency range was greater in the mPFC, STN and mCx during walking compared to inattentive rest. However, the mean peak frequency of low gamma power in the mCx (46 Hz) was lower than in the STN and the mPFC (51 Hz). The presence of significant 45-55 Hz LFP coherence between the mPFC and STN, in contrast to the lack thereof between mCx and STN and between mCx and mPFC, argues that the source of the low gamma activity observed in the mCx is different from that in the STN and mPFC. In the days following DA depletion, 45-55 Hz LFP power decreased in both the mPFC and STN as did the coherence between these 2 structures. However, three weeks after severe DA depletion, the 45-55 Hz power in the mPFC and STN had returned to original levels, implying a non-DA compensatory mechanism in the establishment of this gamma oscillation. Interestingly, neither apomorphine, a DA agonist, nor L-dopa, a DA precursor, increased gamma power in the mPFC or STN at day 7 and day 21 after DA depletion. On the contrary, these treatments induced a decrease in 45-55 Hz power and mPFC-STN coherence. Additionally, no modulation of the 45-55 Hz LFP amplitude was observed in conjunction with the cycle of forepaw stepping during treadmill walking, implying that this low gamma oscillation is related to general activity but not directly connected to repetitive movements involved in stepping. These data suggest that the 45-55 Hz power in the mPFC and STN is modulated by activity state and changes in DA receptor stimulation as well as non-DA mechanisms which, over time, compensate for DA loss.

Title: Effects of NMDA/AMPA receptor blockade on abnormal striatal neuronal activity in parkinsonian monkeys

Authors: *A. SINGH[1], K. BURKE[1], J. WHITHEAR[1], B. DYAVARSHETTY[1], S. TRAYNELIS[2], S. PAPA[1,3];
[1]Yerkes Natl. Primate Res. Center, Emory University,, Atlanta, GA; [2]Dept. of Pharmacol., [3]Dept. of Neurol., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: In non-human primate models of advanced parkinsonism, medium spiny neurons (MSNs) are markedly hyperactive and often exhibit reversal of levodopa-induced firing rate changes ("inversion of dopamine responses") in correlation with levodopa-induced dyskinesias (Liang et al., 2008). Hyperfunction of striatal glutamate signaling is thought to play a primary role in the mechanisms of dyskinesias. However, the impact of glutamatergic transmission on abnormal MSN responses to dopamine has not been studied. The electrophysiological effects of striatal NMDA or AMPA receptor antagonism were studied in four awake, behaving, parkinsonian rhesus monkeys. The competitive NMDA antagonist LY235959 or AMPA antagonist NBQX was delivered by microinjection at the site of extracellular recordings in the striatum of monkeys followed by systemic levodopa administration (s.c.) during the recording session. The doses of antagonist were determined on the basis of *in vitro* tests for selectivity of receptor binding and *in vivo* tests of magnitude of firing frequency reduction. Behavioral effects of the antagonists were also evaluated with systemic administration. We found that the reduction of MSN baseline activity via local microinjection of LY235959 or NBQX completely abolished the abnormal inversions of firing rate changes induced by dopamine inputs. Comparisons with the vehicle alone as control confirmed the specific effect of the local drug microinjection. These NMDA/AMPA antagonists also reduced dyskinesias following systemic injections, demonstrating correlated behavioral effects in the same animals that exhibited physiological effects. These results indicate that the ionotropic glutamate transmission primarily controls the MSN activity in the parkinsonian state. This has profound implications for the striatal pathology developed in advanced PD that is associated with abnormal responses to dopamine.

Biol., Univ. of Barcelona, Barcelona, Spain

Abstract: Although type 1 cannabinoid receptors (CB1Rs) are expressed abundantly throughout the brain, the presence of type 2 cannabinoid receptors (CB2Rs) in neurons is still somewhat controversial. Taking advantage of newly-designed CB1R and CB2R mRNA riboprobes, we demonstrate by PCR and *in situ* hybridization that transcripts for both cannabinoid receptors are present within labeled pallidothalamic-projecting neurons of control and MPTP-treated macaques, whereas the expression is markedly reduced in dyskinetic animals. Moreover, an *in situ* proximity ligation assay was used to qualitatively assess the presence of CB1Rs and CB2Rs, as well as CB1R-CB2R heteromers within basal ganglia output neurons in all animal groups (control, parkinsonian and dyskinetic macaques). A marked reduction in the number of CB1Rs, CB2Rs and CB1R-CB2R heteromers was found in dyskinetic animals, mimicking the observed reduction in CB1R and CB2R mRNA expression levels. Cannabinoid receptors were only found in neuronal cell bodies, with a complete absence of receptors in both pallidothalamic and striatopallidal axon terminals. This cellular localization suggests that the functional role is independent of cannabinoid receptor-mediated control of neurotransmitter release at nerve terminals.

Abstract: Endocannabinoids are neuromodulators acting on specific CB1 and CB2 receptors, and these receptors represent potential therapeutic targets for neurodegenerative diseases. Cannabinoid ligands also regulate the activity of GPR55, another cannabinoid receptor that has been recently ‘deorphanized’. Our working hypothesis is that the pleiotropic signaling of CB1, CB2 and GPR55 receptors is due to heteromers formed between these receptors and that heteromers may be feasible targets for Parkinson’s disease. The aim of the present paper was to characterize cannabinoid CB1-GPR55 receptor heteromers in the basal ganglia input nuclei. Here

the *in situ* proximity ligation assay (PLA) was used to detect the presence of receptor heteromeric complexes within different types of striatal neurons, comprising both projection neurons and interneurons. Striatal medium-sized spiny neurons (MSNs) giving rise to either the direct and indirect basal ganglia pathways were identified following the retrograde transport of biotinylated dextran amine (BDA). BDA was injected into either the external or the internal subdivisions of the primate globus pallidus (GPe and GPi, respectively). Next, triple immunofluorescent stains were carried out to visualize (i) BDA-labeled neurons, (ii) CB1-GPR55 heteromers and (iii) either parvalbumin- or ChAT-positive striatal interneurons. Obtained results showed the presence of CB1-GPR55 heteromeric complexes within both types of projection neurons as well as in parvalbumin-positive interneurons, whereas cholinergic interneurons lacked these types of receptor heteromers. CB1-GPR55 receptor heteromers were found in both the neuronal membrane as well as in intracellular locations. These cellular/subcellular locations suggest a functional role for CB1-GPR55 receptor heteromers independent from cannabinoid receptor-mediated control of neurotransmitter release at axon terminals.

Title: Synchronized oscillatory activity in the striatum of parkinsonian monkeys

Authors: *G. M. JEYARAJ[1,2], A. SINGH[2], J. S. WHITHEAR[2], S. M. PAPA[2];
[2]Yerkes Natl. Primate Res. Ctr., [1]Emory Univ., Atlanta, GA

Abstract: Dopamine depletion in Parkinson’s disease (PD) has been associated with synchronized oscillatory activity at 13-30 Hz (beta band) in the cortico-basal ganglia network. This activity was found in cortex, globus pallidus, and subthalamic nucleus in rodent and primate models, and patients. However, it remains unclear how nigrostriatal dopamine loss leads to

modulate oscillations in the striatum that may cause motor disability in PD. We studied the local field potentials (LFPs) in MPTP-treated non-human primates that had stable, chronic parkinsonism of moderate to severe degree as a primate model of advanced PD. LFPs were recorded in cortex, striatum and globus pallidus during the "off" state (baseline parkinsonian disability). We observed oscillations in the low-beta band frequencies (13-20 Hz) in cortex, striatum, and globus pallidus internus (GPi). High coherence of oscillation in the low-beta band was seen in cortex-striatum and striatum-GPi. In cortex, striatum and GPi, there also was a significant relative power in the alpha band (7-12 Hz), which in the striatum and GPi was more robust than to the low-beta band. No substantial oscillatory activity in higher frequency bands was observed. These results suggest that the striatum and its downstream circuits have a complex pattern of oscillatory activity including alpha and low-beta frequencies with possible contributions to pathological motor behavior. Further studies may elucidate the function of particular basal ganglia oscillations in PD.

Title: Profoundly altered striatal MSN activity in Parkinson's disease patients

Authors: ***S. M. PAPA**[1], A. SINGH[1], K. MEWES[1], R. GROSS[2], M. DELONG[1];
[1]Neurol., [2]Dept. of Neurosurg., Emory Univ., ATLANTA, GA

Abstract: Loss of striatal dopamine modulation in Parkinson's disease (PD) presumably leads to abnormal discharges of striatal output neurons (medium spiny neurons, MSNs) based on recordings in animal models. But the status of the MSN activity in the human disease remains unknown. We examined the MSN firing in patients undergoing deep brain stimulation (DBS) surgery. We analyzed data obtained during electrophysiologic mapping in PD patients (n = 11), along with dystonia (n = 5) and essential tremor (n = 10; ET) patients for comparison. Striatal MSN activity was also recorded in awake, behaving, parkinsonian and normal monkeys (n = 2). Strict criteria were applied for MSN classification. The mean firing rate of MSNs was

significantly higher in PD (32 ± 9 Hz) than dystonia (9.5 ± 4 Hz) and ET (< 3 Hz). Similar to PD patients, the mean firing rate of MSNs was significantly higher in the parkinsonian monkey (23 ± 1.3 Hz) than the normal monkey (2.13 ± 0.2 Hz). In PD, a larger fraction of striatal neurons exhibited burst activity and burst firing rate was also significantly elevated. These findings are aligned with previous data from parkinsonian monkeys (Liang et al., 2008), challenging the classic functional model of PD. The primary role of glutamatergic hyperactivity in these striatal changes suggests that manipulating the glutamate signaling is critical for improved responses to dopamine replacement. The less increased frequencies in dystonia suggest that high MSN activity specifically correlates with PD, but also that there may be grounds for the frequently alluded Dystonia-PD continuum. The very low firing rates in ET resemble MSN activity in normal monkeys, suggesting a parallel with normal humans. These findings demonstrate profound alterations of the MSN discharge in patients with PD. Further analyses of clinical correlates of the MSN changes may help understand their pathophysiological significance.

Title: Phase offset of entrained cortical inputs influences selectivity in a neural model of the basal ganglia

Authors: *Z. FOUNTAS, M. SHANAHAN;
Computing, Imperial Col. London, London, United Kingdom

Abstract: Low-frequency oscillatory activity have been the target of extensive research both in cortical structures and in the basal ganglia (BG), due to numerous reports of associations with brain disorders and the normal functioning of the brain. Whereas a number of computational models of the BG investigate these phenomena, these models tend to focus on intrinsic oscillatory mechanisms, neglecting evidence that points to the cortex as the origin of this oscillatory behaviour. In this study we constructed a neural model of the BG circuitry and used it

to investigate the relationship of wave properties of entrained cortical inputs, dopamine and the steady-state selectivity of the BG, i.e. their effectiveness as an action selection device. Our simulations indicated a significant impact of the phase offset between entrained cortical signals with different amplitudes. In particular, we found that in specific low frequencies, and when the phase of a strong input signal precedes in time the phase of a second, weaker signal, the effectiveness of the BG varies depending on the magnitude of this offset, while in high bands, this effect disappears. Furthermore, we investigated the effect of dopamine on the process of selection which was found to modulate the frequency spectrum of the previous effects. Interestingly, the critical areas of our results match with the frequency bands that are enhanced in Parkinson's disease and suppressed by medication. Numerous further associations can be observed including the entrainment between the prefrontal cortex and hippocampus and various parkinsonian symptoms.

Title: The nature of the connection between internal global pallidus and primary motor cortex in human

Authors: ***Z. NI**[1], S. KIM[1], N. PHIELIPP[1], S. GHOSH[1], C. GUNRAJ[1], A. M. LOZANO[2], M. HODAIE[2], R. CHEN[1];

Abstract: Internal global pallidus (GPi) is the main output nucleus of basal ganglia. Deep brain stimulation (DBS) of the GPi is an effective treatment for dystonia, but its mechanisms of action remains poorly understood. The nature and time course of the connections between GPi and motor cortical areas in humans are not known. We examine the connectivity between GPi and

primary motor cortex (M1) in cervical dystonia patients with bilateral GPi DBS implanted. Ten patients were studied. DBS on one side was set at the lowest frequency of 3 Hz with the clinically used contact and voltage. The contralateral DBS was turned off. Three experiments were performed. The cortical evoked potential induced by DBS was recorded with 64-channel electroencephalograms in Exp. 1. Exp. 2 examined the time course of the effects of DBS on M1 excitability with transcranial magnetic stimulation (TMS). GPi DBS was delivered followed by TMS at interstimulus intervals (ISIs) from 1 to 300 ms. Three different TMS current directions (posterior-anterior, anterior-posterior and lateral-medial) were tested because they activate different cortical circuits. In addition, DBS frequency of 10 Hz was compared to 3 Hz. The effects of different DBS voltages and contact locations were also tested. Exp. 3 tested the hypothesis that cortical plasticity can be induced by an interventional protocol with repetitive pairing of DBS GPi and TMS at specific intervals. Intervention with 180 pairs of GPi DBS and TMS in different ISIs were delivered. Motor evoked potential (MEP) after interventions was compared to that before interventions. We found that GPi DBS produced cortical evoked potential in motor areas with two peaks at latencies of 9.8 ± 1.7 and 25.4 ± 2.1 ms. GPi DBS facilitated MEP produced by TMS with anterior-posterior and posterior-anterior currents at ISI coincident with early peak of evoked potential (~ 10 ms) and inhibited MEP at the later peak (~ 25 ms), whereas DBS had no effect on the MEP induced by lateral-medially directed current. DBS at 3 and 10 Hz showed similar results. Both the early facilitation and later inhibition increased with higher DBS voltages and decreased when DBS was applied at contacts not used for clinical benefit. Long term potentiation-like effect with increased MEP after the intervention was found when DBS and TMS were paired at ISI around later inhibitory phase (~25 ms). Pairing of DBS and TMS at ISI around the early facilitatory phase and that with stimulations delivered in revered order (TMS delivered ~25 ms before DBS) did not produce MEP facilitation. We conclude that GPi interconnects with M1 and the connectivity between two brain areas may be related to the clinical benefit of GPi DBS in dystonia.

Title: Pathway-based genome-wide association analysis of Parkinson's disease

Authors: *M. ZHANG[1], V. PUNGPAPONG[2], D. ZHANG[1];
[1]Statistics, Purdue Univ., West Lafayette, IN; [2]Statistics, Chulalongkorn Business Sch., Bangkok, Thailand

Abstract: We proposed an empirical Bayes variable selection framework to combine pathway information in genome-wide association study (GWAS) analysis, and applied it to the Parkinson's disease GWAS data obtained from the National Center for Biotechnology Information database of genotypes and phenotypes (NCBI dbGaP). Unlike Bayesian variable selection methods that rely on computation-intensive Markov chain Monte Carlo algorithms, we proposed an iterated conditional modes/medians algorithm to implement an empirical Bayes variable selection. First, iterated conditional modes are utilized to optimize values of the hyperparameters so as to implement the empirical Bayes method. Second, iterated conditional medians are used to estimate the model parameters and therefore implement the variable selection function. In addition to the advantages of Bayesian inference, such as natural incorporation of known pathway and other biological information in the statistical model, our proposed method enjoys fast computation, increased statistical power of the analysis, and improved estimation of the model parameters. Extensive computer simulation studies show the more efficient computation and superior performance of our proposed approach, and we got some interesting results from the Parkinson's disease data analysis.

Title: Comparison of progression rate between neural and non-neural rigidity components in parkinson's disease

Authors: *R. XIA[1], D. POWELL[2], Z.-H. MAO[3];
[1]Dept of Physical Therapy, Univ. of St. Mary, Leavenworth, KS; [2]Dept. of Physical Therapy, Campbell Univ., Buies Creek, NC; [3]Dept. of Electrical and Computer Engin. and Dept. of Bioengineering, Univ. of of Pittsburgh, Pittsburgh, PA

Abstract: Parkinson's disease (PD) is a progressive neurodegenerative movement disorder and clinically characterized by rigidity, bradykinesia, tremor and postural instability. Recent imaging studies have shown that rigidity progresses faster than other PD symptoms. Rigidity is defined as a uniform increase in resistance to passive movement throughout an entire range of motion and is accounted by increased reflex responses, referred to as neural component, as well as altered mechanical properties, termed as non-neural component. The purpose of this study was to examine and compare the rate of progression between the neural and non-neural rigidity components over a course of 12 months. Six subjects with idiopathic PD participated in a study protocol including two testing sessions with an interval of approximately 12 months. Torque resistance of the more affected wrist joint was measured during passive flexion and extension movements in patterns of pseudorandom binary sequences. To quantify the neural and non-neural contributions to rigidity, a parallel-cascaded system identification technique was applied. The rate of progression was assessed by calculating the absolute change from the first to the second test (i.e., $T_2 - T_1$) and a percentage of change between the two tests [i.e., $(T_2 - T_1)/T_1$] for both rigidity components. A paired *T*-test was applied to compare the rate of progression between the two rigidity components. Results showed that non-neural rigidity appeared to progress faster than neural rigidity for both absolute (0.055 +/- 0.012 cf. 0.042 +/- 0.006 Nm; P = 0.467) and relative changes (178.9% +/- 57.4% cf. 43.8% +/- 12.4%; P = 0.027). Our finding shows that non-neural rigidity component or myoplasticity of muscle fibers progresses at a faster rate as rigidity became worsening over time. A larger sample size is warranted to confirm this conclusion.

Title: A novel method for describing impaired muscle activation phasing during pedaling post-stroke

Authors: *C. H. MULLENS[1], D. A. BROWN[2];
[1]Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL; [2]Physical Therapy, Univ. of Alabama Birmingham, Birmingham, AL

Abstract: Stroke is a major cause of locomotor disability, with 795,000 people having a stroke yearly and 50% of ischemic stroke survivors showing lasting impairment. One major element underlying this impairment is inappropriate muscle phasing, in which a muscle is active at a phase in the locomotor cycle where it is typically inactive, or vice versa. It is difficult to analyze EMG recordings of this inappropriate phasing, however, because paretic muscle activation often shows reduced amplitude and inconsistent bursting characteristics. Prior work using pedaling (an established, well-constrained model to investigate muscle phasing) has used methods such as comparing activation within 30- or 90-degree regions of the pedaling cycle, or calculating the center of the 90-degree window of greatest muscle activity. These methods have disadvantages, and are imprecise or do not detect changes outside the window of interest. We propose a method of phase estimation based on cross-correlation, and present preliminary results describing cycle-to-cycle variability of phasing in both the paretic and non-paretic vastus medialis (VM) muscle during pedaling. We recorded EMG during motorized pedaling at 40rpm in the VM, a uniarticular knee extensor with prolonged activation post-stroke during walking and pedaling. We compared filtered EMG during individual cycles in paretic (P) and non-paretic (NP) legs against an average activation from all cycles of the non-paretic leg, by circular cross-correlation, and determined angle of greatest correlation. This provided an estimated activation phase shift for individual cycles. Based on preliminary data from two post-stroke subjects (S1 & S2), activation shifts of individual cycles relative to the NP average cycle were normally distributed in both P and NP (based on a Lilliefors test). In both subjects, several P cycles were more delayed than any cycle of NP (11% and 34% of cycles), and average VM activation in P was shifted significantly later (Wilcoxon $p<0.001$) than NP activation (mean shift of 14.6°±9.0° for S1 and 18.9°±14.9° for S2). In both subjects, the relative activation phasing of many cycles in the P leg was similar to those of the NP leg. Surprisingly, some activation shifts of the P leg were even phase advanced relative to the NP average. This preliminary work showed that there is considerable variability in muscle activity phasing during a kinematically-constrained, bilateral, cyclical movement task, and that even when overall average behavior appears delayed, we observed some subset of behavior that was equivalent between the nonparetic and paretic leg.

Title: Association between anticipatory hamstrings activation, pelvic displacement and centre of pressure excursion during unilateral arm raise perturbations in standing

Authors: *K. J. MILLER, C. K. COCHRANE, T. I. IVANOVA, J. GARLAND;
Physical Therapy, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: An experimental paradigm commonly employed to investigate anticipatory postural adjustments (APA) to internal perturbations in standing is the performance of rapid unilateral arm movements in the sagittal plane. In healthy individuals, the APA is associated with feedforward activation of the hamstring (HAM) muscles and an initial posterior shift in centre of pressure (CoP) on the ipsilateral (IPSI) side (Mochizuki et al. 2004). The purpose of the study was to explore the relationships between the initial HAM activity and anterior-posterior (AP) movement of the CoP and pelvis. We hypothesized that the IPSI HAM activation was serving to control the position of the pelvis, thereby minimizing postural sway during the arm movement. Ten healthy right hand dominant participants stood with their feet on two adjacent floor-mounted force platforms and performed 10 trials raising one arm "as fast as possible" to shoulder height. This was repeated for the other arm (order randomized). Kinematics of the pelvic position (10 motion analysis cameras), CoP and electromyography (EMG) data were collected. Arm acceleration was measured using an accelerometer secured on the hand. Total pelvic displacement, derived from the peak anterior and posterior displacement of the anterior superior iliac spine (ASIS) markers, and the corresponding total CoP excursion in the AP direction were measured in relation to the baseline (taken 500ms prior to initiation of arm movement). Associations between the timing of IPSI HAM onset relative to arm movement initiation, IPSI HAM area (normalized to baseline), total IPSI pelvic displacement, total IPSI AP CoP, and arm acceleration were examined. Average arm acceleration varied between participants from 36.3 – 85.7 m/s^2, with no significant difference between arms. Partial correlations (controlling for arm acceleration) revealed a moderately strong relationship between HAM onset and total pelvic displacement (r = 0.41) and a moderately strong relationship (r = -0.40) between HAM area and total pelvic displacement. That is, when there was a more feedforward and larger amplitude

HAM burst, there was less displacement of the pelvis. However, the relationships between AP CoP excursion and HAM onset (r = 0.27), HAM area (r = -0.17) and pelvic displacement (r = -0.22) were relatively weaker. These findings suggest that anticipatory HAM activation contributes to control of the pelvic position during unilateral arm movements. However, the relationships found between HAM activation and AP CoP excursion, and between pelvic displacement and AP CoP excursions were less robust, highlighting the multi-factorial nature of postural control.

Title: The influence of attentional resources on the ability to generate compensatory arm reactions in young and older adults

Authors: J. LAING, *C. TOKUNO;
Brock Univ., St. Catharines, ON, Canada

Abstract: Dual task paradigms have previously been used to demonstrate that attentional resources are required to generate lower limb postural responses for reactive balance control. The purpose of this study was to extend these findings by examining whether the performance of a concurrent cognitive task also affects an individual's ability to produce compensatory arm reactions in response to an unexpected loss of balance. Twenty young adults (18-30 years) and 16 older adults (63 years or older) participated in this study. At the beginning of each trial, participants stood quietly on a moveable platform without (low attentional requirement) or with the presence of a concurrent cognitive task. The cognitive task required participants to count backwards by 2's (moderate attentional requirement) or by 7's (high attentional requirement). At

a random time during each trial, the moveable platform was rapidly translated in either the forward or backward direction. In response to each support surface translation, participants were required to recover their balance as quickly as possible without stepping. The ability to generate compensatory arm reactions was quantified through the measurement of electromyographic (EMG) onset latencies and amplitudes from the shoulder muscles (i.e., anterior, lateral, and posterior deltoids). Results indicate that across all experimental conditions, shoulder EMG activity occurred 11 ms (8.2%) later and 74.6% larger in older compared to young adults. However, the attentional requirements of the cognitive task did not significantly alter EMG onset latencies or EMG amplitudes for both young and older adults ($p=0.125$-0.406). Since compensatory arm reactions were not affected by the availability of attentional resources, this suggests that postural responses involving the upper limbs incorporate different neural processes than those of the lower limbs. Furthermore, contrary to lower limb postural responses, older adults do not appear to require greater attentional resources in order to generate compensatory arm reactions.

Title: Tremor-amplitude and signal-complexity are affected by handgun aiming technique in both experienced and novice shooters

Authors: ***K. J. KELLERAN**[1], S. MORRISON[2], D. M. RUSSELL[2];
[1]Old Dominion Univ., Newport News, VA; [2]Physical Therapy and Athletic Training, Old Dominion Univ., Norfolk, VA

Abstract: In aiming at a target, humans produce small fluctuations in posture, referred to as postural tremor. The dynamics of tremor are influenced by the limb measured and by whether the limb is supported or not. However, research has not yet established whether different arm postures impact postural tremor. This study sought to compare handgun fluctuations during different shooting postures, of: (1) Two handed versus one handed grip, and (2) Straight elbow versus bent elbow. In addition, the impact of skill level on tremor was examined. 15 experienced

and 15 novice shooters volunteered. Participants stood 21 feet from a target and aimed a weighted mock handgun for 10 sec, with an accelerometer affixed near the gun barrel. Participants performed five trials per posture. The amplitude of the signal was computed by the root mean square (RMS), while the signal complexity or irregularity was quantified by Approximate Entropy (ApEn), of the vertical acceleration signal. Two groups, three hand grips (double, right, left), and two arm positions (bent, straight) were analyzed in a 2x3x2 mixed design ANOVA. The double-hand grip significantly decreased tremor amplitude, but increased signal complexity, when compared to either single-hand grip (Double: 0.017 +0.004 G, ApEn 1.194+0.125, Right: 0.022 +0.006 G, ApEn 1.059+0.129, Left: 0.022 +0.005 G, ApEn 1.028+0.114). The bent arm position also significantly reduced tremor amplitude, with no significant difference in tremor complexity, when compared to the straight arm position (Bent: 0.019 +0.005 G, ApEn 1.086+0.142, Straight: 0.022 +0.006 G, ApEn 1.101+.142). Tremor amplitude was not affected by group, however more experienced shooters revealed significantly greater complexity in the tremor signal (0.021 +0.006 G, ApEn 1.136+0.143) when compared to novice shooters (0.021 +0.006 G, ApEn 1.051+0.128). Rather than having an additive effect, using two hands reduced the magnitude fluctuations at the gun. Allowing motion at the elbow also dissipated the fluctuations at the gun. The advantage of a reduction in amplitude were achieved while increasing signal complexity with two hands, but not for bent elbows. Experience failed to impact the amplitude of tremor, however experienced shooters produced a more a complex tremor profile.

Title: Robotic pelvis perturbation during sitting astride improves balance and walking in children with cerebral palsy

Authors: *M. WU[1], J. KIM[2], D. JAEBLER-SPIRA[2], P. ARORA[2];
[1]Dept Physical Med. & Rehabil, Northwestern Univ., CHICAGO, IL; [2]Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Children with Cerebral palsy (CP) typically present with compromised balance control. Impairments in balance control limit their walking capacity and negatively impact their daily activities. As a result, one of the major goals of rehabilitation in children with CP is to improve their balance, particularly dynamic balance. Hippotherapy has been used in clinics to improve balance in children with CP for several decades. However, this beneficial therapy is often not available for a majority of patients because of limited access to horses, weather conditions, and the relatively high cost due to the need for multiple professional staff during a hippotherapy session. As a result, there is a need to develop novel robotic systems to make this type of therapy more widely available for children with CP. In this study, we tested whether providing a controlled 3D perturbation at the pelvis during sitting astride through a cable-driven robotic system will improve dynamic balance and gait in children with CP. We hypothesize that adding a perturbation force to the pelvis during sitting astride will increase the amount of active postural stabilization and trigger reactive postural responses in children with CP. We expect that children with CP will exhibit an increase in muscle activity of trunk flexors and extensors in response to the perturbation load with a subsequent improvement in balance and walking following robotic pelvis perturbation training. Three children with CP were recruited to participate in this study in two test sessions with one week interval in between. In session 1, subjects were fitted with an overhead harness while sitting astride on the robotic horse. A controlled sine wave force was applied to the horse saddle in the anterior-posterior direction through the cable-driven actuators. The frequency of loading was 1Hz and lasted for 15-20 minutes. Standing balance and overground gait speed were assessed before and after robotic horse training. Muscle activity from trunk and leg muscles were recorded during the test. In session 2, a similar protocol was used but a controlled perturbation force was applied in the mediolateral direction. Results indicated that standing balance improved after one session of pelvis perturbation training using the cable-driven robot. In addition, self-selected overground gait speed also slightly increased after training, suggesting a potential transfer from robotic hippotherapy to overground walking in children with CP. The results from this study may be used to develop a training paradigm for improving dynamic balance and walking function in children with CP.

Title: Quantification of gait status through an iPod wireless gyroscope application

Authors: *T. J. MASTROIANNI[1], R. LEMOYNE[2];
[1]Cognition Engin., Pittsburgh, PA; [2]Northern Arizona Univ., Flagstaff, AZ

Abstract: Traditional gait analysis systems are limited to a clinical setting. Wireless and wearable devices enable the capacity to quantify a subject's gait features in a potentially autonomous environment. For example, the wireless accelerometer has been successfully tested and evaluated in the context of a subject's preference, such as a homebound setting. The gyroscope is sensor capable of measuring rate of rotation, as opposed to the accelerometer that measures acceleration. An iPod software application enables the capacity to measure the gyroscope signal as a wireless platform. The data file of the gyroscope signal may be conveyed by wireless connectivity to the Internet as an email attachment. The iPod can be mounted to the subject at a specified and convenient mounting position for gait analysis. The iPod wireless gyroscope application successfully demonstrates the capacity to quantify gait features at a location of the subject's preference.

Title: Bifurcation in lower limb muscle coordination frequency content during quiet standing reflects structure of neuromuscular control

Authors: *K. G. GRUBEN[1], W. L. BOEHM[2];
[1]Kinesiology & Biomed. Engin., Univ. Wisconsin, MADISON, WI; [2]Biomed. Engin., Univ. of Wisconsin - Madison, Madison, WI

Abstract: Human standing requires coordination of muscles crossing multiple joints, which, together with the skeleton, produce force at the foot-ground interface (F). This study analyzed the time course of F to understand the coordinated control used to remain balanced. The focus on F stems from its involvement in producing torque about the center-of-mass (CM), driving angular motion of the body as a whole. To date, research has focused on the location of the center-of-pressure (CP) of F. This neglects the direction of F despite its equally important role in the torque of F about CM. Using a custom force platform with high-precision horizontal force sensors to enable accurate measurement of F direction, we recorded F during quiet human standing. We estimated the horizontal CM location using double integrated horizontal F divided by mass. We expressed F in a reference frame attached to the CM. As CP shifted anterior/posterior to a vertical line through CM, we found that F direction changed systematically with CP. That systematic relationship was well characterized as having an intersection point of F lines-of-action located near the CM. Secondary analysis revealed that shifts in CP included low frequency changes as well as much quicker shifts. The slow changes were of larger amplitude and dominated the relationship, exhibiting the intersection near the CM. At higher frequencies, smaller amplitude changes in CP and F direction occurred that were also well described as having an intersection point. That point was located in a region below the knee joint. A F vector pattern of intersecting near a fixed point in space is the product of coordination among multiple muscles spanning multiple joints. F vectors from multiple limb postures intersecting have been previously reported in seated isometric leg presses, for isolated CP shifts while standing, and while walking in both the observed F and in the modified F (that which remains after accounting for CP shift with respect to the foot). In the seated task, and in the modified force of walking, the intersection point was near the CM just as we observed for the low frequency standing behavior in the present study. The higher frequency behavior with the intersection point below the knee is qualitatively similar to that observed for isolated CP shifts in standing. Thus, we describe the force output of two control modes that appear to regulate upright posture during standing. Those modes resemble control observed in other tasks and thus may represent control strategies that humans use to across tasks for postural stabilization.

Title: Expertise in balance is mediated by a shared set of muscle synergies that generalize across motor behaviors

Authors: *A. B. SAWERS[1,2], L. H. TING[1,2];
[1]Emory Univ., Atlanta, GA; [2]Georgia Inst. of Technol., Atlanta, GA

Abstract: Here we sought to characterize patterns of muscle activity across differences in balance proficiency. Prior research has shown that trained experts use common kinematic patterns to perform skilled and routine grasping behaviors. Furthermore, we have shown that common muscle patterns, or muscle synergies, are shared between overground walking and sub-cortically mediated reactive balance responses. Here we examined whether the same muscle synergies would also be used when performing a more challenging walking balance activity, and whether the degree of sharing is associated with motor expertise. We hypothesize that expertise in balance proficiency is mediated by an increase in the sharing of subcortically encoded muscle synergies across motor behaviors. To test this hypothesis we recruited four ballet dancers (experts), unimpaired adults (novices), and transtibial amputees (TTA). Balance proficiency was assessed using a narrow balance beam walking task. Non-negative matrix factorization was used to extract muscle synergies from EMG signals of 16 leg and trunk muscles on the right side. Muscle synergies during beam walking were compared to those for overground walking and reactive balance. Experts demonstrated substantially better walking balance proficiency, quantified by the distance walked on the narrow beam (experts: 32.6 m, novices: 21.3 m, TTA: 16.9 m, $p < 0.016$). There was no difference in the number of muscle synergies for overground walking (experts: 6.25 ± 0.5, novices: 7.0 ± 1.4, TTA: 5.5 ± 1.3) or beam walking (experts: 6.25 ± 0.96, novices: 5.5 ± 1.3, TTA: 5.25 ± 0.96) within ($p > 0.05$) or between ($p > 0.05$) cohorts. However, experts shared a greater percentage of muscle synergies (60% ± 15%) between narrow beam and overground walking compared to novices (25% ± 21%) or TTA (20% ± 19%). This suggests that the muscle coordination patterns used by experts for beam walking were more

similar to those used for overground walking than in novices or TTA. Experts also shared more synergies between narrow beam walking and brainstem-mediated reactive balance (40% ± 8%) than novices (28% ± 8%) or TTA (19% ± 11%), implying greater reliance on subcortically encoded muscle synergies for beam walking. These results provide initial evidence that motor expertise in balance is mediated by a set of versatile rather than task-specific muscle synergies that generalize across motor behaviors. Moreover, consistent with findings of greater automaticity of motor performance in experts these muscle synergies likely reflect greater input from subcortical versus cortical pathways for motor control.

Title: Cortical responses before and after physically demanding locomotor tasks

Authors: ***J. R. LUKOS**[1], J. BRADFORD[2], A. RIES[1], K. OIE[1], D. FERRIS[2];
[1]Army Res. Lab., Baltimore, MD; [2]Sch. of Kinesiology, Univ. of Michigan, Ann Arbor, Ann Arbor, MI

Abstract: Studies investigating performance in cognitive tasks prior to and succeeding physical activity have resulted in mixed findings. Cognitive performance after physical exhaustion is known to result in impoverished mental abilities (Frey et al., 1997). However, other lines of research suggest that moderate physical activity heightens cognitive-motor responses (e.g., Pesce et al., 2009). To date, the majority of studies investigating the effect of locomotor activity on cognitive performance have been restricted to behavioral outcomes. Additionally, those studies that have looked at cognitive performance changes after physical activity focused on cycling tasks. Thus, the effect of sustained locomotor tasks on electrocortical processing remains unclear. The goal of this study was to investigate the effect of moderate and demanding locomotor tasks on cognitive performance. To do this, we recorded high-density

electroencephalography while healthy young subjects performed a continuous cognitive vigilance task (visual oddball discrimination) in a stationary seated position before and after walking at 1 m/s for one hour. Subjects performed two levels of locomotor activity: carrying an unloaded backpack (unloaded condition) and carrying a backpack with 40% of their body weight added (loaded condition). Based on previous observations of increased P300 amplitude following cycling exercise (Magnie et al., 2000), we hypothesized that the cortical responses to visual stimuli would be affected by locomotor activity. Specifically, the amplitude of the P300 response after walking would increase compared to baseline measures and that the magnitude of these changes would vary based on subjects' level of exertion. Statistical analysis of 10 subjects showed no significant differences in P300 amplitude over the posterior medial cortical midline (~channel Pz) in response to oddball targets when comparing pre- to post- walking trials. Also, no statistical differences were present between loaded and unloaded conditions. Our results suggest that unlike acute, intense cycling exercises, sustained physical exertion of carrying a heavy backpack during walking has minimal after effects on electrocortical event-related potentials. Further analyses of other cortical regions and neurophysiological measures, such as frequency-spectral modulations, functional connectivity analyses, and cortico-muscular coherence, may provide additional insight into the effects of sustained locomotor activity on cognitive processing.

Title: The effect of structured auditory stimulation on movement variability and associated cortical involvement

Authors: ***S. J. HARRISON**[1], M. L. HOUGH[2], N. STERGIOU[2];
[1]Biomechanics Res. Building, Univ. of Nebraska At Omaha, Omaha, NE; [2]Univ. of Nabraska at Omaha, Omaha, NE

Abstract: Movement variability in many rhythmic behaviors often exhibits characteristic temporal structures. In gait and tapping, stride to stride, and beat to beat variations are marked by long-term correlations in time. Motivated by evidence suggesting that changes in the temporal structure of movement variability often accompanies pathology, we explore the possibility manipulating the temporal structure of movement using variants of structured auditory stimuli to which participants in our experiments intentionally coordinated. Stimuli comprised of a rhythmic metronomic beat with varying temporal noise structures (e.g. white, pink, brown) were investigated in both tapping and locomotion tasks. Our results show that the stimuli were effective at changing the variability structure of the observed movement patterns. We also report an accompanying analyses of cortical involvement measured through functional near-infrared spectroscopy.

Abstract: Introduction: An unstable trunk could contribute to lumbar strain injury and subsequently to chronic low back pain. Few studies investigated the effects of postural control, with regard to stability, in subjects that relate mechanical back pain unknown. **Objective:** The purpose of this study was to assess the postural control in subjects with chronic low back pain. **Methods:** Ten chronic low back pain and 10 healthy subjects participated in this study. The subjects performed three trials of one-legged stance task on a force-platform during 30 s (30 s of rest between each trial), with a standardized protocol (without shoes, open eyes regarding target at eye level from 1.5 m of front, arms parallel to trunk). The mean across three trials was retained for analysis, while different balance parameters were computed: center of pressure area (COP);

and mean Velocity of COP in both the anteroposterior and mediolateral directions of movement. **Results:** Chronic low back pain subjects presented poor postural control than control (P <0.01) for mean velocity of COP variable (anteroposterior: 2.75±0.35 vs 1.97±0.19; and mediolateral: 2.96 ± 0.29 vs 2.16±0.15, respectively). Between-groups differences was still reached for sway area of COP variable *(P* = 0.079). **Conclusions:** Chronic low back pain subjects present poor postural control during one-leg stance balance task. These results have implications for rehabilitation programs for balance improvement in subjects with chronic low back pain.

Title: Effect of a sustained load on trunk during postural control measures in healthy subjects

Authors: *E. R. SANTOS[1], L. D. LOPES[1], F. B. PIRES[1], L. A. STURION[1], M. R. OLIVEIRA[1], C. F. AMORIM[2], K. P. FERNANDES[1], R. A. DA SILVA JR[1]; [1]UNOPAR, LONDRINA, Brazil; [2]UNICID, SÃO PAULO, Brazil

Abstract: Introduction: Postural changes with sustained loads as in works lifting load, can lead trunk unstable, spine stress and overload, and subsequently to low back pain. Objective: Asses the effect of a sustained external load on trunk during postural control measures in healthy subjects. Methods: Ten healthy subjects was recruited and performed randomly two experimental tasks on a force platform: 1) bipedal support with open eyes and arms along the body WITHOUT CHARGE (WOC); 2) bipedal support with open eyes and arms along the body WITH CHARGE (WC), corresponding to 10% of body weight, both the tasks were maintained at- 1 minute (with 3 minutes of rest between them). The variables stabilography analyzed were: sway area of Centre of pressure (A-COP), velocity of COP in anteroposterior (VEL-AP) and medial-lateral (ML-VEL) directions. Results: Significant differences between tasks (p <0.05) were found for all COP variables. The mean value for WOC task was 0.9 ± 0.4 cm² and WC of 3.11 ± 3.2 cm ² (221% higher) for A-COP. In VEL AP, the mean value was of 0.66 ± 0.1 cm/s for WOC, while in WC of 0.96 ± 0.3 cm/s(30% higher, p ≤ 0.01). In VEL-ML the differences were of 0.53 ± 0.1 cm/s

for WOC and of 0.67 ± 0.1 cm/s for WC (14% higher, $p \leq 0.01$). Conclusion: Negative effect on postural control was found in healthy subjects when sustaining a load on trunk at 10% of body weight.

Title: Strategic learning neither interferes with nor substitutes for split-belt adaptive learning in walking

Authors: *A. LONG[1], R. ROEMMICH[2], A. BASTIAN[2];
[1]Biomed. Engin., [2]Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Walking rehabilitation ideally makes use of any beneficial interactions between different motor learning mechanisms, such as strategic and adaptive learning. Strategic learning requires a person to explicitly think about how to walk in response to instruction such as "place your foot here." Adaptive learning is a process in which a person learns implicitly from motor errors when a perturbation is introduced. However, little is known about how these two mechanisms interact or if one type of learning can be substituted for the other. We used a split-belt treadmill and a real-time virtual visual environment to compare these learning mechanisms in healthy young adults. To investigate adaptive learning, subjects walked on the split-belt treadmill with one belt moving faster than the other. Subjects learn to place the foot on the fast belt further in front of their body and store a new walking pattern once the belts return to the same speeds. To investigate strategic learning, we provided visual feedback of the subject's foot placement in relation to a visual target on a screen and told them to “step on the target.” We studied people learning from these two methods in isolation and combination. The ADAPTATION group adapted to a split-belt treadmill perturbation gradually introduced but

with no visual feedback. The STRATEGIC + ADAPTATION group performed the same walking protocol (gradually split-belt speeds) but was provided visual feedback of foot placement and targets throughout the entire adaptation period. Visual feedback indicated where to step to adapt, and was easily followed by the subjects. We observed similar amounts of learning and after-effects in both of these experimental groups, demonstrating that strategic learning neither enhanced nor interfered with adaptation. To test whether strategic learning could substitute for adaptive learning, a separate STRATEGIC group was provided with foot placement feedback and targets, but with both belts at the same speed. Subjects easily followed the movement of the target window and reached a final state similar to the adaptation groups. However, we did not observe any after-effect when the feedback was removed. Overall, we find that strategic learning does not interfere with adaptation when both mechanisms are engaged to produce the same motor pattern, and that strategic learning does not substitute for adaptation. These results are important for walking rehabilitation because they suggest that adaptation produces unique benefits for learning new patterns. Supported by NIH HD048741.

Title: A dual-learning paradigm can simultaneously train multiple characteristics of walking

Authors: ***M. STATTON**[1,2], A. TOLIVER[1,2], A. J. BASTIAN[3,2];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Kennedy Krieger Inst., Baltimore, MD; [3]Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Walking is a complex motor pattern that is often impaired after damage to the nervous system. Cerebral stroke survivors, for example, frequently exhibit deficits in their walking pattern including step length asymmetry. We have previously used a split-belt treadmill paradigm to produce adaptive changes and robust aftereffects in interlimb coordination (i.e. step length symmetry), which has proved useful for training stroke survivors to correct this movement

deficit (Reisman et al., 2005; 2007). However, disruption of a global behavior like walking is typically exhibited as a combination of multiple local abnormalities rather than a single deficit. Stroke survivors, in addition to step length asymmetry, also demonstrate deficits in intralimb characteristics of the walking pattern such as decreased paretic knee flexion, resulting in a "circumducted" swing pattern, which are not influenced by split-belt training (Reisman et al., 2005). Here we asked whether a dual-learning paradigm can be used to simultaneously adapt subjects' step lengths and knee flexion patterns, and how this compares to subjects adapting each component separately. Young, healthy adults walked on a split-belt treadmill with the "fast" and "slow" belt speeds set at 1.5 m/s and 0.5 m/s respectively, while watching a real-time visual display which gave feedback on the amount of knee flexion of each leg. Subjects were instructed to match the feedback of both knees while walking - indicating symmetric knee flexion. During adaptation, the gain of the knee flexion display was reduced on the "slow" leg in order to drive the subject to learn to increase it during training. Control groups either adapted knee angle only via visual feedback (no split-belt), or adapted step symmetry only via split-belt walking (no visual feedback). Preliminary results show that split-belt adaptation alone and knee angle adaptation alone led to changes in step symmetry and knee angle symmetry, respectively. When both were adapted simultaneously, both step symmetry and knee angle symmetry were learned at a similar rate and showed similar after-effects post-adaptation compared with controls. Our results demonstrate that we can simultaneously change two features of walking, and these changes appear to be independent - adapting knee flexion does not influence the rate or amount of step symmetry adaptation, and vice versa. Importantly, this suggests that we can be successful in simultaneously training more than one deficit during long-term rehabilitation treatments.

Title: Two ways to save: Different perturbation dynamics lead to savings during split-belt treadmill walking

Authors: *R. T. ROEMMICH[1,2], A. J. BASTIAN[1,2];
[1]Motion Analysis Lab., Kennedy Krieger Inst., Baltimore, MD; [2]Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: "Savings" refers to the observation that relearning is faster than initial motor learning. Thus, some elements of prior learning are stored, recalled, and used to advantage during relearning. Savings occurs across many types of motor learning paradigms, ranging from eye-blink conditioning to reaching and walking adaptation. However, the initial learning conditions that enable faster relearning remain controversial. Here we consider split-belt walking adaptation, and ask if savings depends on 1) a memory of the perturbation that drives learning or 2) a memory of the adapted motor pattern? We collected kinematic data from young adults (n=60) as they walked on a split-belt treadmill. All participants 1) adapted walking to a split-belt perturbation during which one belt moved twice as fast as the other (Adaptation 1, belt speeds 1.4 and 0.7 m/s), 2) underwent a washout period with the belts moving at tied speeds (De-adaptation, belt speeds both 0.7 m/s), and 3) adapted walking again during a second period of split-belt walking (Adaptation 2). Adaptation 2 was structured identically across groups (belt speeds 1.4 and 0.7 m/s for 10 minutes). However, we altered Adaptation 1 and De-adaptation among groups to investigate how dynamics of adaptation and washout affect savings. First, we compared savings after ten minutes of gradual versus abrupt adaptation (both groups underwent identical abrupt 10-minute De-adaptation periods). We observed savings following abrupt adaptation, but no savings after gradual adaptation. Next, we investigated savings after extending the time at plateau (i.e., full adaptation) during gradual adaptation such that the participants here received ten minutes of exposure to the full perturbation (matching the abrupt adaptation group). This also resulted in savings following an abrupt 10-minute De-adaptation period, though to a lesser degree than savings from an abrupt perturbation. Last, we tested whether savings was observed if we introduced the perturbation abruptly, but limited the time at plateau. Savings occurred after short, 2-minute abrupt adaptation, but to a lesser degree than the 10-minute abrupt adaptation. In sum, we found that a memory of the perturbation and a memory of the adapted motor pattern both contribute to savings in a relearning paradigm. Thus, abrupt adaptation or gradual adaptation with extended time at plateau resulted in savings. These findings demonstrate that savings can be achieved via independent behavioral mechanisms, which may also be useful when considering how to improve locomotor learning within the context of rehabilitation.

Title: Mode-dependent control of human walking and running revealed by limited transfer of adaptation across the gaits with different velocities

Authors: *T. OGAWA[1,2], N. KAWASHIMA[3], H. OBATA[4], K. KANOSUE[1], K. NAKAZAWA[4];
[1]Fac. of Sport Sciences, Waseda Univ., Tokorozawa , Saitama, Japan; [2]Japan Society for the Promotion of Sci., Tokyo, Japan; [3]Res. Institute, Natl. Rehabil. Ctr. Persons with Disabilities, Tokorozawa, Saitama, Japan; [4]The Univ. of Tokyo, Tokyo, Japan

Abstract: We have previously demonstrated a specificity in the neural functional networks underlying human walking and running based on the degree of transfer in newly-acquired movement patterns across the gaits. In the current study, we further investigated possible influence of gait velocity (reflecting relative difficulty for executing each gait) on the degree transfer. Sixteen healthy volunteers participated in the experiment. Walk-to-run transition speed (dividing the relative ease/difficulty of walking and running) was 1.68 ± 0.18 m s-1. Subjects participated in two different experiments in random order where in one experiment they adapted to walk and in another to run on a split-belt treadmill driven asymmetrically at 2.0 and 1.0 m s-1 in velocities. To address the degree of adaptation and transfer, six catch trial periods (10 seconds each) to either walk or run on symmetrically-driven belts were interspersed during the adaptation periods. The speed of the treadmill during the catch trials (walking and running) were 0.75, 1.50, and 2.25 m s-1, and were selected to reflect the relative ease to walk (0.75 m s-1), both walk and run (1.50 m s-1), and run (2.25 m s-1). Degree of adaptation and transfer were assessed by calculating asymmetry in the peak values of the ground reaction force in the anterior braking component. The results clearly demonstrated that adaptation to split-belt walking and running resulted in emergence of aftereffect in all the velocities in the respective gait (walk after adapting to walk and run after adapting to run, respectively). On the other hand, the transfer of the adaptation across gaits occurred only partially for both directions (walk to run and run to walk). That is, the emergence of the aftereffect was always greater in walking after adapting to walk and in running after adapting to run despite the relative ease to walk and run at speeds lower and higher than the walk-to-run transition speed. These results suggest that the two major forms of locomotion in humans, walking and running are perceived as being controlled by the central nervous system as a function of different gait modes and are not necessarily dependent on given gait speeds.

Title: Contrasting two strategies accomplishing split-belt treadmill adaptation in humans

Authors: *H. YOKOYAMA[1], T. OGAWA[2], K. NAKAZAWA[1], N. KAWASHIMA[3];
[1]The Univ. of Tokyo, Tokyo, Japan; [2]Fac. of Sport Sciences, Waseda Univ., Saitama, Japan;
[3]Natl. Rehabil. Ctr. for Persons with Disabilities, Saitama, Japan

Abstract: Split-belt treadmill walking has been extensively utilized as a useful model to reveal an adaptability of human bipedal locomotion. Previous studies have clearly identified different types of locomotor adaptation, such as, reactive and predictive controls, and each of those distinct control pattern might be accomplished at different level in central nervous system. In the present study, in order to know how these two types of control pattern contribute to achieve locomotor adaptation, we designed unique experimental conditions, those are "temporal symmetry" and "spatial symmetry" adaptation conditions. While former pattern preserve symmetric rhythm with the guide of auditory cue, latter pattern would preserve symmetric limb motion by accomplishing with the guide of asymmetrically-supplied auditory cue during walking on split belt treadmill. We hypothesized that temporal symmetry condition would facilitate to involve automatically-induced reactive control pattern, and spatial symmetry condition would involve predictive forward control. 15 healthy subjects were asked to walk on split-belt treadmill in three different conditions, (1) temporal and (2) spatial symmetric, and (3) ordinary pattern of split-belt adaptation, on a different day. Three dimensional motion analysis and ground reaction forces measurements were conducted during and after split-belt treadmill walking, and then, general spatiotemporal gait parameters and following parameters were calculated; center of oscillation, phase shift of lower limbs, and braking/propulsive force. The results demonstrated that characteristics of adaptation and the extent of after effect showed differences between temporal and spatial symmetry conditions, for example, anterior component of the GRF (braking force) showed a clear pattern of adaptation and subsequent aftereffects in temporal symmetry but

not in spatial symmetry condition, and the ordinary pattern of split belt adaptation was an intermediate type between contrasting two types. We will discuss about mechanism underlying obtained results from the aspects; (1) contribution of each predictive and reactive control and (2) relevance between cortical modulation and spinal pattern generating network underlying split-belt adaptation.

Title: Optimising filtering parameters for a 3D motion analysis system

Authors: ***J. B. SMEETS**, P. J. BEEK, S. SCHREVEN;
Human Movement Sci., VU Univ. Amsterdam, Amsterdam, Netherlands

Abstract: In the analysis of movement data it is common practice to use a low-pass filter in order to reduce measurement noise. However, the choice of a cut-off frequency is typically rather arbitrary. Here, we propose to use rigid marker clusters to determine the dynamic precision of a given 3D motion analysis system, and to use this precision as criterion to find the optimal cut-off frequency for filtering the data. We tested this method using a model-based approach in a situation in which measurement noise is a serious concern: the registration of the kinematics of swimming using a video-based motion analysis system. For the model data we found that under some conditions, filtering the data with a single cut-off frequency of 6 Hz decreased the accuracy of the reconstruction of the kinematics compared to using the unfiltered data. If the cut-off frequency was used that yielded optimal dynamic precision, then the accuracy improved by 29% compared to using raw data irrespective of the cluster position, close to the optimal accuracy

improvement of 30%. We conclude that 3D motion analysis systems can be made more accurate by optimising the cut-off frequency used in filtering the data with regard to their precision.

Title: Analysis of the turning behavior of the African clawed toad (Xenopus laevis)

Authors: ***R. DEAN**, R. ANDRIKANICH, A. KIFER, S. POLAND, S. SREDNIAWA, M. BARR, S. ADAMS;
Cleveland State Univ., CLEVELAND, OH

Abstract: African clawed toads, which remain aquatic as adults, turn rapidly and accurately towards the origin of surface waves created by prey. Here, we describe basic features of this turn; we focus on the initial direction of body movement and its relation to leg action and hip, knee and ankle movements, characterized respectively as pushing/pulling or extension/flexion/passive return. Stimulus direction determines which of two alternative patterns are performed. Rostral stimuli elicit immediate forward body movement as one or both legs extend and push the body forward. Body rotation and turn angle are adjusted by differential thrust, resulting from stronger extension of leg joints contralateral to the stimulus. Thus, for rostral stimuli, the most frequent pattern utilizes bilateral hip, knee, and ankle extension, which become less bilaterally symmetrical as the stimulus is further from the midline axis until one leg is essentially passive during the turn. This is true whether the toad lunges to strike at close targets or just swims to approach distant ones. In contrast, more lateral and caudal stimuli elicit initial backward movement of the body as one or both hips flex, knees may extend, and legs pull forward. During this pull, joint movements again vary by turn angle and, together with the hip flexion, initiate body rotation. Turning usually continues with a sweeping push by the contralateral leg, resulting from hip and ankle extension and variable knee flexion. As expected, movement patterns for stimuli on the left and right sides are mirror images. Although the most common pattern changes

in characteristic ways depending upon stimulus and turn angles, turns are not truly stereotyped and different combinations of joint movement may be used for similar stimulus angles. Further, patterns change when toads are close to a boundary and modify their turn to clear this obstruction. Patterns also vary among individual toads. Some toads begin almost all turns except lunges by pulling backward to begin rotation. Other toads respond with a forward push for stimuli angles as large as 90° to the side. This behavior is particularly true for the occasional toad that, for unknown reasons, develops a resting posture with abnormally extended legs. For these toads, turning appears less efficient and reaching their final heading may require additional kicks that provide further course correction.

Abstract: For older adults, falls are a serious health problem with over 30% of people over 65 suffering a fall at least once a year. A key component in fall prevention is identifying those predictive variables which lead to falls. An important component often overlooked in the assessment of predictive factors is how these variables change as a function of performing activities of daily living like walking. Although this would appear to be an obvious consideration as most falls occur during movement, the majority of fall risk assessments are performed under resting conditions. The aim of this project was to assess the impact of incline walking at a moderate pace on falls risk, leg strength, simple reaction time and balance in adults. Forty five healthy individuals participated in this study. Subjects were divided into three age groups (Group

1: 30-39 yrs; Group 2: 60-69 yrs; Group 3: 70-79 yrs). Reaction time, leg strength, standing balance and falls risk was assessed prior to and following a period of incline walking on an automated treadmill. Falls risk was assessed using the Physiological Profile Assessment (PPA). For the walking task, three 8-minute trials were performed. Fatigue during walking was elicited by increasing the treadmill incline in increments of 2^0 (from level) every two minutes to a maximum of 8^0. As expected, the results revealed significant age differences in reaction time, strength, balance and overall falls risk prior to performing the walking task. Interestingly, walking had a differential effect on the young and older individuals. Following this activity, both older groups exhibited significantly slower reaction times coupled with diminished leg strength, greater sway and increased falls risk. However, for the young group, the short bout of activity resulted in faster reaction times, increased strength with no subsequent changes in falls risk or sway measures. The general improvements seen in many of the dependent measures within the young group following walking point to the possibility that this activity served as a warm-up, leading to improved post-walking performance. In contrast, older adults exhibited declines in all of the specified fall-related metrics following walking, indicating that this activity had a detrimental impact on their ability to maintain optimal balance. This finding is of particular importance given that, for many older adults, falls occur when they are moving and/or fatigued. The findings of this study demonstrate that a more comprehensive understanding of the problem of falls in older adults can be gained from assessing functional properties related to balance and strength both at rest and following activity.

Title: As risk of falls increases in the elderly, standing postural control shows stronger long-range correlations

Authors: *T. J. RAND, M. MUKHERJEE;
Univ. of Nebraska At Omaha, Omaha, NE

Abstract: Objective: Aging is associated with changes in physical function, such as standing posture, that lead to an increased risk of falling. However, within the aged population, it is not clear how variations in the risk of falls may be associated with postural control. This research investigates postural control in early and late aging and considers overall movement as well as the time-dependent structure of the movement. **Methods:** 34 participants were separated into three groups: young (Y; 19 – 35; n = 10), early aging (EA; 60 – 75; n = 12), and late aging (LA; 76+; n = 12). Each participant stood on a force platform for 90 seconds in three different conditions: normal standing, eyes closed, and sway referenced visual surround. The center of pressure (COP) was recorded and analyzed in the anteroposterior (AP) direction and the mediolateral (ML) direction. The COP values were used to calculate range, root mean square, and long-range correlations (using detrended fluctuation analysis; DFA) of postural sway. The EA and LA group also performed the timed up and go (TUG) test, a functional test related to fall risk, and the Falls Risk for Older People – Community Setting (Frop-Com), a fall risk questionnaire. A 3x3 mixed model ANOVA compared COP variables and an independent samples t-test compared fall-risk measures. **Results:** Comparisons between groups revealed differences between the Y and LA groups for several variables. The LA group had an increased ML range ($P = .019$) and an increased ML DFA ($P = .042$). However, there were no differences between the Y and EA groups, or the EA and LA groups. When comparing the LA and EA groups for measures of fall risk the LA group demonstrated higher scores on the Frop–Com ($P = .005$) and longer time on the TUG ($P < .001$). **Conclusions:** These results demonstrate an increase in overall ML sway for the LA group however such sway patterns are very regular with low variability. Such postural control is constrained with reduced ability to respond to environmental perturbations. This is also demonstrated in an increased fall-risk in this group. Therefore, within an aged group there is deterioration of postural control. Specifically in terms of flexibility within the temporal patterns of ML sway.

Title: Variability in grasp response and the relationship with response time to balance perturbations in older adults at high compared to low risk of falling

Authors: B. JOHNSON[1], R. CREATH[1], R. NEFF[2], *K. P. WESTLAKE[3];
[1]Physical Therapy and Rehabil. Sci., Univ. of Maryland, Baltimore, Baltimore, MD; [2]Univ. of Maryland, Baltimore County, Baltimore County, MD; [3]Physical Therapy & Rehabil. Sci., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Protective arm responses are one strategy that can effectively lessen the potential for a hip fracture and other major injuries in older adults at risk of falling. While a successfully executed response is both rapid and accurate, it is unknown how these variables are affected with age and how they differ between older individuals at high compared to low fall risk. The objective of this study was to determine differences in reach to grasp balance recovery strategies and associated movement time in older adults who fall compared to those who do not fall and to younger adults. Twenty older adults and 10 young adults participated (25 +/-2yrs). Each older adult was categorized into a high fall risk (n=10, mean age 69 +/- 4yrs) or low fall risk (n=10, 69 +/- 5yrs) group. Participants stood on a translatable lateral surface that was used to induce balance perturbations. The feet were restrained and a rail was placed to the right and left of each subject. For each perturbation, subjects were instructed to grab one rail to regain stability. Four conditions were administered: (1) Predictable: subjects were told the direction of perturbation; (2) Unpredictable: subjects were unaware of the direction; (3) Unpredictable with minimally loaded working memory; and (4) Unpredictable with moderately loaded working memory. Results indicated significant differences in the grasping strategy between the groups for all 4 conditions. Cut off percentages for grasping to the rail opposite the direction of platform translation were >90% for the young group, 70-80% for the older low risk group, and 50-60% for the high-risk group. Differences were also identified between groups for the grasp accuracy of conditions 3-4 with 95-100% accurate and complete grasp in the young group, 90-95% for the older low risk group, and 70-80% for the high-risk group. We conclude that older individuals, and in particular older individuals at high risk of falling, demonstrate greater variability in reach to grasp strategy and accuracy than young adults in response to balance perturbations. Future research will examine additional neuromechanical factors underlying this variability.

Title: Effects of attentional dispersion on sensory-motor processing of anticipatory postural control during unilateral arm abduction in the elderly

Authors: *C. YAGUCHI[1], K. FUJIWARA[2];
[1]Dept. of Physical Therapy, Fac. of Human Sci., Hokkaido Bunkyo Univ., Eniwa, Japan; [2]Dept. of Human Movement and Health, Grad. Sch. of Med. Sci., Kanazawa Univ., Kanazawa, Japan

Abstract: The ability of attentional dispersion is one of the factors affecting the deterioration of equilibrium function in the elderly. In this study, we systematically investigated the effects of attentional dispersion during unilateral arm abduction on sensory-motor processing and anticipatory postural control in the elderly. Subjects were 16 healthy elderly persons. A visual cue signal (S1) was presented for 100 ms around the centrally located fixation point. At 1 s after S1 onset, a visual imperative stimulus (6°×6° checkerboard) was presented (S2). Interval between S1s was 3 s. S2 comprised target and non-target stimuli presented at the position (left, right or center) indicated by S1. The distance from the fixation position to left or right S2 and presentation duration of S2 were determined for each subject (6°-9°, 150-250 ms, respectively). If S1 simultaneously indicated three positions, S2 was presented unpredictably in one of the three positions with the equal probability. As results, subjects covertly focused attention on the position (attentional focusing) or divided attention for three positions (attentional dispersion). The order of each S1 and S2 and the presentation positions of S2 were random. In response to the target S2, regardless of the presentation position, subjects abducted their right arm at maximum speed. The reaction time of middle deltoid (MD) to target S2 onset, onset time of postural muscles with respect to MD onset, and the following components of event-related brain potentials were measured. P1-N1, N2 and P3 components were analyzed as indices of the sensory, perceptual and cognitive processing of S2, respectively. The late component of contingent negative variation (CNV) was used to evaluate motor preparation before S2 and anticipatory attention directed to S2. No significant effects of attentional dispersion were found on the amplitude or latency of P1, N1 and P3. N2 and late CNV amplitudes were significantly smaller by attentional dispersion than by attentional focusing ($p < 0.05$). MD reaction time was significantly longer and onset time of postural muscles was significantly later by attentional dispersion than by attentional focusing ($p < 0.05$). These results suggest that the elderly persons would pay a lot of attention to sensory processing even in attentional dispersion condition. Therefore, the attentional allocation on the following higher processing, such as the discrimination or motor preparation would be insufficient by attentional dispersion. These

changes of the sensory-motor processing by attentional dispersion may relate to the delay of MD reaction time and onset time of postural muscles.

Title: Management of different types of exercise for postural control in elderly: A randomized controlled trial

Authors: ***M. R. OLIVEIRA**[1], R. DA SILVA[2], C. SOUZA[2], M. GUARIDO[2], J. DASCAL[3], D. TEIXEIRA[3];
[1]UNOPAR, ARAPONGAS, Brazil; [2]UNOPAR, Londrina, Brazil; [3]UEL, Londrina, Brazil

Abstract: Introduction: Different types of exercise are indicated for the elderly to prevent functional capacities due to aging and increase the balance. Objectives: This study aimed to evaluate the effect of three different types of exercises (mini trampoline, aquatic gymnastic and general floor gymnastics) on postural control measures in elderly. Methods: 39 physically independent elderly women, mean age 69 ± 4 years, were randomly assigned to three intervention groups: 1) mini trampoline (MT, n= 11), 2) aquatic gymnastic (AG, n= 15), e 3) general floor gymnastics (GG, n= 13). Each group performed physical training including cardiorespiratory, muscular strength and endurance, flexibility and sensory-motor exercises at 12 weeks. To determine the effects of each intervention group, five tasks were used to evaluate postural control in different balance tasks on a force platform: two-legged stand with eyes open and closed; semi-tandem stand with eyes open and closed and one-legged stand. During the tasks, Centre of Pressure (COP) measures were computed and analyzed from mean across three trials (with 30 s of rest between them) in each balance task. Results: Postural control in all tasks was significantly improved ($P < 0.05$), after management of three modalities of exercises employed, with effect size in mean for aquatic exercise reaching 0,63 characterized medium effect. Conclusions: These results support that mini trampoline, aquatic and general gymnastics are efficient to improve the balance in elderly women after 12 weeks training.

Title: Relationship between foot posture measures and force platform parameters during two balance tasks in older and young subjects

Authors: *R. A. DA SILVA JR[1], C. E. CARVALHO[2], A. W. GIL[3], M. R. OLIVEIRA[4], J. A. NASCIMENTO[4], D. A. A. P. OLIVEIRA[4];

Abstract: Introduction: Different clinical methods are used to assess the dimensions of foot in order to increase the clinical relevance decisions for posture, balance and deformity of foot in older. **Objectives:** To compare age differences on anthropometric posture measures of foot and balance parameters and determine the relationship between them. **Methods:** Sixty-eight older (mean age 68 yrs) and 42 adults (in mean age 21 yrs) participated of this study. Foot posture was tested across four domains: 1) hallux flexion and extension range of motion (ROM) using goniometer, 2) height navicular and 3) length of the foot both using pachymeter, and 4) foot print: width of fore foot, arch index and hallux valgus. Balance was tested in two conditions on a force platform: bipodal at 60-s trials; and unipodal at 30-s trials (with bref rest across trials). Sway ellipse area of centre of pressure (COP) and sway COP velocity in anteroposterior and mediolateral directions were computed. **Results:** Older shown significant (P<0.01) poor balance than adults only in unipodal condition (COP area 9.97 vs 7.72 cm^2). Older presented significantly (P<0.05) low hallux mobility and high values of the width of fore foot and transverse arch index than adults. The correlations between all foot posture and COP parameters varied, across groups, of weak to moderate (r -0.01 to -.046). Low mobility of hallux was significantly related to higher COP values in older. **Conclusions:** These results have any clinical implications for balance and foot posture assessments.

Title: Small movement errors during split-belt locomotor adaptation do not increase the generalization of learning to natural walking in older adults

Authors: H. M. HARKER[1], C. J. SOMBRIC[1], P. J. SPARTO[2], *G. TORRES-OVIEDO[1]; [1]Dept. of Bioengineering, [2]Dept. of Physical Therapy, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Several studies have investigated mechanisms mediating the generalization of robotic-assisted motor learning to real-life situations (e.g., Torres-Oviedo and Bastian 2012). However, little is known about how these mechanisms are affected by natural aging processes. To bridge this gap, we studied the generalization of motor learning in older adults, and whether it could be manipulated. We know young and old subjects learn a new walking pattern when one leg moves faster than the other on a split-belt treadmill (Reisman, et al. 2005, Bruijn et al. 2012). Interestingly, young subjects learn a more generalized pattern when they experience small errors on the treadmill that are closer to those they experience naturally (Torres-Oviedo, et al. 2012). Here, we investigated whether a similar effect would be observed in older adults. To this end, we compared the generalization of split-belt adaptation effects to over ground walking when two groups (n=8, each) of older subjects (75 ± 5 y.o.) experienced small or large errors during adaptation. Both groups walked over ground and on the treadmill with both belts moving at the same speed for a 'baseline' condition. Then, subjects walked on the split-belt treadmill while the belts changed from a 1:1 to a 2:1 speed ratio either abruptly (large-errors group) or gradually (small-errors group). Directly following these adaptation periods, both groups walked over ground once again. Kinematic data were recorded throughout the experiment to characterize movement patterns. The amount that each group adapted was assessed by finding the steady-state value (i.e. last 40 strides averaged) of the recorded movement pattern during adaptation. Generalization was measured as the difference between the movement pattern observed at the beginning of over ground walking post-adaptation (i.e., first 5 strides averaged) and that

observed during baseline over ground walking. We found that older adults were able to reach similar steady-state at the end of split-belt walking regardless of the size of the errors they experienced during split-belt walking ($p = 0.29$). While we observed large transfer of the learned motor patterns to over ground walking in both groups, it was not significantly different ($p=0.61$). Our results suggest that the generalization of learning in older adults, unlike in young subjects, is not limited by the large errors experienced during adaptation. This could possibly be because older adults naturally experience large errors during their daily walking movements. Our results are promising because they suggest that movement patterns learned on a treadmill could carry-over to natural movements in older clinical populations.

Title: You only get better with age: Age predisposes one to learn new movements slower but to carryover what is learned more to novel situations

Authors: *C. J. SOMBRIC[1], H. M. HARKER[1], P. J. SPARTO[2], G. TORRES-OVIEDO[1]; [1]Dept. of Bioengineering, [2]Dept. of Physical Therapy, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: How does aging affect our ability to learn new movements and generalize them to different situations? We have shown that after split-belt walking (i.e., two legs moving at different speeds) young subjects learn a locomotor pattern with spatial and temporal features that are different from normal gait (Malone et al. 2012). Interestingly, young subjects disengage the locomotor pattern learned on the split-belt treadmill when walking overground (Torres-Oviedo and Bastian 2012). Here we investigated if this capacity is maintained with healthy aging. We further tested whether subjects' ability to switch actions in a cognitive task is correlated with their ability to switch locomotor patterns. Older (76±3 yo, n=8) and younger (27±8 yo, n=8) adults walked on a split-belt treadmill (2:1 belt ratio). Then, all subjects walked on the treadmill when the two belts moved at the same speeds. We quantified learning by computing 1) the

steady-state movements reached during split-belt walking, 2) the rate at which these steady-states were achieved, and 3) the adaptation effects after split-belt walking (i.e., aftereffect) on the treadmill. To assess generalization both groups walked overground after split-belt walking and we calculated the initial aftereffects (first 5 steps) overground. Lastly, we assessed subjects' ability to switch actions with a task in which they had to match two objects based on their shape or color. We found that while older adults learned the split-belt pattern at a slower rate, both groups reached similar spatial ($p=0.35$) and temporal ($p=0.09$) steady states during adaptation. Both groups also learned the same amount, as shown by similar spatial ($p=0.75$) and temporal ($p=0.72$) aftereffects on the treadmill. Moreover, older adults generalized more of the learned movements than young adults in the temporal domain ($p=0.02$), but not in the spatial domain ($p=0.48$). Lastly, while there were trends, the performance in the cognitive switching task was not a predictor of the generalization in the spatial ($p=0.082$) and temporal domain ($p=0.077$). This indicates that the perseverance of treadmill movements in the overground context is not mediated by the same neural mechanisms underlying the perseverance of action selection in the cognitive domain. These results suggest that age related cerebral changes may not affect the centers enabling the learning of new motor patterns, but may affect those underlying the switching of motor patterns across contexts. Therefore, treadmill-assisted rehabilitation would be more effective in older vs. younger clinical populations because older adults will apply more of what they learn on a treadmill to natural overground walking.

Title: Adaptation changes in dynamic postural control and contingent negative variation during repeated transient forward translation in the elderly

Authors: *M. MAEKAWA[1], K. FUJIWARA[2], N. KIYOTA[3], C. YAGUCHI[4];
[1]Shujitsu Univ., Okayama, Japan; [2]Grad. Sch. of Med. Science, Kanazawa Univ., Kanazawa, Japan; [3]Osaka Hlth. Sci. Univ., Osaka, Japan; [4]Hokkaido Bunkyo Univ., Eniwa, Japan

Abstract: Adaptation changes in postural control and contingent negative variation (CNV) for the elderly were investigated during repeated forward floor translation. Fifteen healthy elderly persons, living in the suburban area of Kanazawa City, Japan, underwent backward postural disturbance by a forward-floor translation (S2) 2 s after an auditory warning signal (S1). A set with 20 trials was repeated until a negative peak of late CNV was recognized in the 600-ms period before S2, and the last set was defined as the final set. Electroencephalograms, center of foot pressure in the anteroposterior direction (CoPap), and electromyograms of postural muscles were analyzed. CoPap displacement generated by the floor translation was significantly decreased until the twelfth trial in the first set, and mean CoPap displacement was smaller in the second and final sets than in the first set. The mean displacement was significantly smaller in the final set than the previous set. A late CNV with a negative peak was not recognized in the first and second sets. However, most subjects (13/15) showed a negative peak by the fourth set, when the late CNV started to increase negatively from about 1,000 ms after S1 and peaked at about 300 ms before S2. At about 160 ms before the CNV peak, the CoPap forward shift started. The increase in timing of the gastrocnemius activity related to the CoPap shift was significantly correlated with the CNV peak timing ($r = 0.64$). After S2, peak amplitudes of the anterior postural muscles were significantly decreased in the final set compared to the first set. It was demonstrated that even for the elderly, with so many repetitions of postural disturbance, a late CNV with a negative peak was recognized, leading to accurate postural preparation. This suggests the improvement of frontal lobe function (e.g., anticipatory attention and motor preparation) in the elderly.

Title: Elderly gait dynamics and the effects of environmental constraints

Authors: *E. G. JAMES;
Dept. of Physical Therapy, Univ. of Massachusetts Lowell, Lowell, MA

Abstract: Elderly gait has been found to be characterized by altered stride time dynamics during treadmill walking (Hausdorff et al., 1997). Prior theoretical work has shown that environmental

constraints can alter the organization of motor behavior (Newell, 1986). The present study examined the effects of different levels of environmental constraints on gait in the elderly during treadmill walking. Seven elderly (age 65 - 70 years) and 8 young (age 18-25 years) adults walked at their preferred speed for 10 minutes on a treadmill with lengths of 1 and 1.5 m. The *SD* and long-range correlations (using Detrended Fluctuation Analysis) in stride time were examined to determine possible age and treadmill length effects and interactions. There were no significant differences in the *SD* of stride time. Consistent with prior research (Hausdorff et al., 1997) the elderly had significantly lower stride time Detrended Fluctuation Analysis α-exponents when walking on a 1.5 m long treadmill ($p = 0.009$). However, when walking on a treadmill of 1 m length the elderly stride time α-exponents increased to a level that was not significantly different than those of the young adults ($p = 0.398$). The elderly also had a higher *SD* of stride position on the treadmill than the young adults when walking on the 1.5 m treadmill length ($p = 0.033$) but not the 1 m length ($p = 0.165$). A decrease in the treadmill length led to a decrease in the stride position α-exponents for the elderly ($p = 0.001$). These results indicated that constraining the treadmill length reversed the age-associated change in stride dynamics. Future research is needed to determine whether this alteration in gait dynamics is retained after long-term gait training.

Title: Falls-risk post-stroke: Examining contributions from paretic versus non-paretic limbs to unexpected forward gait slips

Authors: *T. S. BHATT[1], T. KAJROLKAR[2];
[1]Physical Therapy, Movt Sci., Univ. Illinois, CHICAGO, IL; [2]Univ. of Illinois at Chicago, Chicago, IL

Abstract: Balance and gait-related impairments resulting from post-stroke hemiparesis are the main contributors to the high annual incidence of falls in community-dwelling stroke survivors,

especially from environmental perturbations. Previous evidence has demonstrated the importance of reactive stepping strategies in re-establishing one's dynamic stability and preventing perturbation-induced falling. While evidence from stance perturbation studies have demonstrated the preference of non-paretic limb for reactive stepping in people with hemiparetic stroke such preference could be biased as the perturbation was induced simultaneously under both limbs. This study aimed to examine the effect of paretic side versus non-paretic side gait slips on slip outcome, dynamic stability and compensatory stepping response. ***Methods:*** Twenty people with chronic (> 6 months) hemiparetic stroke (57$\pm$ 6 yrs) participated in the study. Low-friction platforms were used to induce an unexpected finite (24 cm) forward slip either under the paretic (n=10) or non-paretic (n=10) limbs while walking in a safety harness. Kinematic data was recorded using an 8-camera passive marker system. Slip outcome (including the incidence of falls and balance loss), dynamic stability (based on the center-of-mass position and velocity) and compensatory step strategy (aborted versus recovery) and kinematics were computed. ***Results:*** There was an equal incidence of falls (50%) between the nonparetic-slip and paretic-slip groups. While the paretic-slip group demonstrated a majority (90%) of recovery stepping responses (a forward step with the non-paretic limb), the non-paretic-slip group however, demonstrated an aborted stepping response (unloading of the paretic limb followed by its immediate re-loading) for 70% of trials. As a consequence, the dynamic stability at contralateral liftoff of the stepping limb was significantly lower for the nonparetic-slip group with a correspondingly greater slip displacement and velocity than the paretic-slip group. ***Conclusion:*** Both the paretic and non-paretic-slip limbs contributed equally to fall-risk on the unexpected finite slip. An aborted stepping response executed by the paretic limb during the nonparetic-slip could lead to fatal vertical falls, especially from infinite slips. Similarly, an unsuccessful recovery step executed by the nonparetic limb during the paretic-slip can increase fall-risk. Intervention strategies targeted towards improving reactive stepping and fall-risk prevention should focus on both paretic and nonparetic limb training.

Title: Long-term retention of locomotor adaptation following short-term training in people with stroke

Authors: D. TAN, *E. V. VASUDEVAN;
Sch. of Hlth. Technol. and Mgmt., Stony Brook Univ., Stony Brook, NY

Abstract: Hemiparesis is a frequent and debilitating consequence of stroke. Lower limb hemiparesis is associated with asymmetric walking patterns, called hemiparetic gait. Training on a split-belt treadmill, which has two belts that can drive each leg at a different speed, can immediately improve hemiparetic gait following a single training session[1], but these effects are assumed to be short-lasting unless training occurs over an extended period[2]. Recent evidence from our lab, however, suggests that neurologically intact adults can retain a long-term memory of split-belt adaptation after only 1 or 2 training sessions[3]. Our objective in the present study was to determine whether stroke affects the ability to consolidate a memory of split-belt adaptation and retain it long-term. The study took place over 3 visits: an initial session ("Day 1") and two subsequent sessions 24 hours later ("Day 2") and 4 weeks later ("1 Month"). At each visit, baseline interlimb coordination was first assessed on an over ground walkway and then on the split-belt treadmill with the belts running the same speed ("tied-belts" at 0.5 m/s). Participants were then adapted to the split-belt treadmill (0.5:1.0 m/s) for 16 min. Near the end of adaptation, changes in walking coordination were briefly assessed on the treadmill (tied-belts) and over the ground. Between visits, participants were told to go about their normal activities, including walking. As in previous studies[1,4], we found that people with stroke were capable of adapting and storing locomotor aftereffects within testing sessions. We also found evidence that they could store a memory of split-belt adaptation long-term - partial aftereffects were still evident during baseline treadmill walking on Day 2 and 1 Month. In contrast to controls, however, people with stroke did not show "savings" - they did not re-adapt faster to split-belts on Day 2 and 1 Month, compared to Day 1. This may reflect an impaired ability to learn and refine specific walking strategies to suit different environments. This ability may be critical for community ambulation, where it is important to anticipate environmental changes and alter gait accordingly. Overall, these results suggest that short-term training can result in long-term retention of locomotor aftereffects post-stroke; however, learning and remembering strategies to adapt to split-belts may be more impaired. 1. Title: All Nintendo Wii Fit games are useful for rehabilitation of all patients with chronic stroke? A study based on learning principles

Authors: *M. E. PIEMONTE, C. S. MIRANDA, T. P. OLIVEIRA, J. X. M. GOUVEIA, D. B. PEREZ, A. E. TEIXEIRA, A. L. COSTA;
Univ. Sao Paulo, Sao Paulo, Brazil

Abstract: Background: Motor rehabilitation can be characterized as a process of 'relearning' how to move to respond satisfactorily to the demands of daily living, and is based on the premise that training leads to improved performance both in terms of acquiring new skills and adapting or refining previously acquired skills. Thus, knowledge on the effectiveness of the motor learning process in patients with stroke is pivotal for planning more effective rehabilitation strategies. In the absence of a clear picture of the changes during the learning process in stroke, and consequent lack of definitive guidelines for devising more effective rehabilitation strategies, it is important to investigate the learning potential of patients with stroke by applying new therapeutic strategies and validating their utility. Objectives: To evaluate the learning, retention and transfer of performance improvements after Nintendo Wii FitTM training in patients with Stroke. Participants: Fourteen chronic stroke patients, with a mean age of 51.42 ± 10.21 years, 8 men and 6 women, mean time poststroke, 4.47± 4.06 years; 60% left hemiparesis and a minimum score of 24 on the Mini-Mental State Examination. Procedures: Evaluation - Both groups were evaluated before the first session of training, 48 hours and 7 days after training. As learning and retention measures were used the game's scores. In order to determine the transfer of learning was used the scores in three force plate tests. Quantitative postural control assessment was conducted using three subtests: limits of stability (LOS), walk across (WA) and step up/over (SUO) of the NeuroComTM Balance Master according to standard protocol. Training - Five attempts were done per game: the first and the last was considered as performance measure. Results: The results evidenced a significant improvement in 3 of the 5 games analyzed. LOS analyses showed that endpoint excursion to paretic side improved significantly post training. There were significant improvement in the speed, and step length. SUO analyses showed significant increases in movement time difference and impact index difference. There was a correlation between global cognitive abilities, but not motor abilities, with the learning in the games. Conclusions: The patients with chronic stroke were able to improve their performance in Nintendo Wii FitTM games according to the demands of games and of the preserved cognitive

capacities. Thus, it is very important to consider these issues to elect this kind of training with therapeutics purposes.

Title: Effects of target uncertainty during arm reaching movements in upright position in stroke individuals

Authors: ***S. M. FREITAS**, C. A. LIMA, A. S. BALDAN, S. R. ALOUCHE;
Mestrado em Fisioterapia, Univ. Cidade De Sao Paulo, Sao Paulo, Brazil

Abstract: Many daily living activities involve movements of the upper limbs during upright standing (e.g., reaching a glass in a cabinet) which depend on the adequate control of reaching the object (focal movement) and on the generation of appropriate postural adjustments. Individuals post-stroke have functional limitations in using their upper limbs to reach an objet during standing. It is unknown, however, if they use different strategies to reach a target in an upright stance when the target position is uncertain. Therefore, the aim of the present study was to investigate the effects of the final target position uncertainty on the balance and focal movement (performed with the limb ipsilateral to the lesion) of post-stroke individuals. Fifteen individuals with hemiparesis (eight on the right and seven on the left side) and eight healthy individuals in upright position (with each foot in an individual force plate) performed reaching movements towards a target shown in the center of a monitor, placed at a distance of 115% of the upper limb's length. The focal movement and postural adjustments were evaluated in certain (target final position was known) and uncertain (target could move to an upper or lower position after the participant started to move) conditions. Joint kinematic of the focal movement (shoulder, elbow and wrist) and postural adjustments (hip, knee and ankle) in the sagittal plane were recorded. Center of Pressure (CP) displacement and joint angles were evaluated 150 ms before and during the movement. The movement onset time was longer in uncertain than in

certain condition; however, the movement time was similar between conditions. Before and during the movement, participants with hemiparesis showed larger CP displacements in the paretic side than in the non-paretic side while the CP displacements were symmetrical for healthy individuals. In the certain condition, the focal e postural joint amplitude was smaller than in the uncertain condition. Participants used mainly the hip joint, regardless the task condition, except those with left hemiparesis that presented greater amplitude at the ankle joint in the uncertain compared to certain condition. Overall, the uncertainty in target position during reaching in an upright position influences the amplitude of joint excursions for both focal and postural movements; however, they do not affect the CP displacement. In addition, the results suggest that stroke individuals, in particular those with left hemiparesis, use different strategies to maintain the postural balance but not to perform the focal movements during the uncertain condition.

Title: Using swing resistance and assistance to improve gait asymmetry in patients post stroke

Authors: *S.-C. YEN[1], B. SCHMIT[2], M. WU[3];
[1]Dept. of Physical Therapy, Northeastern Univ., Boston, MA; [2]Marquette Univ., Milwaukee, WI; [3]Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Patients post stroke often demonstrate step length asymmetry. For those who demonstrate a shorter step length in the affected leg, applying either swing resistance or swing assistance to that leg may help improve symmetry. In principle, swing resistance can augment errors in step length, initiate patients' error correction process, and induce aftereffects consisting of an increased step length following removal of the resistance. On the other hand, swing assistance can directly pull the affected leg forward and result in an increase in step length. However, because such assistance deviates the leg kinematics away from the status quo, patients could treat it as an error perturbation and in turn correct such error by reducing the amplitude of

leg swing, leading to a decrease in step length and worse asymmetry. The purpose of this study was to clarify how patients post stroke adapt to swing resistance and assistance applied to the affected leg during walking. We recruited 9 subjects with chronic stroke to participate in this study; all of them demonstrated shorter step length in the affected leg. They participated in two treadmill adaptation sessions, one for swing resistance and the other for swing assistance. Subjects showed error correction during adaptation to swing resistance and produced an aftereffect consisting of improved step length symmetry. On the other hand, subjects showed improvement in step length symmetry when walking with swing assistance, although the improvement did not sustain following the removal of the assistance. Subjects did not correct swing assistance during adaptation, suggesting that the injured central nervous system may use healthy gait state prior to stroke as a reference to determine movement error rather than using the current gait state. Overall, the results suggest that swing resistance and swing assistance may engage different motor learning pathways for correcting gait asymmetry.

Title: Reactive versus volitional balance training to prevent falls: Pilot study preliminary results

Authors: *D. N. SAVIN JR[1], J. BARTON[2], M. W. ROGERS[3];
[1]Dept Physical Therapy & Rehabil., Univ. Maryland Baltimore, BALTIMORE, MD; [2]Neurol., [3]Dept. Physical Therapy & Rehabil. Sci., Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Background: Neuromotor deficits with advancing age and leading to impaired balance control may precipitate falls and loss of mobility. Falls generally occur in one of two ways: unexpectedly, in reaction to unexpected events (e.g. a slip or trip), or more predictively during a planned voluntary movement such as while reaching. Current neurorehabilitation interventions to enhance balance and prevent falls focus mainly on training planned (expected) voluntary actions (volitional balance control), with little attention directed at improving reactive balance control to unexpected disturbances. Objective: To compare volitional versus reactive balance training to

enhance reactive balance control in older adults at risk for falls. We hypothesized that reactive balance training would result in greater improvements in reactive balance control compared to volitional balance training in fall-risk older adults. Methods: Participants with a history of ≥ 1 fall in the past year and no other significant neurological or orthopedic conditions were enrolled and randomized to either a reactive or voluntary balance training group. All training sessions occurred twice a week for eight weeks with each session lasting 45-50 minutes. Reactive balance control was assessed by using unpredictable lateral waist pulls; volitional balance control was assessed during a standing cued reaching task. Primary outcome measures: number of recovery steps and recovery step length in response to the unpredictable lateral waist pulls (reactive balance), overall excursion of the net center of pressure (volitional balance). Secondary outcome measures: the Berg Balance Scale, Falls Efficacy Scale, and 5 Item Physiological Profile Assessment. Results: Post-training, participants in the reactive balance training group increased recovery step length to a greater degree than those in the voluntary balance training group. Both groups decreased the number of recovery steps required and increased the net center of pressure excursion and postural sway component of the 5 Item Physiological Profile Assessment. There were no significant changes in Berg Balance or Falls Efficacy Scale scores. Conclusions: Our results supported our hypothesis that reactive balance training improves reactive balance control to a greater extent than volitional balance training. This suggested that the different control processes engaged by the two training protocols should be taken into account when designing effective neurorehabilitation programs to enhance balance and reduce fall risk.

Title: Does visual dependency affect standing balance in adults with Cerebral Palsy?

Authors: *Y. YU, I. CHUDNOVSKAYA, S. SNELL, R. LAUER;
Temple Univ., Philadelphia, PA

Abstract: Cerebral Palsy (CP) is a disorder due to brain damage before, during, or shortly after birth. Commonly mistaken as a childhood motor disorder, CP continues into adulthood with motor and sensory deficits. Individuals with CP have been shown to be more visually dependent than those with typical development (TY), which may jeopardize the control of balance in this population. The current study aimed to understand how standing balance control is affected by visual dependency. Nine adults with CP and 14 adults with TY stood in a virtual reality environment in which visual filed motion was manipulated by projecting visual scene either in pitch-up and pitch-down direction at 15 degrees/second or motionless. Five adults with CP were defined as visually dependent for having judgment errors greater than 5° in the Rod and Frame Test. Using a force platform, the trajectory of center of pressure (COP) was recorded separately in the antero-posterior (AP) and medio-lateral (ML). Approximate entropy (ApEn) was calculated and used as an index of the regularity of standing postural sway. A repeated-measure ANOVA (Group as between-subject factor, Condition as within-subject factor) was employed. A significant effect of Condition on COP in ML direction ($p = .042$) was found; regardless of the population, standing posture sway in the ML direction was perturbed by the moving visual scene. To further understand how the standing postural sway is affected by the visual dependency in individuals with CP, a second repeated-measure ANOVA was employed with Visual Dependency being between-subject factor and Condition being within-subject factor. A borderline effect of visual dependency was observed ($p = .060$), indicating that individuals with CP who are visually dependent are more likely to move in a regular and repeated fashion. Such movement flexibility may be used as a means to actively obtain sensory information to orient oneself in the surrounding environment. Future studies are needed to develop potential intervention to reduce visual dependency in this population.

Title: Bracing the trunk and neck alters the spatiotemporal parameters of gait

Authors: *D. M. RUSSELL[1], K. J. KELLERAN[2], S. MORRISON[1];
[1]Physical Therapy & Athletic Training, [2]Human Movement Sci., Old Dominion Univ., Norfolk, VA

Abstract: Older individuals typically display declines in walking performance which include: slower speed, slower cadence, shorter stride length, and greater stride width. These factors have been characterized as a more "cautious" gait pattern. The trunk and neck play an important role in dissipating the transmission of forces from the ground to the head, but this more cautious gait appears to be associated with a stiffer torso. We hypothesize that an increase in body stiffness in older adults, reducing the ability to dissipate forces, may in part be responsible for the change in gait parameters observed with aging. Therefore the aim of this study was to determine if experimentally manipulating the neck and trunk mobility of young, healthy people alters the spatiotemporal parameters of gait. Twelve healthy adults performed 3 walking trials on a flat, straight 70 m walkway, under four different bracing conditions: (1) Control (no brace), (2) Neck brace, (3) Trunk brace, and (4) Neck and Trunk braces. Participants walked across a 6.1 m pressure sensitive GAITRite mat placed in the middle of the walkway. Spatiotemporal parameters of gait could then be computed based on the recording of each footfall on the mat. Participants were instructed to maintain their most comfortable walking pace during each trial. The control condition was always performed first, while the order of the other conditions was randomized. The mean walking speed decreased across the four bracing conditions, but this narrowly failed to reach the level of significance (p = .066). There was no significant difference in the cadence of walking under the different bracing conditions (p =.64). Stride length significantly decreased with bracing (p = .002), while step width increased (p = .014). Overall these results indicate that stiffening the trunk in young, healthy individuals leads to a similar gait pattern observed in older adults. Therefore, reduced mobility of the neck and torso may in part contribute to the decrements in walking observed with aging.

Title: Compulsory joint torque coordination interfaces for neuromuscular training and rehabilitation of human walking

Authors: *W. BOEHM[1], K. GRUBEN[2];
[2]Kinesiology, Biomed. & Mechanical Engin., [1]Univ. of Wisconsin Madison, Madison, WI

Abstract: Walking is an essential means of navigating the world for most humans, yet common approaches to restore this ability after neurological insult disrupts walking fall short of their perceived potential. It is theorized that optimal walking restoration therapy remains elusive due to current therapies approaching the challenge with a scope focused on externally driving the kinematic patterns of typical walking rather than addressing the underlying muscular coordination issues. Our work reveals a specific role of muscle coordination in balance control during walking. Humans coordinate hip, knee, and ankle torque during walking to produce a force of the foot on the ground (*F*) appropriate for regulating whole body angular momentum such that they do not tip over. That specific pattern of force produced through the gait cycle results from coordination of 1) ankle torque that produces heel-to-toe center of pressure shift and 2) hip and knee torques that direct *F* near the center of mass (CM). Immediately following a stroke, it has been shown that the hip and knee torque coordination component is altered in a way such that it would tip the person over if used during walking. Thus, to restore walking functionality, rehabilitation intervention must address this atypical coordination choice and require patients to practice producing the desired (typical) coordination pattern. This approach differs from many current therapies that prescribe the path of the lower limb without constraining the muscle coordination pattern used by the patient. While the limb may be forced through a typical kinematic pattern, that pattern is not necessarily voluntarily controlled by the subject and thus, the underlying muscular activation is not practicing the patterns needed to reproduce those kinematics outside of the rehabilitation setting. We have designed and constructed a rehabilitation device that requires the user to produce the desired muscular coordination (reflected in the direction of the limb endpoint force *F* produced) in order to operate. The device measures and provides feedback on the direction of *F* that the patient produces and adjusts resistance accordingly such that the device allows motion only when the appropriate coordination is learned. Our initial application aims to restore walking after a stroke, however, the system has broad application in neural and physical rehabilitation, fitness and sport-specific training, and injury prevention.

Title: Changes in postural sway as a result of sports concussion

Authors: *K. S. THOMAS, M. MAGAL;
Mathematics and Sci., North Carolina Wesleyan Col., Rocky Mount, NC

Abstract: The incidence of sports related concussions are a growing public health concern. Assessments used to determine return-to-play criteria following a concussive incident are generally related to postural control due to the ability to indirectly measure neurophysiological decline. This study investigated the effects of sports related concussion on postural control. Twelve healthy young NCAA Division III athletes (6 males, 6 females; ages 20.58±1.00) were recruited to participate in the study. Athletes from women's soccer (WSOC), women's basketball (WBB), and football (FB) with a documented concussion in the last year (EXP) were matched with an athlete within the same sport without history of a sports concussion (CON). Participants stood on a Bertec (BP5050) force plate and performed five postural conditions (quiet stance (Eyes Open, Eyes Closed), Anterior-Posterior (A-P) sway, Medio-lateral (M-L) sway, and change of direction sway) for 3-30s trials. For the sway conditions a metronome set at 60Hz in which participants were instructed to keep up with. For the change of direction sway condition, participants began swaying in either the M-L or A-P directions to the metronome and asked to change directions using auditory cues "forward" or "backward" and "left" or "right". The presentation of the auditory cue was randomized to occur within a 10-12s period throughout each trial to control for anticipatory responses. Overall, the results of this study revealed no statistically significant differences in the amount (path length, 95% ellipse), variability (standard deviation - SD), and structure (Approximate Entropy - ApEn) of COP motion between those athletes with a history of concussion compared to those athletes that had not sustained a concussion. These findings are contrary to previous findings which indicated that postural control variables were compromised in those athletes that had sustained a concussion compared to those athletes that hadn't. In conclusion, the postural system of young athletic adults was able to rapidly compensate and adjust to the postural sway tasks regardless of concussion history.

Title: Modulation of the reactive-stepping response to forward-slip perturbations: Effect of central versus peripheral cues on compensatory step initiation with the paretic side

Authors: *P. PATEL[1,2], T. BHATT[1,2];
[2]Physical Therapy, [1]The Univ. of Illinois At Chicago, Chicago, IL

Abstract: Background: The limb preference demonstrated for reactive stepping for people with hemiparetic stroke is the uninvolved (or non-paretic limb). Such preference can however, decrease stability and increase fall-risk due to the inefficient vertical limb support being provided by the paretic limb during step execution. The purpose of this study was hence to determine if providing explicit cues could enhance step initiation from the paretic limb and further to determine the effectiveness of central versus peripheral cues for the same. Methods: Thirteen subjects with chronic hemiparetic stroke (57.7±6.60participated in the study. After being given two familiarization trials subjects were exposed to large-magnitude (velocity 0.67 m/s for 0.04s) forward-slip stance perturbations on the motorized Activestep treadmill (uncued condition, UNC). Subjects were then exposed to three trials of explicit verbal instructional cuing asking them to try their best to initiate a step with their paretic limb (central cueing, CC). The last condition was implicit peripheral cuing (PC) where the non-paretic limb was weighted down with 5% bodyweight equivalent ankle cuffs in order to induce a “constraint” effect. Subjects received three trials of each condition. Kinematic data was recorded using a passive marker system and EMG from bilateral tibialis anterior muscles recorded via wireless sensors. The reaction time (EMG onset), compensatory step characteristics (step initiation time and backward step length) and postural stability were computed and analyzed. Results: Compared to the UNC, (100% step initiation with the non-paretic limb), for the PC condition 90% successful step initiation was with the paretic-limb and even greater for the CC condition (46.66% paretic step initiation). There was no difference in step kinematics (reaction time and compensatory step length) for paretic limb steps between the CC and PC conditions. There was no significant difference in step kinematics between the paretic limb and non-paretic limbs; however, postural stability was significantly greater at instance of step touchdown when steps were initiated with the paretic limb. Conclusion: External cuing can significantly enhance reactive step ability in individuals with hemi-paretic stroke; explicit verbal cues targeting central attentional resources had a significantly greater impact than peripheral cues inducing a limb constraint. Improved step ability with the paretic limb can improve postural stability and decrease fall risk from unexpected

external perturbations. The effect of externally-cued training for improving reactive stepping needs to be further explored.

Title: Effects of a single session of French Auriculotherapy on pain intensity and postural control in individuals with low back pain: A randomized clinical trial

Authors: *P. B. DE FREITAS, JR[1], A. USHINOHAMA[2], B. P. CUNHA[2], L. O. P. COSTA[3]; [1]Inst. de Ciencias da Atividade Fisica e Esporte, Univ. Cruzeiro Do Sul, Sao Paulo, Brazil; [2]Programa de Pós-Graduação em Ciências do Movimento Humano, Univ. Cruzeiro do Sul, São Paulo, Brazil; [3]Programa de Mestrado e Doutorado em Fisioterapia, Univ. Cidade de São Paulo, São Paulo, Brazil

Abstract: Pain is defined as an unpleasant perceptual experience related to a real or a potential tissue injury. It is subjective and depends on individuals' cultural, social, and emotional states. Low back pain (LBP) is prevalent mainly in the economically active population and causes high economic burden to healthy systems worldwide. LBP negatively affects person's ability to perform several motor tasks. For instance, individuals with LBP increase their body sway while they are asked to stand as still as possible mainly in challenging situations. The French auriculotherapy (FA) is a form of acupuncture applied to the external ear and show positive results in pain relief. Thus, the aim of the study was to examine the effects of a single session of FA on pain sensation and on body sway during postural tasks with different degrees of complexity. Eighty young adults, males and females, with chronic LBP and pain intensity equal or larger than 4 at the day of testing in a 0 to 10 pain scale were assessed. Participants were randomly allocated in two groups of 40 individuals: FA group (FAG) and placebo group (PG). Initially, the level of the participants' pain intensity (0-10) was asked. Next, they were asked to stand as still as possible on a force plate either with feet placed in parallel or in semi-tandem stance and either with eyes open or closed. Then, the participants of FAG were treated with FA

for 20 min and the participants of PG were treated with inactive ultrasound with circular movement of its head being slightly applied to the pain site. Immediately after the treatment, the level of pain intensity was asked again and the postural test was repeated. Pain intensity and center of pressure (COP) sway area were the primary and secondary outcome measured. Results of non-parametric tests revealed that pain intensity decreased in both groups after treatment ($p<.001$), but no difference between AFG and PG was observed after the treatment ($p=.063$). For postural control, results revealed effect of treatment in a single and more complex postural situation (i.e. semi-tandem stance with eyes closed - STEC) and only for AFG. Specifically, only AFG reduced COP sway area in this postural condition after treatment. Also, the only difference between AFG and PG was found in STEC condition after the treatment ($p=.049$), with COP sway area being lower in AFG than in PG. In conclusion, AF and placebo reduce pain intensity but only AF affects positively the performance of the postural control system in a more complex postural task. This effect could be caused by a decrease in nociceptive and a consequent increase in proprioceptive activity in the lumbar region, which could improve information about body center of mass position.

Title: Mechanisms behind the transition from acute to chronic whiplash-associated disorders

Authors: ***P.-P. VIDAL**[1], J. LECOMPTE[2], D. WANG[1], S. BLANCHO[3], P. LINDBERG[1], C. DE WAELE[1], J. ADRIAN[4], E. CHIAROVANO[1], B. SANDOZ[2], S. LAPORTE[2];
[1]Cognac G, Univ. Paris Descartes - CNRS - SSA, Paris, France; [2]Lab. de Biomécanique, Ecole

Nationale Supérieure d'Arts et Métiers, Paris, France; [3]Inst. pour la Recherche sur la Moelle épinière et l'Encéphale, Paris, France; [4]CEESAR, Nanterre, France

Abstract: Whiplash is usually defined as an injury of the neck, which most often occurs following car rear-end collision. In the present case they consist mostly in soft tissues injuries since we excluded patients with fractures and dislocations. The main concern with whiplash is that a large proportion of these patients experience disabling symptoms for months if not for years following the accident. The initial and most prevalent complaints are neck and upper back pain. Several other symptoms, the whiplash-associated disorders (WAD), are frequently associated: dizziness and unsteadiness, headache, concentration and memory disturbances, upper limb weakness, paresthesias, and blurred vision. At the chronic stage, sub-acute and chronic symptoms may also include fatigue, sleep disturbances, depression and anxiety. As quoted above, the main problem is that about 50% of patients experience chronic symptoms with considerable direct and indirect costs. In that context, early detection of the WAD patients at risk of developing chronic syndromes is important because it would allow designing better preventive treatment for high-risk individual. However, the great heterogeneity of the methods employed in the studies of WAD has resulted in interesting but often disparate if not contradictory results on that matter. The mechanisms behind the transition from acute to chronic WAD remain to be elucidated and in particular the evaluation of the impact of multiple risk factors in a single patient. In order to tackle with that problem, we set out to combine several methods of investigations in the same WAD patients at the acute stage of whiplash and we have repeated these observation six months later. At both stages, in the thirty WAD patients we investigated and in controls, a neurologist and a neurootologist conducted thorough clinical examinations and clinical tests. Then a project psychologist interviewed participants and the patients were asked to fill in a range of questionnaires. Two projects neurophysiologists submitted also the patients to more specialized test concerning head and postural control. Finally, the patient underwent computed tomography of the neck including a tractograhy study of the descending tract in the spinal cord. The patients had whiplash injury grades II and III. Grade II was defined as neck complaints and musculoskeletal signs; grade III required additional signs (decreased or absent deep tendon reflexes, weakness, and sensory deficits). We found that, when combined, selected neurootological tests, neuropsychological factors, some abnormalities in neck mobility and postural control could predict transition from acute to chronic WAD.

Title: Sensory augmentation for balance control in chronic post-concussive syndrome

Authors: *L. A. KING, M. MANCINI, F. B. HORAK;
Neurol., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: The control of postural sway depends on the dynamic integration of multisensory information in the central nervous system. Augmentation of sensory information, such as during auditory biofeedback (ABF), has been shown to improve postural control when natural sensory information is limited by environmental conditions or pathology. Since impaired postural control is commonly disrupted in chronic post concussive syndrome, the goal of this pilot study was to determine if using ABF to augment sensory information would improve postural control in people with chronic post-concussive syndrome. Methods: Four subjects with chronic non-resolving balance disorders post-concussion participated. The mean age was 19.5 years 4, range 17-25 and the mean time since injury was approximately 4 months (2 sports concussion, 2 falls). Each person was actively being treated for non-resolving balance disorders in our university rehabilitation center. For this pilot study, each participant underwent a balance assessment using an inertial sensor around the waist to measure postural sway under varying sensory conditions. Specifically, subjects were asked to stand quietly for 30 seconds with eyes closed on firm and foam surface, first without and then with ABF. During the trial with ABF subjects were asked to correct their sway according to the feedback, by keeping the volume as low and as balanced as possible. Here we report the percentage change in sway area ($(SA-SA_{ABF}/SA)*100$) during ABF compared to non-ABF trials for the feet together conditions with and without foam. Results: Our preliminary results showed a mean decrease of 43.1% (±35) sway area using ABF compared to non-ABF while standing with feet together in firm surface ($p=0.09$) and a significant mean decrease of 50.3% (±29) sway area using ABF compared to non-ABF while standing with feet together on foam ($p=0.04$) in 4 patients with post-concussive syndrome. Interestingly, the control subject we tested showed an increase of 40% and 24% for the firm surface and foam, respectively. Conclusion: Large sway may indicate a decreased ability of the nervous system to detect, centrally process and/or correct postural sway. People with chronic non-resolving balance

deficits after concussion found the system easy-to-use and they were able to correctly follow the audio information, when available. Such results, while preliminary, are promising and suggest that auditory biofeedback may be beneficial for rehabilitation of balance control in this population.

Title: Quantifying the relationship between step variability and dynamic instability in cerebellar ataxic gait

Authors: *W. ILG[1], Z. FLESZAR[1], C. SCHATTON[1], B. MUELLER[1], N. LUDOLPH[1], M. A. GIESE[1], M. SYNOFZIK[2];
[1]Cognitive Neurology, Section Computat. Sensomotorics, Ctr. For Integrative Neurosci., Tuebingen, Germany; [2]Dept. of Neurodegeneration, Hertie Inst. for Clin. Brain Research,, Tuebingen, Germany

Abstract: Background: The cerebellum is well-known to be crucially involved in balance and locomotion. One of the most characteristic and sensitive signs of cerebellar damage is gait ataxia. Clinically, ataxic gait is typically characterized by an increased step width, variable foot placement and a resulting instable stumbling walking path with very high movement variability and high risk of falling (1). However, the exact features of dynamic instability in ataxic gait have not yet been assessed in detail. Here, we aimed to provide a quantitative analysis of this dynamic instability for different gait phases in ataxic gait. Methods: We analysed gait patterns from 15 patients suffering from cerebellar degeneration or degeneration of afferent pathways (median age: 61, median SARA: 15.7) compared to 15 age-matched healthy subjects. Subjects were instructed to walk normally at a self-determined pace. For quantifying dynamic instability we used the approach of extrapolated centre of mass (XCoM) (2,3). Based on this, a measure of stability is established by determining the 'margin of stability' b, the minimum distance from XCoM to the boundaries of the base of support (BOS). Results: The dynamic stability measure b averaged over the whole gait cycles revealed no significant differences between patients. More meaningful measures concerning stability were obtained by the analysis of stability conditions at

the foot contact of the stepping leg. Compared to controls, patients showed a significant lower stability margin b in mediolateral ($p<0.001$), but not in anterior-posterior direction ($p=0.15$). In addition, variability of b was significantly higher in patients for both directions ($p<0.01$). The variability in b correlated with the clinical SARA score ($r=0.55$,$p=0.03$), confirming variability as a striking feature in ataxic gait. Further analyses will include the relationship between dynamic stability measures and temporal as well as spatial measures of step variability. Conclusion: Our results indicate that the reported measures allow capturing and characterizing dynamic instabilities in ataxic gait. Therefore, these measures are suitable to serve as outcome and monitoring parameter for quantifying changes in balance control in intervention studies. In addition, the analysis of instabilities in specific gait phases could help to distinguish different patterns of ataxic gait (e.g. cerebellar vs. afferent degeneration). Title: The influence of dual tasking on dynamic balance in patient with cerebellar ataxia

Authors: ***B. KANG**, J. PARK;
physical education, Korea Univ., Seoul, Korea, Republic of

Abstract: The purpose of this study was to investigate the effect of dual tasking on the postural control during standing in patients with cerebellar ataxia (CA). It was hypothesized that the CA patients would exhibit different sway characteristics of the center of pressure (COP) and center of mass (COM) by complexity of the secondary cognitive task compared with normal controls. Total 12 CA patients (mean age 45.8, male-7, female-5) and age-matched normal controls participated in this study. Participants were instructed to perform three balance tasks (non-dual, dual ML movement, and dual AP movement) with two different dual-task complexities. Variability, complexity, coupling and symmetric index from the left, right and overall COPs and COMs were measured. Results demonstrated that CA patients showed deficits in balance and

postural control with increased dual-task complexity during overall sway movements, and decreased coupling between left and right limb movements. However, there was no significant difference in symmetric index. With the higher difficulty in cognitive task, CA patients took longer to stabilize their COP and to regain balance, whereas normal controls showed no change between conditions. In addition, CA patients had a greater COM resultant velocity during recovery in the dual-task compared with the single-task condition. These findings suggest that CA patients had compensatory strategies in dual tasking resulting in simple and combined postural movement patterns.

Title: Cervical spinal cord injury model for studying locomotor dysfunction

Authors: *S. K. KARADIMAS[1], S. GOSGNACH[2], K. SATKUNEDRARAJAH[1], M. FEHLINGS[1];
[1]Toronto Western Hospital, UHN, Toronto, ON, Canada; [2]Univ. of Alberta, Edmonton, ON, Canada

Abstract: Introduction: Cervical injury is the most common form of SCI and can result from either an acute traumatic or a progressive compressive injury. The most common form of progressive compressive injury is Cervical Spondylotic Myelopathy (CSM). Cervical SCI leads to devastating locomotor deficits arising from disruption of descending input onto locomotor CPGs residing in the lumbar enlargement. In the past, majority of studies examining locomotor disruption that ensues SCI have utilized acute injury models, which provide a limited understanding of the locomotor changes. For the first time, this study examines changes in locomotor function during the progressive modifications of neural networks that make up the locomotor circuitry. Methods: Chronic compressive cervical SCI was induced in C57Bl mice by inserting a piece of aromatic polyether underneath the C5-6 lamina without the need for laminectomy. This aromatic polyether absorbs phosphate anions and gradually increases calcium phosphate sedimentation to induce new bone formation. A sham operation group was included. MRI was used to confirm progressive compression of the cord. Detail gait (CatWalk) and

hindlimbs kinematic analysis (Photron FASTCAM) were conducted to evaluate locomotor dysfunction. Lumbar motoneuron excitability was evaluated via a detail analysis of H response at various stimulation frequencies. Gait and kinematic analysis were also performed in human CSM patients. ANOVAs were used for the statistical analysis. Results: All compressed mice displayed a progressively significant decrease in hindlimb stride length and swing phase in injury mice compared to controls. In addition, progressively significant increases were observed in running time, hindlimb base of support and hindlimb stance phase duration in injury mice compared to controls. Interestingly, human patients with compressive cervical SCI exhibited a significant decrease in stride length and swing speed as well as significant increase in running time, base of support and hindlimb stance phase duration. Gait analysis also proved that CSM mice exhibit deficits in left-right alternation. Electrophysiological recordings from the lower extremities demonstrated a significant increase in the excitability of lumbar spinal circuitry following chronic compressive cervical SCI as assessed by Hmax/Mmax ratios. Conclusion: This study indicates that CSM mice exhibit locomotor phenotype that mirrors the disruption seen in human patients. Thus, this novel mouse model of progressive locomotor dysfunction provides the opportunity to study the progressive modulation of lumbar CPGs during the course of the disease.

Title: Sub-concussive head impact affects multisensory processing for upright standing

Authors: *J. J. JEKA, S. HWANG, L. B. MOORE, P. AGADA, R. TIERNEY; Kinesiology, Temple Univ., Philadelphia, PA

Abstract: Sub-concussion is an underrecognized phenomenon resulting from low levels of head impact that has the potential to cause significant neurological damage long-term. It has been suggested that head impact affects multimodal sensory processing for postural control, but this has never been observed at low levels of head impact. Here we used soccer heading, a safe and well-controlled human model, to study whether intermodal processing is affected by sub-

concussive impacts . Healthy young adult (ages 18-25) soccer players with at least 5 years of soccer heading experience participated. Soccer balls were projected from a JUGS machine at a speed of 25 mph as subjects performed 10 standing headers over 10-minutes at the beginning of the second test session (0-2hr post-test). Body kinematics was measured in a pre-, 0-2hr post-, 24hr post-heading repeated measures design. For multimodal sensory perturbations, subjects received an 80Hz vibratory stimulus to their bilateral Achilles tendons (stimulus turns on-off at 0.28Hz), a ±1mA bilateral monopolar galvanic stimulus (GVS) at 0.36Hz, and a visual motion stimulus at 0.2Hz at low and high amplitude during 135sec trials. Gain and phase for each modality relative to body kinematics were calculated and compared between test sessions. The results showed that intermodal gain relative to GVS was significantly decreased in 0-2hr post session compared to the pre- and 24h post-session. Gains relative to vision and vibration did not change between test sessions. These results reflect that mild mechanical insults affect intermodal vestibular system processing rather than visual and proprioceptive processing, suggesting that even sub-concussive impact may have detrimental consequences due to long-term repetitive exposure.

Title: Gait characteristics of children with spastic diplegia cerebral palsy

Authors: *C. W. CHAU, K. CARROLL, M. DONAHUE, A. KRAHMER, S. VILLAREALE; Nazareth Col., ROCHESTER, NY

Abstract: Children with Spastic Diplegia Cerebral Palsy (CP) have deficits in locomotion. The aim of this study is to examine gait characteristics in young children with CP and at specific age ranges. Four children with CP (3 male, 1 female, ages 4-13) and Gross Motor Function Measure (GMFM) score of II were studied. All subjects walked independently without assistive device or orthotics on the GAITrite© (CIR System Inc. NJ), a carpeted walkway (3ftx12ft) embedded with electronic pressure sensors that record foot prints. Two to five trials of walking at self-selected pace were videotaped. Spatiotemporal gait parameters were recorded and analyzed with the

GAITrite system which included step length, step cycle duration, velocity, cadence, stance and swing phase duration (as a percent of cycle duration), base of support width, and step length discrepancy (difference between left and right step length). Data from the 4 year old (yo) child with CP was compared to age-matched typically developing (TD) children previously recorded in the laboratory. Data from 7-13 yo children with CP were compared to age-matched normative values reported in the literature. Comparisons between age groups were also made. The preliminary results from the 4yo child with CP showed a decrease in cycle duration (-289ms), step length (-4.2cm), stance duration (-25.5%), an increase in velocity (+34.7cm/s), cadence (+52.9steps/min), swing duration (+25.5%), base of support width (+4.47cm), and step length discrepancy (+6.5cm) as compared to the 4yo TD children. Changes in gait from 4yo to 13yo child with CP included a decrease in velocity (136% to 76% of age-matched control), cadence (141% to 72%), swing duration (161% to 95%), step length discrepancy (6.9 to 3.05 cm), an increase in step length (90% to 97%) and stance duration (56% to 104%). At age 13, the step cycle duration (1389ms ± 172) was longer than that reported in TD children. Our results suggest that the locomotor pattern of the 4yo child with CP was irregular with a decrease in stance and stability. As the age of children with CP increased, the stance duration increased and a more regular gait pattern emerged, possibly due in part to delayed maturation of the locomotion pattern or increased energy efficiency in locomotion tasks. While the step length was slightly decreased at 4 yo child with CP, it was similar to age-matched controls from 7 to 13 yo despite temporal changes suggesting that the spatial parameter is robust. However, the progressive decline in velocity and cadence observed at 13 yo child with CP was consistent with existing literature suggesting that gait in children with spastic CP worsened over time.

Title: The Effects of sensory information distortion by vibrational stimulus on balance control in patients with cerebellar ataxia

Authors: *D.-H. KIM, J. PARK;
Physical Educ., Korea Univ., Seoul, South Korea, Korea, Republic of

Abstract: It has been reported that damage in the cerebellum results in deficits in maintenance of balance and posture. However, there remains a lack of empirical studies investigating the degree to which the involvement of proprioceptive information in balance tasks in patients with cerebellar disease. This study aimed to examine the influence of muscle spindle vibration on the kinematic characteristics of the static balance and postural control in cerebellar ataxic patients. Nine patients with cerebellar dysfunction and 9 age- and sex-matched normal controls participated in the study. The experimental task consisted a total of 8 conditions including with/without leg muscle vibration and with/without visual blocking per 4 situations using stable and unstable platform respectively, and we measured various kinematic variables, such as sway velocity, sway area, and the length of the sway path of the center of mass (COM). The findings revealed that cerebellar ataxia patients demonstrated an increase in COM sway velocity, sway area, and the length of the sway path in all conditions compared with normal controls. They showed the largest sway amplitudes when vibrational stimulus was applied on muscle spindles in tasks on the unstable platform with visual block. These results indicate that balance control was greatly affected by distortion of sensory information in cerebellar ataxic patients suggesting that proprioceptive input of the leg muscle spindles might be involved in sensory integration processes of the cerebellum for maintenance of balance and posture.

Title: The Effects of Parkinson’s disease on adaptation of compensatory stepping

Authors: *D. S. PETERSON[1,2], B. W. DIJKSTRA[3], Y. P. T. KAMSMA[3], F. B. HORAK[1,2];
[1]Oregon Hlth. & Sci. Univ., Portland, OR; [2]Portland Veterans Affairs Med. Ctr., Portland, OR;
[3]Human Movement Sci., Univ. of Groningen, Groningen, Netherlands

Abstract: Falls are common in people with Parkinson's disease (PD), and compensatory steps after a postural perturbation (e.g. a slip) are critical to avoid falls. Postural motor training for PD may provide a means to improve stepping responses; however, whether compensatory stepping can be altered with repeated perturbation exposure, and whether changes are retained or generalize to other postural tasks is not well understood. We measured how stepping responses change after repeated postural perturbations in PD and HO, and whether changes are retained over 24 hrs. Seven PD (on levodopa) and 10 HO completed 25 forward and 25 backward postural perturbations, in which the support surface moved quickly under their feet resulting in a compensatory step. Participants also completed 10 perturbations in the medial-lateral (ML) direction. Twenty four hours later, participants completed 10 forward/backward perturbations (retention assessment), and 10 ML perturbations (generalization assessment). Center of mass (COM) displacement, number of steps, and step length/latency were measured. For forward perturbations (backward compensatory stepping), both HO and PD reduced COM displacement over the 50 trials (Repeated measures ANOVA; main effect for block ($f(4, 56)=18.4$, $p=<0.001$), suggesting improved compensatory responses to perturbations, and these effects are retained (HO: $p=0.02$; PD: $p=0.01$). Number of steps following a forward perturbation reduced over time in HO ($f(4,36=10.8$, $p<0.001$), and trended toward reduction in PD ($f(4,20)=1.9$, $p=0.14$). During backward perturbations (forward stepping), COM and number of steps became smaller in HO ($f(4,36=8.17$; $p=0.02$), but not in PD. Improvement in stepping responses did not generalize to lateral stepping for either group. These preliminary results suggest that while HO and PD improve stepping responses with perturbation training, improvements may not generalize to other balance tasks. This provides support for further investigation of perturbation-type training for fall prevention, however additional research is necessary to identify ways to improve generalization of learning to multiple perturbations.

Title: Effects of locomotor retraining based on the motor learning principle on rehabilitation of gait function in patients with cerebellar disease

Authors: *S.-J. IM, J.-H. PARK;
Physical Educ., Korea Univ., Seoul, Korea, Republic of

Abstract: It has been suggested that the cerebellum is critical for automatic processes of error detection and correction in maintenance of balance and posture. Accordingly, damage to this neural structure frequently results in deficits in static and dynamic balance control. These observations provide important implications for physiotherapeutic interventions for recovery from cerebellar dysfunction. The present study investigated the effects of an explicit strategy for locomotor relearning/training on rehabilitation of gait function in patients with cerebellar disease (CD). A total of 23 patients with degenerative cerebellar disease participated in a 16-week rehabilitation program that initially emphasized conscious awareness and control of the center of gravity (COG) with proper trunk and limb alignment to stabilize balance and posture during body-weight shifting ambulation. Eventually, patients were trained to reach later stages of learning characterized by more accurate and stable performance with minimal demands of attention reflecting increased automaticity in movement control. The results demonstrated that the lateral variability of COG including other gait variability such as stride length and width during gait activities were greatly reduced after intervention indicating improved walking stability in CD patients. In addition, significant improvements were observed in clinical tests that evaluate functional balance and gait capabilities. The results from this study suggest that the benefit and clinical applicability of a gait re-education program developed based on the motor learning principle are evident for the recovery of walking capacity in patients with cerebellar dysfunction.

Title: The effect of obstacle height in stepping strategies in children with autism spectrum disorder

Authors: *S. CHOI, J. PARK;
Physical Educ., Korea Univ., Seoul, Korea, Republic of

Abstract: Obstacle crossing is a complex locomotor task requiring precise limb movements and maintenance of balance. However, the locomotor characteristics of obstacle crossing in children with autism spectrum disorder (ASD) have not been described before. This study investigated how obstructions with different heights influence the capability to plan and execute stepping movements over an obstacle in ASD children. Twelve children with ASD (age: 8~10, IQ: 50~70) and 12 age-matched normal children (age: 8~10 IQ: above 90) participated in the study. Two different obstacle heights were used; 1) 5 cm - similar height of threshold and door sill of bath room, and 2) 15 cm - such as precast pavers in everyday life. The results indicated that ASD children crossed the obstacle through high toe clearance and short take-off and landing distances with relatively large foot abduction and low walking velocity as compared with normal children. Such different stepping characteristics in ASD children are considered as an adaptive control strategies to avoid tripping over obstacles and compensate for body imbalance when negotiating obstacles. In conclusion, the finding of this study suggests that impairments of balance and coordination made children with ASD more vulnerable *in situ*ations that require gait challenges such as stepping over an obstacle, reducing their capability to plan and execute avoidance behaviors.

Title: The effect of visual feedback on interlimb transfer of training during a ballistic movement

Authors: *A. R. BUICK[1], K. L. RUDDY[1,2], M. L. RANKIN[1], R. G. CARSON[1,3];
[1]Psychology, Queen's Univ. Belfast, Belfast, United Kingdom; [2]Neural Control of Movement

Lab., ETH, Zurich, Switzerland; [3]Trinity Col. Inst. of Neurosci. and Sch. of Psychology, Trinity Col. Dublin, Dublin, Ireland

Abstract: Training one limb on a specific motor task leads to strength gains and performance improvement when making the same movement with the opposite, untrained limb. This phenomenon of cross-education has the potential to be influenced through visual feedback (Carson & Ruddy, 2012). The current study sought to manipulate visual feedback of the training limb to examine its effect on performance transfer and also whether this differs depending on the side of the body that is trained. Twenty-four healthy adult volunteers (9 male, mean age 21.6 yrs, right-hand dominant) took part, twelve of whom trained with their left side whilst the remainder performed training with their right side. Each participant completed two sessions (Mirror/Non-Mirror) during which they performed 20 trials (15 movements per trial) of ballistic wrist extension movements, attempting to improve upon their peak acceleration with each subsequent movement. In the Mirror condition, participants were asked to complete the task whilst looking at the reflection of their moving limb, whereas in the Non-Mirror condition participants were required to fixate on a white cross placed on a black drape obscuring their view of the training limb. Performance of this same movement task (Non-Mirror) by the opposite (untrained) limb was assessed prior to, at the mid-point and following training. Transfer was calculated as the change in performance of the transfer limb expressed relative to the peak maximum change in performance exhibited by the training limb (i.e. regardless of the training block in which this occurred). Analysis revealed that training limb percentage improvement data was not normally distributed ($W=0.88$, $p<0.001$), thus the adjusted boxplot (Hubert & Vandervieren, 2004) was used to remove outliers and results indicated that an improvement greater than 18% was considered evidence of learning. Transfer was evident regardless of the side performing the training and the type of visual feedback (>50% across all conditions) and this effect was sustained for at least 10 minutes after the cessation of training. Mixed ANOVA revealed that although there was a trend towards larger rates of transfer when the left limb performed training compared to the right, this did not reach significance ($F(1, 16) = 3.729$, $p = .07$) and there was no effect of using mirrored visual feedback ($F(1, 16) = 2.859$, $p = .11$).

Title: Relationships between structural and functional cortical connectivity and cross education of motor function

Authors: *R. G. CARSON[1,2], K. L. RUDDY[3,1,2], N. WENDEROTH[3], D. G. WOOLLEY[4], A. LEEMANS[5];
[1]Inst. of Neurosci., Trinity Col. Dublin, Dublin, Ireland; [2]Sch. of Psychology, Queen's Univ. Belfast, Belfast, United Kingdom; [3]Neural Control of Movement Lab., ETH, Zurich, Switzerland; [4]Movement Control & Neuroplasticity Res. Group, KU Leuven, Leuven, Belgium; [5]Image Sci. Inst., Univ. Med. Ctr., Utrecht, Netherlands

Abstract: The mechanisms through which the training of one limb leads to improved performance of the opposite (untrained) limb, were investigated using multimodal methods of quantifying structural and functional cortical connectivity. Twenty-four participants underwent a resting-state functional Magnetic Resonance Imaging (rs-fMRI) scan, along with a Diffusion Weighted Imaging (DWI) sequence, prior to an upper limb (wrist) training protocol that engenders transfer of performance to the untrained limb. An equivalent rs-fMRI scan was undertaken following training - 300 resisted discrete ballistic left wrist flexion movements, executed as fast as possible. Participants were instructed to maximise the peak acceleration of the movement. Performance of the right limb on the same task was assessed prior to, at the mid-point of, immediately after, and one week following training. On average, the improvement in performance of the untrained limb was 112% of that observed for the trained limb. At retention, performance of the untrained limb was 57% greater than on commencement. An ROI-ROI analysis revealed that functional connectivity in the resting motor network - between left and right supplementary motor area (SMA), and between left anterior cingulate cortex (ACC) and right posterior primary motor area (M1p), was elevated following training. These changes were not however correlated with or predictive of individual levels of transfer. Analysis of the DWI data using Constrained Spherical Deconvolution (CSD) based tractography indicated that the apparent fibre density (AFD) of the fibre bundles connecting left and right SMA was negatively correlated with (rpb=-0.71,p=0.001) and predictive of transfer both acutely (slope=-655.72,t=-5.01,p<0.001) and one week later (rpb=-0.48, p=0.002, slope=-491.713, t=-3.56,p=0.002). Fractional anisotropy (FA) in the same tracts displayed similar negative correlations with acute transfer, although these were expressed less reliably (rpb=-0.44,p=0.06, slope=-834.75, t=-2.03, p=0.06). A replication including only structural connectivity measures was conducted for a separate group (n=17), wherein both FA and AFD in the tracts connecting bilateral SMA were negatively correlated with and predictive of transfer (FA: rpb=-0.51,p=0.03, slope= -1054.24, t=-2.26, p=0.04; AFD: rpb=-0.70, p=0.002, slope= -338.44, t=-3.05, p=0.008). The findings suggest

that, at least for this motor task, interhemispheric interactions between bilateral SMA play an instrumental role in relation to cross education, and that the structural organisation of the intercalating white matter pathways is related to the level of transfer.

Title: Visuomotor processing in optic tectum - A microcircuit mechanism for selection of action

Authors: *A. A. KARDAMAKIS, B. ROBERTSON, S. GRILLNER;
Karolinska Inst., Stockholm, Sweden

Abstract: Movements towards and away from visual stimuli in the environment are critical for survival. The optic tectum is engaged in selecting which stimuli to attend to, and to generate the required gaze shifts, but the underlying physiological mechanisms remain unclear. To address this, we developed an isolated eye-brain preparation, allowing whole-cell recordings from identified premotor cells in response to visual stimuli, using the lamprey, belonging to the oldest vertebrate group. We first show that the tectal visuomotor pathway is conserved throughout evolution, with parallel excitatory and inhibitory inputs, arising from the superficial layer, converging onto premotor cells in the deep layer mediating orienting or evasive movements. Retinal afferents from the local visual receptive field of a given tectal output cell, provide both monosynaptic excitation and disynaptic inhibition mediated via local GABAergic neurons, while stimulation outside the receptive field yields only inhibition. The local excitatory synaptic response becomes suppressed by concurrent visual stimuli outside the receptive field. This

suppression is mediated through retinal projections to other parts of the optic tectum and further relayed through inhibitory neurons. When inhibition is blocked, the suppression induced by competing stimuli is cancelled and the excitatory responses are enhanced. These excitatory responses are driven by retinal afferents monosynaptically, exposing the bottom-up nature of target selection implemented within the optic tectum. Stimulation of the lateral pallium generates eye and head motor responses and heavily sends projections to the deep layer of the optic tectum (Ocana et al., submitted). We, thus, explore the top-down role of pallial input (homologue to the neocortex in mammals), in modulating the response patterns of tectal output cells to direct retinal input. We used a whole-brain preparation with a sagittal section to expose the tectal layers to record evoked excitatory synaptic inputs with whole-cell recordings from tectal output cells while stimulating the lateral pallium. Taken together, this tectal mechanism, which relies on local excitation and global suppression via competitive inhibition, can also be modulated by pallial/cortical inputs and is most likely conserved throughout vertebrate phylogeny.

Title: Size of visual error does not affect learning of cognitive strategy under mirror-reversal transformation

Authors: *S. KASUGA[1], M. KURATA[1], M. LIU[2], J. USHIBA[1];
[1]Dept. of Biosci. and Informatics, Fac. of Sci. and Technol., Keio Univ., Yokohama/Kanagawa, Japan; [2]Dept. of Rehabil. Med., Keio Univ. Sch. of Med., Tokyo, Japan

Abstract: Humans are capable of adapting their movements to novel environments, thanks to the sophisticated and implicit error correction system. However, such system interferers with the adaptation when the visual information is mirror reversed (MR), because normal trial-by-trial error correction could further aggravate the movement error and make the motor control system unstable as even very small errors could be amplified with trials. This error-amplification

mechanism could make performing even a simple reaching task quite hard without alterations in the error correction rule by cognitive effort. However, it is unclear what triggers such alterations; is it dependent on the size of the visual error or some other signal(s)? To examine these possibilities, we manipulated the gain of visual errors using a virtual-reality display when participants made arm-reaching movements under the MR transformation. We compared the alteration in the error correction rules between the groups where the gain is normal and reduced. Fifteen participants were asked to make 900 trials (a 100 trials of baseline block and 800 trials of perturbation blocks) of straight and fast horizontal reaching movements to a straight-ahead target on the virtual reality display with KINARM exoskeleton (BKIN Technologies, Canada) over 2 days. The participants were randomly assigned to each of the following two groups; the normal-gain group (i.e., the cursor was displayed by simply flipping the signs of x-coordinate of the fingertip at the same scale) and the reduced-gain group (i.e., the cursor was displayed by flipping the signs of x-coordinate of the fingertip while reducing the amplitude in the visual x-coordinate by 20% from the fingertip). Our results showed that in both groups angular errors were accumulated under the MR transformation even though there was only a single target, but suddenly decreased after a few trials. This process was repeated for many times over the experiment. Counterintuitively, the accumulation of errors stopped at significantly smaller size of visual errors in the reduced-gain groups ($P < 0.001$). The number of trials where errors were accumulated was not different between the groups ($P = 0.26$). The finding suggests that the alteration in the error-correction rules from implicit adaptation to cognitive strategy is not dependent on the size of visual errors, but on other error-signals such as size of proprioceptive errors or the number of trials where errors were accumulated.

Title: How visuomotor adaptation in one hand acts on kinesthetic control in the other

Authors: *F. A. KAGERER;
Dept. of Kinesiology, Michigan State Univ., East Lansing, MI

Abstract: Previous research suggests a (non-dominant) left arm advantage for proprioceptive feedback utilization. This experiment determined the robustness of kinesthesia-motor internal representations of either the dominant or non-dominant hand against a visuo-motor perturbation of the contralateral hand. A bimanual center-out task was used to determine cross-modal interference between the two hands when one was exposed to a 60° visual feedback (fb) rotation (either abrupt, or gradual, increasing in steps of 10°), and the other had to rely on kinesthetic fb. 54 participants (21.2 (+-1.3) yrs, right-handed, 27 female) were assigned to 4 groups: right hand abrupt visual perturbation - left hand kinesthetic mode, lh abrupt visual perturbation - rh kinesthetic mode; rh gradual visual perturbation - lh kinesthetic mode, lh gradual visual perturbation - rh kinesthetic mode. Participants simultaneously moved two joysticks under a horizontal monitor displaying two home positions (17 cm apart), two targets per home position (either 90° or 270°, 7.5cm away), and the movement trace produced by the joystick (sampled at 75Hz). Both hands moved in the same direction, either 'up' or 'down'. After 12 trials each of visual baseline (both hands visible), and kinesthetic baseline (one hand without movement trace), the contralateral (visible) hand was exposed to 120 trials of visual fb rotation, followed by 48 trials of veridical visual fb. Variables of interest were initial directional error (IDE, calculated across the first 160ms of movement), representing the feedforward component, and movement time (MT). Results showed no IDE baseline differences between groups, or hands. At the end of exposure in the abrupt condition the 'visible' hands had adapted to similar levels in both groups (rh perturbed, or lh perturbed), as shown by the respective IDE values. In both groups, the kinesthetically controlled hand deviated from an originally straight movement vector in the same direction that the visually perturbed hand took. Both hands ended up with similar degrees of deviation; the left hand responded earlier in the exposure phase to the right hand perturbation, than the other way round. Similar results were found for the gradual condition. MTs in the abrupt condition were faster for the 'invisible' left hand when the right hand was perturbed, than for the right hand when the left hand was perturbed (1076.6 vs. 1462.9 ms), although MTs of the respective 'visible' hands were not significantly different. Results indicate minimal asymmetries between, and similar robustness of kinesthetic-motor representations of either hand when a visuo-motor perturbation is present in the contralateral hand.

Title: Performing, but not learning, a reaching task with one arm while learning the same task with the other leads to complete transfer of visuomotor adaptation across the arms

Authors: *Y. LEI[1], J. WANG[2];
[1]Yuming Lei, Milwaukee, WI; [2]Univ. of Wisconsin - Milwaukee, Milwaukee, WI

Abstract: The extent to which motor learning is generalized across the limbs is typically very limited. In this study, we investigated how two motor learning hypotheses could explain the phenomenon of limited interlimb transfer. According to one hypothesis, we predicted that reinforcement of successful actions by providing binary error feedback regarding task success or failure during initial training would increase the extent of interlimb transfer following visuomotor adaptation (experiment 1). According to the other hypothesis, we predicted that performing a task repeatedly with one arm without providing performance feedback (which prevented learning the task with this arm), as the same task was concurrently learned with the other arm, would increase the extent of transfer (experiment 2). Thus, in experiment 1, our subjects adapted to a 30-degree CCW visuomotor rotation with the left arm first (training session), then again with the right arm (transfer session). During the training session, some subjects received vector error feedback that provided movement direction and amplitude information, while others received binary error feedback. In experiment 2, our subjects adapted to the same visuomotor rotation with the left arm, then again with the right arm. During the training session, however, some subjects performed reaching movements with the right arm toward a target location that they would reach to either prior to or following complete adaptation to the visuomotor condition (i.e., 0-deg. or 30-deg. CW target location, respectively). Results indicated that providing binary error feedback, as compared with vector error feedback, had no influence on the extent of transfer. In contrast, repeatedly performing (but not learning) a specific task with the right arm while the same task was learned with the left arm led to (nearly) complete transfer. This suggests that the absence of motor instances associated with specific effectors and task conditions is the major reason for limited interlimb transfer, and that reinforcement of successful actions during initial training is not beneficial for interlimb transfer. These findings indicate crucial contributions of effector- and task-specific motor instances to optimal motor learning and advance our understanding of the neural processes involved in motor learning, especially those involved in model-free learning.

Title: Performing a reaching task with one arm passively while learning the same task with the other leads to substantial transfer of visuomotor adaptation across the arms

Authors: S. BAO[1], Y. LEI[1], *J. WANG[2];
[1]Univ. of Wisconsin - Milwaukee, Milwaukee, WI; [2]Dept Kinesiology, Univ. of Wisconsin, MILWAUKEE, WI

Abstract: The extent of interlimb transfer of motor learning is typically limited. We have demonstrated that performing, but not learning, a reaching task with one arm repeatedly while learning the same task with the other can lead to complete transfer of visuomotor adaptation across the arms. Based on the finding, we argued that limited interlimb transfer is primarily due to the absence of motor instances that are effector and task specific. In the present study, we examined whether performing a reaching task passively with one arm while learning the task with the other would also lead to complete transfer of visuomotor adaptation across the arms. We reasoned that if effector- and task-specific instances played a substantial role in increasing the extent of interlimb transfer, they should have similar effects whether the instances were accrued actively or passively during reaching movements. In this study, our subjects adapted to a rotated visual display during reaching movements with the left arm first (training session), then with the right arm (transfer session). During the training session, the subjects also performed reaching movements passively with the right arm for 10 trials following every 20 trials with the left arm. The passive movements were induced by a robot arm that moved the right arm in such a way that the instantaneous velocity of the moving arm either changed as that of an active movement would (i.e., bell-shaped velocity profile) or remained constant throughout the movement. Visual feedback was provided only for the left arm during the training, and for the right arm during the transfer session. Our results indicate that the extent of interlimb transfer was greater in both passive conditions, as compared with a condition in which the right arm did not perform reaching movements during the training session. This suggests that providing appropriate effector-specific instances during initial training can facilitate interlimb transfer of motor learning substantially regardless of whether the instances were produced during active or passive movements. We also observed that the extent of transfer was greater when the velocity of the passive movements changed, than when it did not, throughout the movement. This suggests that the similarity in movement velocity between the passive movements performed during the training session and the active movements performed during the transfer session also plays a role in shaping the effector-specific instances that are beneficial for generalization of motor learning.

Title: Visuomotor adaptation influences perceptual decision-making

Authors: N. KUMAR, J. A. MANJALY, *P. K. MUTHA;
Indian Inst. of Technol. Gandhinagar, Ahmedabad, India

Abstract: Accurately predicting the sensory consequences of movement commands using a "forward model" and combining them with actual feedback relayed via sensory systems is thought to yield better perceptual estimates of limb and environmental state than those possible with sensory feedback alone. However, sensory predictions are accurate only if the forward model accurately reflects the properties of the body, the environment and the relationship between the two. This accuracy is maintained via adaptation, in which the forward model is updated based on differences between the predicted and actual sensory consequences of action. Here we investigate how updating sensory predictions through motor adaptation influences perceptual processing and subsequent decisions based on the outcome of those perceptual processes. Twelve young, healthy subjects adapted to a 10 degree visuomotor rotation while using a stylus to trace a trajectory displayed on a computer screen in front of them. Subjects showed clear within- and between-trace adaptation such that the applied rotation was effectively canceled with training. Subsequently, subjects were asked to report the color of a target that moved on the screen among several distractors while they also moved their hand, which was not directly visible. Target motion was either random, matched to that of the hand, or along a path that was rotated by 10 degrees relative to hand motion. Surprisingly, subjects were much more accurate in reporting target color if it moved along the rotated path compared to veridical or random motion. When between-trace adaptation was prevented by means of a secondary cognitive task, subjects showed greater accuracy in reporting the color of a target moving along the rotated path for a few initial trials, reflecting learning that occurred within the last trace of the adaptation block. However, with time subjects shifted towards more accurately reporting the color of the target moving along the actual hand path. These results demonstrate the strong

influence of adaptation and updating of predictive mechanisms that adaptation entails on perception and decisions based on perceptual processing. Perceptual decisions can be clearly modified by manipulating the relationship between movement commands and their sensory consequences, and the degree of modification may depend on how strongly the adapted state is reinforced.

Title: Specificity of visuomotor adaption to movement dynamics

Authors: *M. J. CROSSLEY[1], J. L. FAN[2], R. B. IVRY[2];
[1]UCB, Psychology, [2]UC Berkeley, Berkeley, CA

Abstract: Recent work suggests that the encoding of motor memories is context-dependent, incorporating information about recently past sensorimotor states (e.g., hand position and velocity). Participants can learn to compensate for opposing clockwise (CW) and counterclockwise (CCW) force fields when reaching to a fixed target if the reaches start at unique positions (Howard et al., J Neurophysiology 2012), even though the perturbation was limited to a part of the trajectory that was common to both movements. However, participants failed to compensate when the context was cued statically (e.g., with visual landmarks), or when there was a delay prior to the perturbed phase of the movement. We extend these results in two key ways. First, we show that a similar pattern holds for visuomotor adaptation. Participants made two-stage reaching movements, moving from a start position to a central location and then on to a target. The direction (CW or CCW) of a 20 deg rotation was defined by the particular start-target pair, with the rotation only applied to the second, center-out component. Adaptation was strong when the two components were executed as an integrated smooth movement. In contrast, adaptation was weak when participants paused at the center for 1 s. Second, learning with dynamic cues exhibited marked retention across test blocks. Here we used a design composed of four phases: baseline (80 movements with no rotation), acquisition (80 movements with a CW rotation), washout (160 movements with no rotation), and reacquisition (80 movements with a CW rotation). A set of start-target pairs with one direction of rotation was

used in the acquisition and reacquisition blocks. A different set of start locations, paired with the same targets was used in the washout with no rotation. Changing the dynamic cues in the washout block prevent the expression of an aftereffect. However, when the initial context was reintroduced in the reacquisition block, adaptation returned immediately to a level approximately equal to that observed at the end of initial acquisition, and continued at similar rate. These findings underscore the influence of dynamic cues in both the encoding and retention of sensorimotor memories.

Title: The effects of spacing practice and perturbation session on the motor memory consolidation during the acquisition of visuomotor adaptation task

Authors: *Y.-G. SONG[1], J.-H. PARK[2];
[1]Physical Education, Korea Univ., Korea Univ., Seoul, Korea, Republic of; [2]Korea UNIV., Seoul, Korea, Republic of

Abstract: The memory consolidation hypothesis maintains that the processing of a memory continues long after the completion of a practice repetition. The present study was designed to identify the factors that influence the effectiveness of the consolidation processes, leading to a relatively stable and long-term motor learning in the production of a visuomotor adaptation that required 30° rotation (i.e., clockwise). Four groups of participants (n=36) practiced the task conditions on each group as follows: (i) 1 day group (AAA), (ii) 3 day group (AAA), (iii) 1 day group (ABA) and (iv) 3 day group (ABA). Specifically, 1 day group (AAA) and 3 day group (AAA) performed in 3 sessions of 6 blocks each, and the practice sessions were separated by 10 minutes or 24 hours (1 day). 1 day (ABA) and 3 day (ABA) also practiced the same practice sessions as the above groups, then additional perturbation condition (-30° rotation; counter-clockwise) in 1 sessions of 1 block each, and the practice sessions were separated by 10 minutes or 24 hours (1 day). The distance error (movement accuracy) and velocity (movement time) were calculated using the Motion Tracking System. The results demonstrated that as the amount of the practice increased, distance error and velocity were improved. However, no significant

difference was found among these groups, but no 1 day (AAA) and 3 day (AAA) perturbation groups were improved compared with 1 day (ABA) and 3 day (ABA) perturbation groups. The 3 day group (AAA) also showed accuracy and velocity during the retention test than remaining 3 groups, significant differences were indicated among these groups. These findings suggest that practicing additional tasks after the regular training sessions could perturb memory consolidation processes for visuomotor adaptation learning. In addition, longer space between practice sessions may facilitate production of fast pointing movements during visuomotor rotation tasks. Taken together, consistent with the notion of memory consolidation, these findings suggest that distribution of practice over a relatively long period of time (day), rather than perturbation (i.e., interference), is a more important factor for the enhancement of learning in the production of a visuomotor task.

Title: Motor behavior and associated primary motor cortex excitability differ during relearning of visuomotor gain when unlearning occurs either via washout or a period of inactivity

Authors: ***M. YAROSSI**[1,3,2], S. ADAMOVICH[3,2], J. W. KRAKAUER[4], E. TUNIK[2,1]; [1]Grad. Sch. of Biomed. Sci., [2]Rehabil. and Movement Sci., Rutgers Biomed. Hlth. Sci., Newark, NJ; [3]Biomed. Engin., New Jersey Inst. of Technol., Newark, NJ; [4]Dept. of Neurol., The Johns Hopkins Hosp., Baltimore, MD

Abstract: Recently, savings has been posited to relate to memory of actions rather than of cerebellar-dependent internal models [Huang 2011]. In addition, retention and savings of adapted reaching behavior to a visuomotor rotation has been shown to depend on the form of the unlearning phase interposed between learning and re-learning [Kitago 2013]. We investigated the

possible role of the primary motor cortex (M1) in the learning, unlearning, and relearning of a visuomotor gain by tracking its excitability throughout these phases of adaptation. Healthy right-handed subjects (N=23) participated after providing informed consent. Seated with hands under a display, data glove equipped subjects were given visual feedback of a virtual hand and instructed to make ballistic target directed right index finger flexion movements. Subjects completed 2 baseline blocks (40 trials), 4 initial learning blocks (30 trials), 5 unlearning blocks (30 trials), and 4 re-learning blocks (30 trials). Discordant visual feedback was provided by applying a 0.5 (low gain) scaling factor to the glove data during learning and relearning blocks. Subject groups experienced one of two types of unlearning: either reversion to veridical gain (Washout), or a period of inactivity (Time). In a third condition (Control), extent was manipulated through changes in target angle, i.e., a new mapping was not required. M1 excitability was assessed using TMS-evoked resting motor evoked potentials (MEPs) recorded from the first dorsal interosseous in a 1-minute period following each block. In the Washout group, we observed canonical adaptation, deadaptation (with aftereffects) and re-adaptation (with savings) behavior. The Time group displayed similar initial learning but little unlearning such that relearning started at a high residual gain level. Patterns of M1 excitability were similar for Washout and Time during baseline, learning and unlearning. During relearning, however, despite equal asymptotic performance, MEPs were significantly larger in the Washout group (Students t-test, $p<.05$), suggesting increased excitability was related to savings rather than residual adaptation. Control subjects increased peak velocity to meet the demand of larger target angles in the learning and re-learning blocks with nominal change in excitability. This dissociation between excitability and performance implies that M1 excitability assays learning rather than motor performance. We suggest that for visuomotor gain adaptation M1 excitability relates to both active selection and retrieval of actions when target errors are present and that these processes are distinct from forward-model updating [Jordan 2014].

Title: Savings as an indicator of motor generalization for visuomotor learning

Authors: *C. YIN, K. WEI;
Peking Univ., Beijing, China

Abstract: For studies of motor adaptation, people typically adapt to a certain novel perturbation and their learning and generalization are then assessed by unexpectedly removing that perturbation. The performance during these immediate catch trials was termed after-effect; it is universally used for quantifying directional generalization for visuomotor learning such as visuomotor rotation or gain. However, after-effect decays rapidly thus it has to be tested immediately after learning. Researchers even resort to use refresher trials (original training trials) to maintain the "learning" during the measurement of generalization. Ironically, despite of the importance of refresh trials, its frequency varies across those generalization studies, leaving it hard to compare generalization results across studies. As compared to fragile aftereffect, saving effect, defined as enhanced learning rate at the time of recall, is a robust indicator of learning with much slower decay. Using savings to quantify directional generalization has never been tested. In this study, we trained subjects with visuomotor rotation and evaluated their directional generalization with both savings and after-effects, either immediately after training or 24 hours later. When tested immediately after learning, the generalization indexed by savings was unimodally shaped, similar to but still broader than the aftereffect-based generalization. Interestingly, this unimodal generalization was largely unchanged 24 hours later when the aftereffects disappeared almost completely. Generalization curve has been related to neuronal representations of motor learning and generalization for long. Its exact shape should be reproducible to enable us to make any concrete inference about the neural substrate of motor learning. The aftereffect, given its sensitivity to decay as suggested by our findings, might not be a good candidate for assessing generalization. On the other hand, saving is relatively stable against decay and it does not require refresh trials to maintain the fragile visuomotor learning. Furthermore, savings has also been related to retention, a hallmark of successful motor learning. We thus propose to use saving, as an alternative to aftereffect, for studying motor generalization specifically and for investigating motor learning in general.

Title: Motor and visual directional tuning after visuomotor adaptation

Authors: ***S. HAAR**[1], O. DONCHIN[2], I. DINSTEIN[1,3];
[1]Brain and Cognitive Sci., [2]Biomed. Engin., [3]Psychology, Ben Gurion Univ., Beer Sheva, Israel

Abstract: What happens to directional tuning when reaching movements are dissociated from their visual feedback by rotating the visual field? Do neural populations in motor system areas remain tuned to the reaching direction or shift their tuning according to the visual rotation? We recorded simultaneous movement kinematics and fMRI activity while subjects performed 'out and back' reaching movements to four targets spaced 45° apart. The experiment included three conditions: 1) Baseline - visual and motor mapping were matched. 2) Rotated - the cursor movement was rotated by 45° with respect to the hand movement. 3) Washout - the visual and motor mappings were matched again. A multivariate classification algorithm was trained to identify movement direction according to voxel-by-voxel fMRI patterns in each of several brain areas. The classifier was trained using a subset of trials and then tested by decoding excluded trials. The direction of movements was successfully decoded with above-chance accuracy rates in multiple motor and visual areas when training and testing the classifier on trials within each condition (i.e. within-condition decoding). However, when training the classifier on baseline trials and decoding rotated trials, motor brain areas including primary motor cortex (M1), dorsal premotor cortex (PMd), and supplementary motor area (SMA) exhibited above chance decoding for the original movement direction (as in the baseline condition) while visual brain areas including early visual cortex and superior parieto-occipital cortex (SPOC) exhibited above chance decoding for the rotated visual target location rather than the actual movement direction. Most interestingly, decoding levels in the anterior intraparietal sulcus (aIPS), an intermediate visuomotor area, were at chance level for both visual and motor aspects, suggesting that directional tuning in this area was altered by the visuomotor adaptation. Additional analysis revealed mixed tuning to both original motor targets and rotated visual targets. We interpret these results to suggest that in humans, like monkeys, directional tuning of low level motor areas is not affected by visuomotor adaptation, but directional tuning in higher parietal areas such as aIPS is altered.

Abstract: Visuomotor adaptation is the process by which our motor system adjusts movements to a novel environment. Although abundant evidence points to the formation of long-term motor memories for this type of learning, several previous studies have failed at characterizing the time course of memory consolidation using behavioral protocols of retrograde interference (e.g. Caithness et. al., 2004). This may in part be due to the fact that anterograde effects are very strong, often masking retrograde effects. Here, we took advantage of this phenomenon to explore the time course of motor memory consolidation. Subjects adapted to two opposite visual rotations of 30 degrees following a protocol of anterograde interference. They performed 6 blocks of pointing movements to 8 visual targets using a joystick (1 cycle = 8 targets; 11 cycles per block). Participants were divided in 6 groups, which experienced a clockwise rotation (A), followed, after a variable interval of 1min, 15min, 1h, 3h, 5,5h and 24 h, by a counterclockwise rotation (B). The rate of learning for A and B was computed by fitting individual visuomotor error for all cycles using a single exponential function with a constant (Zarahn et. al., 2008). We assumed that a reduction in the rate of learning of B would reflect the consolidation of the memory for A. In contrast to our own predictions and to previous studies on sensorimotor adaptation (Shadmehr et. al., 1997; Krakauer et. al., 2005), our preliminary results point to a non-monotonic pattern of anterograde interference. Title: Training in native coordinates interferes anterogradely with adaptation to rotated visual feedback

Authors: *J. VILLALTA, A. STOLKINER, E. VIGNETTA, V. DELLA-MAGGIORE; Dept. of Physiology, Buenos Aires Univ., Ciudad Autonoma De Buenos Aires, Argentina

Abstract: Motor adaptation is a type of motor learning that allows maintaining accurate movements in the presence of environmental or internal perturbations by creating new sensorimotor maps. A typical experiment involves a session of familiarization during which subjects move to a visual target in native -unperturbed- sensorimotor coordinates (null trials), followed by an adaptation session to a visual perturbation. Often, null trials are used in savings protocols to equate the initial level of error across adaptation and re-adaptation sessions (to "wash out" aftereffects)[1]. Recently we have shown that a relatively small number of null trials (2 blocks of 88 trials) presented just before the test session can interfere with memory retrieval, thereby reducing the amount of savings [2]. Our results suggest that practice in unperturbed conditions is not innocuous but may lead to the formation of a new visuomotor memory. Here, we addressed this hypothesis by investigating if, like perturbations, null trials can directly interfere with new learning. To test this hypothesis we trained two groups of naïve subjects on a visuomotor adapation task to a -40º optical rotation (6 blocks of 88 trials). The experimental and control groups were preceded by 7 and 1 blocks of null-trials, respectively. We found a decrease in the amount of memory retention measured 1 min after adaptation in the Experimental relative to the Control group ($p=0.04$) . Our results support the idea that null trials form a memory that competes with those formed during adaptation to rotated visual feedback. [1] Krakauer JW et al. Title: In experts, contribution of explicit and implicit processes to visuomotor adaptation is different than in novices

Authors: *C. LEUKEL[1,2], W. TAUBE[2], A. GOLLHOFER[1];
[1]Univ. of Freiburg, Freiburg, Germany; [2]Univ. of Fribourg, Fribourg, Switzerland

Abstract: Motor learning may be based on explicit and implicit processes. Explicit processes are changes in motor performance caused by conscious decisions that require declarative knowledge about the task. In contrast, implicit processes are behavioral changes that are subconsciously driven. Recent studies argue that there exist at least two forms of implicit processes that differ with respect to the rate of learning and the retention of the acquired movement(s) (Smith et al., 2006). In the present study, we investigated contribution of explicit and implicit processes to visuomotor adaptation in subjects with different levels of expertise. Experienced handball players (N = 30) and novices (N = 30) were compared when performing standardized free throws. We used prismatic glasses to induce a visuomotor adaptation and performed three different experiments (subjects were equally assigned to the protocols): in experiment 1, we recorded the aiming strategy of the subjects that informs about contribution of explicit processes. In experiment 2, explicit processes to adaptation were blocked by verbal instructions about the throwing procedure, thus we assessed how adaptations were performed with solely implicit processes. In experiment 3, retention of the adapted throwing movement was tested while contribution of explicit processes was blocked like in experiment 2. The results of experiment 1 indicate that contribution of explicit processes was significantly larger in experts than in novices. Results of experiment 2 showed that experts adapted significantly slower than novices when contribution of explicated processes was blocked. Finally, results of experiment 3 indicate that experts retained the adapted movement longer (i.e. slower forgetting) than novices. These results have important implications. First, they suggest that the standard models of skill acquisition (e.g. Fitts and Posner, 1967), that propose a reduction of explicit and enhancement of implicit processes with increased levels of expertise, may require further critical considerations. Second, the results of experiment 2 and 3 suggest that experts use different implicit processes than novices. Adaptation took longer and retention was better in experts. Thus, one may speculate that learning in experts is optimized in a sense that acquired movements can be retained longer than in novices. A slower rate of learning by these implicit processes would be counteracted by a higher contribution of explicit processes in experts. Fitts PM, Posner MI (1967) Belmont: Brooks/Cole. Title: Time course of changes in functional connectivity induced by visuomotor adaptation: A 24 h resting-state fMRI study

Authors: *V. M. DELLA MAGGIORE[1], J. I. VILLALTA[1], N. KOVACEVIC[2], A. R. MCINTOSH[2];
[1]Dept. of Physiol., Univ. of Buenos Aires, Buenos Aires, Argentina; [2]Univ. of Toronto, Rotman Res. Inst., Toronto, ON, Canada

Abstract: Motor adaptation is a type of motor learning that allows maintaining accurate movements in the presence of environmental or internal sensory perturbations by adjusting motor output. The neural substrates of motor adaptation have been extensively explored in human and non-human primates during acquisition. Yet, when interested in identifying plastic changes associated with learning, the "online" approach is limited by kinematics and dynamics confounds that are very difficult to control for. In this study, we used resting-state fMRI, an offline experimental approach, to characterize the time course of changes in functional connectivity triggered by visuomotor adaptation, throughout a 24 h period. Twenty two normal subjects performed a visuomotor task that required hitting 8 visual targets using a joystick. Experimental subjects (n = 11) did so under a 40 degree clockwise rotation, whereas no perturbation was applied to controls (n = 11). A total of six resting-state runs were acquired following a standard resting-state protocol. One of them was acquired before adaptation (baseline), and the remaining five runs 15min, 1h, 3h, 5.5h and 24 h after adaptation. After standard fMRI preprocessing, data was denoised using ICA and bandpass filtered between 0.08 and 0.009Hz. Twenty-two regions of interest (ROIs) of 5mm ratio were chosen based on previous functional studies carried out during visuomotor learning. Time series were extracted for these ROIs and correlated with each other for each run and each subject. A multivariate statistical approach (PLS, Mcintosh and Bookstein, 1996) was then used to identify a brain pattern that distinguished experimental and control groups based on the time course of functional connectivity. The analysis revealed that the connectivity of the right posterior cerebellum (lobule VIII), left putamen, right inferior frontal

gyrus and left ventral premotor cortex increased as a function of time for the control group. In contrast, the connectivity between the posterior parietal cortex and i) the left primary motor cortex, ii) the left dorsal premotor cortex and iii) the left somatosensory cortex increased as a function of time for the experimental group. The level of connectivity between these regions peaked 5.5 h after adaptation and decreased thereafter. We hypothesize that the connections strengthened during visuomotor adaptation underlie motor memory consolidation associated with this type of learning. References: Mcintosh and Bookstein (1996). Title: From visuomotor to motor activity in the caudal part of the macaque superior parietal lobule: A comparison study between areas PEc and V6A

Authors: *G. DAL BO[1], K. HADJIDIMITRAKIS[1,2], R. BREVEGLIERI[1], C. GALLETTI[1], P. FATTORI[1];
[1]Dip. Farmacia e Biotecnologie, Univ. of Bologna, Bologna, Italy; [2]Dept. Physiol., Monash Univ., Clayton, Victoria 3800, Australia

Abstract: In the posterior parietal cortex, there is a constellation of areas collectively involved in the visuomotor transformations necessary for controlling goal-directed actions. Two neighboring areas of the caudal part of the superior parietal lobe, V6A and PEc, show different cytoarchitecture and connectivity profiles, but have neurons with similar functional properties that are involved in the control of reaches. While we have recently demonstrated that during reaches in 3D space both depth and direction information are represented in V6A (Hadjidimitrakis et al., 2013), the encoding of reach depth has never been investigated in PEc. The aim of this work was to investigate the effect of both target direction and depth on the activity of PEc neurons, and to compare the direction and depth tuning between PEc and V6A in several phases of the reaching task performed in the 3D space. Single unit activity was recorded from three Macaca fascicularis monkeys performing foveal arm reaching towards visual targets placed at eye level at different depths and directions in the peripersonal space. Reaching actions were perfomed in a dark environment. We found that PEc neurons were affected by direction and depth, in some cases by both of them, but these modulations were not equally distributed over

the several phases of the reaching task. In fact, the effect of direction was more common than depth when the monkey was fixating the target without performing any arm movement (28% vs. 14%). The opposite happened after the onset of arm movement, when depth (30%) and jointly depth and direction (27.5%) signals became predominant. In V6A, in contrast, direction and depth information were jointly encoded in the majority of cells during both target fixation and movement execution. It is worthwhile to note that, while both PEc and V6A cells processed depth information during the arm movement, in V6A, but much less in PEc, this type of information started to be encoded at fixation onset, that is well before the onset of arm movement. Altogether, these findings support the idea that while both posterior parietal areas are involved in the visuomotor transformations for reaches in 3D space, there is a posterior-to-anterior gradient from a more visuomotor representation in V6A, to a predominantly motor encoding of the reaching action in PEc.

Title: Low-gain visual feedback improves reaction time in older adults

Authors: ***M. KWON**[1], Y.-T. CHEN[1], A. GARNER[1], D. W. SOLIS[1], F. RACKARD[1], V. J. PEDIGO[1], B. DANCOSE-GIAMBATTISTO[1], C. R. SUE-WAH-SING[2], E. A. CHRISTOU[1,3]; [1]Applied Physiol. and Kinesiology, [2]Hlth. Sci., [3]Physical Therapy, Univ. of Florida, Gainesville, FL

Abstract: Reaction time slows significantly with aging likely due to deficiencies in visual information processing. The purpose of this study was to determine whether the age-related slowing in reaction time was associated with deficiencies in visual information processing. Nine young (20.4 ± 1.1 years) and five older adults (71.8 ± 5.6 years) participated. Participants were asked to match a constant force equal to 15% maximum with ankle dorsiflexion for 20 s and dorsiflex their ankle as fast as possible in response to a visual stimulus. We manipulated visual

information processing by changing the visual gain of force feedback prior to the visual stimulus. Specifically, in a counterbalanced order, subjects performed the constant force task either with low-gain visual feedback (LG, 0.05°; lower visual information processing required) or with high-gain visual feedback (HG, 1.2°; higher visual information processing required). Reaction time was quantified as the interval between the onset of the stimulus and the onset of ankle dorsiflexion force. Reaction time was slower in older adults (607.5 ± 58 ms) than young adults (477.6 ± 16.8 ms). Interestingly, high gain visual feedback exacerbated the age-associated differences in reaction time. Young adults exhibited similar reaction time with low- and high-gain visual feedback (LG: 476.1 ± 17.9 ms; HG: 479.2 ± 16.7 ms). In contrast, the reaction time of older adults was slower with the high-gain visual feedback condition (LG: 590.3 ± 63.0 ms; HG: 624.8 ± 55.4 ms). In summary, these results suggest that reaction time in older adults can be influenced by the gain of visual feedback. Consequently, training paradigms to reduce reaction time in older adults may benefit from lowering the gain of visual feedback.

Title: Brain activity during gradual visuomotor adaptation

Authors: P. BÉDARD, *J. N. SANES;
Neurosci., Brown Univ., PROVIDENCE, RI

Abstract: Interactions in a constantly changing environment require that the brain forms new sensory-motor relationships. While prior work has extensively assessed behavioral and brain concomitants of sudden adaptations, much less is known about gradual adaptation. Prior work suggested that cerebellar processing is more important for sudden than for gradual adaptation

(Criscimagna-Hemming et al. 2010). We used functional MRI to measure whole brain activity as healthy adults reached quickly to visual targets using a cursor to guide movements. In a null condition, the cursor had "normal' hand-cursor mapping, while for a rotation condition, we artificially rotated the cursor by 0.25º counterclockwise each trial, to reach 30° rotation at the end of the learning condition. Participants performed 6 sequential conditions: null (80 trials), resting state (8 min), learning (160 rotation trials), washout (80 null trials), resting state (8 min), and recall (80 rotation trials, 30° rotation). We used a random-effect model to assess brain activation during learning and recall, not yet analyzing the resting state data. Reaching error remained low during application of the gradual rotation, but progressively increased across learning to ~5º when the final 30° rotation occurred. Participants exhibited after-effects, suggesting they had formed a new memory. No participant expressed awareness of the gradual perturbation. At recall, the amount of savings had similarity to a separate group of participants who experienced a sudden visual perturbation. When participants gradually adapted to the visual rotation, we found more activation in various cerebellar areas bilaterally, thalamus, left putamen, anterior cingulate cortex, left primary motor cortex, left somatosensory cortex, and left superior parietal cortex. At recall, we found a wide activation pattern that had similarity to that observed during learning, including activation in cerebellum, left primary motor cortex, left somatosensory cortex, and left parietal cortex. The results of Criscimagna-Hemminger et al. (2010) may predict reduced cerebellar activation during gradual adaptation. However, we found robust cerebellar activation during gradual adaptation and recall, more than we would have expected from earlier results with sudden adaptations (e.g., Bédard and Sanes 2014). The strong cerebellar activation during the learning, and also during recall may relate to the size of error which was relatively high compared to the null phase. Title: Age-related changes in the contribution of reflexive and voluntary corrections of spatial errors in target reaching

Authors: *D. KIMURA, K. KADOTA, Y. HIRAMATSU, H. KINOSHITA;
Grad. Sch. of Med., Osaka Univ., Toyonaka, Japan

Abstract: When reaching a visual target, a sudden shift of the target position elicits a fast reflexive motor-tracking response, so called a "target jump response (TJR)", providing automatic correction of motor errors towards new target position. The effects of aging on the spatial component of this response remain unknown. In the present study, aging-related changes in the spatial accuracy of TJR, and relationship between the TJR directional error and reaching variability were investigated using aged and young individuals. The participants were 15 elderly [mean ± standard deviation (SD) age, 70 ± 5 years] and 16 young (25 ± 5 years) individuals. All were healthy without any neurological or orthopedic problems. The right hand was used to reach and touch a visual target presented in the center of a screen located 0.5 m in front of the participant. After the initiation of reach motion, the target presented in the center either shifted (5° right, left, above, or below the screen center,36 trials for each location) or remained at the same spot (48 trials). In the target-shift trial, the participants were required to correct their reaching trajectory towards a new target location as quickly as possible. Hand kinematics during reaching were monitored using a three-dimensional motion capture system (sampling frequency = 500 Hz), and its velocity was computed subsequently. The directional error of TJR was obtained by the angle between the direction of target-shift and the vector of hand velocity computed at 80 ms before the onset of voluntary correction movement. Repeated measures ANOVA (group × target location) revealed that none of the main and interaction effects on the median values of the directional error was significant, indicating that aging did not affect the reflexive visuomotor transformations for TJR. On the other hand, ANOVA on directional error's SD, a measure of inter-trial variability of the arm trajectory just before touching the target, revealed a significant group effect. Aging thus reduced trial-to-trial consistency in voluntary control of the visuomotor transformations. Furthermore, the directional error's SD for TJR was correlated significantly with the arm trajectory' SD for the young participants, but not for the elderly participants. The findings suggest that TJR plays a role in decreasing variability of limb trajectory for reaching. Aging seems to affect this function.

Title: Linking vision and action in *Drosophila*

Authors: *J. D. SEELIG, R. FRANCONVILLE, V. JAYARAMAN;
Janelia Farm Res. Campus, HHMI, ASHBURN, VA

Abstract: Studies from many labs and in different insects have implicated a central brain region called the central complex in a broad range of visuomotor functions including sun-compass navigation [1], short-term memory for orientation [2], long-term memory for visual patterns [3], visual place learning [4], and locomotion [5]. In *Drosophila*, behavioral genetics experiments have suggested the involvement of specific central complex cell types in such functions [2-4], but little is known about their physiology [6]. Over the past few years, we have developed techniques to monitor neural activity using two-photon calcium imaging in head-fixed behaving flies in a virtual reality arena. We record from genetically identified neural populations during tethered flight and tethered walking on an air-supported ball. Recently, we identified a major source of visual feature input to a substructure of the central complex, in the form of orientation-tuned responses [6]. We will discuss our results from experiments in which we continue to probe the central complex's role in visuomotor integration in flies. [1] Heinze, S., Homberg, U. (2007). Title: Direct observation of ON and OFF pathways in the *Drosophila* visual system

Authors: *J. STROTHER, A. NERN, M. REISER;
Janelia Farm Res. Campus, Ashburn, VA

Abstract: Visual motion perception is critical to many animal behaviors, and flies have emerged as a powerful model system for exploring this fundamental neural computation. Although numerous behavioral studies have suggested that fly motion vision is governed by a relatively simple neural circuit, the implementation of this circuit has remained mysterious for decades. Several recent studies have shown that key neurons associated with this circuit are selective for light increments (ON) or decrements (OFF), but the origin and role of this selectivity in motion vision remains unclear. We examined activity in the neuropil responsible for visual motion detection, the medulla, of *Drosophila* melanogaster in response to a range of visual stimuli using two-photon calcium imaging. We confirmed that the input neurons of the medulla, the LMCs, are not responsible for light-on and light-off selectivity. We then examined the pan-neural response of medulla neurons and found prominent selectivity for light-on and light-off in layers of the medulla associated with two anatomically defined pathways (L1/L2 associated). We next examined the activity of prominent interneurons within each pathway (Mi1 and Tm1) and found that these neurons have corresponding selectivity for light-on or light-off. These results provide direct evidence that motion is computed in parallel light-on and light-off pathways, demonstrate that this selectivity emerges in neurons immediately downstream of the LMCs, and specify where crucial elements of motion computation occur.

Title: Parallel descending pathways for visually-evoked escape in *Drosophila*

Authors: *M. PEEK, S. NAMIKI, G. M. CARD;
HHMI Janelia Farm, Ashburn, VA

Abstract: To understand how nervous systems accomplish fast visual-motor control, we investigated the neural basis of visually-evoked escape behavior in the fruit fly, *Drosophila* melanogaster. Previously we demonstrated that identical looming stimuli evoke two different modes of escape. The fast, unsteady mode requires a pair of descending interneurons, the giant fibers, whereas the neural substrates for the slower, steady mode remain unknown. To determine how slower escapes are controlled, we performed an anatomical search of the Janelia GAL4 expression pattern database for descending neurons that connect the same visual and motor centers linked by the giant fibers. These neurons could form information pathways parallel to the giant fibers to control slow escapes. We found six uniquely identifiable pairs of descending neurons that putatively receive the same visual input as the giant fibers. To assess their visual responses, we are performing somatic whole-cell patch clamp experiments while displaying sets of visual primitives. For one pair, loom-evoked excitatory responses largely overlap with the giant fibers. This pair could provide a parallel pathway for visual information to be conveyed to takeoff motor centers. In future work, we aim to study the behavioral consequences of the activity of these descending neurons.

Title: Functional investigation of a visual projection neuron in the *Drosophila* visual system

Authors: *M. MORIMOTO, M. WU, A. NERN, G. M. RUBIN, M. B. REISER;
HHMI Janelia Farm Res. Inst., Ashburn, VA

Abstract: Fly visual systems have been used extensively for nearly a century to study diverse aspects of vision. While the investigation of local motion detection (mediated by columnar circuits of the medulla) has received much attention, the functions of other pathways within the

optic lobes of flies have been much less explored. To functionally characterize prominent anatomically described pathways we are currently investigating the encoding properties of neurons that project from the lobula to the central brain (so-called visual projection neurons) in *Drosophila*. In recent work, thermogenetic activation of a one such cell-type induced flies to take off, implicating this cell-type as a likely conduit for visual features that elicit escape. Using split-GAL4 lines for *in vivo* two-photon GCaMP imaging, we are imaging from several cellular compartments of this cell-type, while presenting various visual stimuli. Preliminary data from axonal imaging reveal a receptive field size which is consistent with the small spatial extent of this cell type's dendrites. Questions such as how retinotopic information is being conveyed, and whether a predator's loom may be encoded by this cell-type, are currently under investigation.

Title: Neural substrates for looming detection in *Drosophila* melanogaster

Authors: *C. R. VON REYN, W. R. WILLIAMSON, P. BREADS, A. NERN, G. M. CARD; Janelia Farm Res. Campus, HHMI, Ashburn, VA

Abstract: To navigate through complex, dynamic environments, an animal's nervous system must be able to quickly recognize looming threats, approaching on a direct collision course, and engage appropriate evasive maneuvers. How neural circuits extract looming information and drive a behavioral response is still under investigation. "Looming detector" neurons have been identified in the visual system of many vertebrate and invertebrate species. These neurons encode information about the size, velocity, and time to collision of an approaching object - essential information for coordinating evasive maneuvers. In *Drosophila melanogaster*, genetic tools can be applied to further elucidate circuits and mechanisms underling looming-evoked behavioral responses. Using these tools, we have previously shown how giant descending interneurons (the GFs) drive a rapid escape takeoff in response to a looming threat. The visual neurons supplying looming information to the GF circuit remain unknown. Likely candidates are

the lobular columnar neurons type 4 (LC4s) whose axon terminals project to the same optic glomerulus as the GF dendrites. However, the LC4 population of approximately 60 retinotopically distributed neurons differ morphologically from canonical "looming detectors" that consist of a pair of tangential neurons spanning the entire visual field. In addition, the LC4s are thought to be glutamatergic, while data suggests that cholinergic transmission provides the main excitatory drive to the GFs. Here, using selective genetic labeling and targeting, we investigate anatomical and functional connectivity between the GFs and LC4s. Through pharmacological manipulations, we determine the neurotransmitter involved in LC4 to GF communication. Finally, through selective genetic activation and silencing, we investigate whether the LC4s provide the main source of looming information to the GF pathway.

Abstract: Visual space is mapped onto the retina and retinal ganglion cells (RGCs) transmit visual information via their axons to several brain areas for further information processing. Extraction of distinctive features from the visual environment such as direction of motion can already occur at the level of the retina. Therefore, different subtypes of RGCs could carry a rich repertoire of information about visual features to their downstream targets in the central nervous system (CNS). Recent advances in how the 'feature space' at the level of RGCs is mapped onto

their post-synaptic partners has revealed a laminar organization in terms of wiring specificity that may influence local processing and extraction of visual information in RGC target areas. In particular, direction selectivity has been well studied; both at the level of the retina and at the level of its targets such as the optic tectum (superior colliculus), LGN and the visual cortex. However, little is known about how RGC inputs are processed and what kind of local computations occur in retino-recipient brain areas. How these visual processing channels may influence perception and as a consequence, visually guided behavior is also not very well understood. We and others had recently shown that appetitive and aversive behavior in larval zebrafish can be elicited depending on the size of the visual stimulus. This stimulus-response mapping provides a direct link between the processing of stimulus properties and its influence on behavior. Therefore, we performed experiments to determine how objects of different sizes are represented in the population of RGC axons and their downstream targets in the optic tectum in larval zebrafish. Using a combination of transgenic fish lines expressing genetically encoded calcium indicators, functional two photon imaging and statistical analyses, we show that there may be a size selective categorization of visual input to the tectum. Furthermore, our data suggests that the optic tectum has parallel processing channels for visual objects of different sizes. Experiments to determine the morphology of these functional cell classes in the optic tectum may help elucidate the structure-function relationship and wiring specificity of RGC axons to these post synaptic partners with respect to stimulus size processing.

Title: Size-filtering circuits in the retino-tectal pathway

Authors: *S. J. PREUSS, C. A. TRIVEDI, C. M. VOM BERG-MAURER, S. RYU, J. H. BOLLMANN;
Max Planck Inst. for Med. Res., Heidelberg, Germany

Abstract: Processing sensory information is one of the most important functions of the nervous system and the basis of selecting appropriate behavioral output. The optic tectum (homologous to the mammalian superior colliculus), the major retino-recipient area in teleosts, is known to play a vital role in information processing during visually guided behaviors. Visual stimuli detected and preprocessed by the retina get directly mapped to different input layers of tectal neuropil by retinal ganglion cell (RGC) axons. Tectal neurons pick up these signals and further process stimulus features, like motion direction and the size of an object. This processing may be crucial for extracting salient cues in a dynamic environment and for eliciting suitable motor patterns; for example attractive or aversive behavior to prey- or predator-like cues, respectively. Superficial interneurons (SINs) are a subpopulation of tectal neurons thought to play an important role in size-filtering of visual cues during prey capture behavior. Here, we perform a detailed analysis of SINs as putative size-selective elements in the retino-tectal pathway. Using realistic prey- and non-prey-like stimuli previously shown to elicit attractive and aversive behavior, we record size-selective neural responses in this morphologically distinct cell type. Two-photon targeted whole-cell recordings were used to measure the input tuning curves of individual SINs at high temporal resolution. We observed that excitatory inputs of SINs are tuned to the size of moving objects. Several types of input size tuning were observed, suggesting that SINs fall into different functional subclasses. Simultaneously, we labeled SINs through the patch-pipette with a fluorescent dye for subsequent morphological analysis. Arborization profiles of individual SINs were compared with the laminar organization of the tectal neuropil in a transgenic zebrafish line, expressing GFP in a subset of RGCs. We observed that the size tuning of synaptic inputs correlated with the arborization depth of individual SINs in a systematic way. Furthermore, in response to whole-field flash stimuli, SINs arborizing in different layers exhibited markedly different ON or OFF input currents, suggesting that the laminar target zone determines, at least partly, the synaptic input patterns in this cell type. In addition, Ca2+-imaging and current clamp recordings in SINs showed that the spike output pattern correlated with their synaptic input tuning properties, which suggests that SINs may serve different layer-specific roles in the processing and categorization of behaviorally relevant visual stimuli.

Abstract: Information processing in the sensory cortex relies on interactions between excitatory and inhibitory neuronal networks. Inhibitory GABAergic interneurons can be classified into three groups: those expressing the Ca2+-binding protein parvalbumin (PV), those expressing somatostatin (SST) and those expressing the 5-hydroxytryptamine-3A receptor (5HT3AR). The 5-HT3AR-positive interneurons represent the major population of inhibitory neurons in the supragranular layers of the neocortex. However, the properties of these interneurons *in vivo* are largely unknown. In this study, we used transgenic mice expressing enhanced green fluorescent protein (GFP) under the control of the 5HT3A promoter to characterize the spontaneous and visual stimulation-evoked activity of 5-HT3AR-positive interneurons in layers 1 and 2/3 of mouse primary visual cortex. 5-HT3AR-positive interneurons represent a diverse population, including the vasoactive intestinal peptide (VIP)-expressing neurons with a bipolar/bitufted morphology and multipolar neuropeptide Y (NPY) expressing cells. Here, we used two-photon imaging guided whole-cell and cell-attached recordings to characterize their activity *in vivo*. In layer 2/3, bipolar/bitufted 5-HT3AR-positive interneurons exhibited a low spontaneous firing rate (1.03 ± 0.27 Hz, n = 10) and were highly tuned to the orientation of drifting grating stimuli. By contrast, presumed neuroglialform interneurons in layer 2/3 had high spontaneous firing frequencies (3.89 ± 0.69 Hz, n = 13) and increased firing rates for 4/8 up to 7/8 directions. Thus, these interneurons are more broadly tuned than bipolar cells. A separate class of layer 2/3 interneurons had high spontaneous firing frequencies (2.55 ± 0.88 Hz, n = 4) and responded with a decrease in firing for 4/8 up to 7/8 directions. In layer 1, we identified a class of interneurons with high spontaneous firing rates (5.33 ± 1.05 Hz, n = 10) and multipolar dendritic arborization, which increased their firing level for 4/8 up to 7/8 directions. In addition, we found another class of interneurons with low spontaneous firing rates (0.47 ± 0.18 Hz, n = 6) that decreased their firing level for 4/8 up to 7/8 directions. Finally, we identified a third class of layer 1 interneurons with low spontaneous rates (0.45 ± 0.12 Hz, n = 7) and multipolar dendritic arborization, which were highly direction-tuned. In conclusion, our results identify distinct classes of 5-HT3AR-

positive interneurons with specific activity patterns both spontaneously and in response to visual stimulation.

Abstract: Information processing in the sensory cortex relies on interactions between excitatory and inhibitory neuronal networks. In the supragranular layers of the neocortex, an abundantly present population of 5-HT3AR-positive inhibitory interneurons interacts with layer 2/3 pyramidal cells. However, the nature and the extent of these interactions *in vivo* and their specific roles in controlling spontaneous activity remained unexplored. Here, we selectively expressed the light-sensitive proton pump ArcheorhodopsinT (ArchT-GFP) in 5-HT3AR-positive interneurons in layers 1 and 2/3 in order to study the impact of their silencing on the ongoing spontaneous activity of layer 2/3 pyramidal cells in the primary visual cortex of isoflurane-anesthetized mice. In developing this approach, we first characterized ArchT-GFP-expressing interneurons in brain slices. Infected interneurons were illuminated with an optic fiber by a 100 msec light pulse (561nm) at different light intensities (6.9, 11.7, 23.3, 32.2, 47.7 and 54.8 mW/mm2). Infected interneurons showed a linear relationship between light intensity and the amplitude of the resulting photocurrent (67.26 ± 9.14 pA up to 146.22 ± 19.05 pA; n = 8 - 11

interneurons for each point). Then, we confirmed, by using *in vivo* two-photon imaging guided cell-attached recordings, that infected 5-HT3AR-positive interneurons can be effectively silenced. A complete block of activity was achieved by light intensities of about 23 mW/mm2 (n = 22 cells). By combining optogenetic stimulation of 5-HT3AR-positive interneurons with cell-attached and whole-cell recordings of pyramidal cells in layer 2/3, we identified two opposite effects. In 11/33 pyramidal cells, we observed a strong decrease in spontaneous activity (-55.09 ± 7.98% n = 5 cells and 100% in n = 6 cells), reflecting an indirect connection with 5-HT3AR-positive interneurons via some other interneurons. In the majority of pyramidal cells (22/33), we observed a dramatic increase of activity (up to 10-fold), demonstrating a direct and particularly powerful connection with 5-HT3AR-positive interneurons. Overall, our results demonstrate that 5-HT3AR-positive interneurons are, without exception, important determinants of the spontaneous activity of layer 2/3 pyramidal cells *in vivo*.

Title: Coupling of bimanual forces during independent and cooperative hand movements

Authors: ***T. BOYANOSKI**, M. A. PEREZ;
Dept. of Physical Med. and Rehabil., Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Many bilateral motor tasks engage simultaneous activation of distal hand muscles. However, the mechanisms involved in the control of force coupling between hands remain poorly understood. In the present study, we examined human force and electromyographic (EMG) activity in the first dorsal interosseous (FDI) muscle during symmetric and asymmetric increasing levels of bilateral isometric voluntary contractions (5%, 10% and 30% of maximal

voluntary contraction, MVC) into index abduction when subjects controlled, on a computer screen, two independent cursors (dual-task) or a single 2D cursor moved by both hands (single-task) as fast and accurately as possible. During unilateral contractions subjects were able to accurately discriminate increasing levels of force with both hands. We demonstrate a linear increase in all forces in the dual-task, regardless of the level of force and hand tested. When the right hand exerted more force the left hand also generated more force, suggesting a strong bias to produce identical bilateral forces regardless of the force level tested. In contrast, during the single-task subjects were able to discriminate asymmetric and symmetric forces exerted by each hand, regardless of the level of force and hand tested. Trial-by-trial peak forces revealed a strong correlation between peak forces and EMG activity during the bimanual dual-task compared with the single-task. Our results demonstrate that the ability to perform independent movements with both hands can be maximized by coordinated control of a single object, which is influenced by the visual feedback.

Title: Object properties influence symmetry of bilateral reach to grasp movements after tetraplegia

Authors: *F. J. CALABRO, M. A. PEREZ;
Dept. of Physical Med. and Rehabil., Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Most spinal cord injuries in humans result in bilateral anatomical damage to the spinal cord. Recent evidence has indicated that physiological interactions between bilateral hand and arm muscles are impaired after injury. However, the extent to which motion of one arm affects the movement of the other arm is unknown. Using kinematics and electromyographic (EMG)

recordings we studied unilateral and bilateral reach to grasp movements to a small and large cylinder in uninjured controls and in patients with chronic incomplete cervical spinal cord injury (SCI). We demonstrate in controls that movement time during hand opening and closing was delayed with bilateral compared to unilateral movements, regardless of the object or arm tested. In contrast, movement of the weaker arm in patients delayed the stronger arm during hand opening and closing when reaching for a large and small object, respectively. No object specific influences were observed from the stronger to the weaker arm. Patients showed impaired modulation of EMG activity in an intrinsic finger muscle during grasping at times when bilateral delays were observed for each object compared to controls. Thus, our results demonstrate that the symmetry of bilateral reach to grasp movements in humans with SCI can be selectively influenced by the more affected arm according to object properties, likely related to impairments in the bilateral control of EMG activity in hand muscles. We argue that the flexibility of the stronger arm to inputs during bilateral movements may open a critical window to target bilateral control of movement after human SCI.

Title: Increase of interhemispheric coherence during acquisition of asymmetric bimanual movements

Authors: ***S.-W. PARK**, J. COWENHOVEN, D. STERNAD;
Biol., Northeastern Univ., BOSTON, MA

Abstract: Bimanual asymmetric movements are common in everyday life. Previous studies have shown that the corpus callosum plays a vital role not only to enable, but also to constrain bimanual coordination. While symmetric movements are easy, many skilled movements, such as playing the piano, require individuated control of the two hands. How does interhemispheric communication change over asymmetric motor learning? Healthy humans practiced an asymmetric bimanual task, which required independent performance of the two arms. EEG was measured during practice and in a follow-up session two months later. We hypothesized that interhemispheric coherence increases as the asymmetric bimanual performance improved. Six

healthy right-handed subjects were instructed to rotate their forearms in the horizontal plane and to move their right arm to a target cue as fast as possible without disturbing the continuous oscillations in the left arm. During each 45s trial, subjects performed 10 discrete movements triggered at random phases of the ongoing rhythmic arm. Subjects practiced for 10 daily sessions, followed by a 2-month retention session. Each session comprised 16 bimanual trials (45s) and 2 control trials (right-only and left-only). After each trial, subjects received feedback about right-arm peak velocity and their left-arm perturbation, measured by deviations from smooth oscillations. The task was to simultaneously achieve high peak velocity, while minimizing perturbations. Cortical activity during the task was measured using 64-channel EEG electrodes in the beginning, the middle, and the end of practice, as well as the beginning of follow-up sessions. For control, subjects also performed bimanual symmetric reaching for 16 trials. The electric potential was aligned with the visual cue onset. Coherences between EEG electrodes in the motor area (FC1-6, C1-6, CP1-6) were analyzed in alpha and beta frequency regions (8 and 20 Hz, respectively). Behavioral results showed that all subjects increased their right-arm peak velocity over practice. Five out of six subjects reduced the left arm perturbation, although not to zero. All subjects significantly increased their peak velocity in the symmetric condition as well. For the EEG, interhemispheric coherence at 20 Hz increased after 5 sessions for all subjects only in the asymmetric condition. The increased coherence was not maintained until the end of practice. In sum, increased interhemispheric communication was associated specifically with acquisition of the asymmetric bimanual skill. These results suggest that enhanced beta-band coherence plays a crucial role to acquire a novel asymmetric bimanual coordination.

Title: A theoretical framework for simultaneously explaining motor learning effects in unimanual and bimanual movements

Authors: *K. TAKIYAMA;
Tamagawa Univ. / Brain Sci. Inst., Tamagawa-Gakuen, 6-1-1, Machida-Shi, Japan

Abstract: Motor learning in unimanual and bimanual movements have been intensively investigated, but distinct theoretical frameworks were proposed for each of them. This separate modeling failed to explain relationships or transfer of learning effects (generalization) between those movements. Here, we propose a novel model to simultaneously explain motor learning in unimanual and bimanual reaching movements by extending a framework of motor primitives. We analytically proved that, only when preferred reaching directions (PDs) of each primitives are modulated between unimanual and bimanual movements, a framework of motor primitive can reproduce the following generalization between unimanual and bimanual movements which cannot be explained by any conventional models: generalization between a parallel type of bimanual and unimanual movements is partial when the number of target is one (Nozaki et al., 2006, Nat Neurosci), but the generalization is perfect when the number of target is eight (Wang et al., 2013, PLoS One). Our results are independent of shape of tuning curve (activity function of motor primitives), distribution of PDs in unimanual movements, and how different the PDs between unimanual and bimanual movements, which suggests our analytical and numerical results are robust. Although we focused on parallel types of bimanual movements in the analytical and numerical calculations, additional analytical calculation enabled to clarify relationships between unimanual and other kinds of bimanual movements. Furthermore, the PD modulation revealed a novel relation between unimanual and parallel types of bimanual movements: compatibility of specialization and generalization, i.e., after trained with bimanual movements, generalization to other bimanual movements is large but restricted to bimanual movements similar to trained movements (specialization) and generalization to unimanual movements is slight but extended to wide-range unimanual movements (generalization).

Title: Age-related changes in interhemispheric communications during the preparation of bimanual movements

Authors: *H. FUJIYAMA[1], J. VAN SOOM[1], G. RENS[1], O. LEVIN[1], S. P. SWINNEN[1,2];
[1]Kinesiology, [2]Leuven Res. Inst. for Neurosci. & Dis. (LIND), KU Leuven, Leuven, Belgium

Abstract: Introduction. For successful bimanual performance, it is necessary to regulate complex interhemispheric communication (excitation and inhibition). Studies using functional neuroimaging revealed that older adults increase activity of prefrontal brain areas during task performance, suggesting that interactions between prefrontal cortex and primary motor cortex (M1) are likely to be involved in the regulation of motor performance in older adults. However, the exact role of these prefrontal regions in bimanual coordination in older adults is yet to be determined. Here, using a dual-site transcranial magnetic stimulation protocol (dsTMS), we investigated the nature of interactions between prefrontal (non-primary motor regions) and the contralateral M1 during the preparation of a bimanual coordination task in older adults. Methods. A group of healthy young and older volunteers participated in three experimental sessions while performing a bimanual coordination task with their index fingers rotating dials. Participants were instructed to perform isofrequency (1:1) and non-isofrequency movements (3:1, 1:3). In separate sessions, we investigated the interaction between the dorsolateral prefrontal cortex (DLPFC), dorsal premotor (PMd), or M1 and the contralateral M1 assessing interhemispheric inhibition (IHI) in both directions (i.e., from the right to the left hemisphere, and vice versa) at two time points (onset of preparatory cue (PC0ms) and 50ms prior to the imperative stimulation (IS-50ms)) during the preparatory period. Results. For DLPFC-M1 IHI, young adults showed facilitation at IS-50ms relative to PC0ms irrespective of movement ratio and hemisphere (left and right). Interactions between left PMd and right M1 and M1-M1 in both directions became facilitatory from IS-50ms to PC0ms in young adults. Importantly, these facilitations were absent in older adults showing no IHI modulations during the preparatory period. Conclusion. The present findings demonstrate an absence of modulation in IHI in older as compared to young adults, indicating that the declined ability to functionally modulate interhemispheric interactions with advancing age may underlie degraded bimanual coordination performance in older adults.

Title: Effect of single pulse transcranial magnetic stimulation of unilateral motor cortex on bimanual grip coordination: A pilot study

Authors: *R. PATEL, S. AMANO, K. OKI, B. C. CLARK, S. L. HONG;
Ohio Musculoskeletal and Neurolog. Inst., OUHCOM, Athens, OH

Abstract: The purpose of this pilot study was to test the effect of a single pulse transcranial magnetic stimulation (TMS) of unilateral motor cortex during a bimanual grip force task. We tested the hypothesis that a single TMS pulse would disrupt bimanual grip force coordination. Four right-handed healthy young individuals (21± 2years, 174.2±8.8 cm, and 63.9±10.9kg) were asked to generate bimanual grip forces simultaneously with both hands at a target (5% of maximum bimanual grip force). Subjects were only provided with visual feedback of the sum of the forces generated across both hands. The task was performed under two conditions: 1) single pulse TMS stimulus to M1 at an unpredictable time (STIM), and 2) a sham condition (SHAM). Both conditions were conducted for the left and right hemispheres, with a total of five trials per condition (20 trials in total). For each subject, stimulus intensity was set at 100% of active motor evoke potential, and the conditions were presented in random order. Bimanual coordination dynamics were evaluated using 1-second windows from 3 seconds pre- and post-stimulus. The circular standard deviation (CirSD) of the Hilbert relative phase of the dominant and non-dominant grip forces was calculated. The windows were averaged to the three 2-second epochs before (PRE), after (POST) and at the time of stimulus (ST). A 3-way (2 Side x 2 Condition x 3 Time) ANOVA was conducted on the results and post-hoc LSD tests were employed when needed. We observed a significant Condition x Time interaction (p=.03), where the TMS pulse led to an increased CirSD exclusively during the ST window [PRE: .026±.004, ST: .0.48±.011, POST .027±.001 in RH; PRE: .026±.006 ST: .061±.020, POST: .026±.007 in LH], but only for the STIM condition (PRE to ST: p=.03, ST to POST: p=.02). Our results revealed that unilateral motor cortex stimulation could lead to a disruption in bimanual coordination during the 2-second window surrounding the stimulus. The lack of an effect of or interaction with Side indicated that the pattern or degree to which bimanual coordination was disrupted was not affected by hand dominance. These results indicate that the single pulse TMS is able to generate a perturbation to bimanual coordination that persists for over one second, an effect that is present regardless of which hand is stimulated. Further investigation with larger sample size is in process.

Title: Representation of bimanual reach plans in the posterior parietal cortex

Authors: ***E. F. MOOSHAGIAN**, C. WANG, L. H. SNYDER;
Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: The parietal reach region (PRR) in the posterior parietal cortex represents reach plans. The representation is biased for contralateral reaches, though individual neurons in PRR represent reach plans for the contralateral, ipsilateral, or either limb. Since lesions in PRR affect only contralateral limb movements, the utility of the ipsilateral reach representation is unclear. The representation of both contralateral and ipsilateral reach plans makes PRR a candidate region for bimanual coordination. Bimanual coordination shows a range of patterns. The two arms might move together as if to catch a football or they might move independently as in playing the piano. Here, we asked if reach planning activity in PRR is affected by movements of both arms and whether it depends on the pattern of bimanual coordination. We considered four possible profiles for bimanual reach planning activity in the PRR: First, PRR neurons might code just the contralateral movement and be uninvolved in bimanual reach planning. Second, planning activity might be the average of activity preceding planned contralateral and ipsilateral limb movements. Third, activity might be a linear combination of activity preceding planned contralateral and ipsilateral limb movements. Fourth, planning activity might be a non-linear combination of activity preceding planned contralateral and ipsilateral limb movements. To test for representation of bimanual reach plans in the PRR, we trained two male rhesus macaques (Macaca mulatta) to make three types of reaches to visual targets: unimanual (left or right arm) reaches to a single target accompanied by an eye movement to that target, bimanual reaches and an eye movement to a single target, and bimanual movements to different targets with the animal

free to choose which target to saccade to. Most PRR neurons showed higher firing during planning of reaches with the contralateral compared to the ipsilateral arm. For these neurons, planning activity for bimanual reaches did not differ from the contralateral reach condition. Approximately 20% of neurons showed a different pattern of firing. In these neurons, planning activity for bimanual reaches was differentially modulated depending on whether the planned bimanual reach was to be made to the same or separate targets. Thus, bimanual reach planning activity in PRR is a non-linear combination of the unilateral planning responses, suggesting that PRR is involved in bimanual coordination.

Title: Reduced intracortical inhibition is associated with bimanual common and dual goal tasks

Authors: W.-W. LIAO[1], S. KANTAK[2], J. BARTON[3], J. WHITALL[1], *S. MCCOMBE WALLER[1];
[1]Dept. of Physical Therapy and Rehabil. Sci., Univ. of Maryland, Sch. of Med., BALTIMORE, MD; [2]Moss Rehabil. Res. Inst., PHILADELPHIA, PA; [3]Dept. of Neurol., Univ. of Maryland, Baltimore, BALTIMORE, MD

Abstract: Objective: Stroke is the leading cause of long-term disability worldwide with approximately 75% of stroke survivors reporting functional upper extremity dysfunction. Many activities of daily living (ADL's) comprise upper extremity (UE) tasks involving varying degrees of collaboration between the two arms/hands. Some tasks involve a common goal in which the two hands share a single focus, such as picking up a box. Others involve separate goals, such as picking up two different items at the same time. We hypothesize that fundamentally different control mechanisms are involved in each of the two types of tasks, and that this will have important implications for the rehabilitation therapies administered to populations whose UE movement has been impaired. In this pilot we present preliminary results of testing to determine the intracortical inhibition and facilitation to upper extremity muscles during unimanual, bimanual common goal and bimanual separate goal isometric tasks in healthy subjects. Subjects: Six healthy adults. Methods: Intracortical inhibition and facilitation (SICI, ICF) of the dominant

hemisphere were assessed bilaterally for the biceps during three conditions; 1) unimanual isometric task, 2) bimanual common goal isometric task and, 3) bimanual dual goal isometric task. Results: In this preliminary data set, a significant reduction in SICI ($p < .05$) was found for both bimanual common goal tasks and bimanual dual goal tasks compared to the unimanual task condition. While SICI was reduced for bimanual common goals tasks compared to bimanual dual goal tasks it did not reach significance. Discussion: Reduced intracortical inhibition seen during the two bimanual tasks conditions is indicative of a disinhibitory mechanism, at least within the dominant hemisphere, underlying bimanual arm activation compared to unilateral arm activation. In this preliminary data set the two bimanual conditions did not differ in terms of intracortical inhibition. Further work will include increasing the sample size to see if this finding remains consistent and will include an exploration into interhemispheric inhibition to further determine the effects of these different task conditions on interhemispheric interactions. Conclusion: A reduction in SICI or disinhibition was seen during bimanual dual goal and common goal tasks when compared to unimanual task performance. This may have implications for consideration of training approaches for individuals following stroke.

Title: Learning history of unimanual action affects bimanual coordination

Authors: ***A. SARAIVA**[1], N. HAGURA[2], T. KIMURA[3], H. GOMI[3], S. BESTMANN[1]; [1]Sobell Dept of Motor Neurosci. and Movement Disorders, Inst. of Neurology, Univ. Col.

London, London, United Kingdom; [2]Inst. of Cognitive Neuroscience, Univ. Col. London, London, United Kingdom; [3]NTT Communication Sci., Human & Information Sci., Atsugi, Japan

Abstract: Bimanual object manipulation requires distributing the output force between the two hands. This distribution pattern depends both on the variability and the maximum voluntary contraction (MVC) of each hand (O'Sullivan et al 2009). In daily life, however, such bimanual activities are often preceded by unimanual activities, and differ between the left and right hand. Here, we asked whether the preceding schedule of visuomotor gain adaptation for each hand affects the force distribution pattern during bimanual coordination. Participants (n=24) pressed on a left or right force sensor with their left or right index finger to reach a desired force output level (unimanual task, UM). Force, normalised to MVC, was presented online as a vertical moving bar that had to reach a visual target. Each UM task was followed by a bimanual task (BM), where the summed normalised output of both hands was presented, and the target was reached by pressing both force sensors concurrently. Critically, there were three types of force gain change, one for each UM, in which the effect of each schedule was subsequently assessed in BM. Following a baseline UM and BM schedule in which no gain changed occurred, the gain of the force increased (gain-up) differently for both hands: one increased abruptly, and the other increased gradually. In the final UM, the gain decreased back to the baseline (gain-down), with the decrease pattern now reversed between the two hands. While the schedule of gain change differed between the two hands initially, both hands reached the same gain at the end of each UM. The force sharing pattern during BM was significantly affected by the gain change schedule during UM. After gain-up, the hand which was exposed to gradual gain change increased its force contribution during BM. Surprisingly, this effect persisted after gain-down. Further analysis showed that the different gain schedule in the UM lead to differences in within-trial variance of force output between the two hands during BM, and that asymmetry of the variance significantly explained the force distribution pattern. Our data suggest that the bimanual coordination pattern during force sharing is not static; the preceding unimanual activity can dynamically change the way the two hands coordinate and combine forces.

Title: Effect of the number of training contexts on motor learning transfer from bimanual to unimanual movement

Authors: *T. HAYASHI[1,2], D. NOZAKI[1];
[1]The Univ. of Tokyo, Grad Sch. Educ, Tokyo, Japan; [2]JSPS research fellow, Tokyo, Japan

Abstract: It is still controversial how motor memories of a limb are shared between unimanual and bimanual movements. Our previous study has showed partial transfer of learning of a force field from bimanual to unimanual movement (Nozaki et al., Nat Neurosci 2006). In contrast, a recent study has demonstrated almost complete transfer (Wang et al., PLoS One 2013) when bimanual training was performed for reaching toward 8 targets instead of just one target in our previous study. However, in their study, the movement directions were changed not only for the opposite arm but also the trained arm, making the mechanisms of full transfer ambiguous. To examine the problem more directly, we investigated how the number of movement directions of the opposite arm for the bimanual training influenced the amount of learning transfer to unimanual movement, while the movement direction of the trained arm kept constant. Eight right-handed participants performed bimanual reaching movements training under the presence of a velocity dependent force field to the left arm (KINARM End-Point Lab, Bkin Technologies, Canada). There were 4 training sets in which the number of targets for the opposite right arm was gradually increased from 1 to 8 targets [1 (0 deg), 2 (0, 180 deg), 4 (0, 90, 180, 270 deg) and 8 targets (0, 45, 90, ⋯, 315 deg)]. At the end of each training set, error clamp trials were randomly interleaved to quantify the aftereffect of the left arm for unimanual and bimanual (both hands were moved forward) movements. In the first training set, the aftereffect of the left arm was significantly greater for bimanual movement than for unimanual movement. Thus, consistent with previous findings, the motor learning acquired bimanually was only partially transferred to unimanual movement. However, even when the number of targets for the opposite right arm was increased (2nd to 4th training set), the aftereffect of unimanual movement did not increase. Thus, the number of the training contexts was unlikely to be related the amount of motor learning transfer. Future experimental and/or theoretical studies would be necessary to reconcile the present results with those of Wang's study and to clarify how the motor memories are shared between unimanual and bimanual movements.

Title: Dynamic dominance revealed through transcranial magnetic stimulation during bimanual isometric grip force production: a pilot study

Authors: *S. AMANO, R. PATEL, K. OKI, B. C. CLARK, S. HONG;
Ohio Univ., Athens, OH

Abstract: Dynamic-dominance hypothesis suggests that handedness could result from differential specialization of limbs in a motor performance. The purpose of this pilot study was to test this hypothesis using unilateral transcranial magnetic stimulation (TMS). Four right-handed healthy young individuals (21± 2years, 174.2±8.8 cm, and 63.9±10.9kg) were asked to generate bimanual grip forces simultaneously with both hands at a target (5% of maximum bimanual grip force). Subjects were only provided with visual feedback of the total force generated across both hands. The task was performed under two conditions: 1) single pulse TMS condition where a pulse was delivered to M1 at an unpredictable time (STIM), and 2) a sham condition (SHAM). Both conditions were conducted for the left and right hemispheres, with a total of five trials per condition (20 trials in total). For each subject, stimulus intensity was set at 100% of active motor threshold, and the conditions were presented in random order. Detrended Fluctuation Analysis was performed to obtain α-values for 1-second windows between three seconds pre- and post-stimulus, as an index of the spread of fluctuations in the grip force dynamics of the individual hands. The average ratio of α-values of the left (LH) to the right (RH) hand during the three 2-second epochs before (PRE), after (POST) and at the time of stimulus (ST) were used for statistical comparisons. A 3-way (2 Side x 2 Condition x 3 Time) ANOVA was conducted on the results and Sidak-corrected post-hoc tests were employed when needed. A significant main effect of Side was observed where LH α-values consistently exceeded the RH across the three TIME epochs ($p=.01$). A significant 3-way interaction ($p<.01$) revealed that a Side x Time interaction existed only for the STIM condition ($p<.01$), but not for the SHAM. We observed significant changes in the α-value ratio from PRE to ST for both sides (RH: 1.10±.14 to .78±.07, LH: 1.06±.14 to x1.48±.08; both p's=.02). Furthermore, the α-value ratio was significantly higher during PRE when the RH was about to be stimulated (1.10±.14) in comparison to the LH (1.06±.14; $p=.02$). Our results reveal that: 1) LH consistently exhibited slower grip force fluctuations, 2) TMS led to slower grip force fluctuations in the stimulated hand, and 3) unlike

RH, the LH appeared to exhibit anticipatory behavior (faster force fluctuations) prior to the delivery of stimulus to the contralateral side. While further investigation with larger sample size is needed, these observations support the dynamic-dominance hypothesis, where the dominant limb primarily controls the dynamics of a task, and the non-dominant limb is specialized for position stabilization.

Title: Neural activity as a correlate of task difficulty in bimanual coordination

Authors: *L. M. RUEDA DELGADO[1], E. SOLESIO JOFRE[1], A. DAFFERTSHOFER[2], S. P. SWINNEN[1];
[1]KU Leuven- Fac. of Kinesiology and Rehabil. Sci. (faber), Leuven, Belgium; [2]Res. Inst. MOVE, Vrije Univ. Amsterdam, Amsterdam, Netherlands

Abstract: *Background.* Studies using fMRI have shown that increased task difficulty is associated with increased brain activation in different areas [1, 2]. An analogue neural correlate of task difficulty regarding bimanual motor performance using electrophysiology has yet to be examined. Coordination of the upper limbs to achieve a common goal is seminal for challenging motor capabilities. *Methods:* Using a 128-channel EEG system, we recorded the brain electrical activity of 26 participants during a bimanual coordination task consisting on the rotation of two dials while online augmented visual feedback of performance was provided via the PC screen. Three conditions were assessed: the 'simple' 1:1 coordination mode, a more challenging 1:3 polyrhythm (where the right hand moved faster than the left hand), and its more difficult symmetry partner (i.e., the 3:1 task, where the left hand moved faster than the right hand). Motor

performance was quantified as deviation from the target. After artifact-removal, we extracted modulations of the theta band via the Hilbert amplitude of the 4-8Hz bandpass filtered EEG. Principal component analysis (PCA) was applied to determine spatial modes dominating these changes in theta activity. *Results*. Motor performance dropped significantly with increases in task difficulty. EEG power was primarily signified by theta activity. PCA revealed a significant increase of theta power above frontal regions as task difficulty increased. This frontal theta activity is therefore likely to be a proper biomarker for task difficulty modulation during motor performance. *Conclusion*. In line with fMRI studies [1, 2] and EEG studies [3], we found altered fronto-central theta activity with modulation of bimanual task difficulty. This might also be linked to error detection [4]. The better performance during 1:1 coordination was accompanied by a lower theta power indicating low task difficulty or a higher level of 'expertise' on the task. Conversely, performing the more difficult 3:1 mode was associated with higher theta power. Monitoring frontal theta activity may thus serve as a predictor for experienced differences in motor task difficulty. References 1. Debaere et al. (2003). Neuroimage 19: 764–776. 2. Ullen et al. Title: Cortical EEG dynamics related to a delay in selective response execution/inhibition during bimanual Go/Stop tasks

Authors: *K. YAMANAKA;
Showa Women's Univ., Tokyo, Japan

Abstract: Previous studies demonstrated a difficulty in selective inhibition of one motor response with concurrent execution of another response. However, it remains unclear the

underlying cortical mechanism of the selective response execution/inhibition. The aim of this study is to investigate the cortical mechanism of the difficulty to selective response execution/inhibition. Eight right-handed female volunteers conducted bimanual go/stop tasks, in which they were instructed to click two computer mice bimanually when two indicators moving with a constant velocity reached targets simultaneously (both-go), to avoid the bimanual clicks when both indicators simultaneously stopped just before they reached the targets (both-stop), to avoid a left-hand click with executing of a right-hand click when a left indicator stopped unilaterally just before the target (selective right-go/left-stop), and to avoid a right-hand click with executing of a left-hand click when a right indicator stopped unilaterally just before the target (selective left-go/right-stop). For each participant, stop-signal reaction times (SSRTs) in a non-selective (both-stop) and two selective-stop conditions (right-go/left-stop and left-go/right-stop) were calculated from the %correct in stop-response and mean go-response time. Surface electroencephalography (EEG) was recorded during the task and analyzed by a traditional event-related potential (ERP) and a single-trial-based EEG power and phase dynamics. SSRTs in a non-selective condition was significantly smaller than those in two selective-stop conditions, suggesting a difficulty in selective response execution/inhibition. Next, ERPs in the right-go/left-stop and left-go/right-stop conditions about 150-200 ms after the stop-signal onset were slightly lateralized in the opposite hemispheres. These lateralized ERP responses indicate presence of additional EEG responses for delayed go-responses. Finally, power increase and inter-trial phase-locking in the theta-band EEG occurs broadly over the motor-related areas about 150-200 ms after the stop-signal onset. And the phase angles of the EEG oscillation at the ipsilateral motor-related areas consistently precede those at the contralateral ones, suggesting that the lateralized cortical activation patterns are dependent on the responding hand. These results suggest that the difficulty of the selective response execution/inhibition is related to the presence of the additional processes for the delayed go-responses.

Title: Can a single hemisphere control the synchronised execution of asymmetric bimanual actions?

Authors: D. NOBBS[1], L. HAMMETT[1], L. BERTHOUZE[1,2], *F. VARGHA-KHADEM[1,3]; [1]UCL Inst. Child Hlth., London, United Kingdom; [2]Univ. of Sussex, Brighton, United Kingdom; [3]Great Ormond Street Hosp., London, United Kingdom

Abstract: Healthy participants use both cerebral hemispheres to perform asymmetric, bimanual actions. For the hemispherectomised patient, this is not possible: one hemisphere must provide cerebral control of both limbs. Here, we asked if hemispherectomised patients synchronise asymmetric, bimanual movements as healthy participants do. We obtained motion capture recordings from a 33 year old with Sturge-Weber syndrome who underwent left-sided hemispherectomy at 8.5 years and three healthy, age and sex matched controls. As previously reported (Vargha-Khadem et al., 1997) the patient retained contralesional hand function post-operation. The task required the participants to press an empty soap dispenser with the left or right hand (pressing hand) whilst placing the other beneath the dispenser (receiving hand). We computed the average percent of each trial for which the tangential velocity of both arms was simultaneously above 20% of their respective maximum velocities ('simultaneous movement'). For the controls, this was 80.45% (SD = 4.51) when pressing the dispenser with the left hand and 81.42% (SD = 5.85) when pressing with the right. For the patient, this was 37.14% (SD = 10.19) when pressing with the left hand and 21.64% (SD = 11.35) when pressing with the right. This revealed a strong tendency for the patient to move each arm separately. We then computed the average difference between reach onset of the receiving hand and reach onset of the pressing hand and calculated this as a percentage of total reach duration of the pressing hand ('onset latency'). For the controls, onset latency was 0.48% (SD = 6.41) when pressing with the left hand and -1.60% (SD = 6.33) when pressing with the right, indicating left and right reaches began almost simultaneously. For the patient, when pressing with the left hand, the right arm began moving later and onset latencies were highly variable: average onset latency was 52.13% (SD = 31.83). When the patient pressed with the right (paretic) hand, left and right reaches were on, average, entirely sequential: onset latency was 99.52% (SD = 59.94). The cause of this previously unreported deficit is unknown but evidence suggests that asymmetric bimanual movements require independent planning and monitoring for each side, functions performed bilaterally by structures such as the superior parietal cortex (Diedrichsen et al., 2006). After hemispherectomy, cortical preparation of both actions must be completed by one hemisphere, perhaps by a shared neural substrate. We speculate that asymmetric, bimanual actions cannot be prepared simultaneously by one hemisphere, hence such movements are planned and performed sequentially.

Title: What promotes interhemspheric interaction during bilateral tasks? Evidence from intermuscular coherence

Authors: *S. LEE[1,3], H. B. NGUYEN[2,3], M. L. HARRIS-LOVE[4], P. S. LUM[5,3];
[1]Biomed. Engin., [2]Catholic Univ. of America, Biomed. Eng., Washington, DC; [3]Ctr. for Applied Biomechanics and Rehabil. Res., MedStar Natl. Rehabil. Hosp., Washington, DC;
[4]Interdisciplinary Program in Neurosci. and Rehabil. Med., Georgetown Univ., Washington, DC;
[5]Biomed. Engin., Catholic Univ. of America, Washington, DC

Abstract: Bilateral movement training has been shown to improve upper limb functionality of those affected by neurological diseases such as stroke. Interhemispheric interaction, such as motor cortex disinhibition, is postulated as one of the underlying mechanisms facilitating neural plasticity during bilateral tasks, but how such interaction between the hemispheres can be modulated by task conditions has not been quantified in detail. In this study, therefore, we aimed to examine how different types of feedback provided to subjects can affect neural interactions underlying their bimanual coordination, by examining EMG-EMG coherence between task-relevant muscles of the limbs participating in the task. Twelve healthy subjects participated in an experiment in which they generated bilateral isometric hand forces using extension or flexion moments at their elbow joints. During task performance, we provided subjects with three different types of feedback; 1) visual feedback (i.e., tilting bar representing force ratio between hands); 2) visual feedback imposing a task constraint (i.e., balancing of a ball placed on the bar); and 3) haptic feedback provided by a physical apparatus that coupled the two hands together and required equal forces in the two hands to perform the task. EMG-EMG coherence of three muscle pairs, 1) agonist muscle pairs (left and right biceps during elbow flexion; left and right triceps brachii during elbow extension), 2) antagonist muscle pairs (left and right triceps during flexion; left and right biceps during extension), and 3) agonist-antagonist muscle pairs (left triceps-right biceps and left biceps-right triceps), were calculated. The coherence values in the alpha (8-15Hz) and beta (16-35Hz) bands were found to be the major contributors to the total coherence, and the intermuscular coherence was modulated by the different types of feedback during bilateral elbow extension, but not during bilateral elbow flexion. Specifically, the

coherence between the agonist muscle pair (elbow extensors) in the condition 3 (haptic feedback) was significantly higher than those in the other conditions ($p = 0.006$). The coherence values of the other muscle pairs, i.e., antagonist muscle pair (elbow flexors) and agonist-antagonist pair (flexor-extensor), were also the highest in the condition 3, but the difference between the conditions was relatively smaller. Results of this study suggest that sensory modality of the feedback provided to subjects should be properly chosen to promote interhemispheric interaction during bimanual task, and that tasks that mechanically couple the two hands may be the most effective bilateral method of rehabilitation.

Title: Bilateral force transients in the upper limbs following single-pulse microstimulation in the ponto-medullary reticular formation

Authors: *T. J. HIRSCHAUER[1], J. A. BUFORD[2];
[2]Div. of Physical Therapy, Sch. of Hlth. and Rehabil. Sci., [1]Ohio State Univ., Columbus, OH

Abstract: The ponto-medullary reticular formation (PMRF) is a group of brainstem nuclei that gives rise to the reticulospinal tract, which primarily contributes to postural stability and motor control of proximal muscles. The PMRF receives input from both the ipsilateral and contralateral motor cortex and projects to the spinal cord where it synapses on motor neurons and commissural interneurons. These bilateral projections are a potential source of motor recovery following a unilateral motor cortex injury, such as a stroke. While previous studies have assessed EMG responses to microstimulation, they have not determined the resultant movement and force output patterns generated by stimulation of reticulospinal neurons in primates. In this study, muscle activity was recorded using intramuscular EMG electrodes implanted bilaterally in 24 muscles (12 on each side) of the trunk and arms in two M. fascicularis monkeys. Force responses were measured by two force-sensitive joysticks, which the monkeys were trained to grasp while performing bilateral force control tasks. A tungsten microelectrode was placed in the

pontomedullary reticular formation and 2000 30 μA pulses were applied at 5 Hz to 163 reticular formation locations. Force responses to stimulation were collected with the force transducers and analyzed using Spike2 data acquisition and analysis software and MATLAB. Preliminary data analysis identified significant EMG or force responses from 92 sites (56.4%) using stimulus-triggered averaging. Most stimulation sites produced bilateral muscle activation consistent with facilitation of the ipsilateral flexor muslces and contralateral extensors and suppression of the ipsilateral extensors and contralateral flexors in the upper limbs. Force responses revealed a corresponding pattern of motion, toward the body in the ipsilateral arm (directed medially and posteriorly) and away from the body in contralateral arm (directed laterally and anteriorly). These force transients were characterized by amplitudes of 0.05 N with onset latencies of about 15 ms. This work demonstrates that force transients in response to single-pulse microstimulation of reticulospinal neurons can be detected with sensitive force transducers using stimulus-triggered averaging and that these force outputs agree with the general pattern of ipsilateral arm flexion and contralateral arm extension observed in EMG recordings.

Title: Muscle relaxation of the foot induces decrease in muscle activity of hand sustained-contraction

Authors: *K. KATO[1,2], J. WATANABE[3], K. KANOSUE[4];
[1]Grad. school of Sport Sci., Fuculty of Sport Sciences, Waseda Univ., Saitama, Japan; [2]Japan Society for Promotion of Sci. Res. Fellow, Tokyo, Japan; [3]Grad. school of Sport Sci., Tokorozawa, Japan; [4]Fac. of Sport Sci., Saitama, Japan

Abstract: Introduction Muscle relaxation is an important aspect to make a fine control of the body in daily life, but the mechanism has not been well understood. It has been suggested that muscle relaxation is accomplished by an active process in the brain, and not just the end of contraction (Toma et al., 1999). We have recently observed that EMG level of contraction in one limb decreased during the relaxation of the ipsilateral remote limb (Kato et al., 2014). Furthermore, we utilized transcranial magnetic stimulation (TMS) and suggested that muscle

relaxation of foot increased intracortical inhibition for the hand (Kato et al., in preparation). However, in the period of voluntary muscle relaxation of foot muscle, the time-dependent change in EMG activity of hand muscle during sustained contraction has not been well understood. The objective of this study was to clarify how the relaxation of foot muscle influences on EMG activity of hand muscles by utilizing simple reaction task. Methods Ten participants sustained isometric contraction in their right pronated hand with 2, 5 and 10% MVC, then relaxed/contracted their right foot from dorsiflexed/resting position in response to an auditory signal. Force level and EMG activity of hand were recorded based on the relaxation/contraction onset of foot. Mean force level and EMG activity of hand were calculated in each 200 ms period from 0 to 1000 ms from foot relaxation/contraction onset, and were compared with those before the signal. Results After the contraction onset of foot, mean EMG activity and force level of the hand significantly increased for 5 and 10 % sustained contraction. After the relaxation onset of foot, on the other hand, mean EMG activity and force level of the hand significantly decreased for 5 and 10 % sustained contraction. Discussion We demonstrated that muscle relaxation of foot induced temporally decrease in EMG activity and force level of hand muscle, whereas muscle contraction of foot induced temporally increase in EMG activity and force level. Remote effect has been previously observed during muscle contraction of a limb. Present study suggested that muscle relaxation also influences on muscle activity of a remote limb. Abstract: The role of primary motor cortex (M1) in the control of voluntary hand movements is still unclear. fMRI studies of unilateral hand motor performance reported a relationship between level of precision of a motor task and additional ipsilateral M1 activation. In the present study we determined whether the demand on accuracy of a movement influences the magnitude of inhibitory effect between primary motor cortices. We used transcranial magnetic stimulation (TMS) to measure active interhemispheric inhibition (aIHI) in the pre- movement period of a pointing task where precision varied quantitatively. Six healthy participants used a joystick to point to targets of 2 different sizes in a block design. Following the presentation of a fixation square, participants were asked to move a cursor to a target square immediately upon its appearance. Target squares were of small (high precision) or a large (low precision) sizes. Electromyographic (EMG) signal was recorded from both extensor carpi ulnaris muscles (ECU), a muscle supporting the execution of the pointing task. Active IHI was measured by applying a conditioning pulse to the left M1 and a second test pulse to the homotopic right M1 at an interstimulus interval of 10 ms. Paired stimuli were interspersed with single test stimuli applied to right M1. Measurements were obtained at target appearance (0 ms), and 300, 350, 400, and 450 ms after target appearance. We also measured IHI during rest (rIHI) using the same TMS settings. The amount of inhibitory effect of the conditioning pulse on the motor evoked potential (MEP) of the subsequent test pulse was expressed as percentage of the mean MEP amplitude evoked by the single test pulses. Across the 5 time points of aIHI measurements, there was a significant effect for target size (repeated measures ANOVA: $F(1,5) = 13.62$, $p = 0.014$) with aIHI being weaker with high precision movements when compared to low precision movements ($t(5) = 3.60$, $p = 0.014$). This difference was most pronounced in the early pre- movement period (0 - 300 ms; % mean test MEP, high precision: 77.79 ± 14.16 (0 ms), 79.09 ± 11.10 (300 ms); low precision: 64.46 ± 13.17 (0 ms), 68.58 ± 11.91 (300 ms). During this time period, aIHI in the early pre- movement period for low precision movements was similar to rIHI (66.11 ± 13.97 % mean test MEP), whereas aIHI in the high precision movements was below rIHI. The present findings suggest that during the pre- movement period the aIHI between motor cortices is modulated by the demand on accuracy of motor task. This is consistent with previous findings where bilateral M1 activation was seen during high precision movements, whereas unilateral M1 activity was seen with low precision movements.

Title: Interhemispheric inhibition of corticospinal projections to wrist muscles

Authors: *D. A. BOLTON[1], R. J. IBEY[2,3], A. R. BUICK[1], R. G. CARSON[1,3];
[1]Queens Univ. Belfast, Belfast, United Kingdom; [2]Kinesiology, Univ. of Waterloo, Waterloo, ON, Canada; [3]Inst. of Neurosci. and Sch. of Psychology, Trinity Col. Dublin, Dublin, Ireland

Abstract: Interhemispheric inhibition (IHI) is an electrophysiological phenomenon obtained when an initial magnetic (conditioning) stimulus (CS) is applied to one primary motor cortex (M1) shortly (6-15 ms) before a second (test) stimulus (TS) is directed to the other M1. Here, the magnitude of the motor evoked potential (MEP) generated by the TS is smaller than that elicited in isolation. The expression of IHI is typically examined via changes in the excitability of corticospinal projections to intrinsic hand muscles. This is an important consideration as the cortical representations of proximal and distal muscles in the upper limb may be distinguished in terms of their inter-hemispheric projections. Given the practical utility of examining movements generated by muscles proximal to the wrist, particularly in the context of rehabilitation, it is necessary to determine whether optimal IHI parameters established for the hand apply more generally. To address this issue, eleven healthy, right-handed adults were studied. They were seated comfortably with arms supported and elbows semi-flexed. Surface muscle EMG was recorded from the flexor carpi radialis (FCR) and extensor carpi radialis (ECR) of both arms. The TS coil was held over M1L at the optimal position to evoke a motor evoked potential (MEP) in the contralateral right FCR. The CS coil was positioned over M1R to stimulate the left FCR. For both stimulation sites, the resting motor threshold (rMT) was determined. The time course of IHI was probed using seven different ISIs (6, 7, 8, 9, 10, 12 and 15ms). Each ISI was delivered in random order within a given test block for a total of ten trials per ISI. In addition to CS-TS pairings, ten trials of TS alone were included in each test block. TS intensity was fixed at 120% rMT. Conversely, CS intensity was adjusted in five separate test blocks ranging from 110, 120,

130, 140 and 150% rMT (5 minutes rest between blocks). The order of test block presentation (i.e. different CS intensities) was randomly allocated. For FCR, IHI scaled with CS intensity and a progressive increase in IHI was observed as the ISI was extended (up to 10ms). The most consistent and pronounced IHI (per CS intensity) tended to occur at an ISI of 10ms, whereas negligible IHI was present at the 6ms ISI. A similar pattern of outcomes was observed for ECR. While the results are broadly in accordance with those obtained for hand muscles the utility of the present approach lies in the delineation of stimulus parameters that permit changes in IHI in either direction to be resolved. This is an important consideration in the study of neural adaptations associated with motor learning.

Title: Interhemispheric cortical interactions of the caudal forelimb (CFA) area with its contralateral homologue in the rat

Authors: *E. SERRANO, I. MOREAU-DEBORD, L. JEAN-CHARLES, B. TOUVYKINE, S. QUESSY, N. DANCAUSE;
Dept. of Neurosciences, Univ. De Montréal, Montreal, QC, Canada

Abstract: Numerous studies have demonstrated that an interhemispheric dialogue exists between sensory and motor cortical areas of the two hemispheres. In the frontal agranular cortex of the rat, there is a large forelimb area, the caudal forelimb areas (CFA), forming a mosaic of shoulder, forearm, wrist and digits movements. The CFA of the two hemispheres are interconnected, which suggests that they can interact for the production of the corticospinal outputs. However, these interhemispheric interactions are only partially understood. In the present study, we used paired pulse stimulation protocols to investigate how one CFA can facilitate or inhibit its contralateral homologue. Following craniotomy and durectomy, anesthesia was changed from

isoflurane to ketamine (IP). A stimulating electrode placed in the CFA of one hemisphere was used to deliver a sub-threshold conditioning stimulus (C). A second stimulating electrode was placed in the opposite CFA to deliver a supra-threshold test stimulus (T). The C and T stimuli were separated by seven different randomly-presented inter-stimulus intervals (ISIs). Effects of the cortical stimulations were quantified with the recording of motor evoked potentials (MEP) from 3 forelimb muscles and one dorsal muscle in each arm. Overall, we recorded 29 protocols in 6 rats, each testing the effect of one CFA cortical site on the outputs of the opposite CFA. Our results demonstrated a strong relationship between the ISIs and the modulatory effect of the contralateral CFA. The contralateral CFA facilitated the MEP response at short ISIs (0, 2.5 ms) in 64% of our protocols and at long ISIs (20, 35 ms) in 64% of our protocols. However, at intermediate ISIs (5, 10 and 15 ms), the contralateral CFA exerted an inhibitory influence in 54% of our protocols. The data indicate that subthreshold CFA activation can provide both facilitatory and inhibitory effects on the motor outputs of the opposite CFA, depending on when it is activated in relation to the other. These results suggest that the outputs from these homologous areas are not merely summated to provide the MEP response but are instead subject to more complex temporal processing.

Title: Subthreshold activation of ventral premotor cortex produces interhemispheric modulation of contralateral primary motor cortex outputs in Capuchin monkeys

Authors: *S. QUESSY, A. HAMADJIDA, M. DEA, J. DEFFEYES, N. DANCAUSE;
Dept. de Neurosciences, Univ. De Montréal, Montréal, QC, Canada

Abstract: The primary motor cortex (M1) plays a pivotal role in the control of movements in primates. The numerous inputs from several premotor areas can influence its corticospinal outputs. While a lot of efforts have been devoted to the study of the input form ipsilateral ventral

premotor cortex (PMv) on M1 outputs, little is known about the influence of cortical areas of the opposite hemisphere. In the present study we document the modulation of M1outputs by interhemispheric inputs from the contralateral PMv (cPMv). We used paired-pulse stimulation protocols while recording electromyographic (EMG) activity from 8 forelimb muscles in each arm. Following a bilateral craniotomy and durectomy, anesthesia was switched from isoflurane to ketamine. Using standard intracortical microstimulation techniques, we first identified the location of the hand representation area in M1 in one hemisphere, as well as in cPMv. Then, we selected a site in the hand area of M1 where a single pulse stimulation of moderate intensity (30-300 μA) would elicit a clear motor evoked potential (MEP) in at least one of the muscles contralateral to the stimulation. This stimulating electrode would be used as the test electrode (T). A second stimulating electrode was placed in the hand representation of the cPMv to be the conditioning electrode (C). The intensity of the C stimulus was kept subthreshold (typically 75% of threshold). In different conditions, we used 6 relative timings between C and T (range = 0-20ms). Data was collected in 4 adult monkeys from which we tested a total of 11 cPMv-M1 site pairs. At each site pair, we obtained MEP from between 1 and 7 contralateral muscles, allowing us to record a total of 44 interhemispheric interactions. The MEP evoked using paired stimulations were compared to the ones obtained using T only. In general, inhibitory interactions were more common, but the strength of this inhibition depended on the latency between the C and the T. When longer delays between C and T were used (15 and 20ms), the MEPs observed often showed a strong inhibitory modulation of M1 outputs by the cPMv, while shorter delays (0-10 ms) were more likely to produce a more moderate inhibition. Less often, interhemispheric facilitatory effects were also observed but mostly at shorter ISI (0-10 ms). These results suggest that while interhemispheric inhibitory interactions between premotor and motor areas are more common, these interactions are complex and strongly temporally modulated.

Title: Interhemispheric cortical interactions of forelimb motor areas in the rat: Modulation of the caudal forelimb area (CFA) by the contralateral rostral forelimb area (RFA)

Authors: *I. MOREAU-DEBORD, E. SERRANO, B. TOUVYKINE, L. JEAN-CHARLES, S. QUESSY, N. DANCAUSE;
Neurosciences, Univ. of Montreal, Montreal, QC, Canada

Abstract: The interhemispheric interactions between motor areas are not currently well understood. In rats, movements of the forelimb can be evoked from two distinct sensorimotor areas, the caudal forelimb area (CFA) and the rostral forelimb area (RFA). Interhemispheric connections exist between RFA and CFA of the two hemispheres. However, no study has investigated the extent to which RFA can modulate the output of the contralateral CFA. The goal of the current study was to characterize these interactions with paired-pulse stimulation protocols in the rat. After a bilateral craniotomy and durectomy, anesthesia was changed from gas to ketamine. An electrode was placed in the RFA of one hemisphere to provide a sub-threshold conditioning stimulus (C) while a second electrode was placed in the contralateral CFA in order to deliver a supra-threshold test stimulus (T). Seven randomly-presented inter-stimulus intervals (ISIs; 0, 2.5, 5, 10, 15, 20, and 35 ms) separated C from T stimulation to study the effects of different delays on CS output. This output was assessed by recording motor evoked potentials (MEP) from 3 forelimb muscles (palmaris longus, extensor digitorum, biceps brachii) and one shoulder muscle (spinodeltoid) in each arm. In total, 31 paired pulse protocols were recorded in 4 rats. The results demonstrated that the modulation of CS output depends on ISI. With short (0, 2.5, 5ms) and long ISIs (15, 20, 35ms), there was clear facilitation of MEPs in 92% and 81% of protocols, respectively. RFA had an inhibitory effect on the contralateral CFA in 48% of protocols with an ISI of 10ms. Thus, the interhemispheric interactions between RFA-CFA were mostly facilitatory across ISIs. These results contrast from those obtained from paired-pulse stimulation of CFA with its contralateral homologue, for which a greater number of inhibitory responses were observed. The ISI-dependent modulation of CFA outputs by the contralateral RFA reveals that complex interhemispheric interactions between these areas can take place. The contrast between the interhemispheric influence of the contralateral RFA and CFA suggest that these two areas play a different role for the generation of coordinated movements of the two forelimbs.

Title: Observation of unilateral hand movement modulates interhemispheric inhibition on primary motor cortex; a transcranial magnetic stimulation study

Abstract: Introduction: It is presumed that interhemispheric inhibition (IHI) between motor cortical areas is thought to play a critical role in motor control. However, IHI can influence adversely. Murase et al confirmed that stroke patients with abnormal IHI pattern present poor motor performance. Repetitive transcranial magnetic stimulation can modulate IHI, but it's expensive and not diffused widely. To explore an expedient mean to modulate IHI, is crucial. In this study, we investigate the effect of action observation of unilateral hand movement on interhemispheric inhibition. Method: The excitability of the left and right primary motor cortex (M1) (the first dorsal interosseous muscle controlling area) in a resting state during observation of adduction and abduction movements of a unilateral index finger displayed on a monitor were investigated in 11 healthy subjects using two transcranial magnetic stimulators (interstimulus interval, 10 ms). Results: The result indicated an increased excitability of the contralateral M1 and an increased suppression of the ipsilateral M1 in the acion observation condition compared with the condition without action observation. Discussion & Conclusions: Numata et al confirmed activation of the anterior intraparietal sulcus (aIP) during action observation by an fMRI study. The increased contralateral M1 excitability may be attributed to information transmitted from aIP via the premotor cortex, while the increased suppression to the ipsilateral M1 may be attributed to an increased interhemispheric inhibition (IHI) associated with the increased contralateral M1 excitability. Action observation is suggested to be a possible effective means to correct the imbalance of IHI occurring after brain injury and facilitate recovery from paralysis.

Title: Assessment of associated reactions in pediatric and adult onset hemiplegia

Authors: *R. L. HAWE, J. P. A. DEWALD;
Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL

Abstract: In both children and adults with hemiplegia, high effort motor tasks in the lower extremities can result in involuntary upper extremity movements, typically in flexion or extension movement patterns called associated reactions. These associated reactions refer to involuntary movement at one body part in response to a voluntary effort in a different body part. Associated reactions are thought to be the result of an increased reliance on brainstem pathways, specifically reticulospinal or vestibulospinal systems. An example is that when children with hemiplegia run, their upper extremity moves involuntarily into a posture consistent with a flexion synergy. In this study, we aimed to quantify associated reactions in both children and adults with hemiplegia to gain insight into the use of brainstem pathways following unilateral brain injuries to the developing brain as well as mature brain. Individuals performed maximal and submaximal isometric knee flexion and extension tasks while receiving visual feedback on their lower extremity torque production. Individuals were instructed to relax their upper extremities while performing the lower extremity task, though no explicit feedback was given. EMGs were placed on shoulder, elbow, and wrist muscles bilaterally as well as quadriceps and hamstrings to measure muscle activity. All EMG activity was normalized to the maximal voluntary EMG for each muscle. Motion analysis was captured using a Microsoft Kinect system. Our findings show that associated reactions are stronger for knee extension than knee flexion, possibly due to higher neural drive to the knee extensors. Associated reactions were greater when the paretic lower limb was tested compared to non-paretic. Muscle activity and involuntary motion was greater for

maximal efforts compared to submaximal, suggesting a threshold level of neural drive prior to recruitment of brainstem pathways. The results of this study support the hypothesis that associated reactions are due to the recruitment of brainstem pathways during high effort motor tasks when available corticospinal resources are exhausted. The pattern of muscle activity and kinematics is consistent with vestibulospinal or reticulospinal innervation patterns.

Title: Asymmetric Walkway: Novel behavioral assay for studying asymmetric locomotion

Authors: *K. TUNTEVSKI, R. ELLISON, J. M. SHAFFER, S. YAKOVENKO;
Neurosci., West Virginia Univ., Morgantown, WV

Abstract: Behavioral assays are commonly used for the assessment of sensorimotor impairment in the central nervous system. The most sophisticated methods for quantifying locomotor deficits in rodents measure the minute disturbances of overground gait (e.g. manual BBB score or automated CatWalk measures, Noldus). However, the cortical inputs are not essential for the locomotor pattern generation produced by spinal network (Yakovenko, 2011). Thus, unconstrained walking tasks only indirectly test locomotor deficits due to the cortical impairment. In this study, we propose the novel task of measuring the locomotor phase characteristics during precise limb placement that requires cortical control (Drew et al., 2009). The peg walkway was used to set symmetrical and asymmetrical locomotor tasks mimicking lateralized movement deficits. The task imposed consistent shifts (20% of stride length) from the default symmetric foot placement corresponding to the preferred stride length. The forced asymmetric foot placement induced significant changes in the phase relationship characteristics during locomotion measured with the asymmetry and diagonality indices. The stance phase of forelimbs showed significant modulation by the task in both uninjured animals and those with impairment due to focal stroke induced by the occlusion of medial cerebellar artery. The changes in phase modulation were characterized with the model of rhythm generation based on half-

center leaky integrators. In general, the locomotor assay based on the asymmetric walkway is a sensitive measure of asymmetric adaptations.

Title: Primary motor cortical neurons reflect perturbation and torque-related activity from ipsilateral limb

Authors: *E. A. HEMING, S. H. SCOTT;
Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: It is commonly accepted that the primary motor cortex (M1) is involved in controlling the contralateral side of the body. However recent work has shown that many M1 cells are active during ipsilateral limb movements. As feedback plays an important role in voluntary motor actions, we were interested in exploring the relative prevalence of limb feedback in M1 from the ipsilateral and contralateral forelimbs. For our tasks, a non-human primate (NHP) stabilized a cursor representing the location of its right or left hand at a central virtual target. After 1000-1500ms, flexor or extensor step torques were applied to the shoulder, the elbow, or both (9 load conditions). The NHP had 1000ms to return to the target, followed by another 1500-2000ms hold period. The paradigm was then repeated but with a cursor for each hand, and simultaneous perturbations on both arms. Perturbations were selected to activate similar muscle groups or opposing muscle groups in each arm. All trials from all conditions were interleaved. During each task, we recorded the activity of M1 cells using a micro-electrode array. As expected, almost all M1 cells isolated with the array showed responses to perturbations of the contralateral limb.

However we also found about 60% of cells modulated their activity for perturbations on the ipsilateral limb, with about half of the cells showing responses to perturbations of either limb. Although overall responses tended to be larger for contralateral perturbations, about a third of bilaterally responsive neurons had earlier responses to ipsilateral perturbations than their responses to contralateral perturbations. A third of the bilaterally responsive cells also showed larger response magnitudes to ipsilateral perturbations. While individual cells modified their baseline activities between tasks, there was no population rate change between right and left tasks. Additionally, we found that cells often displayed preferred torque directions (PTD) that were different for each limb. Our results surprisingly indicate that M1 shows fast and substantial ipsilateral response to perturbation-related activity from both limbs.

Title: A preliminary multi-level neurocomputational model for overt/covert self-intended and imitated arm reaching movements

Authors: *H. OH[1,2], D.-W. HUANG[3], G. E. KATZ[3], R. H. MILLER[1,2], J. A. REGGIA[3,4], R. J. GENTILI[1,2,5];

Abstract: Humans have the ability to actually and mentally perform self-intended complex actions such as bimanual arm reaching movements. Further, it has been proposed that the human brain incorporates a mirror neuron system that is engaged during observation and imitation of

other's actions. From a neurophysiological point of view, mental simulation theory suggests that such motor performance capabilities are enabled by a simulation network in which the fronto-parietal circuitry is critical, and that allows for performing actual, mental, observed, and imitated actions. Based on mental simulation theory, we present a neurocomputational architecture that includes high (cognitive) and low (sensorimotor) levels of processing that coherently integrate self-intended actual/mental and observed/imitated bimanual arm reaching movements. Here, as a first step, only the sensorimotor level was developed by modeling three fronto-parietal loops that learn to compute the i) inverse kinematics, ii) sensorimotor predictions and iii) visuo-spatial transformations needed to remap the frame of reference from allo- to ego-centric coordinates during the execution of bimanual arm movements. Our results show that this neural model can execute accurate and robust 3D actual/mental reaching movements while generating human-like kinematics. Also, the visuo-spatial remapping network allows for imitating arm reaching independently of the viewpoint from which an action is observed. This is consistent with previous neurophysiological studies showing that the frontal mirror system in monkeys includes independent viewpoint neurons that are activated regardless of the observation viewpoint. The long term goal of this work is to further understand the underlying neural and behavioral principles of actual and mentally-simulated motor performance, especially in the context of human imitation learning. Title: The influence of visual feedback on the intralimb and interlimb generalization of motor adaptation

Authors: *K. MURTHY, J. FITZGERALD, W. M. JOINER;
Bioengineering Dept., George Mason Univ., Fairfax, VA

Abstract: The type of visual feedback during training in a visuomotor rotation (VMR) task has been shown to influence the magnitude of intralimb generalization. Here, we were interested in the effect of this feedback on the interlimb transfer of adaptation. First, we attempted to replicate previous studies that reported an influence of visual feedback on the extent of intralimb generalization to movement directions not experienced during training (Taylor et al. 2013). We tested 14 subjects as they made point-to-point right handed movements to a peripheral target located 9 cm at 90^o. A 30^o clockwise or counterclockwise rotation was applied (the rotation direction was counterbalanced) to the visual feedback of their unseen reaching movements. This visual feedback during training was either for the full movement trajectory (full feedback, FF) or terminal feedback once the radial target distance (9 cm) was surpassed (end point feedback, EPF). In both cases the terminal cursor position was displayed for 1.5 seconds once the movement surpassed 9 cm. Generalization was tested by requesting subjects to make movements to untrained target locations (19 target locations spaced 15^o apart, from 315^o to 225^o) without any performance feedback. We estimated the local (the width at 50% transfer) and global components (the offset from 0% transfer) of the generalization function based on fitting a Gaussian function to the data ($R^2 > 0.91$ in both feedback conditions). Surprisingly, unlike previous reports, we found a substantially broader generalization for the EPF condition—the local and global components were 41% and 17% greater for EPF than for FF. Based on this finding we tested 5 additional subjects on interlimb transfer with either FF or EPF during training. Subjects were trained in the same method as experiment 1, but the untrained left hand was used to make movements only to the trained target without feedback. Based on the results from the first experiment, we hypothesized that EPF would again result in a greater transfer of the adaptation to the untrained left limb. Preliminary results show that the feedback in this case affected the magnitude of learning transferred to the untrained limb; transfer with EPF at the trained location was substantially greater than with FF. In summary, we report that the extent of performance feedback strongly influences the amount of VMR generalization within the trained limb and transfer to the untrained limb. We hypothesize that this variation may be due to a difference in how the resulting movement error is interpreted based on the feedback, and subsequently credited (self-caused vs. externally-caused) during training.

Title: Harnessing tongue movement to decrease RMSE in wrist tracking exercise using exoskeletal assistance

Authors: S. OSTADABBAS[1], J. KIM[1], D. WU[2], K. RICHARDS[2], *A. J. BUTLER[2], M. GHOVANLOO[1];
[1]Electrical & Computer Engin., Georgia Inst. of Technol., Atlanta, GA; [2]Physical Therapy, Georgia State Univ., ATLANTA, GA

Abstract: Robot assisted therapy has been shown to produce positive clinical outcomes. Current robot-assisted technology for the upper extremity (UE) requires patients who are able to actively initiate hand motion before the robot can help to complete the movement task. We investigated the use of an innovative control system that utilizes the tongue to indirectly drive movement of the hand through an existing robotic device, thereby supplementing active movement. Subjects played an interactive target-tracking task that requires up and down movements on the screen, driven by a robotic arm (Hand Mentor: HM). The robot was interfaced with a wireless headset that detects the movements of a small magnetic tracer temporarily adhered to the tongue (Tongue Drive System: TDS). In TDS-HM system, users try to move their paretic hands actively while using their tongue to drive motion. This enables an individual with little or no active hand movement to participate in therapy and has the potential to remodel the brain's neural pathways. The theoretical construct that underpins this notion is that by linking the extensive motor cortical representation of the tongue to that of the hand, an individual with limited UE functionality following a stroke will be able to progress towards active functional movement. We have developed a TDS-HM prototype and tested it with able-bodied individuals. For the pilot study, two subjects were asked to complete a series of computer games in three consecutive days, in which they tracked three target waveforms (rectangular, sinusoidal, and triangular), while receiving visual feedback on the screen. The games are based on the concept that stroke patients have very limited range of motion (ROM). Within the active ROM, they complete the movement with their hand; outside their active ROM, they use the tongue to move their hand with robotic assistance. Limited ROM was simulated in such a way that beyond a certain wrist angle the robot prevented movements not initiated by tongue control. The TDS-HM was able to quantify wrist angles, tongue positions/commands, and tracking performance as the root mean square error (RMSE). Performance improvement between day 1 and 2 was observed as a 30% decreased in RMSE, while RMSE remained constant between days 2 and 3. The results demonstrate TDS-HM interaction can be learned effectively in 3 days. Future studies will include stroke survivors within 3 to 12 months post-injury, who have less than 10 deg. active ROM. Ultimately, TDS-HM

will allow us to understand the potential effects of controlling a therapeutic robotic exoskeleton with the tongue by gradually reducing the role of tongue motion to improve UE ROM and function in stroke survivors.

Title: Training-related improvement in hand force perception in older adults

Authors: ***K. KERN**[1], S. BROWN[2];
[1]Sch. of Kinesiology, [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Deficits in manual dexterity in older adults are well documented (Olafsdottir et al., 2008; Parikh and Cole, 2012;) due, in part, to reduced force control (Cole et al., 1999; Diermayer et al., 2011; Galganski et al., 1993). Impaired perception of force may also contribute to difficulties with hand function as has been shown in force matching tasks in elderly individuals (DeSerres and Fang, 2004). While improvement in hand force control following task-based training in older adults has been demonstrated (Ranganathan et al., 2001), to what extent similar benefits occur in force perception is unclear. Thus, the purpose of this study was to determine if a sensorimotor training program could improve the ability to perceive pinch force in older adults. Eleven right hand dominant older adults (mean age 77.3 y) performed a variety of clinician-designed sensorimotor tasks in a home setting for 30-40 min/day for 6 weeks. Tasks were performed by both the dominant and non-dominant hands. Sensory tasks involved identification of object characteristics in the absence of vision. Motor tasks focused on visually-guided object manipulation and pinch force activities. Force perception was assessed before and after the intervention using a tripod pinch matching paradigm. In the ipsilateral remembered (IR) condition, participants generated a reference force equivalent to 25% of maximum voluntary force with either their dominant or non-dominant hand and then matched the reference force with the same hand. During the contralateral concurrent (CC) task, participants maintained the reference force while matching with the opposite hand. Functional, somatosensory, and cognitive ability was also assessed. Prior to training, matching errors were significantly greater in the CC

compared to the IR task. Following training, matching error decreased but only in the contralateral concurrent task ($p<0.02$). Differences were statistically significant only when matching was performed by the dominant hand ($p<0.02$). Directional error also decreased in the CC but not the IR condition ($p<.05$). Training was associated with improved tactile sensibility and manual dexterity but only for the dominant hand. Lastly, a decrease in cognitive processing was observed ($p<.05$). The results of this study demonstrate that simple object manipulation activities can improve hand force perception in older adults, particularly in tasks where force monitoring of both hands is required. Improvements in tactile function, manual dexterity, and cognition underscore the broad benefits of such training.

Title: Cognitive-motor integration in young elite athletes with a history of concussion

Authors: Y. HAMANDI[1], J. HURTUBISE[1], C. HUGHES[1,2], A. MACPHERSON[1,2], *L. E. SERGIO[1,2,3];
[1]Sch. Kinesiol & Hlth. Sci., York Univ., Toronto ON, ON, Canada; [2]York Univ. Sport Med. Team, Toronto, ON, Canada; [3]Ctr. for Vision Res., Toronto, ON, Canada

Abstract: Our research examines cognitive-motor integration during eye-hand coordination. Such integration is often required when performing non-standard visuomotor tasks, where a rule is used to align the required motor output to the guiding visual information. We propose that measuring visuomotor integration under conditions that place demands on visual-spatial and cognitive-motor processing may provide an effective behavioural means for the early detection of brain alterations associated with concussion. Previous research from our laboratory1 has shown cognitive-motor integration declines in university-level varsity athletes who have a history of concussion (but were deemed recovered at the time of evaluation). To extend our

research, the current study examines cognitive-motor integration in young asymptomatic elite athletes with a history of concussion. The participants were 187 National Hockey League draft prospects, 28 of whom had a history of concussion but were recovered at the time of evaluation during the annual NHL combine fitness testing. Participants were tested on two visuomotor transformation tasks using an Acer Iconia dual-touchscreen tablet. They made movements from a central target to one of four peripheral targets (up, down, left, right) viewed on the vertical laptop screen by sliding their finger 1) across the touch-sensitive surface displaying the targets (direct interaction) or 2) across a horizontal plane with the cursor feedback 180o reversed, so that the motion plane and cursor alignment were decoupled from guiding visual information(requiring cognitive-motor integration). Unlike our previous observations with varsity level athletes, we observed no differences in reaction time, movement time, path length, or trajectory endpoint accuracy/precision between concussion-history and no-concussion-history groups in this elite population ($p>0.05$). There are many possible reasons for our observed resiliency of skilled performance following concussion in this group, including a stronger group selection bias (combine invitation vs varsity inclusion), superior concussion management, and/or a superior movement control brain network resiliency. Future work will examine whether enhanced brain network activity is underlying the maintained motor behavioural performance, something observed for purely cognitive skills in older retired NHL athletes2. Title: Quick, low-cost, and highly sensitive motor assessment using markerless motion capture

Authors: *P. K. JOHNSON[1], M. MCCAIN[2], S. K. CHARLES[3];
[1]Physiol. and Developmental Biol., [2]Mechanical Engin., [3]Mechanical Engin. and Neurosci., Brigham Young Univ., Provo, UT

Abstract: There is a nationally recognized need for more sensitive motor assessments to evaluate movement and diagnose motor impairments following traumatic brain injury (TBI). Properly identifying impairments and the underlying neural injuries is critical in properly diagnosing movement disorders, estimating prognosis, and prescribing an effective rehabilitation program. Unfortunately, many conventional motor assessments rely on subjective observations, fail to detect subtle impairments, and only identify movement impairments without providing insights into underlying mechanisms. The purpose of this research is to 1) develop a motor assessment method that is quick, low-cost, and highly sensitive, and 2) establish normative data for use in future comparisons. By adapting traditional motor assessment tests and automating them using custom software and the Leap Motion sensor, we have developed an integrated system that is quick, low-cost, and highly sensitive. The Leap Motion sensor, which only costs $80, markerlessly measures the position of all ten finger tips in three dimensions with a resolution up to 0.01mm and a sampling frequency up to 200 samples per second. Our custom software programs interface with this sensor and prompt the user via a graphical user interface to perform certain movements and record the user's movements as he or she progresses through a battery of motor tests. The tests include postural tremor, finger tapping, point-to-point movements, reaction time, and postural sway. Because this motor assessment method uses a sensitive sensor, it provides a large amount of movement data with high resolution in both space and time. For data from individual patients to be clinically useful, we are establishing a normative database of unimpaired motor behavior with fifty young, healthy research participants (25 male and 25 female subjects between the ages of 18 and 30). To provide a basis of comparison between our new assessment method and conventional motor assessment methods, we are including in this normative database the traditional finger tap test (using a clicker counter) and the Beery-Buktenica Developmental Test of Visual-Motor Integration. The outcomes of the motion capture assessment will be evaluated against those of the conventional exams. Our novel integrated system increases the sensitivity and objectivity of motor assessments, and the low cost, portability, and ease of use make this system easily accessible to clinicians as well as researchers.

Title: The relation between attention and tic generation in Tourette syndrome

Authors: *E. MISIRLISOY[1], V. BRANDT[2], C. GANOS[3], J. TUBING[2], A. MUNCHAU[2], P. HAGGARD[1];
[1]Inst. of Cognitive Neuroscience, UCL, London, United Kingdom; [2]Inst. of Neurogenetics, Univ. of Lübeck, Lübeck, Germany; [3]Inst. of Neurology, UCL, London, United Kingdom

Abstract: Many neuropsychiatric disorders involve abnormal attentional processing. Tourette syndrome (TS) is a disorder characterised by multiple motor and phonic tics. Systematic investigations of how attention may affect tic frequency in TS are lacking. Here, we test experimentally whether shifting attention away from tics reduces tic frequency. We developed a novel paradigm in which patients performed a self-paced finger movement task. Throughout each 1 minute trial, patients opposed a finger of their choice against the thumb of their dominant hand, approximately once every 2 seconds. Movement of each digit triggered a unique visual colour stimulus. We manipulated attentional focus by asking patients to monitor and remember their finger actions, the external colours caused by their actions, or their tics during action. Recall was tested after each trial. A group of 16 adult TS patients participated in a single testing session. They performed each task twice: once while voluntarily inhibiting tics, and once without inhibiting tics. During the 'freely tic' condition, patients had significantly fewer tics when attending to finger movements, or to the ensuing colours, compared to when attending to their tics. Attention to fingers produced the fewest tics overall. During tic suppression, there was no such pattern. Instead, tic frequency was reduced to the same level in all conditions. This suggests that effects of attentional focus on tic generation are markedly different from the effects of voluntary tic inhibition. In conclusion, focussing attention away from tics significantly reduces tic frequency. This attentional process may operate by regulating motor noise. Attentional regulation and intentional tic inhibition are distinct cognitive processes.

Title: The effect of paretic ankle plantarflexion in spontaneous and voluntary joint torque coupling patterns

Authors: *N. SANCHEZ, J. P. A. DEWALD, R. LOPEZ-ROSADO;
Northwestern Univ., Chicago, IL

Abstract: Introduction: Clinical observation of the loss of independent joint control after stroke has defined a dominant lower extremity synergy: the extensor synergy. This coupling pattern is characterized by spontaneous coupling of hip extension, hip adduction, knee extension and ankle plantarflexion. Clinical observation however, has not determined the joint torque patterns that drive this synergy. Research in our lab has found abnormal extension/adduction coupling, as described in the clinic, during the generation of maximal and submaximal hip extension torques in the paretic lower extremity. We have also shown that the paretic lower extremity is constrained to this abnormal extension/adduction coupling when executing a dual degree of freedom task. In the present study we explored the effect of the ankle plantar flexion in eliciting the extensor synergy. Spontaneous joint torque coupling generated during maximal and submaximal ankle plantarflexion was quantified. Furthermore, the ability of individuals post-stroke to combine ankle plantarflexion with volitional hip abduction torques or whether they are constrained to extension/adduction coupling during ankle plantarflexion was determined using a dual degree of freedom tack. Methods: Subjects were fitted into an isometric device capable of quantifying torques generated simultaneously at the hip, knee and ankle. Subjects generated maximum voluntary torques for ankle plantarflexion and hip abduction/adduction with their paretic and non-paretic or control lower extremities. Subjects then generated 25, 50 and 75% of their plantarflexion torque and attempted to combine them with maximum hip abduction torques. EMG activity of 10 lower extremity muscles was measured. Results: We quantified spontaneous extensor/adductor coupling during maximum ankle plantarflexion torques in the paretic extremity of post-stroke individual but not on the non-paretic extremity or in controls. EMGs supported this finding: greater coactivation was observed on the paretic extremity. Significantly greater EMGs were measured in the paretic Adductor Longus ($p=0.000$), Rector Femoris ($p=0.000$), Vastus Medialis ($p=0.002$) and Biceps Femoris ($p=0.003$). During submaximal ankle

plantarflexion, associated spontaneous hip adduction was quantified on the paretic lower extremity. In contrast, when instructed, individuals were able to neutralize the hip adduction torque and generate a net hip abduction torque. This indicates that neural resources are available to decouple ankle plantarflexion/hip adduction contrary to the hip ext/add which could not be decoupled in individuals with chronic hemiparesis due to a stroke.

Title: Transcallosal effects of chronic below-elbow amputation: Behavior and physiology

Authors: *E. CHAN[1,2], E. BRECEDA[1,3], F. SANDBRINK[3], A. DROMERICK[1,3,4], P. LUM[3,5], S. MOHAPATRA[1,2,4], R. SILVA[1], M. HARRIS-LOVE[1,4];
[1]Res. Div., Natl. Rehabil. Hosp., Washington, DC; [2]MedStar Hlth. Res. Inst., Washington, DC; [3]Washington DC Veterans Affairs Med. Ctr., Washington, DC; [4]Georgetown Univ., Washington, DC; [5]Dept. of Biomed. Engin., The Catholic Univ. of America, Washington, DC

Abstract: Background: Large-scale cortical reorganization is known to occur after unilateral below-elbow amputation. The motor cortex representation for muscles proximal to the amputation extends into territory previously representing the distal arm muscles. The physiological effects of this "affected" hemisphere reorganization on homologous muscle representations in the "unaffected" hemisphere, and on motor performance of the intact arm, are not known. Methods: A convenience sample of 3 chronic (>1 yr) below-elbow amputees (age 33 ± 21 yrs) were enrolled. Participants performed a planar center-out reaching task using the IM2 Manus robot in which they were asked to use a manipulandum to reach out toward 1 of 3 visual targets displayed on a computer screen. Repetitive reaching tasks were performed with each arm (intact or prosthetic) under two task conditions: null field and force field. In the null field condition, no perturbation was applied and no visual feedback of the manipulandum position was provided until the end of the trial. In the force field condition, a velocity-dependent force field

was applied to the manipulandum during early trials of the task and "catch" trials (force field unexpectedly removed) were randomly introduced afterwards. In a separate visit, transcranial magnetic stimulation was used to test interhemispheric inhibition of the biceps and triceps brachii representations of each hemisphere. Results: All participants performed the movements successfully with both the intact and the prosthetic arms. In the null field, 2 of the 3 participants showed greater endpoint error in the intact arm than the prosthetic arm: one participant had greater endpoint error for all 3 reaching targets (4.4 ± 0.7 cm vs. 3.5 ± 0.7 cm), and one participant had greater endpoint error for the target opposite to the reaching arm (5.1 cm vs. 3.9 cm). The third participant showed no such difference. The 2 participants with greater endpoint error in the intact than the prosthetic arm also had greater inhibition from the affected to the intact hemisphere than vice versa (55.2% vs. 35.5% and 41.7% vs. 21.6%, respectively). The participant who did not show this between-limb difference in endpoint error also did not show this imbalance in interhemispheric inhibition. In the force field conditions, between-limb differences were also observed, but were more variable among participants and reaching targets. Discussion: The preliminary analysis suggests that an imbalance in the strength of interhemispheric inhibition between proximal muscle representations after unilateral below-elbow amputation can contribute to the intact arm motor deficits that have been previously reported.

Title: Convergence of ipsilateral pyramidal and bilateral medial brainstem pathways onto cervical spinal interneurons after unilateral pyramidal tract lesion in monkeys

Authors: *B. ZAAIMI, S. N. BAKER;
Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: We recently demonstrated that there are minimal direct connections from the ipsilateral corticospinal tract to cervical motoneurons in primates (Soteropoulos et al, 2011); this situation is unchanged after recovery from a unilateral pyramidal tract (PT) lesion (Zaaimi et al, 2012). On the other hand, the reticulospinal tract can activate primate hand muscles in healthy animals (Riddle et al., 2009), and these connections undergo changes after corticospinal lesions (Zaaimi et al, 2012), forming part of the substrate for functional recovery. Here we investigated the extent of ipsilateral cortical projections onto spinal interneurons and their convergence with pathways emerging from ipsilateral and contralateral brainstem involved in hand movement after the lesion of the contralateral pyramidal tract. Two female adult Macaca mulatta monkeys underwent a unilateral pyramidal tract lesion (left PT). After a six moths of recovery, an ipsilateral PT electode (iPT), bilateral medial longitudinal fasciculus (MLF) electrodes, and bilateral EMGs over 8 muscles were implanted. A stainless steel recording chamber was fixed above a laminectomy covering spinal segments C5-T1. Single neuron extracellular recordings were made in the intermediate zone from the right (recovered) side. During PT/MLF stimulation the animal was seated quietly. A total of 130 spinal interneurons in two monkeys were tested for responses to stimuli delivered through electrodes implanted in the iPT and right and left MLFs. Across recorded neurons which responded to at least one stimulus, convergent input from the iPT and both MLFs was the most common result (39/102 cells, 38%). Fewer neurons were excited solely by both MLFs without receiving an excitatory input from the iPT (16 cells, 16%). Cells that received an input from the iPT and only from one of the MLFs were rare (7% iPT and RMLF, and 5% iPT and LMFL). A small fraction of cells received an exclusive input from iPT (12 cells, 12%). These results show a high convergence of iPT with brainstem output onto interneurons in the spinal cord. This convergence may be enhanced by the plasticity occurring during recovery from the lesion, and could serve as a structural path for the ipsilateral cortex to control and modulate brainstem influence on hand movement.

Title: Effects of specific unilateral lesion of the primary hindlimb motor cortex on treadmill locomotion in adult rats

Authors: *M. DELCOUR, H. DELIVET-MONGRAIN, N. DANCAUSE, S. ROSSIGNOL; Univ. De Montréal / Dept. of Neuroscienc, Montreal, QC, Canada

Abstract: Motor rehabilitation strategies after spinal cord injury in humans and animals highlight that anatomical and functional plasticity occur at various levels of the Central Nervous System to support the motor recovery. It becomes therefore important to try and extricate the specific contributions of both supraspinal and spinal structures to the recovery movement such as locomotion. The present study aimed to determine how the primary motor cortex (M1) contributes to locomotion of the hindlimbs in rats. In preliminary experiments, we used intracortical microstimulation (ICMS) techniques to map the hindlimb (HL) representation in M1 of Long Evans rats and obtain stereotaxic coordinates for our lesions. In experimental rats (n = 7), we produced unilateral ischemic lesions (9 microinjections of 330 nl of Endothelin-1 diluted at 0.3 µg/µl) of the HL area. We investigated the impact of this lesion during 28 days on 1) locomotion on a treadmill, with video recordings taken at 120 Hz and speeds of 20 and 26 m.min-1 from which various kinematic parameters were extracted to evaluate the step cycle characteristics and interlimb coordination; 2) voluntary motor control of HL on a grid walk by measurements of foot faults. Preliminary results showed that the cortical lesions induced clear motor deficits of the contralateral HL during locomotion on treadmill in half of experimental rats (n = 3) while all animals exhibited deficits of locomotion on grid walk. Rats with deficits on treadmill displayed hyperextension of the ankle, drag or dorsal placement of the foot and hyperflexion of the knee. The cortical lesions also induced specific alteration of the left forelimb/HL coordination as well as of the hindlimbs coordination. On the grid walk, there was an increase of foot faults of the contralesional HL, supporting the idea that the lesions induced deficits of the voluntary control of this HL. So far, our results indicate that the locomotor impairments on treadmill decrease after the first postlesional week while deficits on grid walk persist. At the 35th postlesional day, we found, using ICMS techniques, that the HL representation in the ipsilesional M1 was completely destroyed by the lesions. In the contralesional M1, the total HL map area was larger than in control rats. Several questions are raised by these observations and will be pursued in the coming months. Is the fast recovery of the hindlimb dependent on compensatory mechanisms of preserved descending pathways or through changes occurring rapidly within the spinal cord? Are anatomical changes occurring fast enough to account for such recovery or are these mainly dependent on physiological changes in spinal and supraspinal pathways?

Title: A novel, automated test of forelimb supination in the rat provides a sensitive measure of corticospinal tract function

Authors: ***A. SINDHURAKAR**[1], B. FLYNN[1], E. MEYERS[2], D. SLOAN[2], R. RENNEKAR, II[2], J. B. CARMEL[1,3];
[1]Burke Med. Res. Inst., White Plains, NY; [2]Biomed. Engin., Univ. of Texas at Dallas, Richardson, TX; [3]Brain and Mind Res. Inst. and Dept. of Neurol. and Pediatrics, Weill Med. Col. of Cornell Univ., New York, NY

Abstract: The corticospinal tract (CST) is the primary motor pathway for voluntary movement, and CST injury is largely responsible for motor impairment after injury. We study CST function in the rat to understand motor control, its loss with injury, and strategies for repair. Current tests of motor function in the rat are relatively insensitive to corticospinal injury. One movement that is highly impaired with CST injury in both rats and humans is forearm supination, turning the hand palm up. Supination brings the hand into position for manipulation, and loss of supination strongly impairs hand function. We developed a task to test supination in the rat. In this task, rats are placed into a reaching box and trained to reach through an aperture to a spherical manipulandum. Rats must grasp this "knob" and turn it in supination in order to receive a food reward. The knob is mounted to a rotary encoder that measures angles within a quarter of a degree of accuracy, and an attached computer samples angle position at 100 Hz. When the turn angle exceeds a user defined threshold, the computer signals a pellet feeder to give a reward and plays a reward tone. Rats associate the turning of the knob with a food reward over a few days. We then increased the angle the rats need to supinate in order to receive the reward using a continuous performance measure. This allows us to create learning curves. Training to a criterion turn angle of 60 degrees took an average of 4 weeks after which, we cut the CST at the pyramid. This lesion severely compromised the rats' ability to perform the supination task. We then

trained the rats intensively and measured their performance for 6 weeks. Rats regained only 40% of their supination ability on average compared to their baseline. Thus, we have created a novel test of rat forelimb function that measures key components of CST function: motor learning, loss with injury, and partial recovery with rehabilitation. The task is automated to allow testing and training of several rats at a time. We acquire quantitative data not just about turn angle, but about task kinetics: how quickly, smoothly, and accurately the knob is turned. Thus, we can accurately measure supination in the rat and use this to measure motor learning in health and after injury. We also show that this behavior relies strongly on the CST and allows an automated and quantitative assessment of CST function in the rat.

Title: Locomotor adaptation in Cerebral Palsy patients is constrained by their increased performance variability

Authors: *F. MAWASE, L. SHMUELOF, S. BAR-HAIM, A. KARNIEL;
Ben-Gurion Univ., Beer Sheva, Israel

Abstract: Cerebral Palsy (CP) results from an insult or an injury to the developing brain before birth or in early childhood causing physical disability and a-typical motor patterns such as asymmetrical walking. Consequently, rehabilitation treatments for CP patients should address both the motor disability and the possible control impairments over the damaged system. To examine the interaction between these components in a rehabilitation-like treatment protocol, we studied the dynamics of step-asymmetry during a longitudinal locomotor adaptation task. Six

teenagers with CP were exposed to 30 sessions of adaptation to a novel split-belt treadmill over four months. Aged and gender matched controls were exposed to 10 sessions of adaptation. Adaptation rates and motor variability were computed throughout the adaptation sessions by analyzing the asymmetry and the variability of the center-of-pressure (COP). Compared to controls, CP patients showed slower adaptation (e.g., reduction in COP asymmetry) in the first session ($p<0.05$) and higher COP variability ($p<0.001$). By the last session, CP subjects adapted significantly faster ($p<0.01$) and showed a marked reduction in COP variability ($p<0.001$). To examine the improvement of CP patients at the control level, we modeled the data using a dual-state state-space model, assuming that locomotor adaptation is driven by a fast and a slow adaptation processes. Results showed that initially, CP subjects relied mainly on the slow stable process and the contribution of the fast process during initial adaptation was negligible. With practice, both the learning rate and the contribution of the fast liable process significantly increased. In addition to the changes in learning rates, the single subjects' fits to the models improved, pointing to the reduction in COP variability with training. To incorporate the improvement in adaptation with the changes in variability, we used a Bayesian state estimation model with a single state. Results showed that the improvement in learning can be explained by an increased sensitivity to prediction errors due to the reduction in observation noise, rather than by changes in state uncertainty. Our results suggest that the impaired adaptation of CP patients is primarily a result of their variable performance, and not of an impairment in state estimation. Thus, effective rehabilitation of CP patients should rely on two interacting processes: adaptation of a-typical motor patterns through shaping and reduction in variability through repetition training.

Title: Transcranial direct current stimulation and upper extremity robotic therapy improves upper extremity function in an adult with cerebral palsy: a pilot study

Authors: ***K. M. FRIEL**[1,2], P. LEE[1], D. GUPTA[1], A. R. P. SMORENBURG[1], H.-C. KUO[3], D. J. EDWARDS[1,2];

[1]Burke Med. Res. Inst., White Plains, NY; [2]Brain and Mind Res. Inst., Weill Cornell Med. Col., New york, NY; [3]Biobehavioral Sci., Teachers Col. of Columbia Univ., NEW YORK, NY

Abstract: Cerebral palsy is caused by a nonprogressive brain injury or stroke before birth or during the first two years of life. In unilateral spastic cerebral palsy (USCP), the damage has a unilateral predominance, resulting in weakness and motor skill deficits on one side of the body. People with USCP tend to under-use their paretic side, and do not develop robust motor control of the paretic side. As people with USCP age, motor deficits on the paretic side persist due to disuse of the paretic side. Few therapies exist for upper extremity rehabilitation in adults with USCP. The goal of the present study was to determine feasibility and efficacy of upper limb therapy in adults with CP. Upper extremity robotic therapy can improve arm movement deficits in adults after stroke. Transcranial direct current stimulation (tDCS) can augment the efficacy of robotic therapy when delivered immediately before training. We tested this same protocol in USCP. We hypothesized that tDCS plus upper extremity robotic training would be a safe, feasible protocol that improved upper extremity function. This pilot study is the first to our knowledge to test the efficacy of tDCS plus robotic therapy in an adult with USCP. Single-pulse transcranial magnetic stimulation (TMS) was used to map the motor representation of both hands. The participant received thirty-six sessions of therapy. During each therapy session, the participant received 20 min of 2mA anodal tDCS, immediately followed by robotic arm therapy. We applied anodal tDCS over the motor map of the paretic hand. During robotic therapy, the participant used his wrist and upper arm to follow a cursor in a center-out task for 1000 movements. We measured side effects of tDCS, kinematics of movements on the robot, and motor function of the affected upper extremity. Side effects of tDCS were mild transient scalp tingling and headache. Side effects dissipated within ten minutes of cessation of tDCS. No serious adverse events occurred. Therapy resulted in improved reaching accuracy and smoothness on the robotic task. These findings indicate that tDCS combined with robotic therapy can be used to safely improve motor deficits in adults with cerebral palsy.

Title: Motor cortex inactivity during a key period of development permanently alters the organization of the rubrospinal system

Authors: *P. T. WILLIAMS, D. ZUELKE, S. KIM, A. P. CHANG, J. H. MARTIN;
Dept Physiology, Pharmacology, and Neurosci., City Col. of CUNY, New York, NY

Abstract: Forelimb motor skills require two key inputs from the brain—the corticospinal (CS) system and the rubrospinal system (RS), the other major descending system for forelimb control—to act precisely on spinal motor circuits. The interplay of these two systems during development is poorly understood and knowledge may inform the pathophysiology of common developmental motor disorders, such as cerebral palsy. We previously showed in cats that disrupting activity of the CS system during a key developmental period (postnatal weeks, PW, 5-7) diminishes the cortical motor map and miswires connections with spinal circuits. To further understand how CS impairments affect motor system development we looked for changes in the RS system, which originates in the red nucleus (RN). Our hypothesis is that the RS motor map and spinal connections can compensate for impaired CS development. To determine the role of motor cortex activity on RS development we continuously infused muscimol (10mM, 0.5ul/hr) into the M1 forelimb area unilaterally via an osmotic minipump from weeks 5-7 in cats. We traced RS tract projections to the spinal cord using BDA or BDA-Alexafluor 488. In a terminal experiment at weeks 7-8 (previously reported for some findings; SFN 2012), or 12-14 (young adulthood) when the RS map has reached a mature organization, the RN motor maps were examined bilaterally using microstimulation. Motor cortex inactivation accelerated development of the RN motor map on the side in which M1 was inactivated (termed “inactive side”) at PW 7/8, and this persisted into young adulthood. Microstimulation thresholds in the inactive side to evoke contralateral forelimb movements were decreased compared to age-matched controls. Conversely, the RN map on the side in which M1 remained active (“active side”) had a paucity of effective sites and elevated thresholds at PW 7/8, suggesting a delay in RN map maturation. Remarkably, the RS never recovered; thresholds on the active side remained elevated and the number of effective sites were decreased compared with age-matched controls. Analyses of changes in RS tract axon terminations are ongoing. These results demonstrate that reducing M1 activity alters development of the RS system. The increased efficacy of RN output from the inactive side suggests competition between the developing CS and RS for access to spinal motor circuits during a key period of development. Harnessing this competition between CS and RS may lead to new therapeutic approaches to treat developmental motor disorders.

Title: Antagonist muscle responses during sustained isometric maximal voluntary contraction

Authors: *J. L. TAYLOR[1], C. J. MCNEIL[2], S. C. GANDEVIA[1], D. S. KENNEDY[1];
[1]Neurosci. Res. Australia, Sydney, Australia; [2]Univ. of British Columbia, Kelowna, BC, Canada

Abstract: Agonist and antagonist muscles are often co-activated. For example, during a fatiguing submaximal contraction, descending drive increases to recruit more of the agonist muscle to maintain force. At the same time, antagonist muscle activity increases, as do the antagonist muscle's responses to cortical and subcortical stimulation (Levenez et al. 2008). During fatiguing maximal efforts, descending drive becomes suboptimal to produce maximal muscle force but it is not known whether it decreases in absolute terms (Gandevia et al. 1996). Here we examined activity and responses to stimulation in the antagonist muscle during a sustained knee extensor maximal voluntary contraction (MVC). Methods. Subjects (n=9) performed brief MVCs and then a fatiguing 2-min MVC of the knee extensors on 2 days. Surface EMG was recorded from an agonist muscle, vastus lateralis, and an antagonist, biceps femoris. On one day transcranial magnetic stimulation elicited motor evoked potentials (MEPs) during MVCs. On the other day, electrical stimulation over the thoracic spine to activate descending tracts elicited thoracic motor evoked potentials (TMEPs). Results. During the brief extensor MVCs, biceps femoris rms EMG was ~20% of maximal. During the sustained MVCs, knee extensor force fell by 69±9 %, vastus lateralis EMG fell by 45±39% and biceps femoris EMG fell by 50±19%. For the agonist muscle vastus lateralis, MEP area increased by 45% (42±18 to 61±2 mVms; $p<0.05$) from the brief MVCs to the end of the 2-min MVC whereas TMEP area did not change. In contrast, for the antagonist muscle biceps femoris, MEP area decreased 46% from 46±21 to 25±12 mVms ($p<0.01$) and TMEP area decreased 66% from 17±12 to 6±3 mVms ($p<0.05$). Conclusion. Thus, as previously seen, excitability of motor cortex related to the agonist muscle increased during a fatiguing maximal contraction despite the fall in agonist EMG. For the antagonist muscle, falls in the EMG, TMEP and MEP indicate that net excitatory drive to the motoneurones decreased. We propose that the fall in antagonist motoneurone activity suggests that descending drive to the agonist muscle is also reduced during a sustained fatiguing maximal effort. References Levenez et al. Title: Interactions between I-waves in human motor cortex

Authors: ***M. A. SAVISKY**, J. CIRILLO, M. A. PEREZ;
Dept. of Physical Med. and Rehabil., Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Paired transcranial magnetic stimulation (TMS) applied over the motor cortex has been used to assess the temporal discharge of corticospinal volleys in surface electromyographic recordings in intact humans. Although indirect (I) wave volleys have been described at rest and during voluntary activity, little is known about the interactions between early and late volleys. Here, we used paired-pulse TMS over the hand representation of the motor cortex at a range of interstimulus intervals and intensities to assess the latency, amplitude, and duration of I-waves (I1, I2, and I3) in the first dorsal interosseous muscle across multiple trials. We demonstrate that I-waves occurred at consecutive intervals of around 1.5 ms (I1=1.37±0.10 ms, I2=1.33±0.14 ms, I3=1.56±0.18 ms) and that the amplitude and duration of the I3 (171±23 %, 0.45±0.14 ms) was lower than those of the I1 (234±75 %, 0.57±0.15 ms) and I2 (204±42 %, 0.60±0.20 ms). The variability between trials for latency (I1=0.03±0.09 ms, I2=-0.01±0.08 ms, I3=0.08±0.21 ms), amplitude (I1=-1.68±49.09 %, I2=12.64±29.51 %, I3=-1.78±21.05 %), and duration (I1=0.02±0.20 ms, I2=-0.04±0.27 ms, I3=-0.04±0.15 ms) was similar across I-waves. The amplitude but not latency and duration of successive I-waves correlated with that of the

preceding I-wave. I3 and I1 amplitudes were also correlated. Our findings provide evidence for a specific relationship between consecutive I-waves amplitude in humans, although a different configuration exists among late and early I-waves. Thus, our results argue against the possibility that the generation of I-wave periodicity involves a neural oscillator model, but instead it might result from a combination of neuronal elements with fixed and independent temporal characteristics.

Title: The influence of spontaneous movement tempo on motor resonance during action observation

Authors: *M. BOVE, G. LAGRAVINESE, A. BISIO, L. PERASSO, P. RUGGERI, L. AVANZINO;
Univ. of Genoa, Genoa, Italy

Abstract: Previous studies have shown that during action observation (AO) we use specialized motor representations to understand the observed actions. The higher is our motor familiarity with the observed action the more the “mirror system” is active. Thus, the observation of action involves matching to the individual’s motor repertoire. In this context, a question that remains still open is whether the temporal aspects of the subjective motor repertoire can influence the “mirror system” in the process of recognizing a certain movement. Our motor repertoire includes over-learned movements, that are well characterized in terms of temporal organization and it has been shown that, during the execution of a number of voluntary movements, healthy subjects have a common spontaneous movement tempo (SMT) ranging around 2Hz. To elucidate the influence of SMT in AO, in a first experiment we investigated the excitability of the left primary motor cortex (M1) during the observation of videos showing a right hand performing repetitive finger opposition movements at a rate similar to, lower or higher than the spontaneous one (i.e., 2Hz). As a result, we found that, during the 2Hz video presentation, left M1 excitability was increased more than during a video showing finger movements performed at a rate lower or higher than 2Hz. Starting from the notion that the motor evoked potential (MEP) facilitation is

considered evidence of motor resonance effects, here we demonstrated that motor resonance is influenced by the temporal properties of the observed movements (temporal motor resonance). To better address this last assumption we designed a second experiment aimed to (i) modify the SMT by a training based on AO and (ii) evaluate whether and how this training could affect the temporal motor resonance of the left M1. Here, we hypothesized that if the execution-observation matching system selectively recognizes the 2Hz rate as the SMT for finger movements, a training based on the observation of a 10-minutes video showing finger movements performed at a rate higher than 2Hz (3Hz video) could modify the SMT and consequently the temporal motor resonance. The results of this second experiment showed that training induced a shift of the SMT towards 3Hz and this was associated with changes in left M1 excitability during AO. Indeed, the MEPs collected during the 2Hz video presentation after the training were less facilitated than those collected in the same condition before it. Our results suggest that during AO the temporal properties of a movement are recognized and that the temporal motor resonance can be modulated by means of an AO training.

Title: Effects of concussion on motor cortex inhibition: A one-year follow-up

Authors: *A. L. YASEN, N. R. MILLER, L. F. MAYNARD, A. D. CHRISTIE;
Human Physiol., Univ. of Oregon, Eugene, OR

Abstract: In a previous study, we documented greater intracortical inhibition in acutely-concussed individuals, which did not recover to control levels two months post-injury. The time course of recovery of inhibition, therefore, remains unclear. As such, in the current study we re-evaluated motor cortex function in concussed participants at one year post-injury to determine recovery of cortical excitability and inhibition. Five concussed (20.2 ± 0.8 yr; 3 females) individuals, who had previously been tested at 72 hours and two months post-injury, returned for assessment one year following injury. Cortical excitability of the first dorsal interosseous (FDI) muscle was assessed through the resting motor threshold (RMT) using transcranial magnetic

stimulation (TMS). Intracortical inhibition was assessed in the FDI through the duration of the cortical silent period (CSP), obtained with a TMS pulse delivered at 120% RMT during an isometric contraction at 50% of maximum EMG activity. RMT values were higher at the 72-hour time point than at the two month time point (effect size (ES)=0.84) and the one year time point (ES=1.04). However, there was no difference in RMT between two months and one year post-injury (ES=0.05). As noted in our previous study, there was no difference in CSP duration in concussed individuals between 72 hours and 2 months post-injury (ES=0.37). However, at one year post-injury, CSP duration was shorter than both the 72-hour (ES=0.48) or two month (ES=0.94) time point. These results suggest that although cortical excitability is acutely affected by concussion, it appears to resolve within two months and is maintained at one year post-injury. Although inhibition of the motor cortex remains elevated up to two months post-injury, it appears that this enhanced inhibition is resolved within one year after injury.

Title: Neural network model including muscle synergies constructed based on redundant motor control simulation

Authors: *S. HAGIO[1,2], M. KOUZAKI[1];
[1]Grad. Sch. of Human and Envrn. Studies, Kyoto Univ., Kyoto, Japan; [2]Res. Fellow of the Japan Society for the Promotion of Sci., Tokyo, Japan

Abstract: Introduction The concept of muscle synergies has been proposed to simplify redundant motor control by low-dimensionally organizing functionally similar muscles (Hagio and Kouzaki, 2014; Tresch et al, 1999). However, muscle synergies remain no more than conjecture, and it is necessary to examine the interaction between synergies and neurons in the neural circuitry and the contributions of synergies to motor control, such as motor learning. The purpose of this study was to construct neural network model including muscle synergies.

Methods The neural network model including 3 intermediate layers was constructed based on the previously used model (Hirashima and Nozaki, 2012). We assumed isometric force-generation around right wrist on a horizontal plane (elbow and shoulder joint flexion angles: 90°and 30°, respectively). The first intermediate layer contained 1000 neurons in the primary motor cortex (M1). Each neuron received a desired shoulder flexion and/or elbow flexion torque vectors from the input layer with a synaptic weight (W_{neu}). These M1 neurons were connected to the second intermediate layer that indicated the muscle synergies with a uniformly distributed constant innervation. Therefore, we assumed that muscle synergies were intermediate neurons in the spinal cord: the connections between M1 neurons and muscle synergies were cortico-spinal pathway. The muscle synergies controlled 26 muscles spanning elbow and shoulder joints with a synaptic weight (W_{syn}) in the third intermediate layer. The muscle mechanical pulling vector was determined by physiological parameter of each muscle. An error back-propagation algorithm (Rumelhart et al., 1986) was successively used to modify W_{neu} and W_{syn}. The network was trained to produce appropriate output torque by randomly presenting 12 target torques, which were uniformly distributed on the two joint torque plane with the same intensity. The experiment was additionally conducted, which required the same task as above (5 repetitions in one direction). We then extracted muscle synergies by 8 recorded muscle activities using non-negative matrix factorization (Lee and Seung, 1999). **Result & Discussion** At least 4 synergies were required to appropriately produce the desired torques. The synaptic weights (W_{syn}) between synergy and muscle layers were similar to the extracted muscle synergy weightings in the experiment, when we assumed 4 synergies (the 26 muscles in the model were grouped into 8 groups). Therefore, we could construct the neural network model including muscle synergies, which demanded the similar muscle activations in the actual neural circuitry to achieve the desired torques.

Title: Is there a link between pre-synaptic inhibition and muscles mechanics?

Authors: *F. CREVECOEUR, S. H. SCOTT;
Ctr. For Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: A large literature documents the presence of inhibitory interneurons in the spinal cord forming axo-axonic connections with sensory afferents. This pre-synaptic inhibition is known to be active during voluntary movements and is hypothesized to filter relevant information during movement control. However, it also synapses onto motoneurons and reduces the gain of sensory feedback. Notably, recent work emphasizes that removing this set of interneurons results in oscillations during reaching but not during postural control in rodents (Fink et al., Nature, 508:43-48), suggesting that pre-synaptic inhibition plays a central role during control. However, this role remains unclear and the reasons why motor deficits were induced during reaching and not postural control remains to be elucidated. There is also a large literature illustrating that muscle exhibit dramatic changes in intrinsic elastic properties between posture and movement. Muscles generate high resistive force when stretched over a short range (high stiffness), which drops by an order of magnitude when muscles are stretched beyond ~2.5% of their initial length (low stiffness). This drop in stiffness also occurs when we generate movement. Here, we hypothesize that the pre-synaptic inhibition and changes in muscle stiffness are intimately linked, such that spinal feedback processes complement the mechanical properties of muscles. Specifically, high stiffness during posture can support higher direct feedback gains without compensating for temporal delays, whereas the presence of low stiffness during movement requires a reduction of these control gains to avoid oscillations or instability. This relationship also suggests that reducing spinal feedback during movement requires a greater reliance on internal models expressed by supra-spinal circuits in order to handle low stiffness and larger sensorimotor delays. Further, we present simulations highlighting two sources for the generation of oscillatory behavior when pre-synaptic inhibition is removed. First, oscillations can occur because spinal gains adequate during posture become too high during movement due to the change in muscles properties. A second possible source of oscillations upon removal of pre-synaptic inhibition is the mismatch between expected and actual spinal feedback, which can destabilize long-latency (cortical) control as a consequence of internal model error. To summarize, we suggest that control solutions of spinal and supra-spinal pathways are partially shaped by muscles thixotropic properties and account for changes in muscles biomechanics occurring between posture and movement tasks.

Title: Common low-frequency dynamics in movement and sleep

Authors: *A. JACKSON, T. M. HALL, F. DE CARVALHO;
Instit of Neurosci., Newcastle Univ., Newcastle-upon-Tyne, United Kingdom

Abstract: It has been known for over a century that upper-limb movements are often composed of discrete submovements, but the origin of this intermittency remains unclear. While neural correlates of submovement frequencies around 2-3 Hz can be found in the primary motor cortex (M1), the temporal profile of movement kinematics is usually assumed to be determined by extrinsic factors such as limb biomechanics and sensory feedback delays. However, another possibility is that movement intermittency arises from intrinsic rhythmicity in motor networks generating low frequencies in behavior. Delta activity recorded in the electroencephalogram during slow-wave sleep and from isolated cortical slices points to the existence of neural oscillators at frequencies similar to those found in behavior. However, to our knowledge the low-frequency dynamics of brain activity during movement and sleep have not been directly compared. We therefore used chronic multi-electrode arrays to record neural activity and local field potentials (LFPs) from M1 and ventral premotor cortex (PMv) in monkeys during an isometric movement task, natural sleep and ketamine sedation. We used principal component analysis to project the low-frequency LFP onto a plane, and observed cyclic trajectories in M1 that were phase-locked to each submovement. The areal velocity of trajectories increased for faster submovements, but the angular frequency remained constant at around 3 Hz. During sleep, LFP activity traversed cycles with the same frequency and direction of rotation (albeit with larger amplitude) and under ketamine sedation these were phase-locked to K-complexes occurring at the transition from down- to up-states of the cortex. Neural activity was locked to LFP cycles within the same cortical area under all behavioral conditions, and became synchronized across areas during sleep and sedation. Since the same cortical dynamics are observed during movement and in the absence of behavior during sleep and sedation, we suggest that the motor networks controlling the upper-limb possess intrinsic, low-frequency rhythmicity.

In the awake state, periodic descending drive from M1 constrains the temporal structure of tracking movements, while widespread synchronization across cortical areas generates the well-known delta rhythms associated with slow-wave sleep.

Title: Distinct interneuronal networks influence excitability of the surround during movement initiation in humans

Authors: N. THIRUGNANASAMBANDAM[1], R. KHERA[1,3], H. WANG[1,4], S. KUKKE[1,5], *M. HALLETT[2];
[1]NINDS/NIH, Bethesda, MD; [2]Human Motor Control Sec, NINDS/NIH, BETHESDA, MD; [3]Univ. of Iowa Carver Col. of Med., Iowa City, IA; [4]Peking Union Med. Col. Hosp., Beijing, China; [5]Catholic Univ. of America, Washington, DC

Abstract: Surround inhibition (SI) is a feature of motor control for which the physiology is still unknown (Beck and Hallett, 2011). This phenomenon is impaired in patients with focal hand dystonia (Sohn and Hallett, 2004, Beck et al. , 2008) and hence it becomes relevant to study it more in detail. Several studies have demonstrated SI in the human motor system using transcranial magnetic stimulation (TMS) (Beck et al. , 2008, Sohn and Hallett, 2004, Kassavetis et al. , 2012). In all these studies SI was measured by applying a single suprathreshold TMS pulse during the movement initiation phase. The figure-of-eight coil was positioned such that it induced current along the postero-anterior (PA) direction in the brain. We were interested to study SI not just at a single intensity, but at intensities ranging from sub-threshold to supra-threshold levels. Also, we wanted to explore if SI could be elicited when the motor cortex was stimulated along other directions (antero-posterior (AP), latero-medial (LM)). Fifteen healthy volunteers participated in the study. Their task was to perform a brief isometric index finger flexion on hearing a tone. EMG was recorded from the first dorsal interosseous (active) and the abductor pollicis brevis (surround) muscles. Single-pulse TMS was applied at intensities ranging

from 20% to 100% of maximum stimulator output at 5% intervals either before the tone (rest) or after the tone ~50 ms before expected onset of muscle activity (SI). The MEP amplitudes were then plotted against stimulation intensities to obtain the MEP recruitment curves for the rest and SI conditions separately. The recruitment curves were plotted with the coil held in three directions for every subject. We found that SI can be elicited when the coil was positioned in the P-A direction. Stimulating the motor cortex along the A-P direction did not elicit SI, rather showed surround facilitation. LM stimulation elicited inhibition non-specific to the surround muscle. We can therefore conclude that SI can be elicited in those neuronal groups that can be stimulated best along the PA direction. The clinical relevance of surround facilitation needs further exploration.

Title: Representing the dynamic effects of neural populations in the motor system

Authors: *T. D. SANGER[1], S. F. GISZTER[2];
[1]Biomed. Engin., USC, Los Angeles, CA; [2]Neurobio., Drexel Univ., Philadelphia, PA

Abstract: We have developed the theory of "Stochastic Dynamic Operators" in order to describe the effect of populations of neurons on dynamical motor behavior. SDOs are the equivalent of a state-dependent spike-triggered average, but they operate on probability distributions. As a result, SDOs have the following properties: Linearity: The effect of populations of neurons can be predicted by adding the operators for each neuron. Stability: Different stability types

including point attractors and cyclic pattern generators can be modeled. Interconnectivity: The effect of neurons on other neurons can be modeled using the same methods. Reflex Response: State-dependence of action means that reflexes can be easily described. Measurability: Quantitative predictions of operators can be derived from standard datasets. Controllability: Once estimated, operators can be selected to achieve real-time control, either by emulating control on a robot or by modulation of populations of neurons with known responses. We recorded from 8 well-isolated units on each of 6 tetrodes implanted in the lumbar spinal cord of decerebrate frogs during reflex wiping movements triggered by skin stimulation. EMG was recorded for 10 minutes from 10 hindlimb muscles. The position and velocity of the ankle were recorded. SDOs were calculated from the firing pattern of each cell and the immediately preceding and following kinematic variables (position and velocity) and EMG. SDOs were also calculated that related the firing of each cell to the preceding and following firing of the other recorded cells. We found subsets of cells that had different effects on the dynamics. Certain cells appear to cause a relatively pure translation, whereas others appear to stabilize at specific positions or velocities. Certain cells appear to either increase or decrease EMG, while others appear to stabilize EMG at intermediate values. When a cell was found whose firing was related to the modulation of other cells, the SDOs could be compared. In particular, we found examples where cell A appeared to modulate the firing of cells B and C, and the effect of cell A on EMG (estimated from its SDO) was well-predicted by the combined effect of cells B and C, consistent with cell A exerting its effect at least partially through modulation of cells B and C. Therefore stochastic dynamic operators appear to be a new and highly useful tool for understanding the effect of individual cells and populations of cells on movement. This theory extends the basic techniques of spike-triggered averaging and peri-stimulus-time histograms to be directly applicable to cells that have both sensory tuning and motor effects.

Title: Latency of LFP beta power peak during movement preparation correlates with reaction time

Authors: *L. ZEHL[1], M. DENKER[1], S. GRÜN[1,2,3], A. RIEHLE[4,1,3], T. BROCHIER[4]; [1]Inst. of Neurosci. & Med. (INM-6), Inst. for Advanced Simulation (IAS-6), Jülich Res. Inst., Wako-Shi, Japan; [4]Inst. de Neurosciences de la Timone (INT), UMR 7289, CNRS – Aix Marseille Univ., Marseille, France

Abstract: Beta oscillations (15-30 Hz) are a prominent feature of neuronal population signals recorded in the sensorimotor cortex during motor behavior [rev.: Kilavik et al, Exp Neurol 245:15 (2013)]. They have been extensively studied in instructed delay tasks in which a cue provides prior information about the movement to be performed after a GO signal presented at the end of the delay. In such tasks, beta power often exhibits an initial peak of high power shortly after the cue presentation, then decreases during the delay and is lowest during movement execution. It was proposed that the pre-movement decrease in beta power is related to an increased activity in motor cortex related to the upcoming movement execution [e.g. Kilner et al, Eur J Neurosci 21:2547 (2005)]. Thus, we aim to test the hypothesis that the temporal profile of beta power modulations during movement preparation correlates with behavioral measures of the movement. To address this issue, we here analyze how reaction time (RT) as a behavioral measure relates to the modulations of motor cortical LFP beta power in monkeys trained to perform a delayed reach-to-grasp task. In this task, a cue instructs to use either a precision grip (PG) or a side grip (SG) to grasp an object. After a fixed delay of 1 s, the GO signal provides additional information about the object load and instructs the monkey to grasp the object, pull it and hold it in a narrow position window for 500 ms to receive a food reward. In the reverse task, the object load is provided first. Neuronal activity was recorded by using a 100 electrode "Utah" array, chronically implanted at the MI/PMd border. We quantify the beta power using the amplitude of the analytic signal of the beta filtered LFP and confirm that the averaged time course of beta power across trials shows the described temporal profile of power modulations. On a single trial basis, we find that the beta profiles indeed vary with RT. When the cue provides information about the grip, we observe that for short RTs (<200 ms) the initial power peak during the delay appears earlier than for long RTs (>400 ms), and find that the latency of the power peak significantly correlates with the RT. In addition, in trials with short RTs the power for PG is on average larger than for SG. In contrast, in trials with long RTs both grip types exhibit similar power profiles. Finally, in the reverse task, the profiles during the preparatory period do not correlate with the RT and are independent of the grip type. Based on these

findings, we suggest that the power peak during the delay period reflects processes which are functionally related to movement planning and affected by the characteristics of the upcoming movement such as the selected grip type.

Title: Sequence generation within spatio-temporal cycles of inhibition

Authors: ***J. CANNON**, J. MARKOWITZ, N. KOPELL, T. GARDNER;
Boston Univ., Boston, MA

Abstract: Overview: We propose a theory for robust sequence generation in neuronal networks. In previous papers, rhythmic neural activity has been characterized as counterproductive for reliable sequence generation [1]. In our model, rhythm plays a key role in sequence generation. The model is based on two recent observations in songbird premotor cortex: (1) interneuron and principal cell activity are locked to different phases of the 25-35 Hz band of a stereotyped LFP [2], and (2) principal cells are strongly coupled via disynaptic inhibition [3]. In the model, long sequences of principal cells fire within the constraints of larger-scale inhibitory network dynamics. When principal cell activity reaches a cortical subregion, it triggers strong, locally diffuse feedback inhibition on a 30ms time scale. The feedback quickly suppresses local activity, but other cortical subregions are disinhibited at any given time, allowing activity to continue and propagate from one subregion to the next as each becomes disinhibited. Results: Due to this spatio-temporal coordination, the timing of sequence playback is robust to noise and to various

perturbations even in the absence of redundant feed-forward connectivity, making the model fundamentally distinct from the synfire chain. We draw on the theory of discrete dynamical systems to analytically demonstrate timing stability. We also present preliminary simulations that show that the proposed mechanism produces long, stereotyped sequences even when the connections between principal neurons are randomly generated. The model concisely accounts for the observed single-cell and network-level dynamics in songbird, and can be generalized to provide a similar explanation for traveling waves observed in primate motor cortex. Title: Spatiotemporal properties of current source density in the prefrontal cortices of behaving monkeys

Authors: *N. KAWAGUCHI[1,2], K. SAKAMOTO[3], K. YAGI[2], M. AOKI[1], H. MUSHIAKE[2,4]; [1]Dept. of Neurol., Tohoku University, Sch. of Med., Sendai, Miyagi, Japan; [2]Dept. of Physiol., Tohoku Univ. Abstract: Various types of information are integrated and processed in the prefrontal cortices (PFC), and thus exploring the input-output properties of the neuronal networks is fundamental to

understand mechanisms underlying the function of the PFC. However, it has been technically difficult to examine synaptic inputs into neuronal circuits of behaving animals. Recent development of multi-contact electrodes allow us to evaluate the synaptic inputs by current source density (CSD) analysis of local field potentials (LFPs) in addition to recording spikes. We conducted CSD analysis on LFPs recorded in the PFC during monkeys performing a shape manipulation task. We observed task-dependent spatiotemporal patterns of current sinks, which were considered to reflect the synaptic inputs to neurons adjacent to the recording sites. Specifically, the current sinks in the inferior convex of the PFC were observed during the delay period, whereas the current sinks in the principal sulcus were observed selectively during the sample cue and test cue periods. We found tangentially periodic patterns of current sinks, which appears to correspond to the columnar structures suggested in the PFC microcircuits. The input-output properties revealed by the CSD analysis will elucidate how the PFC plays executive roles in terms of local neural networks.

Title: Children with autism show decreased cortical activation with praxis movements

Authors: ***J. B. EWEN**[1], B. M. LAKSHMANAN[2], C. NETTLES[3], M. HALLETT, MD[4], N. E. CRONE[5], S. H. MOSTOFSKY[3];
[2]Neurol. and Developmental Med., [3]LNIR, [1]Kennedy Krieger Inst., Baltimore, MD; [4]Motor Control Lab., NINDS/NIH, Bethesda, MD; [5]Neurol., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Objective: While altered cerebral connectivity has long been a dominant systems-level theory in the pathophysiology of autism spectrum disorders (ASD), relatively little is known

about the role of altered local cortical functioning. We leveraged the ability of EEG to record oscillatory activity involved in cortical function: theta (3-7 Hz), alpha (8-12 Hz) and beta (13-30 Hz). Individuals with ASD have well documented deficits in complex motor control, such as imitation and praxis. Praxis competence correlates with social and communicative abilities in ASD. Because the motor network is particularly well mapped, examination of motor function in ASD provides a clear window into abnormalities of brain function. We hypothesized that children with ASD would demonstrate alterations of event-related power modulation associated with performance of a praxis task. Methods: In 17 children with ASD (ages 8-12y) and 25 typically developing (TD), age-/sex-matched controls, we recorded full-scalp EEG while the children performed a task in which they pantomimed the use of 12 different tools with their right hands. The task included a preparation phase and a gesture execution phase. Event-related desynchronization (ERD) refers to a task-related decrease in the power in a specific frequency band, whereas event-related synchronization (ERS) refers to an increase. We examined ERD/S in the three frequency bands, at left central and posterior (parietal/occipital) sites: regions known to be associated with praxis function. Results: Compared with controls, children with ASD demonstrated less ERD: 30% less left central beta ($p = 0.005$) and 43% less left posterior alpha ($p = 0.006$) ERD during the preparation phase, as well as 33% less posterior alpha ERD ($p = 0.048$) during the execution phase. Other comparisons did not show significant differences. It is meaningful that alterations of beta ERD were seen at central sites, given the known role of beta in motor function. Similarly, alpha ERD has a role in visual function.

Title: Development of functional mu-rhythm from infancy through adulthood, and relations to upper/lower alpha

Authors: *S. G. THORPE, E. CANNON, N. FOX;
Dept. of Human Develop. and Quantitative Methodology, Univ. of Maryland Child Develop. Lab., College Park, MD

Abstract: Previous EEG/MEG studies with infants and children have established that a developmental analogue of adult occipital alpha-rhythm is present in lower frequency bands which increase with age towards the 8 - 13 Hz band typically seen in adults. Additional studies have described a functionally distinct rhythm observable at central electrodes at frequencies overlapping the developing alpha band. This infant/child central rhythm has been shown to desynchronize during voluntary motor acts, and so shares some topographic and functional properties with adult mu-rhythm, with which it has been proposed to be analogous. In this study we characterize the evolving properties of mu and alpha rhythms in three subject populations consisting of 12-month old infants, 4-year old children, and mature adults. We show that EEG for all subject groups contains spectral peaks evident in both the lower and upper developing alpha band, and that spectral and topographic properties of functionally identified mu rhythm (characterized by desynchronization during voluntary reaching/grasping movement) strongly reflect those of upper alpha in all subject groups. We also investigate structural development of mu-rhythm via sLoreta source reconstructions and show that the distribution of cortical desynchronization observed during movement becomes more focal to central and parietal cortices with age. These results provide insight into the developmental trajectories of the upper and lower alpha bands, as well as compelling evidence that the status of infant/child central rhythm as analogue of adult mu should no longer be considered ambiguous.

Title: Modulation of tactile sensory responses during a sensory-triggered decision task in mouse forepaw primary motor cortex

Authors: *L. ESTEBANEZ, J. POULET;
Max Delbrück Centrum, Berlin, Germany

Abstract: M1 fires action potentials during voluntary movement but also to sensory stimulation. Here we address the function of sensory responses in M1 by developing a sensory triggered reach-and-press task in the awake, head-restrained mouse. Mice were trained to respond to a brief vibrotactile stimulus of the forepaw with a quick reaching movement of the same paw (<500ms) from a "rest" sensor, positioned under the mouse, to a "reach" sensor, positioned in front of the mouse. A "no-reach" task was interleaved with the "reach" task where the mouse learnt to withhold reaching after the same stimulus in a different context. Mice learned to perform hundreds of accurate reaches in less than 10 days of training (two 20 min sessions a day). Extracellular polytrode recordings were performed in forepaw M1 layer V in parallel with forepaw camera tracking at 200Hz. During the task, a large proportion of neurons displayed short latency spiking following the vibrotactile stimulus onset. The strength of firing to the stimulus was often different in reach trials as compared to no-reach trials.

Title: Analysis of electrode configurations for the decoding of knee angles from EEG signals during gait

Authors: *J. M. AZORIN, A. UBEDA, D. PLANELLES, A. COSTA, E. HORTAL, E. IAÑEZ;
Miguel Hernandez Univ. of Elche, Elche, Spain

Abstract: Although walking is automatically based on reflexes governed at the spinal level, there are evidences that suggest that the motor cortex is particularly active during specific phases

of the gait. In this work, we analyze the influence of walking speed by decoding knee angles from low frequency EEG components. Linear regression models are applied to show significant correlations between actual and decoded angles while different walking speeds are performed. To that end, three healthy subjects were asked to walk on a treadmill with three different speeds: 2, 3 and 4 km/h. Eight sessions were performed with one minute walking for each speed. Three different electrode configurations have been applied with 8, 16 and 32 electrodes distributed mainly over the motor cortex. Frontal electrodes were discarded and blinks were manually rejected. Afterwards, EEG signals and knee angles were simultaneously recorded. The EEG signals were filtered below 2 Hz and standardized. Knee angles were also standardized. The decoding method is based on a multidimensional linear regression. The decoding correlation coefficient was computed by applying an 8-fold cross-validation for each speed and electrode configuration. The results of the decoding performance show improvements when the number of electrodes increases (see Figure). The decoding performance is also affected by speed. For Subject 1 and 2, the decoding correlation coefficient significantly increases when the gait speed decreases. This is not so clear for Subject 3. However, future tests with more subjects will serve to generalize these preliminary results. This study has shown significant decoding correlations in the reconstruction of knee angles from low frequency EEG components. It has been also proved that the number of recorded electrodes affects the final decoding performance.

Abstract: Amyotrophic lateral sclerosis (ALS) is a degenerative motor neuron disease causing paralysis and progressive degeneration of muscles, and it can lead to the completely locked-in state (CLIS) that is characterized by total paralysis. Brain-Computer Interfaces (BCIs) have been used to allow paralyzed people to regain basic communication. Gallegos-Ayala et al. presented the case where an NIRS BCI led to communication with a completely locked-in patient, and here we report the brain communication in the patient using an EEG system. A CLIS ALS patient participated (68 y.o., female). We asked her to answer yes or no questions. The questions presented as auditory sentences, which were recorded with the voice of her husband. We presented 10-20 auditory sentences in one trial. Intersentence interval (ISI) was 25s. Two - 5 trials were conducted in each day, and we performed the experiment in 34 days. Two-channel (P3, P4) EEG data were recorded, and these channels were referenced to Fpz and grounded to AFz. The signal was notch-filtered at 50Hz, and digitized (Sampling rate: 500Hz) with a BrainAmp MR (Brain Products GmbH, Germany). Non-adhesive solid-gel EEG electrodes were used (Toyama et al. 2012). Thirteen-second EEG data (from 2 to 15sec after the auditory presentation) was analyzed. The EEG data was high-path filtered at 2 Hz, and the filtered data was used to compute power spectrum. Window size was set at 2 sec (1.5 sec overlapped), and the imaginary part of the power spectrum was averaged to drive features. For offline classification, we used support vector machine (L1 regularized L2 loss), and used a leave-one-out cross-validation method in each trial. When we created a representative feature vector from all data for the classification, the mean accuracy was 53.9%. When we created a best feature vector in each day, the mean accuracy increased to 74.1%, which was sufficient for practical use (>70%). These results suggest that the EEG system is possibly useful for communication in CLIS patients.

Title: Decoding of goal-directed behaviors from scalp electroencephalography (EEG) in freely behaving infants

Authors: *Z. R. HERNANDEZ, T. TSE, J. L. CONTRERAS-VIDAL;
Electrical and Computer Engin., Univ. of Houston, Houston, TX

Abstract: The human mirror neuron system (MNS) is thought to be critical for perceiving and later learning and imitating actions performed by others. Human sensorimotor alpha-band electroencephalographic (EEG) desynchronization at central electrodes, observed both during execution and observation of goal-directed actions (i.e., mu suppression), has been considered an electrophysiological correlate of MNS function. However, current methods of investigating mu-rhythm in MNS development rely on constrained experimental paradigms that have yet to fully represent the behavior of infants in an ecological setting. It is therefore important to redefine a paradigm that instead studies the human NMS under conditions where infants are free to evoke an action or behavior at his/her will. Furthermore, a mechanistic relationship has yet to be determined between EEG mu-rhythm and MNS function, and the extent to which EEG can be used to infer intent during MNS tasks remains unknown. We present a novel methodology using active EEG and inertial sensors to record brain activity and movement from freely behaving 6-24 month old infants during interaction with an adult actor in the context of MNS tasks, including exploration, imitation, attentive rest, pointing, reaching-to-grasp, and reaching-to-offer an object. Multiple time lags of delta-band (1-4Hz) EEG were extracted as features to a machine learning algorithm that first reduced feature dimensionality (locality-preserving Fisher's discriminant analysis, LFDA) in order to construct a model (Gaussian mixture models, GMMs) for decoding each MNS task. Here, we present decoding results and analysis of potential motion artifacts that illustrate our approach and demonstrate the feasibility of EEG-based classification of freely occurring MNS behaviors displayed by infants. These results provide an alternative and novel paradigm and computational analysis to the mu-rhythm theory of MNS function and further indicate the informative nature of EEG in relation to the intentionality (goal) of each MNS task,

which may support action understanding and thus bear implications for advancing the understanding of MNS function.

Title: High Density Electroencephalography (EEG) correlates of pain- related changes in upper limb movements

Authors: *G. MISRA, E. OFORI, J. CHUNG, S. A. COOMBES;
Applied Physiol. and Kinesiology, Univ. of Florida, Gainesville, FL

Abstract: The experience of pain changes the way we execute movements. While much work has focused on mechanisms in the spinal cord and muscle, very little is known about how the brain controls movement in painful contexts. There is a long history of using Electroencephalography (EEG) recordings to study the brain oscillations associated with movements and the brain oscillations associated with pain processing. In the current study, we build on this literature by identifying brain oscillations that are associated with pain-related changes in upper limb movements. We employed high density EEG to examine electro-cortical dynamics while participants produced visually guided ballistic upper limb movements under two stimulation conditions: while feeling a pain-eliciting thermal stimulus on the bicep of the moving arm (PAIN) and while no stimulus was delivered/felt (CONTROL). Significant reductions in reaction time and significant reductions in error were found for the PAIN condition as compared to the CONTROL condition, revealing that movements were faster and more accurate when coupled with a pain-eliciting stimulus. Compared to the CONTROL condition, movements in the PAIN condition were associated with increased alpha de-synchronization in sensorimotor regions and increased alpha and beta synchronization in dorsolateral prefrontal regions. Our findings demonstrate that pain driven changes in movement are associated with cortical oscillations that vary systematically across region and frequency.

Title: EEG correlates of a prospective sense of agency

Authors: *N. SIDARUS, P. HAGGARD;
Inst. of Cognitive Neuroscience, UCL, London, United Kingdom

Abstract: Sense of agency (SoA) refers to the feeling that we are in control of our own actions and, through them, of events in the outside world. One influential view claims that the SoA depends on a retrospective matching between the expected and actual outcome of an action. However, recent studies have revealed an additional, prospective component to the SoA, related to action selection. The present study aimed to clarify the neural mechanisms of this prospective mechanism by means of event-related potentials (ERPs). Participants responded to imperative left/right arrow stimuli that were preceded by either a compatible or an incompatible subliminal prime. After a variable delay, action outcomes were displayed, and subjective agency ratings were collected. Results show that compatibly primed actions led to a stronger SoA over action outcomes, relative to incompatibly primed actions. Target-locked lateralised readiness potentials were positively associated with subjective agency ratings in compatibly-primed trials. Action priming did not influence outcome-locked ERPs. Thus, replicating previous studies, we found that an unconscious influence on action selection processes can affect the conscious experience of agency. These findings also suggest that a metacognitive signal related to action selection fluency can prospectively inform the SoA. This signal is related to activity in the brain's motor

system. Furthermore, the influence of this prospective, fluency-based, component on SoA is independent from retrospective outcome monitoring.

Title: Three-class classification of motor imagery EEG data including “rest state” using Common Spatial Pattern

Authors: ***T. SHIRATORI**[1], H. TSUBAKIDA[1], A. ISHIYAMA[1], Y. ONO[2];
[1]Waseda Univ., Tokyo, Japan; [2]Meiji Univercity, Kanagawa, Japan

Abstract: Our purpose is to develop the 3-class Brain Machine Interface (BMI) incorporating the classification of resting state using Electroencephalography (EEG). The 3 classes we defined in this experiment were (1) motor imagery of moving right hand, (2) motor imagery of moving left hand, and (3) rest state. Conventionally the most of BMI systems only accept EEG data when a subject performs some kind of task, such as motor imagery and gaze at visual stimuli. However, performing task causes fatigue of the subject. It is therefore important to develop classification algorithm for BMI system that utilizes rest state-EEG as one of the classes. Eight healthy young subjects (20-25 years old) participated in the study. We measured their EEG signals from 15 electrodes distributed over the scalp, sampled at 125Hz.Subjects looked at the computer screen in front of them during the whole experiment. The screen alternately showed an instruction (4s) and a fixation point (3s) for 60 times. An instruction of single state among the three states was displayed at the beginning of instruction display for 1s, and count-down displayed for 3s. After count-down subject performed the instructed state for 3s. Subject performed three kinds of states each for 20 times. We extracted feature vector using FIR filter and Common Spatial Filter (CSP) from EEG data, and made three 2-class classifiers (1-vs-2, 2-vs-3, and 3-vs-1) using Gaussian kernel Support Vector Machine (SVM). Majority voting among the classified results from 2-class classifiers decided the final output of the 3-class classifier. Mean accuracy rate of 2-class classifier was 69.1±7.6%(1-vs-2), 74.1±.5.0%(2-vs-3,), 69.4 ±6.0% (3-vs-1), the developed 3-class classifier was 54.8±8.8%.Result indicated that mean accuracy rate of 2-class incorporating resting state classifier is equivalent to 2-class motor

imagery classifier. Mean accuracy rate of 3-class classifier suggested that mean accuracy rate of proposal method is higher than our previous paper(42.9±0.72%).

Title: On the potential effects of motion artifacts during decoding of lower-body movement kinematics from scalp electroencephalography (EEG)

Authors: *J. L. CONTRERAS-VIDAL, Ph.D., K. NATHAN;
Electrical and Computer Engin., Univ. of Houston, Houston, TX

Abstract: Recent studies have questioned some conclusions drawn in previous studies on the delta-band EEG decoding of gait kinematics ([1] Castermans et al. Neurosci Lett., 2014, doi: 10.1016/j.neulet.2013.12.059) as well as the suitability of inferring movement kinematics using Wiener decoders ([2] Antelis et al. PLoS ONE, 2013, p. e61976). Unfortunately, there are severe methodological and theoretical flaws in [1]-[2] that in turn invalidate their conclusions. Here we will discuss these pitfalls: a) Distortion of Measurement: In [1], the authors fixed a piezoelectric accelerometer to a large rigid plate mounted on a three-point linkage that was firmly strapped on top of the EEG cap donned by the subject. This large setup, of unknown but significant mass, and in contact with the EEG electrodes most likely introduced distortions in the measurements by introducing mechanical artifacts (non-existing during proper measuring techniques) directly to the EEG electrodes therefore violating good and common measuring practice in instrumentation and measurement; b) Theoretical pitfalls: In [2] the authors claim that low-frequency sinusoidal signals lead to overly optimistic correlation results and that this assertion is used to explain the positive correlation coefficients around 0.3 in random-chance models with shuffled and synthetic data. What [2] does not consider is the length of the signals under consideration (see http://www.plosone.org/annotation/listThread.action?root=69163 for full discussion), which was very short, about 3.75s. Moreover, a peculiarity in the results of [2] is that there are not roughly an equal number of positive and negative correlations in their chance-

level models questioning further their claims. Also, [2] did not filter out very low frequency noise. EEG exhibits 1/f noise, and, with very few exceptions, in decoding studies EEG data are high-pass filtered upon acquisition (~0.05 to .3 Hz). It is unclear how neglecting to high-pass the EEG data would affect decoding results; hence, confounding the results of [2]. Finally, neither [1] and [2] used active EEG systems which help minimize motion artifacts while increasing the signal-to-noise ratio. We have redone [1] with an appropriate set-up and experimental protocol that follow good standard measuring practices that shows that EEG decoding is not significantly affected by head/body motion. This research will be discussed in this presentation.

Title: Simultaneous scalp EEG and multiunit recording from monkey ventral premotor cortex reveals the contribution of mirror neurons to alpha and beta desynchronization

Authors: M. BIMBI[1], *G. COUDE[1], F. FESTANTE[1], R. E. VANDERWERT[2], N. A. FOX[3], P. FERRARI[1];
[1]Univ. Parma, Dept Neurosci., Parma, Italy; [2]Harvard, Cambridge, MA; [3]Univ. of Maryland, College park, MD

Abstract: Most of our knowledge of mirror neurons comes from single unit recordings, made in premotor and parietal cortices of the macaque monkey. On the other hand EEG studies in humans have shown significant desynchronization in the alpha (9-13 Hz) and beta (15-25 Hz) bands during observation and execution of actions, thus providing an indirect signature of the activity of mirror neurons. However, it is not known whether the activity of mirror neurons contributes to the observed EEG desynchronization. Here we used simultaneous EEG and multiunit recording to understand the link between these two signals. We first performed a series of extracellular multiunit recordings in two macaque monkeys, using 16-channel Plexon electrodes. We identified premotor cortical area F5 and the subsector where mirror properties could be recorded. We then simultaneously recorded scalp EEG using a 7-channel lycra cap and

LFP with a 9-channel probe inserted in the contralateral hemisphere. The task carried out by the monkey consisted of the observation of a grasping action done by an experimenter in front of the monkey. The ERDs analysis showed the presence of both alpha and beta band desynchronizations, during grasping observation, in both frontal and central regions, but not in the occipital one. A coherence analysis between EEG and LFP signals showed moderate values in the alpha band for frontal and central EEG regions, while high coherence values were observed for two very narrow bands centered on 20 Hz and 22 Hz for all LFP channels recorded. There was no significant coherence between occipital EEG and any LFP channels. These data, for the first time, show that activity of mirror neurons in F5 contributes to the desynchronization of the scalp recorded EEG signal from frontal and central sites, especially in the beta band.

Title: Decoded neurofeedback training for MEG/SSVEF

Authors: ***H. ORA**[1,2], K. KANSAKU[1,2];
[1]Sys. Neurosci. Sect., Dept. of Rehab. for Brain Funct., Res. Inst. of Natl. Rehabil. Ctr., Tokorozawa, Japan; [2]Brain Sci. Inspired Life Support Res. Ctr., The Univ. of Electro-Communications, Chofu, Japan

Abstract: Decoded neurofeedback method was recently proposed to lead brain activity to a target state (Shibata, et al., 2011). While researchers utilized functional magnetic resonance imaging in the former studies, little is focused on magnetoencephalography (MEG). Real-time magnetoencephalography (rtMEG) is an emerging neurofeedback technology that could potentially benefit multiple areas of basic and clinical neuroscience, and in this study, we used an

rtMEG system to perform decoded neurofeedback training for MEG/steady-state visual evoked field (SSVEF). Five able-bodied participants (age 33.2 years old, 5 females) participated in this study. The visual stimuli were displayed on a screen in front of the participant, and consisted of a circular checkerboard patch on the left and a circular checkerboard patch on the right. The checkerboard patches flickered at 5 (left) or 6 (right) Hz. They were asked to attend to the left, right, or middle of the screen in a SSVEF task. The used MEG scanner was a 306-channel Elekta Neuromag system (Elekta Oy, Helsinki, Finland). We constructed a sparse multinomial logistic regression (SMLR) decoder from MEG signals during the SSVEF task in each participant. We then conducted 3-day MEG neurofeedback training. In a trial, a white fixation cross was turned green for 5 second, then a green solid circle, whose radius indicated a score of the SMLR decoder, was presented. Participants were asked to "somehow regulate your brain activity to make the green solid circle bigger while the fixation cross is green." During the trainings, any flickering visual stimuli was not presented. After the trainings, the SSVEF task was used again to evaluate the training effects. The SMLR decoder was able to classify the MEG signals into 3 attentional directions (left, right or middle) (88.2 %). The participants were able to increase decoder scores through the trainings ($p<0.05$). In the post-training SSVEF task, accuracy for the target orientation was higher than that for the non-target orientation ($p<0.05$). The results suggest that the decoded neurofeedback training was effective for MEG/SSVEF, and the method may enhance robustness of steady-state visual evoked potential (SSVEP)-based Brain-Computer Interface (BCI).

Title: The performance of a SSVEP classifier under well-lit and dim-lit room environment

Authors: ***K. SAEKI**, Y. ONO, K. IKEMOTO, T. YOKOYAMA, T. URANO;
Sch. of Sci. and Technol., Meiji Univ. C/O Prof., Kanagawa, Japan

Abstract: Brain Computer interface (BCI) utilizes brain activity to operate external machine, which has a potential to allow people with severe motor disabilities to communicate. It is therefore important to investigate the usability of BCI system in the daily environment. We

investigated whether the difference in environmental brightness affect the performance of a steady-state visual evoked potential (SSVEP)-based BCI, which is one of the easy and promising techniques of BCI. Seven participants with normal or corrected-to-normal vision (21-35 years old, mean age 23.8) enrolled in the experiment. We recorded electroencephalogram (EEG) from the occipital area of O1, O2, and Oz according to the international 10-10 system. Participants watched one of the three white LEDs flickering at 6, 7, 8Hz arranged in front of them to enter a single command. Our in-house developed SSVEP-BCI system classified the EEG responses every 4s and gave feedback to them. Each participant was given a random sequence of 6 commands to complete, each of which corresponds to one of the three LED stimuli (For example, 6Hz>7Hz>8Hz>7Hz>6Hz>8Hz). The order of commands was randomized using Latin square. The total time required to complete the whole sequence was compared between when the BCI was operated in a well-lit environment (1455 lux) and in a dim-lit environment (4 lux). The mean durations to complete the sequence were 76.4±6.3s and 53.7±5.9s in a well-lit and a dim-lit room environments, respectively. The mean duration to enter single command was 12.7±1.1s and 8.9±0.9s in a well-lit and dim-lit room environments, respectively. Statistical analysis showed significant difference in these durations between both conditions (t-test, p=0.02). These results suggest that brightness of the environment influences the strength of SSVEP and affect the performance of SSVEP-based BCI system. Reduced contrast of stimuli might attenuate SSVEP response in a well-lit room. Enhancing local contrast of LED stimulus might improve the performance of the SSVEP-based BCI even in a well-lit room.

Title: Changing power spectrum of SSVEP in blinking

Authors: ***A. FUNASE**, I. TAKUMI;
Dept. of Computer science, Nagoya Inst. of Technol., Nagoya, Japan

Abstract: Purpose: Recently, many researchers develop Brain-computer interfaces by EEG signals. Especially, we focus on the BCI based on the steady-state visual evoked potential

(SSVEP). The BCI based on the SSVEP is some advantages against another types of BCIs. SSVEP is generated by an external visual stimulus and SSVEP has the same frequency as frequency of an external visual stimulus. Therefore, it is easy to observe SSVEP. However, it is difficult for subjects to watch only external visual stimulus during an experiment; for example, eye blinking. Therefore, power spectrum of SSVEP is changing during an experiment. In this research, we focus on power spectrum of the SSVEP before eye blinking and after eye blinking. Experimental task: The visual stimulus for generating SSVEP is a matrix LED. The matrix LED is illuminated like a checker-flag. Flicking frequency of the matrix LED is 15 or 20 [Hz]. Subjects are watched this matrix LED during 120 [sec] and are recorded EEG signals. Electrodes are attached according to international 10-20 system method and the number of electrode is 19. Sampling frequency of EEG amplifier is 1000 [Hz]. Subjects are five males. Results and Discussion: The figure shows the power spectrum of SSVEP (Frequency of visual stimulus is 15 Hz). Horizontal axis indicates time and vertical axis indicates the power of SSVEP. In this figure, frequency of the SSVEP is 15 Hz. From this result, firstly, power of the SSVEP has fluctuation and power of the SSVEP is non-stationary signals. Therefore, in order to analyze SSVEP, it is important to decide suitable window-size for analysis. Secondly, we compare power of the SSVEP before eye blinking to after eye blinking. After eye blinking, power of the SSVEP decreases because subject cannot watch visual stimulus. Then, power of the SSVEP increases in this figure. The average of power of the SSVEP after eye blinking is larger than the average of power of the SSVEP before eye blinking. This tendency is observed in the case of all subjects' experiments. Therefore, in order to develop the BCI based on SSVEP, we should focus on analyzing the SSVEP after eye blinking.

Title: SSVEP-BCI system with an supervised classification algorithm

Authors: *K. IKEMOTO, T. URANO, K. SAEKI, Y. ONO;
Sch. of Sci. and Technol., Meiji Univ., Kanagawa, Japan

Abstract: Steady-state visual evoked potential (SSVEP) is one of the easiest and promising techniques of brain-computer interface (BCI). Conventional classification algorithm using linear discriminant analysis (LDA) based on spectrum power of electroencephalogram (EEG) has disadvantages of low accuracy rate and the requirement of training data sets. We therefore developed an unsupervised classification algorithm of SSVEP-based-BCI, which uses features both from spectrum power of raw EEG data and from averaged EEG signals. Thirty-two participants with normal or corrected-to-normal vision (aged 21.09±2.80, 27 males and 5 females) enrolled in the experiment. We recorded EEG at O1, O2, and Oz in the international 10-10 electrode system. Subjects gazed at each flickering LED at 6Hz, 7Hz, or 8Hz for 28 seconds individually four times per frequency. Each EEG data were divided into seven 4 s-fragments. The developed method consists of two methods, Spectrum Method and Average Method. The developed method adopts Spectrum Method in case that signal-to-noise ratio of the spectrum power is large enough, and otherwise adopts Average Method. Spectrum Method detects the frequency which gives the maximum difference of spectrum power between maximum (±0.1Hz) and median (±0.8Hz) of each frequency band corresponding to the flickering light stimuli. Average Method detects the frequency which gives the largest peak-to-peak amplitude of visual evoked potential by dividing and averaging the raw EEG data with different cycles corresponding to the flicker frequencies. Both methods are applied to the data at each electrode and majority voting among the results at three electrodes determine the final output of the classifier. The mean accuracy in 3-class classification in the offline analysis was 75.1±3.1% with the developed algorithms, which was significantly larger than that using conventional Linear Discriminant Analysis (68.5±3.7%, $p<0.01$). In order to confirm the developed algorithm can achieve accurate performance online, the proposed algorithm was implemented as online BCI system working on a MATLAB Simulink. Seven participants with normal or corrected-to-normal vision (aged 21.43±1.19, 6 males and 1 females) enrolled in the experiment. Three LDAs flickering at 6Hz, 7Hz, or 8Hz were arranged on a breadboard and participant gazed at one of

them for four seconds 12 times per each frequency. The mean accuracy was 74.6±6.1%, which is comparable to the accuracy in the offline analysis. These results suggest that our proposed algorithm successfully implemented as online programs.

Title: EEG-based classification of video quality perception using steady state visual evoked potentials (SSVEP)

Authors: ***L. ACQUALAGNA**[1], S. BOSSE[2], A. K. PORBADNIGK[3], G. CURIO[4], K. R. MÜLLER[3], T. WIEGAND[2], B. BLANKERTZ[3];
[1]TU Berlin, Berlin, Germany; [2]Fraunhofer Inst. for Telecommunications, Berlin, Germany; [3]Technische Univ. Berlin, Berlin, Germany; [4]Charité, Berlin, Germany

Abstract: Current methods for video quality assessment mostly rely on behavioral ratings that are affected by subjective factors and have a high inter-subject variability. Recent studies investigate neural correlates of the perception of video quality to establish a direct measure. This approach capitalizes on the cognitive P3 component of the EEG. However, the P3 is not directly linked to the sensory process of the stimuli and requires a high amount of trails to provide a distinctive signal. Our approach exploits SSVEPs as EEG features to classify perceived quality changes. Besides, we correlate our results with the Mean Opinion Score (MOS) values that the subjects gave during the conventional behavioral assessment, using the Degradation Category Rating. Sixteen people participated in the experiment. Six gray-level texture images were chosen as the basis for stimuli generation and presented in six levels of distortion (D1, ⋯, D6), introduced by coding the textures using the HM10.0 test model of the High Efficiency Video Coding (H.265) standard. The textures were grouped in 51 videos, 117 s long. In each video, they were presented in random order alternating between distorted and undistorted images with a stimulus onset asynchrony of 333 ms. This succession of quality changes gave the flickering effect that elicits SSVEPs whenever the threshold of sensory processing is exceeded. In the data

analysis, we calculated spatio-temporal features and used Linear Discriminant Analysis with shrinkage of the covariance matrix to detect SSVEP modulations. In ten-fold cross-validation, we obtain mean classification accuracy (AUC values) of 0.84±0.1 for D6, 0.75±0.12 for D5, 0.61±0.1 for D4, and chance level for the first three levels of quality change (which were around or below perception threshold). Classification accuracy significantly correlated with MOS values for all the subjects ($p<0.01$). These results show that SSVEPs are significantly modulated by the quality changes above perception threshold and can be related to the behavioral measurements and therefore give rise to a graded neural index of video quality change perception.

Title: A monolithic portable fNIRS system with 1cm spatial resolution for functional brain imaging

Authors: ***J. KIM**[1], J. CHOI[2], M. CHOI[2], H. WON[2], G. HWANG[2], H. BAE[2];
[1]KAIST, [2]Electrical Engin., KAIST, Daejeon, Korea, Republic of

Abstract: Functional near-infrared spectroscopy (fNIRS) is an effective and non-invasive functional brain imaging method. Neuronal activities of the brain are strongly coupled with the hemodynamics in the local cerebral cortex. Such hemodynamics can be extracted by using the fact that the absorption spectra of oxy hemoglobin (HbO) and deoxy hemoglobin (HbR) differ in the near-infrared region of the spectrum. The fNIRS has an apparent advantage over functional magnetic resonant imaging (fMRI) in terms of cost and portability. However, the inherent limitation of the spatial resolution of the fNIRS restricts its widespread use in clinical applications. In addition, the conventional fNIRS devices have yet to utilize its potential for portability to the fullest extent. In this paper, a monolithic high resolution portable fNIRS system is proposed. Variety of innovations at the algorithmic, architectural, and circuit levels are applied to overcome aforementioned technical limitations. Each individual laser sources are modulated with their own Walsh codes for uncompromised temporal resolution and a matched filtering scheme is incorporated at the receiver to maximize the electrical signal-to-noise ratio (SNR). In

addition, multi-input-multi-output (MIMO) scheme is employed to enhance the spatial resolution without increasing hardware complexity. Furthermore, in order to enhance the portability of the device to the fullest extent, the receiver containing variable amplifiers, analog-to-digital converters, and multiplexers is monolithically integrated and fabricated in a 0.35um 1P4M CMOS process. The IC occupies 5 x 2 mm2 and consumes 3.2mW per channel. To the best of author's knowledge, the proposed system achieves the highest level of spatial resolution and portability among recently published fNIRS systems.

Title: Decoding daily behaviors from NIRS signatures by using a portable NIRS device in the daily-life environment

Authors: ***T. OGAWA**[1], P. K. GUPTA[2], K. YANO[2], J. A. ABDUR-RAHIM[2], H. MORIOKA[2,3,4], J.-I. HIRAYAMA[2], S. YAMAGUCHI[5], A. ISHIKAWA[5], Y. INOUE[5], M. KAWANABE[2], S. ISHII[2,3];
[1]Seika-cho, [2]Dynamic Brain Imaging, ATR, Kyoto, Japan; [3]Syst. Science, Grad. Sch. of Informatics, Kyoto Univ., Kyoto, Japan; [4]JSPS, Tokyo, Japan; [5]Shimadzu Corp., Kyoto, Japan

Abstract: Thanks to the development of technologies to miniaturize the sensor device (EEG, NIRS, etc.) and wireless communication, portable/wearable devices are recently available. A challenging issue within the field of neuroimaging is elucidation of natural brain processing in less-controlled environment. Participants are allowed to be released from tight experimental conditions. To examine "natural behavior" signatures based on such portable devices, however, , there are two main problems, i) how to analyze recorded signals with external/internal artifacts in

the real environment, ii) how to detect spontaneous behavior events from the signals without cue stimulus. To this end, we developed a wearable multi-channel fNIRS-EEG system (kNIRS-EEG). In the unique experimental environment that mimics in a living house, called BMI (Brain Machine Interface) house, we developed a system to record NIRS-EEG and environmental data simultaneously. We examined NIRS-EEG recordings from both single-participant and dual-participants simultaneous sessions. The participants were instructed to perform sequential daily-life and free moving behaviors. In off-line analysis, we labeled each behavior a tag and registered it to a "Brain-log database". After each segment of 8ch NIRS signals was associated with the behavioral tag that signifies the class of daily-life behaviors (i.e. operating TV/AC, reading etc.), we attempted to decode each behavior from the NIRS data to discriminate daily behavior. We applied SVM for the decoding and evaluated the classifier and timing of the decodable period. Our preliminary results found that the classification accuracy rose after the onset, in particular, by using SVM. This results suggested that we could extract some behavior-related information from the recorded signal even if it contains motion artifacts. It is plausible to decode a subject's action and/or intention based on single-trial NIRS signals using subject behavior as a label. In addition, we would discuss relationship between environmental sensor information and NIRS information.

Title: Ultrasound modulation in frog nerve

Authors: *D. W. GULICK, B. C. TOWE;
BME, Arizona State Univ., Tempe, AZ

Abstract: We looked for ultrasound (US) effects on *ex vivo* bullfrog sciatic nerve, using pulses similar to US brain stimulation. We saw no clear effect. We first applied electrical stimulation to elicit a half-maximum compound action potential (CAP), then added US pulses to look for a change in the CAP amplitude [1]. Because many nerve fibers are near threshold, any US effect on the membrane or ion channels should increase or decrease the CAP. We looked for an effect

under conditions similar to recent brain stimulation results (sub-MHz US, ~10 W/cm2 power, ~100 ms pulse) [2]. The US appeared to have no strong direct effect on the CAP. Our observation is compatible with human results that US stimulates sensory receptors but not nerves in passing [3]. There are several reasons we might not have seen the nerve effects reported by others: Mihran et al. used shorter pulses with much higher peak power [1]. Colucci et al. used higher average power, causing heating [4]. We did find an apparent artifact by which US affected the CAP in our setup. The artifact appeared to be caused by US radiation pressure rippling the water around the stimulation electrodes, because it could be blocked by placing plastic wrap or tissue paper over the nerve. It is unclear if this artifact may appear in any other work. It occurs only when the nerve is stimulated at the water surface - if the stimulation site is in air or is submerged, the water level would not affect the stimulation current. We also tested the combination of US and direct current (DC) on the nerve. US and DC together had no effect beyond that of the DC alone. This suggests that any synergy between US and DC might be specific to the brain, rather than a general physical effect [5]. [1]R. T. Mihran, F. S. Barnes, and H. Title: Ultrasound neuromodulation frequency dependence is not fully explained by changing sonication duration

Authors: *P. P. YE[1], J. BROWN[2], K. B. PAULY[3];
[1]Stanford Univ., Palo Alto, CA; [3]Radiology, [2]Stanford Univ., Stanford, CA

Abstract: Ultrasound neuromodulation is known to be capable of stimulating neural activity but response efficacy is highly dependent upon sonication parameters. Previous work has shown a strong dependence on the carrier frequency, where lower frequency sonication requires significantly less intensity to achieve the same success rate for eliciting a motor response [King et al., 2013]. Understanding the cause of this frequency dependence could cast light on the underlying mechanisms of ultrasound neuromodulation which currently remain unknown. We performed experiments to examine whether controlling for sonication duration could account for all or some of the frequency dependence. Six mice were sonicated with ultrasound transcranially at four carrier frequencies at various intensity levels, while keeping the number of cycles constant (40,000 cycles) and again while keeping sonication duration constant (80 ms). The mice were lightly anesthetized at 0.34% isoflurane at 1 liter per minute O2 throughout the experiment. Electromyograms were measured in the forelimbs and processed to calculate the success rate of eliciting muscle contractions. Our data suggests a frequency dependence where lower frequencies require reduced intensities to achieve the same success rates whether or not sonications used constant cycles or constant durations. Success rates were greater with longer duration sonications at 300 kHz, and success rates were lower with shorter duration sonications at 600 kHz ($p = 0.03$, one-tailed Wilcoxon signed rank test). By directly comparing constant cycle and constant duration sonications on the same mice, we show that keeping sonication duration constant only partially explains the observed frequency dependence. Future work examining other frequency-dependent factors such as standing waves and focal spot size may be necessary to fully explain the frequency dependence of ultrasound neuromodulation.

Title: fMRI BOLD response in humans using transcranial focused ultrasound

Authors: *J. MUELLER, W. LEGON, W. TYLER;
Virginia Tech. Carilion Res. Inst., Roanoke, VA

Abstract: Previous research has demonstrated transcranial focused ultrasound (tFUS) in humans to affect the amplitude of somatosensory evoked potentials, as well as broad spectrum EEG power (Legon et al. 2014). Here, we test the effect of tFUS for induction of a blood oxygen level dependent (BOLD) response in humans using functional magnetic resonance imaging (fMRI). Participants (N = 6) were fitted with one of two different 0.5 MHz ultrasound transducers having an axial and lateral resolution of 30 mm. An event-related design was used where 90 US stimuli were delivered every 12-14 seconds. Each stimulus was created using a two-channel function generator where channel 1 served as the trigger for channel 2. Channel 1 had a pulse repetition frequency (PRF) of 1kHz and total number of pulses of 500 for a 0.5 sec duration. Channel 2 had an acoustic frequency of 0.5 MHz of 180 cycles for a duration of 0.36 msec. This corresponded to an intracranial peak-to-peak pressure intensity of Isppa = 5.9 W/cm2. Group whole head and region of interest (ROI) analyses were conducted, as well as on a subject by subject basis. ROI analysis was concentrated on areas of the brain within the focal axes of the ultrasound beam and surrounding beam penumbra. Preliminary results indicate tFUS to have variable effects upon BOLD response between subjects. There was no statistically significant area of activation on the group level. However, individual participant analysis revealed 3 of 6 participants demonstrated a focal increase in BOLD response within the US beam maxima. 2 of 6 participants showed no discernible BOLD activation pattern to US stimulation and 1 participant demonstrated a combination of increased and decreased BOLD response in the general area of the US beam axes. These results, though variable, suggest that focused ultrasound can induce detectable BOLD signature changes in humans but that refinement of US stimulus parameters is likely needed and optimization of signal to noise ratios is necessary to induce a stable effect across subjects.

Title: At diestrus-2 muscarinic receptor type 1 (M_1R) of the left or right ovary participates in the progesterone (P_4) and 17β-estradiol (E_2) secretion on proestrus day

Authors: *M. B. CRUZ, A. FLORES, R. DOMÍNGUEZ;
Investigacion Y Posgrado, Univ. Autonoma De México, Mexico DF, Mexico

Abstract: Previously we have shown that at 13:00 h of diestrus-2 the injection of pirenzepine (PZP) (a blocker of M_1R) on the left and right ovaries resulted in the blockade of ovulation (87.5% of the treated animals) at the predicted estrus day (Cruz et al., 2013). LHRH injection induced ovulation in rats treated with PZP. The injection of estradiol benzoate (EB) did not induce the ovulation in the rats treated with PZP in the left ovary, while ovulation occurred in almost all rats with PZP injected in the right one, after EB treatment. These results suggested that at diestrus-2 the stimulation of M_1R on the left or right ovary regulates the GnRH secretion of proestrus day, as a result of the modifications on the surge E_2 secretion. The aim of present study was to analyze the effects of the blockade of M_1R at diestrus-2 on P_4 and E_2 serum levels measured at 11:00 and 15:00 h of the predicted proestrus day. Groups of cyclic rats were anaesthetized at 13:00 h on diestrus-2 with ketamine-xylazine and micro-injected in the left or right ovary with 0.5 μL of sterile water or PZP (19ng/0.5 μL), and sacrificed at 11:00 or 15:00 h of the predicted day of proestrus. Groups of untouched control cyclic rats were sacrificed at same times. The vehicle injection into the left or right ovary resulted in lower P_4 serum levels at 11:00 h of the proestrus day (left ovary: 8.2±0.9, right ovary: 7.2±1.5 vs. control: 19.4±2.1, $p<0.01$) and did not modify the E_2 levels. The PZP injection in either ovary increased the P_4 levels in comparison with animals injected with vehicle (left ovary: 19.7±2.3 vs. 8.2±0.9, right ovary: 33.7±4.0 vs. 7.2±1.5, $p<0.01$. E_2 serum levels were higher in those rats injected with PZP in the left ovary than those injected with the vehicle (90.1±9.4 vs. 65.7±5.2, $p<0.05$). in those animals sacrificed at 15:00 h vehicle injection on either ovary did not modify the P_4 levels, while E_2 levels were lower than control (left ovary: 84.7±10.1, right ovary: 92.3±6.3 vs. 138.2±8.9, $p<0.01$). Present results suggest that at diestrus-2 the stimulation of the M_1R on the ovaries regulates in an inhibitory way the P_4 and E_2 secretion at proestrus day. Based on these results and the asymmetric effects of the EB on ovulation on PZP-treated rats (Cruz et al., 2013), we suggest that the stimulation of the M_1R on the left ovary participated in the regulation of the positive feed-back estrogen effects.

Title: Unraveling the cellular mechanisms triggering GnRH release

Authors: *S. S. CONSTANTIN, S. WRAY;
NINDS / NIH [C], Bethesda, MD

Abstract: Fertility relies on communication between gonadotropin-releasing hormone (GnRH) neurons, pituitary gonadotrophs and gonads, a “ménage à trois”, where all information is conveyed through discrete secretory patterns. For ~40 years, the critical role of pulsatile release of GnRH in the portal blood system has been known. Chaotic GnRH release occurs in polycystic ovary syndrome, one of today’s leading causes of infertility. However, the cellular mechanisms that drive secretion and pulsatility in GnRH neurons still remain unknown. At the single cell level, electrical activity in GnRH soma show no obvious pattern that could trigger a pulse of secretory activity at their terminals. The goal of this study is to unravel GnRH secretion to better understand the etiology of reproductive pathologies. Since GnRH neurons release peptide into the blood stream, their terminals are not classical synapses. In addition, GnRH is packaged in dense core vesicles (DCV) in contrast to synaptic vesicles (SV). Thus, two approaches are being used to identify mechanisms underlying GnRH secretion using primary cultures. First, the secretory apparatus of GnRH neurons is being characterized by immunocytochemistry, using an extensive list of vesicle and synaptic active zone markers. However, as SV and DCV emerge from the Golgi apparatus, they share many markers, making it difficult to distinguish between DCV and SV at the light microscopic level and only helping to identify putative secretion sites. Thus, an assay for GnRH secretion is being developed. Since GnRH neurons lack a postsynaptic partner, secretion must be assessed directly on GnRH neurons or indirectly on their physiological partners, gonadotrophs. FM1-43, a dye commonly used to study exocytosis, was used for direct

measurements. A range of field stimulations was tested to determine the protocol to optimally label vesicles. FM1-43 labeling was confirmed by post-hoc immunocytochemistry for GnRH. To ensure GnRH was effectively released, the same stimulation will be applied to GnRH cultures while their media is dialyzing on gonadotrophs. Gonadotroph responses will be monitored via calcium imaging, an increase in calcium will unequivocally indicate release of GnRH. Finally, the same stimulation will be applied to GnRH neurons and activity monitored via calcium imaging, allowing, for the first time, one to record a cellular event concomitant with secretory activity in GnRH neurons.

Title: Defining the neuronal network mediating impaired progesterone negative feedback in a mouse model of polycystic ovarian syndrome

Authors: A. M. MOORE, M. PRESCOTT, *R. E. CAMPBELL;
Univ. Otago, Ctr. Neuroendocrinol, Dunedin, New Zealand

Abstract: Polycystic ovarian syndrome (PCOS) is the most common cause of female infertility worldwide. In this syndrome, an increase in luteinising hormone (LH) pulse frequency is suggestive of changes in gonadotropin-releasing hormone (GnRH) neuron regulation by progesterone negative feedback. Previously, we have shown in a mouse model of PCOS generated by prenatal androgen (PNA) exposure that progesterone receptor (PR) expression is reduced in the arcuate nucleus (ARC) and that GnRH neurons receive a greater number of GABAergic inputs, which may contribute to modified GnRH neuron activity. We therefore sought to test the hypothesis that impaired progesterone negative feedback may result from reduced progesterone sensitivity in ARC GABAergic afferents that project to GnRH neurons. To achieve this, we assessed the negative feedback effects of progesterone in vehicle-treated control

(n=8) and PNA-treated (n=7) mice by measuring LH before and after ovariectomy and after implanting a progesterone pellet. We then identified the percentage of progesterone sensitive ARC GABAergic neurons by performing immunohistochemistry for PR on brain slices collected from vesicular GABA transporter (vGaT)-cre/tdTomato control (n=6) and PNA-treated (n=5) mice. Finally, we injected a Cre-dependent adenovirus expressing farnesylated enhanced green fluorescent protein (EGFPf) into the ARC of vGaT-cre control (n=5) and PNA-treated (n=6) mice to address whether progesterone sensitive ARC GABAergic neurons project to GnRH neurons. Compared with controls, PNA-treated mice exhibited a blunted postcastration rise in LH ($p<0.01$) and an absence of LH suppression by progesterone. PR colocalization with tdTomato positive-GABAergic neurons was significantly decreased in the ARC of PNA-treated mice compared with controls ($p<0.05$), suggestive of decreased progesterone sensitivity of ARC GABAergic neurons in PNA-treated mice. Remarkably, ARC GABAergic projections were found to contact 67.5±9.5% and 62.5±10.9% of GnRH neurons from control and PNA-treated mice, respectively. Interestingly, the density of ARC GABAergic fibres apposing the primary dendrite of GnRH neurons was significantly increased in PNA-treated mice compared to controls ($p<0.05$), in line with our previous findings. Finally, PNA-treated mice exhibited a significant decrease in the percentage of EGFPf-positive GABAergic neurons colocalised with PR in the ARC ($p<0.01$) compared with controls. Together, these data describe a novel, robust GABAergic input to GnRH neurons that originates in the ARC and may underpin decreased progesterone feedback to GnRH neurons in PCOS.

Title: Morphological and physiological interactions between GnRH3 and hypocretin/orexin neuronal systems in zebrafish

Authors: *Y. ZHAO[1], C. SINGH[2], M.-C. LIN[1], D. PROBER[2], N. WAYNE[1];
[1]Dept. of Physiol. David Geffen Sch. of Med., UCLA, LOS ANGELES, CA; [2]Div. of Biol., Caltech, Pasadena, CA

Abstract: Hypocretin/orexin (Hcrt) is a neuropeptide produced in the dorsal and lateral hypothalamus, and is best known for regulating arousal and food intake. Recent evidence indicates that it is also involved in reproduction as an inhibitor of hypothalamic gonadotropin-releasing hormone (GnRH) neurons. However, little work has been done on the anatomical and functional relationships between these two neuronal circuits. In the present experiments, we combined optical imaging and electrophysiology to explore the interaction and regulation between these two neural circuits in the hypothalamus. First, we generated a dual transgenic zebrafish line hcrt:RFP; GnRH3:EMD in which Hcrt and GnRH3 neurons are genetically labeled with red and green fluorescent proteins, respectively. Using confocal microscopy, this animal model allows us to study the development and interactions of these two neuronal systems from the embryonic stage (20 hours post-fertilization, hpf) to larval stage (8 days post-fertilization, dpf) *in vivo*, as well as in the excised adult brain. Similar to our published work, genetically labeled GnRH3 neurons started emerging in the hypothalamus around 20 hpf, gradually increasing in number and were located in the periventricular area throughout the hypothalamus. In contrast, genetically labeled Hcrt neurons were expressed in two bilateral clusters in the dorsal hypothalamus starting around 25 hpf. By 8 dpf, both Hcrt and GnRH3 neuronal processes projected widely throughout the brain. Furthermore, we observed close apposition of Hcrt and GnRH3 neurons in the hypothalamus, accompanied by focal co-localization of these two neuropeptides expression. Second, using *in situ* hybridization, we found that the hcrt receptor is expressed in hypothalamic GnRH3 neurons (5 dpf), indicating that Hcrt can directly regulate GnRH3 neurons. To elucidate the role of Hcrt in regulating GnRH3 neuron activity, we recorded the electrical activities of GnRH3 neurons using whole-cell and loose-patch electrophysiology and studied responses to Hcrt application with and without the Hcrt receptor antagonist almorexant. Similar to findings with hypothalamic GnRH neurons in mice, Hcrt significantly inhibited action potential firing frequency of GnRH3 neurons in adult zebrafish, and this effect was abolished with almorexant pretreatment. In summary, this study reveals that Hcrt neurons in zebrafish may play an important role in regulating reproduction through anatomical and physiological interactions with the GnRH3 neuronal system.

Title: Hypothalamic NPY neurons decrease their npya expression after food depletion

Authors: *S. KANDA, S. KITAHARA, Y. OKA;
Dept Biol. Sci., Dept Biol Sci, Grad Sch. Sci, Univ. Tokyo, Tokyo, Japan

Abstract: Neuropeptide Y is supposed to be one of the most potent orexigenic peptides, and their expression in hypothalamus is increased after food restriction in mammals to regulate their energy condition. Moreover, it was recently reported that NPY directly inhibits firing activity of GnRH1 neurons in mice (Roa and Herbison, 2012). Thus, the NPY neurons are considered to regulate energy homeostasis as well as reproduction in concert in accordance with energy conditions. In spite of the importance of the NPY neurons in the energy homeostasis in mammals, neither the localization nor their physiological functions has been fully understood in vertebrate species other than mammals. Here, we used a small teleost, medaka, in which one can easily apply genetic manipulations as well as electrophysiology, and we detailed NPY neuron distribution by *in situ* hybridization and analyzed changes in *npy* expressions in accordance with the energy conditions. Here we showed that *npya* is expressed in many hypothalamic nuclei, optic tectum, and telencephalon, while its paralogs, *npyb*, which is considered to be duplicated in the 3R whole genome duplication, is expressed only in limited areas of telencephalon. Then, we examined differences in their expression levels between the well-fed group and the starvation group. Among all NPYa and NPYb neurons, the number of *npya* mRNA positive neurons that are distributed in areas ranging from nucleus ventralis tuberis (NVT), nucleus recessus lateralis (NRL) and nucleus anterior tuberis (NAT) specifically decreased in one day to two week-starvation groups. From these results, it was suggest that NPYa neurons in NVT, NRL, and NAT are sensitive to energy conditions, and they probably have functions related to food intake, although there has been no clear demonstration of NPY neuronal functions in teleosts. In addition, we examined co-expression of *npy* and *agrp* mRNA, which has been demonstrated in mammalian species. Surprisingly, there was no *npy* and *agrp* co-expressing neuron in medaka hypothalamus, although they were closely distributed. In summary, we found similarities and differences between mammals and teleosts. As in mammals, the hypothalamic *npya* expression in medaka varies in accordance with the energy status. However, contrary to the situation in

mammals, the *npya* expression decreases after food restriction in hypothalamic nuclei, and there was no colocalization with *agrp* expression. Further comparison between mammals and teleosts may provide clues to understanding the differences in energy balance strategies between poikilothermic and homoeothermic animals as well as general mechanisms common to both.

Title: Impact of bisphenol A on the developing GnRH3 neural system and locomotor behavior in Japanese medaka

Authors: *T. INAGAKI[1,2], E. K. LEE[2], S. RAMAKRISHNAN[1,2];
[1]Biol., [2]Neurosci. program, Univ. of Puget Sound, Tacoma, WA

Abstract: Bisphenol A (BPA), a xenoestrogen, disrupts normal brain function and behavior mediated by neuroendocrine systems. Gonadotropin-releasing hormone (GnRH) neurons in the brain play a crucial role in reproductive physiology and behavior in most vertebrates. In fish, three types of GnRH neurons, GnRH1 at the preoptic area (POA), GnRH2 at the midbrain, and GnRH3 at the terminal nerve (TN), have been identified. While it is known that GnRH3 neurons project widely throughout the brain and spinal cord, and that neuromodulatory roles in reproductive behavior have been suggested, their functions remain unclear. Aside from reproduction, recent studies have also alluded to a role for GnRH in locomotion, with GnRH receptors found in the spinal cord. Here we examine effects of chronic exposure to low dose BPA through development on GnRH3 neuronal systems, and locomotor activity in transgenic Japanese medaka with GnRH3 neurons tagged with green fluorescent protein (GFP). Fertilized medaka eggs were collected daily, and placed individually in 12- or 24-well plates. Embryos in BPA groups were chronically exposed to 200 ng/ml of BPA starting on 1 day post-fertilization (dpf), through hatch until 10 days post hatch (20 dpf). To assess effects of chronic BPA exposure on GnRH3 neurons, brain images were taken from live embryos in eggs at 1, 2, 3 and 4 dpf, and intensity of GnRH3-GFP neurons were analyzed using an upright epifluorescence microscope.

At 3 dpf, GnRH3-GFP neurons in BPA-treated embryos showed 23.7% increased fluorescence in the terminal nerve population and 14.3% reduced intensity in the trigeminal population when compared to vehicle treated control embryos. Hatched larvae were kept in glass petridishes with continued exposure to 200 ng/ml BPA. Locomotor activity of larvae was observed at 20 dpf (~10 days post hatch) and analyzed using Noldus Ethovision XT. Head-growth, body sizes, times to hatching were also measured. We found that BPA exposed larvae (n=12 each group) showed significantly decreased locomotory activity both in total distance covered (88.36 ± 28 mm vs. 176.2±14.6 mm controls, $p<0.012$) and velocity of movement (2.53 ±0.6 mm/s vs. 4.74± 0.72 mm controls $p<0.013$). There were no significance differences in head-growth, body sizes and times to hatching between BPA and the control groups. This study will allow us to understand BPA effects on GnRH3 neuron development and how it may affect locomotion. (Supported by NSF Career Award 1253126 to SR).

Title: Dopaminergic regulation on gonadotoropes in medaka

Authors: ***T. KARIGO**, Y. MOCHIZUKI, Y. OKA;
Dept Biol Sci, Grad Sch. Sci, Univ. Tokyo, Tokyo, Japan

Abstract: The inhibitory functions of dopamine (DA) on the hypothalamic-pituitary-gonadal (HPG) axis regulation have been suggested in some mammalian species (ewe, Goodman et al., 2012; mice, Liu and Herbison, 2013). Also in teleost fish, the inhibitory effect of DA on reproduction has been studied especially in goldfish. DA has been suggested to inhibit GnRH release from the hypothalamus and GTH release from the pituitary (Yu and Peter, 1990, 1992). We have already shown the involvement of DA on the HPG axis regulation at the levels of both GnRH1 neuron and gonadotropes in medaka (Karigo et al, SfN 2013 abstract). We found that

TH immunoreactive (ir) neurons project to the ventral preoptic area GnRH neurons, which in turn directly project to the pituitary, and also directly project to LH and FSH cells in the pituitary. We also showed that DA significantly inhibits the neural activities of GnRH1 neurons. However, we have not examined the physiological effects of DA on the gonadotropes. To examine such effects, we here performed the following experiments. First, by using retrograde axonal tracing experiments with biocytin, we identified some groups of pituitary projecting TH-ir neurons in the hypothalamic nucleus, nucleus ventralis tuberis (NVT) and nucleus anterior tuberis (NAT). Next, we analyzed the distribution of DA receptors in the brain and pituitary. DA receptors are generally known to be classified into two families and five subtypes; D1-like receptor family (D1R and D5R) and D2-like receptor family (D2R, D4R and D5R). We found eight subtypes of DA receptors from medaka genome database; two D1Rs, two D2Rs, one D3R, two D4Rs, and one D5R. As Fontaine et al. (2013) reported in zebrafish that they have three types of D2 receptors, D2a, D2b, and D2c, and LH cells express all three, we first focused on D2 receptors, D2-1R and D2-2R, in medaka. We performed *in situ* hybridization of D2-1R and D2-2R and found that D2-1R is mainly expressed in the brain, while D2-2R is strongly expressed in the pituitary. We performed double labeling of LH or FSH cells and D2-2R mRNA and found that some of the LH and FSH cells express D2-2R. The two types of gonadotropes, LH and FSH cells, are separated into two different cell populations in teleosts, and we have already generated transgenic medaka lines that express Ca^{2+} indicator separately in those cells (Karigo et al., 2014). We are currently analyzing the effects of DA on LH and FSH cells by Ca^{2+} imaging using those transgenic medaka lines. LH and FSH cells tend to show different Ca^{2+} responses to DA applications. Here we suggest characteristics of complex dopaminergic regulations on the HPG axis.

Title: Immunocytochemical localization of gonadotropin-releasing hormone (GnRH) neurons in the brain of the American alligator, alligator mississippiensis

Authors: K. HUANG[1], Y. GAO[2], *R. TERUYAMA[1];
[1]Dept of Biol. Sci., Louisiana State Univ., Baton Rouge, LA; [2]Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: The gonadotropin-releasing hormone (GnRH) system plays a fundamental role in coordinating reproductive physiology and behavior of animals. The present study was conducted to localize GnRH neurons in the alligator brain. Because nomenclature for specific neural structures is not determined in the alligator brain, we first constructed a stereotaxic atlas of the alligator hypothalamus. Six alligators were deeply anesthetized and perfused with 0.9% saline, which was followed by buffered 4% paraformaldehyde fixative. Animals were decapitated and the heads were stored overnight in the same fixative then transferred to 20% sucrose in PBS overnight for cryoprotection. The top of the skull was removed to expose the brain, and the head was then mounted on a modified monkey stereotaxic apparatus with the mouth placed 45° below the horizontal axis of the instrument. A portion of the brain that containing the hypothalamic region was blocked in the stereotaxic apparatus. Each block was then sectioned using a cryostat or a freezing microtone. Brain sections obtained from the cryostat were stained with Nissl stain and used for construction of a stereotaxic atlas. Nomenclature for specific neural structures was selected from several stereotaxic atlases for avian brains based on similarities in staining characteristics and relative locations of the specific structures. Brain sections obtained from a freezing microtome were used for immunocytochemical localization of GnRH using the free-floating incubation technique. GnRH immunoreactive structures were then mapped in the atlas. Groups of GnRH immunoreactive neurons were found along the midline in the preoptic area close to the third ventricle and in the lateral septal area close to the lateral ventricle. Dendritic processes of some of the GnRH immunoreactive neurons appeared to penetrate the ependymal cell layers of the lateral and the third ventricle indicating that some GnRH neurons are "the cerebrospinal fluid contacting neurons". These results demonstrate that the distribution of GnRH neurons in the alligator is similar to that found in avian brains.

Title: Revealing synaptic inputs along the full extent of gonadotropin-releasing hormone (GnRH) neuron processes using an *in vivo* viral-mediated cell filling technique

Authors: *S. YIP, R. CAMPBELL;
Ctr. for Neuroendocrinology, Dept. of Physiol., Univ. of Otago, Dunedin, New Zealand

Abstract: Gonadotropin-releasing hormone (GnRH) neurons are critical for the regulation of fertility. The morphology of GnRH neurons is unique in that some neurons extend one or two lengthy dendrites millimeters away from the somata and, intriguingly, elaborate into axons in the median eminence (ME). Much of our understanding of the synaptic regulation of GnRH neurons has been limited to investigating GnRH somata and proximal dendrites scattered around the rostral forebrain due to limitation of the length of dendritic that can be imaged. An *in vivo* cell-filling approach has overcome this limitation and enabled us to investigate the density of synaptic inputs throughout the rostral to caudal extent of GnRH neuron processes. Adult female GnRH-Cre mice (n=4) were stereotaxically injected with 100nl (5.1x1011 pfu/ml) of a Cre-dependent recombinant adenovirus containing a farnesylated enhanced green fluorescent (EGFPf) gene into the rostral preoptic area (rPOA) and animals were perfused 5 days later. Half of each fixed brain was cut into 30μm sagittal sections and immuno-labelled for GFP, to identify the full extent of GnRH neuron and synapsin (a pre-synaptic marker). Adenoviral-mediated cell filling was restricted to a small number of GnRH neuron exclusively. The rostral to caudal extent of GFP-positive fibre projections was divided into 3 zones (approximately 1000μm each) between the rPOA and the ME. The number of GFP-positive fibres were counted in each zone and their morphologies were characterised as type 1 smooth fibre or type 2 fibre with swellings. The total density of synapsin puncta in close apposition to GFP-positive fibres were then evaluated for each fibre type from each zone using confocal microscopy. Our results showed that approximately 2 to 15 GnRH neurons, restricted to the rPOA were filled in each animal. Both fibre types were found in equal number throughout the rostral to caudal zones investigated. Evaluation of synapsin close appositions to GFP-positive GnRH processes found a total synapsin density of 0.27±0.02, 0.33±0.06 and 0.24±0.01 puncta per μm for type 1 fibres and 0.24±0.05, 0.28±0.04 and 0.22±0.03 puncta per μm for type 2 fibres from zones 1, 2 and 3 respectively. These data indicate that the lengthy processes of rPOA GnRH neurons possess synaptic input, equally distributed throughout their entire length, regardless of the distance from the somata. Thus this study has opened a new window to explore the hierarchy of synaptic inputs and their function related to plasticity in GnRH neurons, for example, during different stages of reproductive cycle and in states of infertility.

Title: Optogenetic activation of mouse GnRH neurons *in vivo*

Authors: P. CAMPOS, B. HYLAND, *A. E. HERBISON;
Ctr. for Neuroendocrinology, Univ. of Otago, Dunedin, New Zealand

Abstract: The gonadotrophin-releasing hormone (GnRH) neurons represent the key output cells of the neuronal network controlling the hypothalamic pituitary-gonadal axis and thus fertility in all mammalian species. The patterns of neuronal activity by which GnRH neurons generate pulses of GnRH and thus luteinizing hormone (LH) are unknown. To date, the scattered distribution of the GnRH cell bodies remain the main limitation to investigating the cellular events that lead to pulsatile secretion of LH. The ability to remotely manipulate the neuronal activity of GnRH neurons in a selective manner *in vivo* would facilitate our understanding of the patterns of GnRH neuron activity required to generate pulses of LH. We have used a Cre-dependant adeno-associated virus (AAV) in transgenic GnRH-Cre mice to target channelrhodopsins (ChR2) to the GnRH neuronal phenotype. Taking advantage of the retrograde transport properties of AAVs, we injected AAV into the median eminence of GnRH-Cre mice to target expression of ChR2 to only hypophysiotropic GnRH neurons. Immunofluorescence studies showed that ≈93% of all ChR2-expressing cells in the brain expressed GnRH. First, to characterize the ability of ChR2 to modulate GnRH neuron excitability we prepared acute brain slices from AAV-injected GnRH-Cre mice and undertook cell attached recordings of ChR2-expressing GnRH neurons. Blue light stimulation using 5 ms pulses at 10Hz and 30 Hz for up to 5 minutes induced action potential firing with a response fidelity of 85% and 72% respectively. Second, we stimulated the GnRH neurons *in vivo* in AAV injected GnRH-Cre female ovariectomized mice by placing an optic fiber in the rostral preoptic area and applying different patterns of activation in order to elicit LH secretion. Activation of GnRH neurons for 5 minutes at 1 Hz and 5 Hz was found to have no effect on LH secretion. Blue-light stimulation at 10Hz ($p=0.0024$) and 30Hz ($p=0.0008$) produced significant pulse-like increases in LH secretion. Synchronized burst firing has been suggested to underlie GnRH pulsatility. As such, GnRH neurons were synchronously activated for 5 minutes to fire in bursts using the burst patterning previously detected for GnRH neurons *in vivo*. This was found to have no effect on LH secretion.

Together, these studies are highlighting the patterns of GnRH neuron electrical activity required to generate pulsatile LH secretion.

Title: GnRH-(1-5)-mediated regulation of the extracellular milieu in the migration of GN11 cells

Authors: ***D. O. LARCO**[1], S. MANI[2], T. WU[1];
[1]OBG, Uniformed Services Univ., Bethesda, MD; [2]Mol. and Cell. Biol., Baylor Col. of Med., Houston, TX

Abstract: Gonadotropin-Releasing Hormone (GnRH) neurons originate outside the central nervous system (CNS) in the nasal placode where their migration to the basal forebrain is dependent on the integration of multiple signaling cues during development. The proper migration and establishment of the GnRH neuronal population within CNS is critical for normal pubertal onset and reproductive function. The endopeptidase EP24.15 is expressed along the migratory path of GnRH neurons and cleaves the full-length GnRH to generate the metabolite GnRH-(1-5). Using the GN11 cell model, which is considered an immature GnRH neuronal cell line, we recently demonstrated that GnRH-(1-5) inhibits cellular migration in a wound closure assay by binding the orphan G protein-coupled receptor 173 (GPR173). GnRH-(1-5) activating GPR173 initiates the formation of a complex with Beta-arrestin 2 and phosphatase and tensin homolog to subsequently inhibit the signal transducer and activator of transcription 3 (STAT3) pathway to regulate migration. In this study, we screened for genes and secreted factors implicated cell migration that are regulated in response to GnRH-(1-5) in GN11 cells. To do so, we used a PCR array (Qiagen) to measure changes in 84 genes in cells treated with GnRH-(1-5) for 30 min. Acute GnRH-(1-5) treatment significantly decreased members of the cytokine signaling pathway such as IL-1alpha (0.62 relative to 1.0) and IL-4Ralpha (.73 relative to 1.0), which correlates with our previous finding that GnRH-(1-5) inhibits the normally cytokine-activated STAT3 pathway. We also measured members of the transforming growth factor beta

family and found that GnRH-(1-5) had no effect, indicating a cytokine-specific mechanism of regulation. These results suggest that GnRH-(1-5) may modulate the response of migrating GnRH neurons to external cues present in the extracellular milieu (ECM). Therefore, we examined the effect of GnRH-(1-5) on the migration of GN11 cells in the presence of an *in vitro* ECM using a matrigel invasion assay (BD biosciences). Interestingly, GnRH-(1-5) (100 nM) significantly ($p < 0.05$) inhibited the ability of GN11 cells to migrate through matrigel environment relative to control cells. Collectively, our studies demonstrate that the downstream mechanism of GnRH-(1-5) binding GPR173 to decrease cell migration and invasion is ECM-dependent and likely involves changes in the response and sensitivity of GnRH neurons to external cues.

Title: Estradiol and progesterone regulation of Jak/Stat signaling in hypothalamic neuronal cells

Authors: H. L. ADAMS[1], K. A. INTLEKOFER[2], *S. L. PETERSEN[3];
[1]Univ. of Massachusetts, Amherst, MA; [2]Univ. of Vermont, Burlington, VT; [3]Life Sci. Labs., Univ. of Massachusetts Amherst, Amherst, MA

Abstract: Progesterone (P_4) acts rapidly to maximize estradiol (E_2)-dependent gonadotropin-releasing hormone (GnRH) neuronal activity and luteinizing hormone (LH) surge release. Subsequently, P4 inhibits the daily LH surge initiated by E_2. Regulation of the surge is most likely through neurons in the anteroventral periventricular nucleus (AVPV), a preoptic region that communicates steroid signals to GnRH neurons. Our previous studies localized expression of a non-classical progestin receptor, progesterone receptor membrane component 1 (Pgrmc1), as well as its interacting partners, to the AVPV. Little is known about Pgrmc1 signaling in the brain; therefore, to identify pathways through which it may act, we used mouse N42 hypothalamic cells that model AVPV neurons. We previously performed microarray analyses with and without Pgrmc1 silencing and probed the resulting data sets with Ariadne Pathway

Studio™. Four out of the five pathways identified as significantly regulated by Pgrmc1 involved signal transducer and activator of transcription (Stat). To determine whether Stat signaling molecules may play a role in mediating steroid hormone effects, we first verified that *stat3, stat5a, stat5b, janus kinase 1 (jak1) and jak2* genes were all expressed in N42 cells. We then examined effects of E_2 and P_4 on expression of each of these genes using QPCR. We found that Stat3 and Stat5A mRNAs were significantly increased by 10nM E_2, but not by P_4 alone. In contrast, there were no steroid effects on Stat5B, Jak1 or Jak2 mRNA levels. To determine whether Pgrmc1 regulated Stat3 signaling, we silenced the gene in N42 cells transfected with a Stat3 reporter construct. Although P_4 failed to regulate Stat3 mRNA levels, we found that Stat3 promoter activity was repressed by Pgrmc1. These findings suggest that E_2 stimulation of Stat3 expression and P_4 blockade of Stat3 signaling may explain differential effects of these steroids on GnRH and LH surge release. Studies in progress are testing whether Pgrmc1 gene targets previously identified using microarrays are regulated by STAT3.

Title: Effects of the blockade of DA1 ovarian receptors on spontaneous ovulation and steroids hormones synthesis

Authors: *B. VENEGAS MENESES[1], M. GARCIA[1], J. L. MORAN[1], C. MORAN[1], A. HANDAL[1], N. H. ROSAS-MURRIETA[2], R. DOMINGUEZ[3];

Abstract: There is evidence that the ovarian innervation participates in the regulation of gonadotropin effects on the ovaries. The participation of the DA2 receptors in the regulation of the gonadotropin secretion and ovulatory process have been described. The effect of the peripheral blockade of dopaminergic system on ovulation varies during the estrous cycle and

presents some type of circadian variations. The aim of this work was to evaluate the effects of local blockade of DA1 ovarian receptor at 8:00, 13:00 or 20:00 h on dioestrous-1 on spontaneous ovulation, the synthesis of steroid hormones: progesterone (P4) and estradiol (E2) on estrous predicted. Cyclic rats of the CIIZV strain, maintained under controlled light/dark cycle (lights on 05.00-19.00) were used. On diestrous-1 at 8:00, 13:00 or 20:00 h, the animals were laparotomized dorsolaterally and the bursas of the ovaries were injected with 20 µL per ovary, SCH-23390 [5 µg/µL] or with vehicle. An untouchedcontrol group was included. The animals were sacrificed at 9:00 h of the next predicted estrous day. The blood of the trunk was collected, centrifuged and stored at -20 °C until hormones were measured in the serum by RIA. At autopsy, the oviducts were dissected and the number of ova present was counted with the aid of a dissecting microscope. The vehicle injection did not modify the spontaneous ovulation on D1. The blockade of DA1 receptor in ovaries on D1 blocked the spontaneous ovulation in all animals. The P4 and E2 levels in non-ovulating rats resulting by the injection with SCH not modify The E2 levels in non-ovulating rats resulting by the blockade of the DA1 ovarian receptors at 08:00, 13:00 or 20:00 h on D1 were higher than in control animals. Most of the differences were not significant because the high dispersion of data resulted in higher levels than control group. Based on the results suggest that blockade of ovulation can be the result of increased blood concentrations of P4 and E2.

Title: Examination of hypothalamic POMC cells in GnRH deficient mice

Authors: *C. TAYLOR-BURDS, B. POPE, S. WRAY;
CDNS, NIH/NINDS, Bethesda, MD

Abstract: Recently, selective ablation of the transcription factor NSCL-2 under the Gonadotropin releasing hormone-1 (GnRH) promoter was found to reduce the number of GnRH

neurons in the preoptic area and proopiomelanocortin (POMC) neurons in the Arc in male mice (Schmid et al., 2013). GnRH neurons located within the brain are integral components of the hypothalamic-pituitary-gonadal axis, and as such, control reproduction and puberty. It is well established that metabolic state can alter or disrupt reproductive function and puberty onset. This interaction has been associated, in part, with POMC neurons in the arcuate nucleus (Arc), key players in energy homeostasis. GnRH neurons contact POMC Arc neurons (and vise versa) and GnRH1R is expressed in neurons within the Arc, enabling direct interactions to occur between these two systems. However, it is also known that the GnRH promoter is transiently expressed in many cells during development. Thus, it is unclear whether the loss of POMC cells after ablation of NSCL-2 under the GnRH promoter was due to 1) direct reduction of neuroendocrine GnRH neurons or 2) indirect developmental changes associated with loss of the NSCL-2 in transient expressing non-neuroendocrine GnRH cells. To determine if GnRH signaling can alter expression of, or number of POMC hypothalamic neurons, we are utilizing the HPG mouse which lacks GnRH peptide. Preliminary data indicate that the number of POMC ARC is similar in brains from WT and HPG adult males. These findings suggest that loss of GnRH itself does not reduce POMC expression or the number of POMC Arc cells. Further experiments will determine whether age differences or sex differences occur in the POMC ARC cells in HPG compared to WT mice.

Title: Environmental pollutant BPA inhibits GnRH neuronal activity

Authors: ***U. KLENKE**, S. WRAY;
CDNS/NINDS/NIH, Bethesda, MD

Abstract: Reproduction is dependent on a functional hormonal cascade between hypothalamus, pituitary and gonads. However, peripheral feedback of estrogens coming from the gonads towards the hypothalamus is critical for proper timing of reproduction. Bisphenol-A (BPA), an

environmental pollutant with estrogenic actions, can disrupt this feedback and lead to infertility in both humans and animals. Although the hypothalamic neurons secreting gonadotropin-releasing hormone (GnRH) are potential targets for endocrine disruptors, to date direct effects of BPA on GnRH neurons have not been shown. Our study investigated the effects of BPA on GnRH neuronal activity using an explant model. In this *in vitro* model, large numbers of primary GnRH neurons are maintained that express many of the receptors found *in vivo* and exhibit oscillations in intracellular calcium that correlate with electrical activity. Single-cell RT-PCR analysis confirmed GnRH neurons express estrogen receptor (ER) β, GPR30 and estrogen related receptor γ, all potential targets for BPA. Calcium imaging was used to assay BPA effects on GnRH neuronal activity. Exposure to BPA (50 μM) significantly decreased GnRH calcium activity by 20%. Notably, population analysis revealed that only 20% of GnRH neurons responded to BPA, but that these had a decrease in activity of >50%. Blockage of GABAergic and glutamatergic input did not abrogate the inhibitory BPA effect, suggesting direct regulation of GnRH neurons by BPA. Perturbation studies of the signaling pathway revealed that both ERβ and GPR30 are involved in the BPA-mediated inhibition of GnRH neuronal activity. These data show that the endocrine disruptor BPA can directly affect a subpopulation of GnRH neurons via ERβ and GPR30. These results provide the first evidence of a direct effect of BPA on GnRH neurons.

Title: Are GnRH neurons affected by prenatal exposure to the endocrine-disrupting-compound BPA?

Authors: *H. STONER, U. KLENKE, S. WRAY;
NIH/NINDS, Bethesda, MD

Abstract: Bisphenol-A (BPA) is an estrogenic endocrine disrupting compound (EDC) used in production of polycarbonate plastics, including food and drink storage containers. There is a

growing concern over the effects of BPA on the development of the reproductive axis, which is estrogen sensitive. Gonadotropin-releasing hormone-1 (GnRH) neurons are an integral component of the reproductive axis and express estrogen receptors. As BPA is an estrogenic EDC, the reproductive axis - and possibly the GnRH neuron population - may be vulnerable to disruption. This study investigated the effects of prenatal BPA exposure on GnRH neuronal development. GnRH neurons migrate from the nasal placode to the brain between embryonic day (E) 11.5-16.5. Once within the brain, GnRH neurons are distributed bilaterally throughout the forebrain. BPA (50 mg/kg/day) or vehicle solution (castor oil) was delivered to pregnant dams for five days (E10.5-14.5) via gavaging. Embryos (E14.5, E16.5), as well as brains of prenatally exposed adult males and females (postnatal day (PN) 36) were collected and fresh-frozen. Tissue was serially sectioned, stained for GnRH, and the location and number of GnRH-positive neurons quantified. Preliminary analysis indicates that at E14.5, and in adults, BPA does not change the total number of GnRH neurons but alters the distribution of the cells. At E14.5, BPA decreased the number of GnRH neurons located in the forebrain junction and increased the number in the brain, suggesting accelerated migration. In adult brains (PN36, male), a difference between the distribution of GnRH neurons in BPA-treated versus control mice was detected, with GnRH cells located more caudally in treated mice. Whether the change in GnRH cell location after BPA exposure alters reproductive function is currently being examined.

Title: Fast glutamatergic transmission to hypothalamic kisspeptin neurons is regulated in an estrous cycle-dependent manner

Authors: *L. WANG[1], S. M. MOENTER[1,2,3];
[1]Mol. and Integrative Physiol., [2]Intrnl. Med., [3]Obstetrics & Gynecology, Univ. of Michigan, Ann Arbor, MI

Abstract: Gonadotropin-releasing hormone (GnRH) neurons of the hypothalamus form the final common pathway for central control of reproduction. Estradiol, via estrogen receptor alpha (ERα), is a major hormone providing feedback to GnRH and subsequent luteinizing hormone (LH) release. Relatively low levels of estradiol through most of the reproductive cycle provide negative feedback (-FB) regulation of the hypothalamus. During the preovulatory stage, estradiol levels rise and estradiol action switches from negative to positive feedback (+FB) to initiate the GnRH/LH surges, causing ovulation. Blockade of ionotropic glutamate (iGlu) receptors in the hypothalamus blocks the LH surge *in vivo*. Since GnRH neurons receive limited iGlu input and are under indirect ERα regulation, we tested if iGlu input to afferents of GnRH neurons are regulated by estradiol. Kisspeptin-producing neurons in the anteroventral periventricular nucleus (AVPV) and arcuate nucleus (ARC) are probable estradiol-sensitive GnRH afferents. Kisspeptin increases GnRH neuron activity. Estradiol increases kisspeptin gene expression in AVPV and decreases it in ARC. This evidence led to a model that kisspeptin AVPV neurons mediate estradiol +FB actions and ARC neurons mediate -FB actions. We hypothesize that iGlu input to these two kisspeptin populations is differentially regulated by estradiol during the cycle. To begin to test this, we studied presynaptic iGlu input to kisspeptin neurons in adult female C57BL/6-Tg Kiss1-hrGFP mice in the afternoon of proestrus (+FB, high estradiol level) and diestrus (-FB, low estradiol level). Spontaneous excitatory postsynaptic currents (EPSCs) mediated by AMPA receptors were recorded via whole-cell voltage-clamp. Membrane potential was held at -66mV to isolate AMPA-mediated EPSCs; blockade of AMPA receptors eliminated all PSCs (n=4). AVPV kisspeptin neurons exhibit increased EPSC frequency during +FB compared to -FB (3.8±0.5 n=11 vs 1.4±0.3 Hz n=12; $p<0.001$). In contrast, ARC kisspeptin neurons exhibit decreased EPSC frequency during +FB (1.5±0.2 n=9 vs 2.8±0.4 Hz n=10; $p<0.01$). EPSC amplitude was unaffected by cycle stage, suggesting no change of postsynaptic receptor expression or affinity. Altered EPSC frequency suggests that glutamatergic neurons presynaptic to kisspeptin neurons are also under cyclic estradiol regulation, changing either activity or the number of synapses. Future studies will help distinguish between these mechanisms. Our observations further imply that while kisspeptin neurons are involved in estradiol -FB and +FB during the cycle, upstream Glu neurons also appear to be critical elements of the feedback circuits.

Title: Kisspeptin stimulates gonadotropin-releasing hormone (GnRH) release detected by fast-scan cyclic voltammetry (FSCV) via mechanisms requiring both mobilization of intracellular Ca2+ stores and its influx through Ca2+-permeable membrane channels

Authors: *K. M. GLANOWSKA[1], S. M. MOENTER[2];
[1]Neurosci. Grad. Program, Univ. of Virginia, Charlottesville, VA; [2]Mol. and Integrative Physiology, Intrnl. Med. and Obstetrics and Gynecology, Univ. of Michigan, Ann Arbor, MI

Abstract: GnRH release is the final output for central control of fertility. Kisspeptin increases GnRH release in the median eminence (ME) for control of reproduction, and in the preoptic area (POA), where GnRH is a neuromodulator. GnRH release evoked by local thapsigargin differs between these regions, being action potential (AP)-dependent in ME but not POA. We tested the mechanisms of GnRH release evoked by locally-applied kisspeptin in the ME vs POA. FSCV was used to detect GnRH release in brain slices from adult male GnRH-GFP mice. FSCV electrodes were placed to detect GnRH release near neuron terminals in the ME or between GFP-identified GnRH neuron processes in the POA. To study the role of intracellular Ca^{2+} stores, xestospongin C (XC) was used to block IP_3-mediated Ca^{2+} release. XC (local, near kisspeptin application) blocked kisspeptin-induced GnRH release in 5 of 6 ME slices, but 0 of 5 POA slices. To test if XC failed to block GnRH release in the POA because its targets are more distal than kisspeptin receptors, XC was bath-applied; this blocked GnRH release in 7 of 7 slices. This suggests different arrangement of kisspeptin receptors relative to intracellular stores in POA vs ME processes and/or differences in local networks in these regions. We next tested if kisspeptin-evoked release in the ME is AP-dependent. Surprisingly, kisspeptin evoked release in 8 of 9 slices after blocking APs with TTX. Thapsigargin mobilization of intracellular Ca^{2+} failed to evoke GnRH release when APs were blocked, suggesting kisspeptin evokes GnRH release via additional mechanisms. Kisspeptin depolarizes GnRH neuron membrane potential, which could open voltage-gated Ca^{2+} channels. To test if extracellular Ca^{2+} influx contributes to kisspeptin action in the ME, we tested kisspeptin-evoked GnRH release in the presence of the Ca^{2+} channel blocker Cd^{2+} plus TTX. This combination successfully blocked kisspeptin-evoked GnRH release in 4 of 4 slices, indicating that kisspeptin stimulation of GnRH release requires both entry of extracellular Ca^{2+} and mobilization of intracellular Ca^{2+} stores. Both mechanisms appear to be required since inhibition of either prevents GnRH release. The ability of kisspeptin to induce GnRH release in the ME in the absence of APs indicates local interactions among kisspeptin and GnRH neuronal processes in this region could stimulate GnRH release without involving the somatic regions of GnRH neurons. This suggests the hypothesis that tight coupling between action potential generation and hormone release may not occur in GnRH neurons. Further, the

variations in GnRH release between the POA and ME suggest functional differences in GnRH processes in these two regions.

Title: Estradiol modulates the number of GABAA receptors binding GABA at arcuate nucleus kisspeptin (KNDy) neuron synapses

Authors: *R. A. DEFAZIO[1], C. F. ELIAS[1,2], S. M. MOENTER[1,2,3];
[1]Mol. and Integrative Physiol., [2]Obstetrics and Gynecology, [3]Intrnl. Med., Univ. of Michigan, Ann Arbor, MI

Abstract: KNDy neurons are components of the central circuitry controlling fertility. Estradiol feedback alters the postsynaptic response of KNDy neurons to GABA. Specifically, estradiol reduces the amplitude of action potential-independent (miniature) postsynaptic currents (mPSCs). $GABA_A$ receptors ($GABA_A$Rs) are ligand-gated ion channels and changes in mPSC amplitude typically depend on postsynaptic factors such as receptor (i.e., channel) number, conductance and affinity. To identify which of these contribute to estradiol-induced changes in mPSC amplitude, we used non-stationary noise analysis (NSNA), which allows conductance and channel number to be estimated from the variance of the current during the decay phase of individual mPSCs. Briefly, mPSCs occurring in isolation were aligned and averaged to generate the mean mPSC (I_{mean}). I_{mean} was scaled to the peak of each individual event, subtracted from it and the difference was squared to calculate variance. Variances of individual mPSCs were averaged and plotted as a function of I_{mean}. This plot was fitted with a parabola: variance = $i*I_{mean} - I_{mean}^2/N$, where 'i' is the current via an individual channel (unitary current), and 'N' is the number of $GABA_A$R channels activated by synaptic GABA release. Unitary current was divided by driving force to yield unitary conductance. To validate the method, we recorded mPSCs from cortical pyramidal neurons (n=2) at holding potentials of -60mV and -80mV. Consistent with previous studies, mean unitary conductance was 24.2 pS, regardless of holding potential, and the

mean number of channels was 23.3. To assess the role of estradiol on KNDy neuron $GABA_A$Rs, recordings were obtained from ovariectomized (OVX) mice ± estradiol (E). Estradiol did not alter unitary conductance (OVX 46.4±6.6 vs OVX+E 54.5±5.3 pS; $p>0.3$, n=6 cells/group). In contrast, estradiol decreased the number of activated channels (OVX 44.9±5.4 vs OVX+E 25.1±3.1; $p<0.02$). Changes in the number of postsynaptic $GABA_A$Rs activated by synaptic GABA release can be due to changes in number of available receptors or to changes in receptor affinity. We tested this with diazepam, which increases affinity of $GABA_A$Rs for GABA and thus increases mPSC amplitude if there are unbound postsynaptic $GABA_A$Rs. Diazepam increased mPSC amplitude in 5 of 5 recordings, suggesting that $GABA_A$Rs are not saturated by synaptic GABA release. NSNA confirmed diazepam increased the number of channels activated by GABA by 26% without changing conductance ($p<0.03$, n=5). We conclude estradiol reduces $GABA_A$R mPSC amplitude by decreasing the number of receptors activated by GABA, at least in part via a decrease in the affinity of the $GABA_A$R.

Title: Membrane-initiated signaling mediates estradiol-induced kisspeptin in immortalized anterior hypothalamic kisspeptin neurons

Authors: *M. A. MITTELMAN-SMITH[1], P. E. MICEVYCH[2];
[1]Neurobio., [2]David Geffen Sch. of Med., UCLA, Los Angeles, CA

Abstract: Kisspeptin neurons in the anteroventral periventricular region of the hypothalamus (AVPV) are hypothesized to mediate estrogen positive feedback on gonadotropin release. This estrogen feedback is a critical precursor to the LH surge underlying ovulation. However the nature of estrogen signaling in these kisspeptin neurons remains unknown. Because dissection of intracellular signaling pathways in kisspeptin neurons is difficult to achieve *in vivo*, we used an

immortalized cell line isolated from adult female mouse hypothalamus (mHypoA-51, CELLutions Biosystems, ON, Canada) as a model for AVPV kisspeptin neurons. Immunocytochemistry and western blot revealed expression of kisspeptin, estrogen receptor alpha and progesterone receptor (PR) in mHypoA-51 neurons. A 48-hour treatment with 1 nM 17B-estradiol (E2) induced significant increases in kisspeptin mRNA and protein. Similar results were observed when cells were treated with membrane-impermeable estradiol (E-6-BSA) for 48 hours, suggesting that upregulation of kisspeptin expression is mediated by E2 membrane-initiated signaling. PR mRNA and protein were also increased following a 48-hour E2 treatment. However, no induction of PR mRNA was observed following 48 hours of E-6-BSA, suggesting the involvement of a classical nuclear mechanism for PR induction. Data presented here suggest that membrane-initiated estrogen signaling may play an important role in kisspeptin signaling underlying the LH surge. Supported by HD04612 and 5T32HD007228

Title: AVPV kisspeptin neurons mediate neuroprogesterone induction of the luteinizing hormone surge

Authors: *L. K. PAASKE[1], T. CHUON[1], P. MICEVYCH[2], K. SINCHAK[1];
[1]Biol. Sci., California State University, Long Beach, Long Beach, CA; [2]Dept Neurobiology, David Geffen Sch. of Med. at UCLA, Lab. of Neuroendocrin, UCLA, Los Angeles, CA

Abstract: On the afternoon of proestrus, estradiol positive feedback stimulates the de novo synthesis of neuroprogesterone in hypothalamic astrocytes, which is needed to trigger the luteinizing hormone (LH) surge in the rat. Given that diagonal band of Broca (DBB) gonadotropin-releasing hormone (GnRH) neurons do not express progesterone receptors (PR), the actions of neuroprogesterone must be mediated by PR-expressing interneurons that synapse on DBB GnRH neurons that mediate the release of pituitary LH. Anteroventral periventricular nucleus (AVPV; aka RP3V) kisspeptin neurons co-express PR, and directly activate DBB GnRH

neurons to induce the LH surge. Therefore, we hypothesized that these AVPV kisspeptin neurons mediate induction of the LH surge by neuroprogesterone. To demonstrate that kisspeptin release is downstream of neuroprogesterone synthesis in this neurocircuit, progesterone synthesis was inhibited with aminoglutethimide (AGT; 1 mg/kg; s.c.) in ovariectomized (ovx) and adrenalectomized (adx) Long Evans rats and either kisspeptin (20 nmol/µl) or saline was infused into the DBB. Trunk blood was collected 53 hours post-EB injection, and serum LH levels analyzed by sandwich ELISA kit (Shibayagi, via BioVendor). AGT inhibition of neuroprogesterone synthesis blocked the EB-induced LH surge. Compared with saline controls, DBB infusion of kisspeptin and subcutaneous progesterone each restored the LH surge (SNK $P < 0.05$). In a second set of experiments, DBB infusion of kisspeptin receptor (GPR54) antagonist (kisspeptin-234) blocked EB- and kisspeptin-induced LH surges compared to saline infused rats (t-test $P < 0.05$). Finally, we tested whether kisspeptin synthesized in the AVPV was necessary for the LH surge. Kisspeptin asODNs were infused into the 3V at the level of the AVPV in EB and oil treated animals. Blocking kisspeptin mRNA translation in EB-primed rats blocked the LH surge compared to rats infused with scrambled ODNs (SNK $P = 0.011$). These results are consistent with the hypothesis that estradiol induces AVPV synthesis of kisspeptin, which estradiol-induced neuroprogesterone releases to activate DBB GnRH neurons to trigger the LH surge.

Title: A Kiss-Clock times estrous cycle

Authors: *D. CHASSARD, I. BUR-PIVERT, J. MENDOZA, V. SIMONNEAUX;
INCI, STRASBOURG, France

Abstract: Ovulation is triggered by a LH surge occurring at a specific time on the day of the proestrus, typically at the end of the day in nocturnal rodents. The LH surge timing depends on an interaction between an oestrogenic and a circadian signal. The kisspeptin (Kp) neurons in the anteroventral periventricular nucleus (AVPV) have been reported to regulate the GnRH-induced release of LH in female. Here we have investigated whether Kp neurons could be the site where both oestrogenic and circadian signals are integrated in female mice. Kp content displays a marked and transient decrease at late day, 2 hours before the LH surge on the day of proestrus, but not in diestrus, indicating that a daily regulation of Kp secretion occurs only when estrogen level is elevated. It has been reported that a circadian signal (vasopressin) originating from the master clock in the suprachiasmatic nuclei (SCN) activates Kp neurons in the AVPV. Additionally we investigated whether these AVPV Kp neurons could host a “peripheral” circadian clock. Our data show that AVPV Kp neurons express a daily rhythm of the clock protein PER1 with a 4h phase delay compared to the PER1 rhythm in the SCN. Furthermore, isolated AVPV explants from PER2-luciferase mice display marked circadian oscillations of bioluminescence activity with a circadian period of 23,31 ± 0,49h. This period is shorter than the circadian period in the SCN (25,09 ± 0,61h). In conclusion, our data demonstrate that AVPV Kp neurons display a estrogen-dependent daily activity probably driven by a endogenous Kiss-Clock, acting in synergy with the SCN clock to time the the preovulatory LH surge.

Title: Multidisciplinary analyses of gpr54-EGFP transgenic medaka reveal novel functions of the kisspeptin neuronal system

Authors: *M. NAKAJO, T. KARIGO, S. KANDA, Y. OKA;
Dept. of Biol. Sciences,Graduate school of Sci., The Univ. of Tokyo, Tokyo, Japan

Abstract: Kisspeptin-Gpr54 system has recently been considered as the key player of HPG-axis regulation in mammals. Despite the importance of hypothalamic kisspeptin neurons in mammalian reproduction, a growing body of evidence in non-mammalian vertebrates suggests important non-reproductive functions of kisspeptins. For instance, GnRH neurons do not express gpr54 mRNA and adjacent non-GnRH cells do so in some teleosts (Escobar et al., 2013; Grone et al., 2010; Kanda et al., 2013). Furthermore, it has been recently reported by electrophysiology and calcium imaging studies in medaka that kisspeptin does not affect GnRH neurons nor gonadotrophs (Karigo et al., 2012). In addition to these previous results, the complete lack of kisspeptin genes in avian species may even suggest that kisspeptin is not essential for reproduction in non-mammalian species in general. We have been searching for novel functions of Kisspeptin-Gpr54 system by using the transgenic medaka whose gpr54-1 expressing cells are labeled specifically by GFP (Kanda et al., 2012). Here, GFP-labeled Gpr54-1 cells are mainly located in some ventral telencephalic nuclei (Vd/Vs/Vp), preoptic area (POA), nucleus preopticus pars magnocellularis (POm), and nucleus posterioris periventricularis (NPPv). First, we performed electrophysiological experiments in POA Gpr54-1 cells and examined effects of Kiss1 peptides on them. Loose cell patch clamp recordings showed that the neuronal activities of these cells were persistently up-regulated by Kiss1 peptides perfusion (1μM) by ~5-fold on average. This result suggests that kisspeptin may stimulate POA Gpr54-1 cells to release unidentified neurotransmitter(s) to activate downstream neural circuitry. Therefore, we performed deep sequencing in harvested GFP positive cells. Among ~4000 candidate genes from the deep sequencing, we performed a detailed analysis of co-expression of some highly expressed neurotransmitters and Gpr54-1 by dual labeling of GFP immunohistochemistry and *in situ* hybridization. We identified that some neuropeptides that are suggested to be related to endocrine functions and feeding behaviors are expressed in Vd/Vs/Vp and POA Gpr54-1 neurons. Besides, detailed immunohistochemical analysis of GFP-labeled axons also suggested that POA Gpr54-1 cells heavily project to the pituitary, whereas Vd/Vs/Vp cells project to the medulla oblongata via hypothalamus. Thus, our present strategy using the receptor-expressing transgenic animals is expected to provide various novel insights into the kisspeptin functions that are common to and have been conserved in many vertebrate species.

Title: Electrophysiological analyses of sex steroid-sensitive Kiss1 neurons in a seasonal breeder, medaka

Authors: *M. HASEBE, S. KANDA, H. SHIMADA, Y. AKAZOME, Y. OKA;
The Univ. of Tokyo, Grad. Sch. of Scienc, Bunkyo-ku/Tokyo, Japan

Abstract: Kisspeptin neurons express sex steroid receptors and show drastic changes in their Kisspeptin gene expression in accordance with the serum sex-steroid concentration in various vertebrates, including mammalian and non-mammalian species. Thus, in vertebrates, Kisspeptin neurons are suggested to modulate various neuronal activities according to reproductive status. However, in spite of the importance of their reproductive state-dependent regulation in vertebrates, there has been no physiological analysis of Kisspeptin neurons in seasonally breeding animals. Here, by using a kiss1-EGFP transgenic line of a seasonal breeder, medaka, we performed electrophysiological analyses of sex steroid-sensitive Kiss1 neurons in a hypothalamic nucleus (Kanda et al., 2008), nucleus ventralis tuberis (NVT). By whole-cell and on-cell loose-patch recordings, we found that NVT Kiss1 neurons in a breeding condition exhibit a variety of spontaneous firing patterns; burst, regular, irregular, and silent patterns. We also found that NVT Kiss1 neurons show different firing patterns according to the different average resting membrane potential (RMP), and continuous current injections caused shifts in the firing pattern among silent, irregular, and regular. These results suggest that RMP plays an important role in determination of firing pattern in NVT Kiss1 neurons, as demonstrated in other neurons (Augustinaite and Heggelund, 2007). On the other hand, the burst firing could not be induced from other firing patterns by a current injection, which suggests that the burst firing in NVT Kiss1 neurons requires some additional acute/chronic modulations, such as synaptic inputs and/or changes in the intrinsic ion channel properties. Finally, we analyzed the neuronal activities of NVT Kiss1 neurons between breeding and non-breeding conditions. NVT Kiss1 neurons in the non-breeding conditions showed significantly lower neuronal activities than those

in the breeding conditions. Thus, the results suggest that sex steroid-sensitive Kiss1 neurons in NVT change their neuronal activities in accordance with the reproductive state, which likely reflects the serum sex steroid levels.

Title: Kisspeptin increases the spontaneous firing rate of vasotocin (VT) neurons in the brain of medaka

Authors: *Y. SHIKANO, S. KANDA, Y. OKA;
Biol. Sci., Univ. of Tokyo; Grad. Sch. of Sci., Bunkyo-Ku, Tokyo, Japan

Abstract: The central regulatory mechanism of reproduction, HPG axis, is comprised of various “key players” including neuropeptides and hormones such as gonadal sex steroids. Among them, a hypothalamic neuropeptide kisspeptin has been the focus of intensive research in this decade. In mammals, accumulating evidence suggests that kisspeptin neurons receive estrogen feedback signals from the gonads and regulate GnRH neurons. In most nonmammalian vertebrates, however, kisspeptin neurons do not necessarily regulate GnRH neurons directly. Given that birds have lost their kisspeptin genes during evolution and can still do without any kisspeptin genes for reproduction, the essential nature of kisspeptin for reproduction may be restricted to mammalian species, and kisspeptin may not be essential for reproduction in nonmammalian species. This prompted us to focus on the possible non-reproductive function(s) of vertebrate kisspeptin neuronal systems by using medaka brain. Medaka has several experimental advantages for the

study of neuronal regulatory mechanisms of reproduction; molecular genetic tools are available, and their small and transparent brain allows us to perform physiological analyses by using whole brain *in vitro* preparations in which the synaptic connections and other regulatory mechanisms are kept intact. Based on our previous finding that vasotocin (VT; ortholog of mammalian vasopressin) neurons express kisspeptin receptor, gpr54-2 mRNA, we generated transgenic medaka expressing DsRed under the control of VT 5' flanking region, and the effects of kisspeptin on VT neurons in the magnocellular preoptic area (POm) were analyzed by loose patch voltage clamp recoding. Here we examined the effects of Kiss2 peptide, because its affinity to Gpr54-2 is higher than that of Kiss1 peptide. We found that the firing rate of VT neurons transiently increased after five minute-administration of 1μM synthetic Kiss2 (12 amino acid residues with its C-terminus amidated) in about 80% of male madaka. On the other hand, Kiss2 increased only 20% of female VT neuron activity, probably due to a lower receptor expression rate in the breeding female (Kanda et al., 2013). Taken together with previous reports, it is suggested that kisspeptin may control behaviors or homeostasis such as osmoregulation by directly regulating VT neurons, although the functional meaning of sexual difference remains to be elucidated. Given that intracerebroventricular administration of KP10 (synthetic Kiss1) increases plasma vasopressin levels in rats (Scott and Brown, 2011), the regulation of VT neuron may be a widely conserved common function of vertebrate kisspeptins.

Title: 17-beta-Estradiol reduces the dendritic spine density of KNDy neurons in the arcuate nucleus of ovariectomized Tac2-EGFP transgenic mice

Authors: M. CHOLANIAN[1], S. J. KRAJEWSKI-HALL[1], N. T. MCMULLEN[2], *N. E. RANCE[1];
[1]Pathology, [2]Cell. and Mol. Med., Univ. of Arizona Col. of Med., TUCSON, AZ

Abstract: Neurons in the arcuate nucleus that coexpress kisspeptin, neurokinin B, and dynorphin (KNDy neurons) play an important role in the regulation of reproduction. Estradiol markedly decreases NKB and kisspeptin gene expression, as well as the electrical excitability of KNDy neurons (Cholanian et al., Endocrinology 2014). Here we examined whether the dendritic architecture of KNDy neurons is also altered by estradiol. Tissue slices from the arcuate nucleus of ovariectomized (OVX) and OVX plus 17β-estradiol-treated (OVX + E2) Tac2-EGFP (Tachykinin 2-enhanced green fluorescent protein) mice were used to target and fill KNDy neurons with biocytin. Biocytin-filled KNDy neurons were visualized with anti-biocytin immunohistochemistry and manually digitized using an image combining computer microscope equipped with Neurolucida software. KNDy neurons exhibited two to three primary dendrites with few branches. Spiny and spine-free (smooth) KNDy neurons were present in both OVX and OVX + E2 groups. The axons of KNDy neurons originated from the cell body or proximal dendrite and branched extensively within the arcuate nucleus. In addition to their local projections within the nucleus, the axons of KNDy neurons terminated in the adjacent median eminence, ependymal layer of the third ventricle and outside of the arcuate nucleus. Quantitative analysis revealed that treatment of OVX Tac2-EGFP mice with physiological levels of E2 decreased the cell size and dendritic spine density of KNDy neurons. These results provide the first detailed description of morphological features of arcuate KNDy neurons. In parallel with its effects on neuropeptide gene expression and electrical excitability, E2 treatment of OVX Tac2-EGFP mice induces structural changes of the dendrites of KNDy neurons.

Title: Early onset of reproductive senescence programmed by intrauterine growth restriction in the female rat is accompanied by altered KNDy cell peptide expression and hypertrophy in the arcuate nucleus of the hypothalamus

Authors: *C. FERGANI[1], S. INTAPAD[2], S. ROLLINS[1], M. N. LEHMAN[1], B. T. ALEXANDER[2], L. M. COOLEN[2];
[1]Neurobio. and Anatom. Sci., [2]Physiol. and Biophysics, Univ. of Mississippi, Jackson, MS

Abstract: Low birth weight is associated with earlier age at menopause suggesting that early life events program reproductive senescence; yet, the mechanisms involved remain unknown. Placental insufficiency in the rat results in low birth weight indicative of intrauterine growth restriction (IUGR) and the development of persistent anestrous and age-dependent hypertension by 12 months (m) of age. KNDy (kisspeptin/neurokinin B/dynorphin) cells in the arcuate nucleus (ARC) of the hypothalamus play a key role in steroid feedback control of gonadotropin-releasing hormone neurons necessary for the maintenance of estrous cyclicity. Therefore, we hypothesized that an earlier onset of reproductive senescence in IUGR females would be accompanied by alterations in kisspeptin and/or NKB peptide expression in the ARC. Reduced uteroplacental perfusion was used for induction of IUGR. Sprague-Dawley pregnant rats were anesthetized at day 14 of gestation and silver clips were placed around the lower abdominal aorta above the iliac bifurcation and around both branches of the ovarian artery. Offspring from control (sham) pregnant and reduced uterine perfusion pregnant rats were monitored for estrous cycles. Based on vaginal smears, at 12 m of age, control animals cycled regularly whereas IUGR females exhibited persistent anestrous. At 18 m of age, estrous cyclicity had ceased in both control and IUGR groups. Next, brains were fixed (n=5-9/group) and hypothalamic sections processed for kisspeptin or NKB. Numbers as well as size of immunopositive cells were measured in the ARC. At 12 m of age, IUGR females had significantly fewer kisspeptin and NKB cells compared to controls. At 18 m of age, there were no differences in NKB cell number between groups; however, the numbers of NKB cells in controls was reduced compared to the 12 m old control females. Analysis of NKB cell size showed that NKB soma area and perimeter were significantly increased in IUGR females compared to controls at 18 m, but not 12 m of age. These data support the hypothesis that IUGR programs early onset of reproductive senescence, possibly via a reduction in kisspeptin and NKB peptide in ARC, and perhaps reduced responsiveness to steroid negative feedback. Furthermore, the NKB cell hypertrophy observed in 18 m old IUGR females closely resembles findings in long term ovariectomized monkeys and post-menopausal women, and may therefore be indicative of ovarian failure. Early menopause is a risk factor for increased cardiovascular outcomes. Thus, the possibility that the earlier onset of reproductive senescence is a major risk factor for the development of hypertension in middle-aged IUGR female offspring remains to be explored.

Title: Glutamatergic neurotransmission of paraventricular nucleus of the hypothalamus modulates cardiovascular responses evoked by hemorrhage in rats

Authors: *C. BUSNARDO[1], C. C. CRESTANI[2], A. FASSINI[1], L. B. M. RESSTEL[1], F. M. A. CORRÊA[1];
[1]Pharmacol., Univ. of São Paulo, Ribeirão Preto, Brazil; [2]Dept. of Natural Active Principles and Toxicology, Sch. of Pharmaceut. Sciences, UNESP, Araraquara, Brazil

Abstract: Introduction: The glutamatergic neurotransmission of paraventricular nucleus of the hypothalamus (PVN) has been implicated in several aspects of cardiovascular control. Moreover, using the technique of immunohistochemistry to detect Fos protein, a marker of neuronal activation, it was shown that there was a greater increase in the number of Fos-immunoreactive neurons in the parvocellular region of PVN, known to contain neurons that connect with autonomic regions of the brain stem and spinal cord after hemorrhagic hypotension. Therefore, the present work studied the possible involvement of PVN glutamatergic neurotransmission in the mediation of hemorrhage-induced cardiovascular changes. Methods: Guide cannulas were implanted into the PVN of rats. Catheters were introduced into right and left femoral artery for blood pressure recordings and for bleeding. We submitted rats to hemorrhage and studied the effect of the microinjection of the selective NMDA glutamate receptor antagonist LY235959 (LY, 2nmol/100nL) or the selective non-NMDA glutamate receptor antagonist NBQX (2nmol/100nL) into the PVN on mean arterial pressure (MAP) and heart hate (HR) responses induced by hemorrhage. Results: Microinjection of LY into the PVN did not affect baseline MAP or HR (before LY: MAP = 95±1 mmHg, HR = 365±1.4 bpm; after: MAP = 95±0.3 mmHg, t = 0.3, P = 0.7, HR = 372±3.2 bpm, t = 2, P = 0.06, n = 5). Two-way ANOVA indicated a significant effect of LY on cardiovascular responses to hemorrhage [ΔMAP: $F(1,136) = 16.2$, $P<0.0001$; ΔHR: $F(1,136) = 73.1$, $P < 0.0001$], a significant effect over time [ΔMAP: $F(16,136) = 3$, $P = 0.0008$; ΔHR: $F(16,136) = 10.3$, $P<0.0001$], and an interaction between treatment and

time ΔMAP: F(16,136) = 2.1, P = 0,01; ΔHR: F(16,136) = 6, P < 0.0001]. Microinjection of NBQX into the PVN did not affect baseline MAP or HR (before NBQX: MAP = 93±0.5 mmHg, HR = 379±1.3 bpm; after: MAP = 92±0.7 mmHg, t = 1.3, P = 0.2, HR = 377±2.8 bpm, t = 0.5, P = 0.6, n = 5). Two-way ANOVA indicated a significant effect of NBQX on cardiovascular responses to hemorrhage [ΔMAP: F(1,136) = 20.8, P<0.0001; ΔHR: F(1,136) = 13.7, P = 0.0003] and a significant effect over time [ΔMAP: F(16,136) = 17.3, P<0.0001; ΔHR: F(16,136) = 28.7, P<0.0001]. Conclusion: These results show that local PVN glutamatergic neurotransmission is involved in the neural pathway of cardiovascular responses to hemorrhage. Title: Surface sugars in the nucleus of the solitary tract alter neuronal excitability to modify blood pressure and the baroreflex

Authors: *P. BOKINIEC[1], L. BOU-FARAH[1], S. MCMULLAN[1], N. H. PACKER[2], A. K. GOODCHILD[1];
[1]Australian Sch. of Advanced Med., Macquarie Park, Australia; [2]Dept. of Chem. and Biomolecular Sci., Macquarie Univ., Macquarie Park, Australia

Abstract: Background- The surface sugar polysialic acid, most commonly attached to NCAM has a restricted abundance in areas of the adult brain primarily associated with synaptic plasticity. It has been associated with BDNF and GluN2B activity. The nucleus of the solitary tract (NTS) has high expression levels of PSA in adult and receives and integrates sensory afferent traffic arising from diverse sources including baroreceptors, chemoreceptors etc. Although stimulation of afferent nerves decreases the expression of PSA (Bouzioukh et.al., 2001), the functional role of PSA in the NTS has not been determined. Our aim therefore was to determine in the NTS the role of PSA in the control of cardiovascular homeostasis. Methods- *In vivo* electrophysiological recordings of blood pressure (BP), heart rate (HR) and splanchnic

sympathetic nerve activity (sSNA) were made in the urethane anaesthetised, paralysed and ventilated male Sprague-Dawley rats. The effects of microinjecting enzymes within the NTS which cleave different sugar residues (Neuraminidase [NEU], β -Galactosidase [β-GAL] and Peptide-N-Glycosidase F [PNGase-F]) as well as those which inhibit endogenous cleavage of PSA (N-Acety-2,3-dehydro-2 deoxyneuraminic acid[NADNA]). The neuroanatomical and molecular localisation of PSA within the NTS is also been determined. Finally whole cell patch clamp recordings were made within the medial NTS of P16 Sprague-Dawley pups. Slices were either incubated in ACSF or ACSF containing NEU after which cells were subjected to a voltage step protocol. Results- NEU (n=8) compared to vehicle (n=7) evoked significant increases in BP (22.4±5 vs 3.3±1mmHg), HR (41±10 vs -18±4bpm) and sSNA (32±12.6 vs -10±6%). Furthermore, sympathetic baroreceptor reflexes were significantly attenuated (n=3). In contrast, β-GAL (n=3) or PNGase-F (n=3) or NADNA (n=3) failed to evoke any changes in BP, HR, sSNA or reflex function. At the cellular level, NEU significant enhanced currents generated by depolarizing voltage steps above 0mV (n=15 vs 8 control, $p<0.001$). PSA-NCAM is also not associated with glia, and shares close appositions with synaptophysin throughout the rostrocaudal extent of the NTS. Conclusions- Our data indicate that PSA exhibits tonic inhibitory effects within the NTS, and alters neuronal signalling which regulates baroreceptor mediated reflex activity. These results suggest that cleavage of PSA alters transmission. Hypotheses currently being tested at the cellular level explore associations of PSA with BDNF and/or the Glu2NB receptor.

Abstract: The projections of the RVLM-CA neurons have been mapped in rodents, but their inputs are not entirely defined. Whether different groups of RVLM-CA neurons have different inputs and outputs is also unknown. We sought answers to these questions by using the glycoprotein-deleted rabies virus pseudotyped to recognize an avian receptor, TVA (SADΔG-B19-eGFP-EnvA) (Wickersham et al., Neuron 53:639-647, 2007). Both TVA and rabies glycoprotein were introduced selectively into the RVLM-CA neurons of DβH-Cre mice with a unilateral injection of 2 AAV5 Cre-dependent viral vectors encoding TVA-mCherry or rabies-glycoprotein, respectively. After 4-6 weeks, the modified rabies virus was injected into the hypothalamus (n=13) or upper thoracic spinal cord (n=4), both known projection fields of RVLM-CA neurons. Ten days later, brain and spinal cord were examined by immunocytochemistry to detect the presence of TVA (mCherry), tyrosine hydroxylase (TH) and GFP. Most TVA expressing cells were RVLM-CA neurons (~270/ animal, 94% TH+). Approximately 54 "seed" cells (mCherry+ GFP+TH) / mouse were found in the RVLM. These cells were infected with rabies virus via their TVA+ terminals and were extensively GFP-labeled throughout their entire structure. The seed cells were located in more rostral VLM following spinal cord injections and in more caudal VLM after hypothalamic injections consistent with the location of hypothalamic vs. spinal projecting RVLM-CA cells reported in rats. The axonal terminals of the seed cells were observed in DMV, LC, Sp5, raphe pallidus, NTS, PBN, and contralateral RVLM consistent with known projections from the RVLM-CA cells in mice and rats. There was no discernible difference in the terminal fields of the seed cells labeled from hypothalamic vs. spinal cord rabies injections. GFP+ cells without TVA were considered to be presynaptic to the seed cells. These neurons were located within the LTF and medullary and pontine reticular formation, NTS, spinal trigeminal nucleus, raphe pallidus and magnus, PAG, PBN, and deep cerebellar nuclei. Again, there was no discernible difference in the location of the first order afferents to RVLM seed cells labeled following hypothalamic or spinal cord injections of rabies virus. In summary, the populations of mouse RVLM-CA neurons projecting to the hypothalamus or the spinal cord are located at different positions in the rostro-caudal RVLM. These neurons receive input from the same brain regions and innervate a common set of targets via their axonal collaterals. Thus, the spinal- vs. hypothalamic-projecting RVLM-CA neurons cannot be discriminated on the basis of their anatomical connections.

Title: Liver cirrhosis differentially modulates neuronal excitability in cardiac sympathetic and parasympathetic ganglia

Authors: *C.-K. LEE[1], S.-W. JEONG[1], K.-H. PARK[2];
[1]Dept. of Physiol., [2]Dept. of Pathology, Brain Res. Group, Yonsei Univ. Wonju Col. of Med., Wonju, Kang-Won, Korea, Republic of

Abstract: Patients with liver cirrhosis frequently experience cardiac autonomic dysfunctions such as augmented cardiac sympathetic and reduced cardiac vagal functions which are highly associated with mortality. Until now, however, the cirrhosis-induced autonomic imbalance has not been studied at cellular and molecular levels. Here we tested whether liver cirrhosis differentially modulates excitability of cardiac sympathetic and parasympathetic neurons. In this regard, cirrhotic rats were produced by bile duct ligation (BDL) or intraperitoneal injection of thioacetamide (TAA, 200 mg/kg). Three week after BDL or chemical injection, development of liver cirrhosis and blunted arterial baroreflex were evaluated. Action potentials (AP) were recorded in single neurons isolated from the stellate ganglia (STG) and the intracardiac ganglia (ICG) using the gramicidin-perforated patch-clamp technique. Both types of neurons mostly show tonic firing. In response to current injection (1X, 2X, and 3X), the frequency of action potentials (AP) was significantly increased in the STG neurons, while decreased in the ICG neurons of cirrhotic rats when compared with sham control. Liver cirrhosis altered rheobase and AP duration in the opposite direction in the STG and the ICG without affecting other parameters including input impedance, resting membrane potentials, AP amplitude, and afterhyperpolarization amplitude/ duration. Real-time PCR analysis and voltage-clamp recordings revealed that expression and activities of A-type K^+ and N-type Ca^{2+} channels were decreased, respectively in the STG and the ICG neurons of cirrhotic rats. Taken together, our data suggest that BDL- and TAA-induced liver cirrhosis causes the imbalance between cardiac sympathetic and parasympathetic activities through down-regulation of A-type K^+ and N-type Ca^{2+} channels. Therefore, liver cirrhosis-blunted baroreflex may arise from impaired functions of the autonomic motor limbs in the reflex arc in addition to the afferent limb (baroreceptor neuron) dysfunction.

Title: Cardiovascular autonomic function in hypertensive subjects

Authors: *R. K. GOIT[1], B. H. PAUDEL[2];
[1]Nepalgunj Med. Col., Banke, Nepal; [2]B P Koirala Inst. of Hlth. Sci., Dharan, Nepal

Abstract: Objective: The aim of the study was to compare heart rate variability (HRV) and vibration perception threshold (VPT) of hypertensive subjects with control. Research design/ Methods: The study was conducted on 50 hypertensive subjects and 50 controls. The short term HRV and VPT were assessed in both the groups. Results: All the time domain measures, standard deviation of all RR intervals (SDNN) [26 (15.5-35) vs 36 (30-40.25) ms, P=0.002], the square root of the mean of the sum of the squares of differences between adjacent RR intervals (RMSSD) [25.9 (11.95-40.45) vs 36.65 (27.05-44.13) ms, P=0.002], and percentage of consecutive RR intervals that differ by more than 50 ms (pNN50) [3.5 (0.23-21.83) vs 16.4 (4.45-27.63) %, P=0.002] were significantly less in hypertensive subjects. In frequency domain measures, low frequency (LF) [115.5 (83.75-140.75) vs 141 (104.25-249.75) ms2, P=0.021], high frequency (HF) [114.5 (74.5-179) vs 182.5 (104.25-247) ms2, P=0.006], HF [33.3 (24.52-53.22) vs 56.8 (43.02-69.17) nu, P=0.002], LF [45.2 (35.4-57.02) vs 49.8 (36.97-69.55) nu] and LF/HF [0.85 (0.5-2.02) vs 0.98 (0.65-1.62) %] were significantly less in hypertensive subjects. However, VPT was comparable between the groups. Conclusion: The hypertensive subjects had reduced cardiovascular autonomic activity.

Title: Gender differences in the distribution of Urocortin-1 immunoreactivity in brainstem autonomic nuclei

Authors: *J. CIRIELLO[1], M. M. CAVERSON[2];
[2]Schulich Sch. of Med. and Dent., [1]Univ. Western Ontario, London, ON, Canada

Abstract: Urocortin-1 (Ucn-1), a neuropeptide closely related to the hypothalamic hormone corticotropin-releasing factor, has been shown to be associated with stress and feeding behaviors and to have significant gender differences. Additionally, central administration of Ucn-1 has been shown to elicit transient changes in arterial pressure and heart rate in the male rat. We investigated whether estrogen (E; 17β-estradiol) treatment (9 weeks) affected the expression of the Ucn-1 in brainstem autonomic nuclei in female Wistar rats. Experiments were done in age matched adult males (controls), ovariectomized (OVX) only and OVX+E (30 pg/ml plasma) treated females, perfused transcardially with Zamboni's fixative. Brainstem sections (40 μm) were cut and processed immunohistochemically for Ucn-1. In the male, moderate Ucn-1 fiber labeling was found in the nucleus of the solitary tract (NTS) and throughout the rostral ventral lateral medulla (RVLM). Additionally, a few Ucn-1 immunoreactive neurons were observed in nucleus ambiguus (Amb). In OVX+E females, fewer labeled fibers were found within NTS compared to males, although RVLM was more densely innervated by Ucn-1 fibers. Furthermore, in the OVX+E female Ucn-1 labeled neurons were found not only within Amb, but also in NTS. In the OVX only animals, moderate to dense Ucn-1 fiber labeling was observed in NTS and throughout RVLM compared to males. Furthermore, numerous Ucn-1 labeled neurons were found within Amb, NTS, dorsal motor nucleus of the vagus, hypoglossal nucleus, RVLM, magnocellular reticular nucleus and nucleus raphe pallidus. These data suggest not only that gender differences exists in the distribution of Ucn-1 within brainstem autonomic areas, but that the circulating level of E may play an important role in the function of these autonomic structures during stress responses. Title: Sex differences in NMDA receptor trafficking in angiotensin receptor type 1A containing neurons in the mouse hypothalamus following slow-pressor angiotensin infusion

Authors: *J. MARQUES LOPES[1], M.-K. LYNCH[1], T. VAN KEMPEN[1], E. M. WATERS[2], C. IADECOLA[1], V. M. PICKEL[1], T. A. MILNER[1,2];
[1]Div. of Neurobio., Weill Cornell Med. Col., New York, NY; [2]Lab. of Neuroendocrinology, The Rockefeller University, NY

Abstract: In mice, slow-pressor angiotensin II (AngII) infusion induces hypertension in males but not in young (2 mo) females [Xue et al., 2005]. Renin-angiotensin system over-activity, up-regulation of post-synaptic NMDA receptor (NMDAR) function, and increased reactive oxygen species (ROS) production in the hypothalamic paraventricular nucleus (PVN) are hallmarks of AngII-induced hypertension [Veerasingham and Raizada, 2003; Wang et al., 2013]. We hypothesize that differential AngII-induced changes in post-synaptic NMDAR density and trafficking, and in ROS production in PVN angiotensin type 1a receptor (AT1aR)-expressing cells could be associated with sex differences in hypertension. Moreover, given our recent results showing protection from AngII-induced hypertension associated with decreased NMDAR density in estrogen receptor (ER) β-containing PVN dendrites of young female mice [Marques-Lopes et al., 2014], we assessed PVN AT1aR and ERβ co-localization. AngII (600ng/kg/min) or saline were infused for 14 d in 2 mo male and female transgenic mice expressing enhanced green fluorescent protein (EGFP) in AT1aR-containing cells (N=8-10/group). In males, AngII increased systolic blood pressure, and ROS production in the PVN at baseline and following NMDA in males but not females. Immunoelectron microscopy showed that AngII increased cytoplasmic and total NR1 density in AT1aR-EGFP dendrites in both males and females. However, unlike in females, AngII enhanced plasmalemmal and near plasmalemmal NR1 density in AT1aR-EGFP dendrites in males. Sexual dimorphism also was observed in morphology of AT1aR-EGFP dendrites. In males, AngII decreased area and diameter in small (<

1μm) and large (> 1μm) dendrites. Conversely, in females, AngII increased dendritic area of small dendrites and decreased diameter of large dendrites. Fluorescence microscopy revealed that AT1aR and ERβ do not co-localize in the PVN. The data suggest that increased post-synaptic plasmalemmal and near plasmalemmal NMDAR density, and augmented ROS production in AT1aR-containing PVN neurons are associated with AngII-induced hypertension in male mice. The observed AngII-evoked sex differences in PVN AT1aR neurons may be due to estrogen-mediated decreased excitatory input arising from other brain areas, including circumventricular organs.

Title: Liver cirrhosis-blunted baroreflex is associated with down-regulation of voltage-gated sodium channels in aortic baroreceptor neurons

Authors: C.-K. LEE[1], K.-H. PARK[2], *S.-W. JEONG[1];
[1]Dept. of Physiology, Brain Res. Group, [2]Dept. of Pathology, Brain Res. Group, Yonsei Univ. Wonju Col. of Med., Wonju, Gangwon-Do, Korea, Republic of

Abstract: Arterial baroreflex is a central mechanism for maintenance of cardiovascular homeostasis. Some evidence has shown that liver cirrhosis in humans and experimental animal models is associated with attenuated baroreflex sensitivity (BRS). To date, however, neural mechanisms underlying the liver cirrhosis-blunted baroreflex remain unknown. In the present study, we hypothesized that liver cirrhosis would attenuate excitability of aortic baroreceptor neurons located in the nodose ganglia. To address the hypothesis, cirrhotic rats were produced by bile duct ligation (BDL) or intraperitoneal injection of thioacetamide (TAA, 200 mg/kg). Three week after BDL or chemical injection, expression of cirrhosis markers including α-smooth muscle actin, collagen, and transforming growth factor-β was significantly increased in the liver.

These findings were consistent with histological examination of the liver tissues acquired from BDL and TAA groups. At the same period of time, BRS was significantly impaired in cirrhotic rats. Using the gramicidin-perforated patch-clamp technique, action potentials (AP) were recorded in Di-I-labeled baroreceptor neurons from sham control and cirrhotic rats. As results, excitability of tonic (A-type) and phasic (C-type) neurons was significantly attenuated with increased rheobase and decreased AP amplitude in cirrhotic rats. Consistent with the findings, TTX-sensitive and TTX-insensitive sodium currents were significantly decreased in both types of the baroreceptor neurons. RT-PCR and immunoblotting analyses revealed that expression of $Na_v1.7$, $Na_v1.8$, and $Na_v1.9$ was down-regulated in the baroreceptor neurons from the cirrhotic rats. Taken together, these data suggest that BDL- and TAA-induced liver cirrhosis blunts arterial baroreflex through attenuating excitability of the aortic baroreceptor neurons. The ionic mechanisms underlying the hypoexcitability may include down-regulation of voltage-gated sodium channels.

Title: A stress-quantification gadget: Detrended fluctuation analysis of heartbeats, from crustacean animal models to humans

Authors: *T. YAZAWA;
Tokyo Metropolitan Univ., Hachioji, Japan

Abstract: Heartbeats are controlled by the nerves (ANS). In hermit crabs (*Aniculus aniculus*) both, the acceleratory nerves (CA) and the inhibitory nerves (CI) fired at about 0Hz - 5Hz and 0Hz - 60Hz, respectively. When I experimentally approached the crabs, the activity of CI dropped and CA remained, i.e., the heart rate was increased by stress. I defined this “unhappy” state into an “acute-stressful” state. In turn, CI was active a lot, while resting in a “peaceful” state: A brief-period-slowdown in rate was observed, which repeated itself regularly. I called this an ANS-induced slowdown. The period length of slowdown varied, from 1 to 5 min. I called this

state a “stress-free” state. Meantime, a lobster (*Homarus americanus*, naturally lives in clean water) died of an illness, because it was forced to live in an aquarium, together with dirty shrimps (*Squilla mantis*), naturally living in a muddy sea. The poor lobster got sick and maintained a steady heart rate, but never showed a slowdown for two weeks, before dying. So, it died of an environmental crisis. I thus knew that I can tell whether a crab is happy or nervous by the EKGs. These crustaceans were found to be a miraculous specimen for studying stress-quantification. As a quantification tool, a detrended fluctuation analysis (DFA) was used. Our modified DFA (mDFA) checked power-law characteristics of the heartbeat-intervals data. I studied both crustaceans and humans to determine whether mDFA could be a useful tool, a gadget, for the evaluation of the subject’s quality of an illness and/or a normal healthy state. Heartbeats of stress-free lobsters (*Panulirus japonicus*) exhibited a normal scaling exponent (*SI*) of 1 ($SI = 0.99 \pm 0.38$), and stressful lobsters (*P. japonicus*) exhibited a lower scaling exponent of 0.5-0.7 ($SI = 0.55 \pm 0.21$). Interestingly, human hearts reflect a mental condition, as in a chronic job stress, for example, President of Univ., $SI = 0.84$; Dean, $SI = 0.72$; Teaching Only Prof., $SI = 0.98$, etc.). The perceived level of wellness varies among the subjects, because there are no two individuals existing, who are physiologically identical. Present case studies have shown, how the wellness of subjects can be evaluated by using EKGs. DFA is a new tool, to quantify the degree of wellness and the transition from sickness to wellness and vice versa. The exponent reflects the ANS functions.

Title: Central administration of nesfatin-1 reverses hypotension in hemorrhagic shock

Authors: *M. S. YILMAZ[1], B. ALTINBAS[2], C. SEVIM[1], G. L. ERKAN[2], G. GUVENC[2], N. GUNGOR[1], M. YALCIN[2], V. SAVCI[1];
[1]Uludag Univ. Fac. of Med., Bursa, Turkey; [2]Uludag Univ. Vet. Fac., Bursa, Turkey

Abstract: Nesfatin-1 has been identified as one of the most potent centrally acting anorexigenic peptides, and it has also been shown to play important roles in the control of cardiovascular function. Intracerebroventricularly (i.c.v.) injected nesfatin-1 induced an increase in blood pressure in conscious rats. The hypertensive effect of nesfatin-1 is thought to be mediated via the activation of sympathetic nerves through acting on melanocortin-3/4 receptors. It was further shown that the hypertensive effect of nesfatin-1 is mediated via acting on hypothalamus oxytocin receptor, which is thought to be downstream of the melanocortin system. Another recent study has also revealed that nesfatin-1 modulates blood pressure through directly acting on peripheral arterial resistance. The present study was thus undertaken to investigate the possible protective effects of nesfatin-1 against hemorrhagic shock. Male Sprague-Dawley rats were used in the study. In normotensive animals, after the connection of arterial catheter to the transducer, baseline blood pressure and heart rate measurements were recorded. Rats were allowed to be stabilized for 15 min. At the end of this period, i.c.v. injections were made. In hemorrhaged animals 20 min after hemorrhage; saline (5 μL) or nesfatin-1 (100 pmol) was injected i.c.v. just after the hemorrhage. Mean arterial pressure (MAP) and heart rate (HR) were evaluated through the experiment. For measurement of plasma catecholamine levels, blood samples (100 μl) were withdrawn from arterial catheter. In normotensive rats, blood samples were collected just before and 20, 40 and 60 min after saline or nesfatin-1 injections. In hypotensive rats, blood samples were withdrawn before and 20 min after hemorrhage and 20,40 and 60 min after saline or nesfatin-1 injections. In normotensive animals; nesfatin-1 slightly increase MAP but HR was not significantly increased by nesfatin-1 administration. Treatment with nesfatin-1 reversed hypotension in hemorrhaged rats. Nesfatin-1 caused an increase in plasma catecholamine levels in normotensive rats. Hemorrhage, itself, caused significant increases in plasma levels of catecholamines. Intracerebroventricular administration of nesfatin-1 produced additional increases in plasma catecholamine levels. Our results provide that nesfatin-1 increases blood pressure and reverses hypotension in hemorrhagic shock and increases in plasma catecholamine levels mediate this effect.

Title: Arterial pressure, baroreflex, chemoreflex and sodium excretion in rats treated with chronic infusion of aldosterone into the 4th ventricle

Authors: ***S. GASPARINI**, M. R. MELO, G. M. F. ANDRADE-FRANZÉ, P. J. RUCHAYA, M. BASSI, J. V. MENANI, E. COLOMBARI;
Sao Paulo State University. Dep. of Physiol. and Pathology, Araraquara, Brazil

Abstract: Recent results have shown that aldosterone infused into the 4th ventricle (4th V) produces intense sodium intake and positive sodium balance. In the present study, we investigated whether aldosterone infused into the 4th V modifies arterial pressure, baroreflex, chemoreflex and renal sodium excretion. Male Holtzman rats (n = 4-7/group) with stainless steel cannulas implanted into the 4th V were used. Arterial pressure was recorded continuously for 14 days by telemetry and baroreflex sensitivity and chemoreflex were tested on the 7th day of aldosterone (100 ng/µl/h) infusion into the 4th V. Chemoreflex was tested with intravenous potassium cyanide (40 µg/rat) and baroreflex sensitivity with intravenous phenylephrine (40 µg/kg body wt) and sodium nitroprusside (30 µg/kg body wt). In rats that had access to 1.8% NaCl, chronic aldosterone infusion into the 4th V impaired baroreflex (-2.8 ± 0.5, vs. vehicle: -5.1 ± 0.9 bpm/mmHg) and the bradycardic response to chemoreflex activation (-30 ± 12, vs. vehicle: -101 ± 15 bpm), without changing mean arterial pressure in the light (101 ± 3, vs. vehicle: 104 ± 6 mmHg) or dark period (110 ± 5, vs. vehicle: 113 ± 6 mmHg). In rats that had no access to 1.8% NaCl, the infusion of aldosterone into the 4th V did not modify sodium excretion (0.7 ± 0.1 to 0.9 ± 0.1 mEq/24 h, vs. vehicle: 0.1 ± 0.2 to 0.7 ± 0.1 mEq/24 h). The present results show that chronic infusion of aldosterone into the 4th V reduces baroreflex sensitivity and the bradycardic responses to chemoreflex activation, without changing arterial pressure. In addition, the results suggest that sodium intake induced by aldosterone infused into the 4th V is not dependent on the natriuresis.

Title: Stress evaluation using changes in pupillary diameter of human eyes

Authors: *N. BINTI ALUWI[1], Y. ONO[1], N. HARA[2,3];
[1]Sch. of Sci. and Technol., Meiji Univ., Kanagawa, Japan; [2]Dept. of Orthoptics and Visual Sci., Intl. Univ. of Hlth. and Welfare, Tochigi, Japan; [3]Dept. of Ophthalmology, Kanagawa Dent. Col. Yokohama Dent. and Med. Clin., Yokohama, Japan

Abstract: Information on the autonomic nervous system can be derived both from heart rate variability (HRV) and pupil size, however their functional relationship needs to be elucidated. We have carried out two types of cognitive and behavioral tasks that modify autonomic balance to test the significance in the changes of the pupillary diameter and its correlation with the HRV in healthy young adults. We adopted Verbal Fluency Task (VFT) and Eye Massage to simulate stressful and less stressful condition, respectively. Participants performed VFT of phonemic category in which they have to say as many words as possible that begin with a specific letter in a given time (60s) followed by rest (60s) for 3 times while their pupil diameter and electrocardiogram were continuously measured. For eye massage task, pupil diameter was measured for 5 minutes each before and after subjects put on the eye massager (mild periocular mechanical stimulation with warm steam) while electrocardiogram were continuously measured throughout the experiment. The WEB-1000 multi-telemetry system (Nihon Kohden Co. Ltd., Japan) was adopted to obtain ECG signals in the lead-II configuration. Pupil diameter was continuously recorded using an infrared electronic pupillometer (IRISCORDER DUAL, Hamamatsu Photonics, Japan). The mean pupil diameter and LF/HF of HRV during VFT showed concurrent increase compared to those during rest period. The mean pupil diameter significantly decreased at post eye-massage period compared to that at pre eye-massage. The mean HF and LF/HF for post eye-massage were significantly changed from pre massage with increased HF and decreased LF/HF respectively. These results suggest that there is a common tendency between change in pupil diameter and both the sympathetic and parasympathetic component of heart rate variability. Correlation between pupil diameter and sympathetic/parasympathetic marker of HRV might reveal the potential of evaluating human stress by monitoring the changes in pupil size.

Title: Characterization of the central neurons responsible for parasympathetic regulation of choroidal blood flow in rat eye using pseudorabies virus

Authors: *C. LI[1], M. E. C. FITZGERALD[1,4], N. DEL MAR[1], S. CUTHBERTSON[1], M. S. LEDOUX[1,2], S. GONG[1], P. RYAN[3], A. REINER[1];
[1]Anat. & Neurobio., [2]Neurol., [3]Microbiology, Immunology, and Biochem., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN; [4]Biol., Christian Brothers Univ., Memphis, TN

Abstract: Parasympathetic control of choroidal vasodilation is mediated by the superior salivatory nucleus (SSN) of the pons via its projection to pterygopalatine ganglion (PPG) neurons innervating choroidal blood vessels. The central neuronal cell groups upstream from the SSN neurons controlling choroidal blood flow (ChBF) have, however, been uncertain. We therefore made restricted injections of minute amounts of the Bartha strain of the retrograde transneuronal tracer pseudorabies virus (PRV) into choroid in rats in which the superior cervical ganglion had been completely excised (to prevent labeling of sympathetic circuitry). In this manner, transneuronal transport was confined to higher order neurons controlling choroidal SSN. Several neuronal populations showed prominent PRV+ immunolabeling following restricted intrachoroidal injections, in addition to the part of ipsilateral SSN previously shown by us to contain the preganglionic neurons innervating choroidal PPG neurons. The major higher order neurons included preoptic hypothalamus, the paraventricular nucleus (PVN) of the hypothalamus, the central gray, raphe magnus (RaM), the A5 cell group, the nucleus of the solitary tract (NTS), the rostral ventrolateral medulla (RVLM), and the caudal spinal trigeminal nucleus. Detailed mapping and fluorescent double-labeling was carried out to characterize the location and neurochemical phenotype of PRV+ neurons in several of these cell groups. In the PVN, PRV+ neurons were localized to its parvocellular subdivision, and they did not

immunolabel for oxytocin, vasopressin, or neuropeptide Y. In RaM, PRV+ neurons co-contained serotonin. Consistent with a serotonergic input from RaM to choroidal SSN, SSN was found to be rich in 5HT2A receptors, and serotonergic terminals were seen to make direct contact with choroidal SSN neurons. PRV+ neurons in NTS were located in its baroreceptive dorsal, intermediate and solitary tract subdivisions. Many contained calretinin but few contained tyrosine hydroxylase (TH). By contrast, many PRV+ RVLM neurons contained TH. The neuron types of PVN, RaM, NTS and RVLM projecting to choroidal SSN are responsive to systemic blood pressure signals and/or are involved in systemic sympathetic blood pressure regulation. Our results thus indicate that the brain sites responsible for parasympathetic control of ChBF are also involved in sympathetic control of the systemic vasculature. This implies that the blood pressure, salinity and volume signals that drive sympathetic constriction of the systemic vasculature may also drive parasympathetic vasodilation of the choroidal vasculature.

Title: Direct visualization of oxytocin release in the brainstem upon photoactivation of fibers originating from parvocellular neurons in the paraventricular nucleus of the hypothalamus

Authors: *H. JAMESON, R. PINOL, D. MENDELOWITZ;
George Washington Univ., WASHINGTON, DC

Abstract: In addition to the classic effects of the hormone oxytocin (OXT) on uterine contraction and milk ejection, recent work has suggested OXT can act as a neuromodulator upon synaptic release from parvocellular neurons originating in the paraventricular nucleus of the hypothalamus (PVN). One such target of PVN neurons is the parasympathetic neurons in the

brainstem that generate parasympathetic activity to the heart. Recent studies using optogenetic stimulation of the PVN neurons that express channelrhodopsin (ChR2) revealed a direct pathway from these PVN neurons to brainstem parasympathetic cardiac vagal neurons (CVNs). Photoactivation of ChR2 containing PVN fibers elicited paired-pulse facilitation of glutamatergic neurotransmission to CVNs and this enhancement was diminished after application of the OXT receptor antagonist OTA suggesting this excitatory pathway is facilitated by endogenous OXT release from these synaptic terminals. In order to further test this hypothesis and additionally elucidate the conditions required for OXT release from PVN fibers, we dispersed within the brainstem sniffer CHO cells highly sensitive to oxytocin. These sniffer CHO cells were stably transfected to express the human recombinant OXT receptor, and calcium changes within these cells could be visualized as these cells also express the red fluorescent calcium indicator, R-GECO1. Our data shows optogenetic stimulation of PVN fibers evoked large, reproducible, and transient increases in Ca2+ within the sniffer CHO cells. The photostimulation-elicited increase in Ca2+ in the sniffer CHO cells upon PVN fiber activation was abolished by application of the oxytocin receptor antagonist OTA. This work supports and extends the hypothesis that excitation of parvocellular PVN fibers releases OXT at their brainstem CVN targets. Ongoing experiments will examine whether OXT release is blunted or absent in animals exposed to chronic intermittent hypoxia/hypercapnia, an animal model of the cardiovascular disease obstructive sleep apnea.

Title: Proton modulates axo-axonal transmission of perivascular nerves in the rat mesenteric artery

Authors: ***H. KAWASAKI**[1,2], S. TAKATORI[2], S. OZAKI[3], P. TANGSUCHARIT[4]; [1]Departmen of Clin. Pharm., Matsuyama, Ehime, Japan; [2]Dept. of Clin. Pharm., Col. of Pharmaceut. Okayama city, Okayama, Japan; [4]Dept. of Pharmacol., Fac. of Medicine, Khon Kaen Univ., Khon Kaen, Thailand

Abstract: Previous studies demonstrated that nicotine released protons from adrenergic nerves via stimulation of nicotinic acetylcholine receptors (nAChR) and activated transient receptor potential vanilloid-1 (TRPV1) receptors located on calcitonin gene-related peptide (CGRP)-containing vasodilator (CGRPergic) nerves, resulting in vasodilation. The present study investigated whether perivascular nerves release protons that modulate axon-axonal neurotransmission. Rat denuded small mesenteric arteries with active tone produced by methoxamine were treated with a fluorescent pH indicator (Lysosensor green DND-189) and fluorescence and the width of artery were observed. Application of nicotine, acetylcholine and capsaicin increased fluorescence outside small mesenteric arteries due to perivascular pH-lowering and caused increase in width of arteries due to vasodilation. Nicotine-induced increase in fluorescence (pH-lowering) was markedly inhibited by guanethidine (82%) and Ca2+-free medium, while capsaicin pretreatment at high concentration caused significant inhibition (50%) of the nicotine-induced pH-lowering. Guanethidine, capsaicin pretreatment (high concentration) and Ca2+-free medium inhibited nicotine-induced vasodilation. Acetylcholine-induced increase in fluorescence was almost abolished by capsaicin pretreatment (high concentration) and Ca2+-free medium. Guanethidine resulted in 20% inhibition in pH-lowering induced by acetylcholine. Additionally, guanethidine, capsaicin pretreatment (high concentration) and Ca2+-free medium inhibited acetylcholine-induced vasodilation. Capsaicin (low concentration)-induced pH-lowering (increase in fluorescence) was markedly inhibited by capsazepine, capsaicin pretreatment (high concentration) and the Ca2+-free medium. Capsazepine, capsaicin pretreatment (high concentration) and the Ca2+-free medium also inhibited capsaicin-induced vasodilation. These results suggest that protons are released from perivascular adrenergic and CGRPergic nerves upon nerve excitement and that released protons modulate axo-axonal neurotransmission in perivascular adrenergic and CGRPergic nerves.

Title: The optogenetic photoactivation of the pathway from the hypothalamic paraventricular nucleus to parasympathetic cardiac neurons in the brainstem is blunted following chronic intermittent hypoxia and hypercapnia (an animal model of obstructive sleep apnea)

Authors: *O. Y. DERGACHEVA, D. MENDELOWITZ;
Pharmacol. & Physiol., GW Univ., Washington, DC

Abstract: Introduction: Patients with obstructive sleep apnea (OSA) have an increased risk of cardiovascular diseases. The mechanisms of these cardiovascular diseases likely include diminishing cardioprotective parasympathetic activity to the heart due to inhibition of excitatory inputs to cardiac vagal neurons (CVN) in the brainstem. One important excitatory pathway to CVNs originates from the hypothalamic paraventricular nucleus (PVN). We hypothesized that chronic intermittent hypoxia and hypercapnia (CIHH) inhibits the glutamatergic neurotransmission from the PVN to CVNs. **Methods**: The fluorescent tracer rhodamine was injected into the pericardial sac of rats to label CVNs. A lentivirus vector that drives expression of channelrhodopsin (ChR2) was injected into the PVN to express ChR2 in hypothalamic PVN neurons and fibers that project to CVNs. Synaptic events in CVNs were studied using whole cell patch-clamp techniques. A pulse of laser light photoactivated ChR2 PVN fibers and evoked glutamatergic monosynaptic transmission to CVNs. **Results**: Glutamatergic synaptic events, and paired pulse facilitation of this neurotransmission in CVNs evoked by photostimulation of PVN fibers were diminished following 4-weeks CIHH. Acute hypoxia and hypercapnia (H/H) did not significantly alter glutamatergic neurotransmission to CVNs in control animals; however, H/H inhibited synaptic currents in CIHH animals. **Conclusion**: The PVN excitatory pathway to CVNs is diminished in CIHH animals. This would elicit a reduced parasympathetic activity to the heart and an enhanced risk of adverse cardiovascular events in OSA.

Title: A novel approach for the analysis of respiratory sinus arrhythmia using breath phase information

Authors: *S. BARREDA, J. R. VRANISH, E. BAILEY;
Univ. of Arizona, Tucson, AZ

Abstract: Respiratory Sinus Arrhythmia (RSA) refers to periodic oscillations in heart rate in synchrony with respiration. RSA is considered a healthy form of heart rate variability and is thought to facilitate pulmonary gas exchange and to reflect the level of cardiac vagal tone. As a result, the measurement and quantification of RSA provides researchers and clinicians with a useful, fast, and non-invasive methodology to investigate the relationship between the cardiovascular and respiratory systems, and to assess autonomic system function. Unfortunately, the most commonly used analysis methods do not typically take respiratory information into account, and seek to quantify and describe RSA based solely on fluctuations in heart rate. Here, we propose a simple method to assess RSA that accounts for respiratory information, and places changes in heart rate in the context of the respiratory cycle. In this way, heart rate variability associated with RSA may be separated from variability arising from other sources. We collected heart rate and respiration information from five healthy, young-adult subjects using a pulse oximeter and respiratory inductance plethysmography. Data was collected during two-minute intervals of eupneic breathing, followed by two minutes of volitionally controlled breathing at several different rates (6, 7.5, 10, and 15 breaths/minute). Each record was then analyzed by treating the respiratory cycle as an almost-sinusoidal oscillation, and associating each heartbeat with the phase of the respiratory cycle during which it occurred. The results of this analysis indicate that, in healthy individuals at rest, typically around 70% of the variability in heart rate may be explained by the location of a beat within the respiratory cycle. Importantly, in many cases, there are substantive differences between RSA as measured using more traditional methods which ignore respiration, and the method outlined here. Furthermore, increases in respiratory rate lead to predictable changes in the phase relationship between RSA and the respiratory cycle which are easily quantified using this methodology. We suggest that the method outlined here is a useful tool for the investigation of RSA and cardio-respiratory coupling that offers several advantages over more common time- and frequency-domain analysis methods.

Title: Pharmacological analysis of the α1- and α2-adrenoceptors subtypes on the vasopressor responses induced by dihydroergotamine in pithed rats

Authors: *E. RIVERA, G. MANRIQUE-MALDONADO, A. H. ALTAMIRANO-ESPINOZA, I. RUIZ-SALINAS, B. VILLANUEVA-CASTILLO, C. M. VILLALÓN;
CINVESTAV-IPN, México D.F., Mexico

Abstract: Dihydroergotamine (DHE) is a semisynthetic ergot alkaloid used in acute treatment of migraine that displays affinity for a wide variety of receptors including dopamine D_2-like, serotonergic 5-$HT_{1/2}$ and $\alpha_{1/2}$-adrenoceptors. Indeed, DHE produces: (i) vasoconstriction in the canine external carotid artery bed via 5-HT_{1B} and $\alpha_{2A/2C}$-adrenoceptors; and (ii) increases in blood pressure (systemic vasoconstriction) via 5-HT_{2A} receptors and yohimbine-sensitive α_2-adrenoceptors in pithed rats. Nevertheless, no study has yet reported the α_1- and α_2-adrenoceptor subtypes involved in DHE-induced vasopressor responses. Hence, the present study was designed to identify, using selective antagonists, the specific α_1- and α_2-adrenoceptor subtypes involved in the vasopressor responses induced by DHE in pithed rats. For this purpose, male Wistar rats were anesthetized, pithed, artificially ventilated with room air (56 strokes/min and stroke volume of 20 ml/kg) and systematically pretreated with an intravenous (i.v.) bolus injection of 100 µg/kg ritanserin (to exclude the involvement of 5-HT_2 receptors). Ten min later, i.v. bolus injections of DHE or equivalent volumes of vehicle (20% propylene glycol; 1 ml/kg given 8 times) were administered in cumulative doses (1-3100 µg/kg), and the resulting effects on diastolic blood pressure were noted. DHE, but not the corresponding vehicle, produced dose-dependent increases in diastolic blood pressure. These vasopressor responses to DHE: (i) were similar ($P>0.05$) in control animals and in animals pretreated (i.v.) with the vehicles 1% ascorbic acid or physiological saline; (ii) slightly attenuated in animals pretreated (i.v.) with the α-adrenoceptor antagonists prazosin (α_1, 10 and 30 µg/kg) or rauwolscine (α_2, 100 and 300 µg/kg); and (iii) markedly blocked with the combination of 30 µg/kg prazosin plus 300 µg/kg rauwolscine. These findings clearly support the role of α_1- and α_2-adrenoceptors in the vasopressor responses to DHE. Interestingly, when pretreating (i.v.) the animals with subtype-selective antagonists in doses high enough to block their respective receptors, the vasopressor responses to DHE were significantly attenuated after 5-methylurapidil (α_{1A}, 30 and 100 µg/kg),

L-763,314 (α_{1B}, 30 and 100 µg/kg), BMY 7378 (α_{1D}, 30 and 100 µg/kg), BRL44408 (α_{2A}, 100 and 300 µg/kg), imiloxan (α_{2B}, 1000 and 3000 µg/kg) or JP-1302 (α_{2C}, 1000 µg/kg). In conclusion, these results suggest that the vasopressor responses induced by DHE are mediated by activation of the α_{1A}, α_{1B}, α_{1D}, α_{2A}, α_{2B} y α_{2C}-adrenoceptor subtypes.

Title: Effects of cold exposure on autonomic function during sleep and early-morning blood pressure surge in prehypertensives

Authors: *C.-H. HONG, T. KUO, C. YANG;
Inst. of Brain Sci., Natl. Yang-Ming Univ., Taipei City, Taiwan

Abstract: Cardiovascular events occur more frequently in the morning, during which there is an acute change in blood pressure (BP), called morning blood pressure surge (MBPS). Prehypertension is related to a high risk of cardiovascular events than normotension. Our previous study reported that cold exposure elevates the amplitude of MBPS and is associated with late sleep stage transition sympathetic activation, which might be important implications for cold-related cardiovascular events in normotensives. However, few studies have been done on the effects of cold exposure on autonomic function during sleep stage transitions and changes of sleep architecture of prehypertensives. Therefore, we carried out an experiment aiming to test the hypothesis that the effects of cold exposure on changes of autonomic function during sleep and MBPS in young prehypertensives were more exaggerate than young nonmotensives. Fourteen normotensive and prehypertensive male adults with a mean age 24.36±0.77 and 27.00±1.38, respectively. Subjects underwent cold (16 ℃) and warm (23 ℃) conditions randomly. BP was

measured every 30 minutes by an autonomic BP monitor. The electroencephalograms (EEGs), electrooculograms (EOGs), electromyograms (EMGs), electrocardiograms (ECGs) and near body temperature were recorded by miniature polysomnography. Under cold exposure, (1) a significant higher amplitude of MBPS than in warm conditions among normotensives ($p < .05$), however, such changes were more exaggerate in prehypertensives. (2) a significant decrease on HF during the last sleep stage transition from NREM to REM in prehypertensives, whereas no such change was found in normotensives; (3) a higher early-morning (2 h before waking) surge on BP and on sympathetic activity than that during the first 2 h of sleep period ($p < .05$) in prehypertensives than normotensives; (4) a significant decrease in number of REM periods ($p < .05$) was observed under cold exposure in normotensives, whereas no such changes was found in prehypertensives. Our study reinforces cold exposure might increase the risk of sleep-related cardiovascular events for prehypertensives.

Abstract: There is growing recognition of descending endocannabinoid modulation of sensory pathways from the midbrain dorsal periaqueductal gray (DPAG) contributing to the relief of neuropathic pain. Endocannabinoids also activate the sympathetic nervous system through

actions at cannabinoid 1 receptors (CB1Rs) in the stress networks of the dPAG. We have established a link between pain susceptibility and autonomic activation by showing that rats with elevated initial heart rate (HR) and sympathetic tone do not develop neuropathic hyperalgesia when subjected to spinal nerve ligation. These studies were designed to determine if baseline HR is correlated to altered components of the endocannabinoid system in the dPAG. Male Sprague-Dawley rats (320-340 gm) were implanted with telemetric units to monitor blood pressure. HR and HR variability were derived from the blood pressure measurements on days 5-7 following implantation surgery. Brains were removed on day 7, and the dPAG region was excised and quick-frozen in liquid nitrogen. Real time RT-PCR was performed to analyze the tissue samples for mRNA expression of the endocannabinoid metabolic enzymes fatty acid amide hydrolase (FAAH) and monoacylglycerol lipase (MAGL) and for CB1Rs. Transcript levels were plotted against HR and HR variability for regression analysis to determine correlations between components of the endocannabinoid system in the dPAG and baseline HR and sympathetic tone. We found a significant, inverse correlation between HR and amounts of FAAH and MAGL mRNA. There was a similar tendency for the low frequency/high frequency ratio of HR variability, an indicator of sympatho-vagal balance. Transcript levels for CB1R did not change with HR or HR variability. Downregulation of FAAH and MAGL expression at high baseline HR would be expected to result in increased concentrations of the endocannabinoids, anandamide and 2-arachidonoylglcyerol, respectively. These data suggest a link between altered endocannabinoid signaling in the dPAG, sympathetic tone and predisposition to neuropathic pain. Title: The stressed synapse: Effects of corticosterone (CORT) and corticotropin-releasing hormone (CRH) on hippocampal dendritic spines

Authors: *Y. CHEN[1], P. SEE[1], J. MOLET[2], X. ZHUO[1], T. BARAM[3];
[1]Pediatrics, [2]Anatomy/Neurobiology, [3]Pediatrics & Anatomy/Neurobiology, Univ. Cal Irvine, IRVINE, CA

Abstract: Rationale: Multiple molecules are released in response to stress, and both steroids and the stress hormone CRH bathe hippocampal synapses during stress. Both CORT and CRH contribute to stress-induced deficits in hippocampus-dependent memory, and the mechanisms seem to involve the integrity and function of hippocampal synapses located on dendritic spines. Much work has focused on the individual effects of these stress-related molecules on dendritic spines: CORT has complex effects on spine structure and turnover, and we found that CRH application results in selective loss of thin spines already within hours. Here we describe the individual and combined effects of CORT and CRH on spines of CA1 pyramidal neurons. Methods: Dorsal hippocampal slices from 3-month-old Thy1-YFP mice or C57BL/6 were assigned to one of four experimental groups: vehicle, CORT, CRH, and CORT plus CRH. CORT (100 nM) and CRH (50-100 nM) alone or together were infused for 40-120 min. Spine numbers and types were assessed in YFP-expressing mice on specific dendritic segments of CA1 pyramidal neurons. Hippocampal synaptic structure was assessed using quantitative immunohistochemistry for postsynaptic density protein (PSD)-95 followed by deconvolution analysis of wide-field 3D images. In addition, the fate of individual spines was assessed dynamically, using live imaging with two-photon microscopy. Results: Upon a two hour exposure, CORT alone had little effect on thin spines and enhanced the size of mushroom spines, as reflected also from a shift in the size distribution of synapses. CRH alone resulted in reduction of thin spine numbers, with little effect on mushroom-type spines, leading to augmented relative abundance of mushroom-type spines. The combined application of CORT and CRH led to a significant shift of synapse size distribution as represented by an increased number of large PSD-95-immunoreactive puncta (between 0.3-0.8 μm3) compared with vehicle, CRH, or CORT alone. The underlying mechanisms and the relevance to memory processes are under current examination. Conclusions: These preliminary data suggest that the effects of combined CORT and CRH are not simply additive, and have implications for understanding the effects of stress on hippocampal synaptic structure and memory functions.

Physiol. & Biophysics, Vanderbilt Univ., Nashville, TN

Abstract: Objective: Corticotropin-releasing hormone (CRH) activation of the R1 receptor acts throughout the brain and pituitary to facilitate endocrine and behavioral stress responses, while the endocannabinoid (eCB) CB1 receptor acts in an opposite direction. Although these signaling systems have overlapping distribution, few have investigated if these systems interact. Methods & Results: Using adult male Sprague Dawley rats, we found that icv CRH decreases eCB levels (anandamide) and increases FAAH activity in the amygdala, but not the PFC, at both 10 and 30 min post-CRH administration, and that these effects are mediated by CRH-R1 activation and not CRH-R2. Consistent with these findings, CRH-R1 antagonism attenuated stress-induced increases in FAAH activity and reduced amygdalar AEA content. Mice lacking CRH-R1 exclusively on glutamatergic forebrain neurons similarly showed a lack of stress-induced changes in amygdalar FAAH activity and AEA tone, suggesting CRH-R1 activation removes the 'tonic brake' normally exerted by anandamide within the basolateral amygdala, by rapidly increasing anandamide hydrolysis via FAAH activation. We also revealed that CRH-R1

glutamatergic cells co-express both FAAH protein and mRNA, suggesting this cascade appears specialized to excitatory pyramidal cells. Lastly, we have also found that CRH-R1 activation of FAAH increases anxiety-related behavior, and that this effect is attenuated by pretreatment with FAAH inhibitor. Conclusions: This CRH-driven anandamide decline seems to disinhibit the amygdala and contribute to the generation of behavioral and endocrine stress responses. Interestingly, this model likely accounts for why FAAH inhibitors only exert anxiolytic actions in aversive environments as they simply block the effects of CRH signaling.

Title: Cannabinoid type 1 receptor co-localizes with corticotropin-releasing factor in the noradrenergic nucleus locus coeruleus

Authors: *R. WYROFSKY, B. A. S. REYES, E. J. VAN BOCKSTAELE;
Pharmacol. & Physiol., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The noradrenergic system has been shown to play a key role in the regulation of stress responses, arousal and mood. The locus coeruleus (LC) provides the sole source of norepinephrine (NE) to the frontal cortex and dysregulation of cortical NE has been implicated in the pathophysiology of stress-related psychiatric disorders. Via corticotropin-releasing factor (CRF) neurotransmission, stress exposure activates LC neurons resulting in an increase in LC firing rate and increased release of NE. The endocannabinoid (EC) system has been shown to modulate NE through modulation of cannabinoid type 1 receptors (CB1R). While it is known that both CRF and CB1R regulate noradrenergic neurons in the LC, whether CB1R are co-localized to CRF-containing axon terminals in the LC has not yet been examined. To further investigate the cellular sites for interactions between CB1R and CRF, coronal sections through

the LC were processed for immunocytochemical detection of CB1R and CRF in male rat LC. Using immunofluorescence microscopy, we observed that CB1R and CRF are frequently co-localized within varicose processes in the LC. High-resolution immunoelectron microscopy using gold-silver labeling for CB1R and immunoperoxidase labeling for CRF confirmed that single axon terminals exhibited both CB1R and CRF immunoreactivities in the LC. Semi-quantitative preliminary analysis revealed that of 228 dual-labeled CB1R and CRF-containing axon terminals, 25% (56/228) formed symmetric-type synapses while 17% (39/228) formed asymmetric-type synapses with dendritic processes in the LC. The remainder of the dually labeled axon terminals analyzed (58%, 133/228) could not be unequivocally classified into either category based on the plane of section analyzed and were classified as undefined. These results reveal an anatomical basis for modulation of CRF neurotransmission by CB1R, indicating that the endocannabinoid system is positioned to modulate stress-responses in the LC. Title: Noradrenergic activation of CRH neurons via a novel retrograde trans-neuronal-glial circuit

Authors: *C. CHEN, Z. JIANG, J. G. TASKER;
Cell & Mol. Biol., Tulane Univ., New Orleans, LA

Abstract: Corticotropin releasing hormone (CRH) neurons of the hypothalamic paraventricular nucleus (PVN) release CRH as an initial signal in the hypothalamic-pituitary-adrenal (HPA) response to stress. CRH neurons in the PVN are activated by ascending noradrenergic projections from the A2 cell group in the caudal nucleus. The noradrenergic afferents provide a major excitatory drive to the HPA axis. Using whole-cell patch clamp recordings of identified CRH neurons in hypothalamic brain slices from CRH-eGFP mice, we found that norepinephrine (NE) activated local glutamate and GABA synaptic circuits via a postsynaptic α1-adrenoceptor-mediated retrograde nitric oxide release and activation of glial signaling. Glial calcium signaling resulted in ATP release and P2X purinergic receptor activation of presynaptic glutamate and

GABA neurons, which resulted in a net excitation of the CRH neurons. This represents a novel mechanism of stimulation of the CRH neurons by NE via a neuronal-glial retrograde trans-synaptic circuit.

Title: Cellular substrates for interactions between delta opioid receptors and corticotropin-releasing factor in the basolateral nucleus of the amygdala

Authors: ***N. A. HELDT**[1], B. A. S. REYES[1], J. STERLING[1], E. M. UNTERWALD[2], E. J. VAN BOCKSTAELE[1];
[1]Dept. of Pharmacol. & Physiol., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Ctr. for Substance Abuse Res. & Dept. of Pharmacol., Temple Univ. Sch. of Med., Philadelphia, PA

Abstract: The delta opioid receptor (DOR) plays an important role in mood, learning and memory. Dysregulation of the DOR system may contribute to heightened levels of anxiety, particularly during withdrawal from chronic cocaine administration. Anatomical studies show that DOR levels are high in the basolateral nucleus of the amygdala (BLA), a region involved in orchestrating emotional and behavioral responses to drug withdrawal. Withdrawal from drugs of abuse is known to engage the corticotropin-releasing factor (CRF) system, and CRF antagonism can block anxiety-like behaviors. The present study sought to elucidate the distribution of DOR with respect to CRF and the norepinephrine transporter (NET) using light, immunofluorescence and immunoelectron microscopy in the BLA. Forty-micron thick tissue sections of male Sprague Dawley were collected and processed for immunocytochemical detection of DOR, CRF, and NET. Light microscopy showed robust and a very dense distribution of DOR in the BLA. Using immunofluorescence, DOR exhibited a topographic distribution within the BLA, and frequently co-localized with CRF-immunoreactive neurons. NET-containing fibers were localized in close

proximity with DOR and CRF-containing amygdalar neurons. Using immunoelectron microscopy, rat brain sections were processed for the detection of DOR or DOR and CRF. Immunoperoxidase labeling for DOR was localized to both dendritic processes and axon terminals. Dual immunoelectron microscopy using gold-silver labeling for DOR and immunoperoxidase labeling for CRF, confirmed that dendritic processes exhibited both DOR and CRF immunoreactivities in the BLA. In addition, DOR was localized to axon terminals and formed synapses with CRF-containing neurons in the BLA. These results provide anatomical evidence for the interaction of the DOR and CRF systems. The present results also suggest a role for NE in modulating DOR and CRF-containing neurons that may be critical for the regulation of anxiety-like behaviors. Abstract: Corticotropin releasing factor (CRF) and orexin/hypocretin play key, sometimes parallel, roles in a host of arousal/stress responses. They have been implicated in a range of stress-induced psychiatric disorders including addiction, depression and sleep disorders. There is evidence that these systems interact and regulate each other - perhaps providing a feed forward mechanism for enhanced stress responses. Numerous lines of evidence have shown that these neuropeptide systems mutually excite each other. We and others have provided clear anatomical evidence of CRF receptors on ORX neurons and the reciprocal; ORX innervation and ORX receptors on CRF neurons. Finally, Scammell and Yanigasawa's groups have done excellent

work elucidating general afferent pathways of orexin neurons. Orexin neurons receive inputs from many CRF-rich neuronal fields including the paraventricular nucleus of the hypopthalamus (PVN), bed nucleus of the stria terminalis (bnst) and central nucleus of the amygdala (CeA). Using a combination of neuronal tracing methods and immunohistochemistry we sought to build on this earlier work and clarify if these afferent pathways include CRF neurons. This is the first study to identify CRF neurons in these regions specifically projecting to ORX neuron fields. There appears to be specific topographic distribution of these CRF inputs to different regions of the LH that supports the hypothesis that perifornical ORX neurons preferentially contribute to stress and anxiety responses.

Title: Localization of crf receptors using a newly-elucidated radioligand, pd-sauvagine

Authors: *L. A. TAN[1], M. H. PERRIN[2], J. M. VAUGHAN[2], K. A. LEWIS[2], C. J. DONALDSON[2], J. E. RIVIER[2], P. E. SAWCHENKO[1];

Abstract: The corticotropin-releasing factor (CRF) family of peptides includes CRF and the three urocortins, which signal through two distinct G-protein coupled receptors, CRFR1 and CRFR2. These receptors have been intensely studied since their discovery in the mid-90s for their role in mediating/integrating the neuroendocrine, autonomic, and behavioral responses to diverse stressors. Although the CRFR distribution has been well characterized at the mRNA level, the mapping of CRFR proteins have been limited by the absence of reliable methods for immunolocalization of either receptor. Binding of radiolabeled sauvagine, a CRF-related peptide from the skin of the frog, Phyllomedusa sauvagei, has provided perhaps the best available means of localizing CRF binding sites in the brain. Recently, a similar ligand was isolated from another

frog species, Pachymedusa dacnicolor, and called PD-sauvagine. In binding studies on membranes from COS cells transfected with cloned receptors, we confirmed that PD-sauvagine is a high-affinity agonist for both CRFRs. The radiolabeled analog, [125I-Tyr0,Glu1]-PD-sauvagine, reveals significantly more CRFR binding sites than the traditional radioligand, [125I-Tyr0,Glu1,Nle17]-sauvagine, owing likely to a slower off rate. When applied to fresh frozen sections of mouse brain and other tissues, the PD-sauvagine radioligand binds more robustly than the traditional sauvagine radioligand, and in a manner more consistent with the (cellular) CRFR mRNA distribution. Binding is competed in a dose-related and region-specific manner by subtype-specific antagonists, and is absent in double CRFR knockout mice. *In situ* binding of radiolabeled PD-sauvagine represents a sensitive and accurate means for localizing CRFR proteins in future studies.

Title: Ketamine reduces BNST CRF levels and ethanol withdrawal-induced depressive behaviors

Authors: *K. LOUDERBACK[1,2,3,4], T. L. FETTERLY[1,2,3], H. H. WILSON[2], D. G. WINDER[1,2,3,4];
[1]Mol. Physiol. and Biophysics, [2]Brain Inst., [3]Neurosci. Program in Substance Abuse, [4]Kennedy Ctr., Vanderbilt Univ., Nashville, TN

Abstract: Low-dose ketamine induces rapid and long-lasting antidepressant effects in humans, and this effect has been replicated in rodent models of depression. Ketamine acts as a noncompetitive N-methyl D-aspartate receptor (NMDAR) antagonist, but the mechanisms underlying its antidepressant effect are not fully understood. Studies, including our own, have

demonstrated that the ifenprodil derivative Ro 25-6981 (Ro), which inhibits GluN2B-containing NMDARs, is also capable of reducing depression-like behaviors in rodents. We have demonstrated that targeted knockdown of GluN2B within the bed nucleus of the stria terminalis (BNST) produces reductions in depression-like behavior in the novelty-induced hypophagia (NIH) test similar to effects observed with systemic ketamine or Ro administration. We sought to understand how GluN2B containing NMDARs in the BNST may be involved in modulation of affective behavior. It has been demonstrated that corticotropin releasing factor (CRF) within the BNST also plays a role in depression-like behaviors. CRF enhances excitatory drive onto VTA-projecting BNST neurons, and overexpression of CRF within the BNST results in increased immobility in the FST. We hypothesized that ketamine may act to inhibit activity-dependent CRF gene expression in the BNST through its blockade of NMDARs. Male C57Bl/6J mice were treated with 3mg/kg ketamine 4 hours, 24 hours, or one week prior to collection of punches containing the BNST from coronal sections. Using qRT-PCR, we observed a significant decrease in CRF transcript levels at the 24 hour time point, compared to vehicle treated controls, which returned to control levels by the one week time point. Finally, our lab has previously identified GluN2B as a major contributor to BNST NMDA receptor acute and chronic ethanol sensitivity. Long-term withdrawal from chronic voluntary ethanol administration has been demonstrated to induce depression-like behaviors in forced swim (FST) and novelty-suppressed feeding (NSFT) tests in female C57Bl/6J mice that are individually-housed. We found that these behaviors are ameliorated with systemic administration of ketamine (3mg/kg) in withdrawn mice.

Title: Basolateral Amygdala circuitry underlying modulation of stress-related behavior

Authors: ***M. BOMPOLAKI**[1], T. UNHAVANE[1], W. F. COLMERS[2], J. H. URBAN[1];
[1]Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL; [2]Pharmacol., Univ. of Alberta, Edmonton, AB, Canada

Abstract: The amygdala is traditionally regarded as the emotional center of the brain, and as such it functions as a central hub interconnecting a variety of brain regions. The basolateral nucleus of the amygdala (BLA) plays an important role in the balance between anxiolysis or stress resilience (seen with intra-BLA effects of neuropeptide Y-NPY) and anxiogenesis or stress vulnerability (seen with intra-BLA effects of corticotropin releasing factor-CRF). The effects of these endogenous neuropeptides are mediated by inhibition or potentiation, respectively, of the hyperpolarization activated current (Ih). These actions result in inhibition or potentiation of BLA output, which is then consistent with the behavioral outcomes observed. However, the neuroanatomical circuit responsible for the manifestation of these behaviors in response to NPY and CRF is currently not well understood. The goal of these studies was to examine the neurochemical phenotype of the BLA projections to the central nucleus of the amygdala (ceA) and to the bed nucleus of the stria terminalis (BST). We used a combination of retrograde and anterograde tracers combined with immunohistochemistry to characterize BLA projections and their downstream targets. The anterograde tracer Phaseolus vulgaris-leucoagglutinin (PHAL) was injected into the BLA. Examination of the tissue 7 days later demonstrated strong projections to the ceA, the lateral division of BST and the oval BST. Furthermore, the retrograde tracer Fluorogold (FG) was injected into either the ceA or BSTL resulting in retrograde identification of BLA neurons. Multiple-label immunohistochemistry was used to characterize whether these cells expressed hyperpolarization-activated, cyclic nucleotide-gated channel subunit 1 (HCN1) immunoreactivity. A number of FG-filled cells expressing HCN1 immunoreactivity were identified within localized regions of the BLA. These data indicate that alterations in BLA output mediated by the Ih current are poised to manipulate the activity of ceA and BSTL. This knowledge will aid our understanding of the functional neuroanatomy of NPY- and CRF-related circuits in the BLA and how their projections coordinate stress or anxiety related behaviors.

Title: Mapping CRF projections from the bed nucleus of the stria terminalis (BNST) using adeno-associated viral vectors in mouse and rat

Authors: *J. A. DABROWSKA, D. G. RAINNIE;
Emory Univ., ATLANTA, GA

Abstract: The bed nucleus of the stria terminalis (BNST) is known to play a critical role in mediating the behavioral and autonomic responses to a variety of stressors. The oval and fusiform nuclei of the anterolateral cell group of the BNST (BNSTALG) contain cell bodies that synthesize the stress hormone, corticotropin releasing factor (CRF). Although afferent fibers originating from the BNSTALG have been shown to innervate several key structures of the neuroendocrine and central autonomic system, the question remains as to whether, some of these fibers are CRF-positive. To directly address this question, we injected a "floxed" anterograde tracer (rAAV5/EF1a-DIO-mCherry) into the oval nucleus of the BNSTALG of CRFp3.0CreGFP transgenic mice, which express a green fluorescent protein (GFP) under the control of the CRF promoter. Two weeks after the AAV injection, serial sections were cut through the entire brain and analyzed for the presence of dual-labeled fibers (GFP-mCherry) in potential projection sites using confocal microscopy. Our results show high GFP-mCherry co-expression in cell bodies of the oval nucleus of the BNSTALG and in several terminal fields. Notably, dual-labeled fibers were observed in the dorsal raphe nucleus (DRN), the vetral tegmental area (VTA), as well as in the paraventricular nucleus of the hypothalamus (PVN). To further explore whether CRF neurons in the rat BNSTALG send analogous projections, we injected the oval nucleus with an AAV in which the human synapsin promoter-5 (hSyn) drives GFP expression. Six weeks later serial sections were cut from the entire brain, stained with an anti-CRF antibody, and visualized with an Alexa 586 secondary antibody. Sections were analyzed for the presence of dual-labeled fibers (GFP-Alexa 586). Injection of rAAV5-hSyn-GFP showed robust somatodendritic GFP expression in the oval nucleus of the BNSTALG. Dual-immunofluorescence studies revealed that the subpopulation of GFP-positive neurons in the BNST co-expressed CRF. AAV5-hSyn-GFP also resulted in robust GFP expression in fibers and terminal fields. Analysis of dual-labeled fibers confirmed the presence of CRF-GFP fibers in several divisions of the PVN: namely the anterior (PaAP), and the medial parvicellular (PaMP) divisions, the ventral (PaV), the posterior (PaPO), and PaLM-lateral magnocellular division. CRF-GFP terminals were also seen in the VTA and the central nucleus of the amygdala. The results of our study indicate that CRF neurons in oval nucleus of the BNSTALG send projections not only to the regions critically involved in the neuroendocrine and autonomic regulation, but also to centers modulating reward and affective behavior.

Title: Behavioral effects of chronically elevated corticosterone in the bed nuclei of stria terminalis: Role of corticotropin releasing factor

Authors: *J. D. SHEPARD, K. KINSLEY, E. TYLER, E. GLOTFELTY;
Towson Univ., Towson, MD

Abstract: Glucocorticoids secreted during adversity play an important role in sustaining fear and anxious behaviors during a protracted threat and may make the organism more reactive to novel threats in the future. The bed nuclei of stria terminalis (BNST) expresses glucocorticoid receptors and is a key limbic structure involved in fear and anxiety. We previously discovered that local administration of corticosterone (CORT) into the lateral BNST increases anxiety-like behavior in rats. The present study extends these findings by examining the effects of glucocorticoids in the ventromedial BNST (Exp. 1); effects of CRF in mediating the anxiogenic effects of CORT in the BNST (Exp. 2); and the potential role of CRF within the BNST in mediating anxiety (Exp. 3). We used the elevated plus maze to assess anxiety 7 days post treatment in all 3 experiments. For Exp 1, micropellets containing 30 μg of CORT or cholesterol (CHOL; control) were stereotaxically implanted in the vmBNST of Wistar rats. In contrast to the anxiogenic effects of CORT in the dlBNST, there was no effect on open arm exploration with elevated CORT in the vmBNST (ps > 0.40). Taken with earlier findings, this result supports regional specificity for the effects of CORT in the BNST. Next, we examined the effects of a CRF1 receptor antagonist (Antalarmin) on the anxiogenic effects of elevated CORT in the dlBNST (Exp. 2). One week after implanting CORT in the dlBNST rats received the plus-maze test preceded with a systemic injection of Antalarmin. Chronically elevated CORT in the dlBNST increased indices of anxiety (ps < 0.04) and this effect was abolished with Antalarmin treatment (ps < 0.05). We then instrumented rats with guide cannulas in the dlBNST and elevated systemic CORT using subcutaneous implants. Preliminary data indicate that elevated CORT increased anxiety (ps < 0.05) with a trend toward Antalarmin blocking the anxiogenic effect (ps < 0.14). Conclusions: The behavioral effects of chronically elevated CORT can be

localized to specific regions of the BNST. Further, preliminary data suggest CRF1 receptors in the dlBNST may play an important role in mediating the anxiogenic effects of chronically elevated CORT.

Title: Epigenetics of stress effects in hippocampus: The ehRatio on H3K27

Authors: *B. S. MCEWEN[1], B. BIGIO[2], D. ZELLI[1], C. NASCA[1];
[1]Lab. of Neuroendocrinology, [2]Ctr. for Clin. & Translational Sci., The Rockefeller Univ., NEW YORK, NY

Abstract: A wealth of studies has shown the involvement of histone modifications in several behavioural and neurobiological phenomena. However, in the investigation of epigenetic control of gene transcription via histone modifications, one of the challenges is yet to understand potential interplays between different processes of histone modifications and how the large numbers of histone modifications interact with each other. The evidence that H3K27ac is implicated in the mechanism of action of a novel antidepressant candidate, acetyl-L-carnitine (LAC), in either stressed or genetically vulnerable animals led us to investigate BDNFVal/Met SNP effects as well as acute stress (ARS) effects in BDNFVal/Val mice on a potential interplay between histone modification processes, such as acetylation and methylation and whether oral LAC treatment, which directly resets the chromatin assembly, may prevent the stress molecular and behavioral effects and restore vulnerable BDNFVal/Met phenotype. Thus, we provide evidence for an underlying molecular mechanism by which a dynamic interplay among two histone modifications on histone H3 controls the brain responses to environmental stressors regulating the expression of a gene, mGlu2, in hippocampus that is a marker of anxiety- and mood-related behaviors. In particular, ARS-BDNFVal/Val mice show reduced mGlu2 and

mGlu3 transcripts in hippocampus but not in prefrontal cortex (PFC), whereas BDNFVal/Met mice show a selective mGlu2 reduction in hippocampus. mGlu2 reduction correlates with a dynamic interplay between H3K27acetylation and H3K27trimethylation and chromatin immunoprecipitation (ChIP) assays link H3K27acetyl with mGlu2, but not mGlu3 reduction, in hippocampus. Both mGlu2 and histone mark changes are prevented by oral LAC treatment. ARS-induced elevated anxiety-like behavior in a light-dark test and the associated anxiety behaviour of SSRI-resistant BDNFVal/Met mice are rescued by one day of LAC oral treatment. Furthermore, BDNFVal/Met mice and ARS on BDNFVal/Val mice show reduced expression of the transcriptional coactivator with intrinsic histone acetyltransferase activity (HAT), P300, which is prevented by LAC, while the methylating enzyme, Ezh-2 is not affected. We propose an Equilibrium Histone Ratio (ehRatio) that underscores the importance of interplay between multiple epigenetic modifications, in the control of stress responses and related anxiety-like behaviors. Given the reversible nature of histone modifications, next-generation epigenetic drugs, such as HDACs' inhibitors and LAC, provide some hope for developing rapidly acting psychiatric drugs.

Title: Stress exposure induces resistance to LAC oral antidepressant treatment in a subset of vulnerable FSL rats

Authors: *A. A. MATHE[1], C. NASCA[2], V. SOUSA[1], T. L. STAN[1], P. SVENNINGSSON[1], B. S. MCEWEN[2];
[1]Clin. Neurosci., Karolinska Inst., Stockholm, Sweden; [2]Dept. of Neuroendocrinology, The Rockefeller Univ., New York, NY

Abstract: Depression, a growing problem that needs new therapeutic approaches, is often triggered by stressful experiences through a stress induced epigenetic reprogramming of gene expression. Current antidepressants require in general 2-3wks to significantly improve mood and approximately 40% of patients are considered treatment resistant. Recently, we showed that the intraperitoneal administration of acetyl-L-carnitine (LAC) induces rapid and long lasting antidepressant effects in two rodent models of depression through the epigenetic regulation of the metabotropic glutamate receptor, mGlu2, in brain regions critically involved in the pathophysiology of depression: the hippocampus and prefrontal cortex. Here we asked whether LAC, administered orally, will rescue the depressive-like phenotype of Flinders Sensitive Line (FSL) rats and whether in a context of stress Thus, FSL rats and their controls (FRL) were treated with vehicle or LAC at the low dose of 300mg/Kg dissolved in the drinking water for 7 days and subjected on day 6 to 15 min long forced swim test (FST) used as stressor and as behavioral test to assess antidepressant responses. FSL/FRL rats were also subjected to a second session of FST on day 7 to test whether the treatment worked after a stress manipulation. We found that, on the first session, Veh-FSL rats showed a higher immobility time vs Veh-FRL rats. Moreover, LAC restored the depressive-like FSL behavior in the FST. In agreement with previous findings LAC showed no effect on FRL rats, supporting the idea that LAC may supplement the lower endogenous levels of acetylcarnitine found in FSL rats. In the second FST, we again found an increased immobility time of Veh-FSL rats vs. Veh-FRL rats. Interestingly, LAC restored immobility time only in a subset of FSL rats, suggesting that the first swim session may induce a resistance in the brain responses to antidepressant treatment because of individual differences in stress responsiveness. A further molecular analysis is in progress to better understand the nature of the individual difference in brain response to potential next-generation treatments (LAC). Moreover, ChIPseq analysis will investigate differences in the chromatin structure which may account for the stress-induced resistance to LAC in a subset of animals. Comparing animals which differ in responsivity to antidepressant treatments may provide clues for identifying markers of risk and resilience to stress that can be used to promote early intervention and develop therapeutic next-generation treatments.

Title: mGlu2 is a key mediator in the responses to next-generation antidepressant treatments: Epigenetic mechanisms of neuronal plasticity

Authors: *C. NASCA, D. ZELLI, B. S. MCEWEN;
Neuroendocrinology, The Rockefeller Univ., New York, NY

Abstract: Targeting the epigenetic control of the glutamatergic synapse has the potential for rapid treatment of stress-related actions on brain, including mood related disorders. Recently, we showed that the naturally-occurring compound Acetyl-L-carnitine (LAC) causes rapid antidepressant effects through the epigenetic induction of mGlu2 receptors in both a genetic rat model of susceptibility, FSL rats, and following chronic unpredictable stress exposure. Since there is no single animal model that is relevant to human psychiatric disorders in their multiple forms, the efficacy of a new treatment should be validated in multiple animal models. Here, we tested the efficacy of LAC in effects of chronic restraint stress (CRS) in C57bl mice, comparing LAC efficacy with the SSRI fluoxetine (FLUOX) and the acetyl-donor N-acetyl-cysteine (NAC) with the ultimate goal to determine whether acetyl-donors may correct the stress-reprogrammed transcriptional machinery and promote antidepressant-like responses. In particular, we found that exposure to chronic restraint stress alters the glutamatergic homeostasis in the hippocampus and in the prefrontal cortex, causing strong reductions in mGlu2 mRNA levels, which exert an inhibitory tone on glutamate release, and that CRS does this via a down-regulation in the histone H3K27ac, a mark of active transcription. The acetyl-donors LAC and NAC, orally administered for 3 days to CRS mice, restored mGlu2 mRNA levels in the hippocampus and prefrontal cortex, whereas 3 days of FLUOX did not block the stress effects. Moreover, the stress induced dysregulation of the glutamatergic homeostasis is associated with occurrence of a depressive-like behavior, which we show is rescued by 3 days of oral administration with LAC and NAC, whereas 14 days of FLUOX oral administration are required to restore the CRS-induced depressive behavior. A chromatin immunoprecipitation analysis (ChIP and ChIPseq) for the histone H3K27ac is in progress to test the hypothesis that next-generation epigenetic drugs exert fast antidepressant responses correcting the stress-altered chromatin remodeling. Understanding the epigenetic hypothesis of the rapid treatment of stress-related mood disorders may also facilitate development of a rapidly acting suicide deterrent.

Title: Young BDNFmet carrier mice show a positive effect to stress: Is such positive effect lost with aging?

Authors: *E. M. WATERS, D. A. ZELLI, S. MAZID, B. S. MCEWEN, C. NASCA;
Lab. of Neuroendocrinology, Rockefeller Univ., NEW YORK, NY

Abstract: The hippocampus, which is involved in stress responses and mood regulation as well as in memory, displays remarkable structural and functional plasticity over the life course. Our and other labs supported a key role of the glutamatergic activity in stress-related mood disorders. Recently, we showed that acute restraint stressed (ARS) BDNFVal/Val mice and naïve BDNFVal/Met mice show a selective mGlu2 reduction in hippocampus which correlates in a light-dark test with elevated anxiety-like behavior. This evidence led us to investigate whether the met allele may confer a greater or lower vulnerability to negative events, such as a single episode of ARS. Interestingly, we found that ARS in BDNFVal/Met mice results in a decreased anxiety-like behavior in the light-dark test. Moreover, the positive response to stress in BDNFVal/Met mice correlates with an increased mGlu2 mRNA levels in hippocampus and no change in the cognate presynaptic mGlu3 receptor, suggesting that the met allele, which is carried by the 33% of human population, makes individual more reactive to either a negative or, most likely, to a positive events. Since a wealth of studies suggest that age-reduced BDNF level correlate with decreased hippocampal neuronal plasticity and cognitive functions, ongoing studies are investigating whether the ARS-induced positive response is impaired with aging in BDNFmet carrier mice. These findings open up a window of opportunity for intervention whereby BNDF signaling on glutamatergic function may be a counter-regulatory advantage under negative life events.

Title: Stress elicits contrasting patterns of responses in the dorsal vs ventral hippocampus

Authors: *D. A. ZELLI[1], B. BIGIO[2], S. CHATTARJI[3], B. S. MCEWEN[1], C. NASCA[1]; [1]Neuroendocrinology, [2]Ctr. for Clin. and Translational Sci., The Rockefeller Univ., New York, NY; [3]Neurobio., Natl. Ctr. for Biol. Sci., Bangalore, India

Abstract: The hippocampal formation, which is a target of stress and stress hormones, is a functionally and structurally complex brain region that plays a key role in regulating mood as well as memory. Previously, our and other labs have shown that stress acts synergistically with excitatory amino acids (EAA) to induce complex changes in various brain regions at several points of regulatory control. In particular, we have discovered that the glutamatergic synapse is differentially responsive to acute and chronic stress since, shedding light on a more sensitive response of the hippocampus to an acute stress and its dynamic habituation induced by chronic stress in regard to the glutamatergic synapse, except for the presynaptic mGlu2 receptors. Here we asked whether the two subregions of the hippocampus, the dorsal and ventral parts, show a different vulnerability to chronic restraint stress (CRS). The dorsal hippocampus, which corresponds to the human posterior hippocampus, is principally involved in memory function, whereas the ventral hippocampus, which corresponds to the anterior hippocampus in humans, modulates emotional and affective processes. Thus, we used both the Zivic brain blocks 1.0 and 0.5 ml to dissect the two brain regions from coronal sections of mice subjected to 21 days of chronic stress and their controls. We found that exposure to chronic stress in mice caused substantial habituation within the dorsal hippocampus, underlined by reductions in the cystine/glutamate exchanger xCT and up-regulations in the mGlu2, mGlu3, NMDA receptors as well as in the glial glutamate transporter Glt-1. Interestingly, we found that the ventral portion appears to be selectively vulnerable to chronic stress, showing a deregulated glutamate homeostasis, as underlined by decreased mGlu2 and mGlu3 receptors and no changes in the NMDA receptor and xCT and Glt-1 transporters. A further RNA-seq analysis will investigate the

different patterns elicited by CRS in the two hippocampal subregions. In parallel, presynaptic glutamate release will be studied to investigate more in depth the opposite changes induced by CRS in the two hippocampal subregions. These results underscore the importance of better understanding how stress induces transcriptional changes in hippocampal subregions that are known to play different roles in brain functions and, by extension, structural and functional changes in higher level cognition brain regions.

Title: MicroRNA profiles in medial prefrontal cortex and amygdala in rats resilient or vulnerable to chronic stress

Authors: ***R. CHEN**[1], S. BELTRAMI[1], G. KELLY[1], A. SENGUPTA[1], B. NICHOLAS[1], S. LUZ[1], W. HEYDENDAEL[1], S. BHATNAGAR[1,2];

Abstract: MicroRNAs are small endogenously expressed non-coding RNA molecules that are important post-transcriptional regulators of gene expression. Changes in expression of some microRNAs have been observed in neuropsychiatric and neurodegenerative disorders. However, little is known about changes in brain microRNAs as a result of stress, which is important in the etiology of many psychiatric disorders. In the present studies, we assessed profiles of all known mature microRNAs in two brain regions in rats that regulate behaviors relevant to psychiatric disease- the medial prefrontal cortex (mPFC) and basolateral amygdala (BLA). We exposed rats to chronic social defeat stress in a 7-day resident-intruder paradigm, in which we have previously shown the emergence of two subpopulations: a vulnerable subpopulation that exhibits short latencies (SL) to defeat associated with increased anxiety- and depressive-type behavior and

neuroendocrine dysfunction and a resilient subpopulation that resists defeat (long latencies, or LL) and that does not exhibit behavioral or neuroendocrine dysfunction. We analyzed microRNAs in the mPFC and in the BLA 24 hours after the end of the 7 days of stress. MicroRNAs were isolated and their content was analyzed on Affymetrix GeneChip microRNA 3.0 Arrays, which analyze expression of known pre- and mature microRNAs in the miRBase database (v17). In the mPFC, we observed elevated expression of miR-126 in SL vulnerable rats compared with LL resilient rats and elevated expression of miR-708 in SL rats compared with LL rats and controls. 30 total gene targets were implicated by the 2 differentially expressed microRNAs and current work is aimed at identifying pathways enriched with these gene targets. In the BLA, the expression of a total of 77 microRNAs was significantly different between SL rats and control rats, and a total of 42 microRNAs was significantly different between LL rats and control rats. All but one of the microRNAs (miR-27a) that were significantly different between LL and control rats were also significantly different between SL and control animals. For the remaining microRNAs that were significantly different between SL and controls, the general trend was one of similar effects in LL rats compared to controls as well. These results suggest 1) a potentially important role for microRNAs in the mPFC in mediating stress vulnerability but 2) that microRNAs in the BLA are not important in differentiating resilient from vulnerable phenotypes. Together, the results indicate that microRNAs are potential novel regulators of adaptations to stress.

Title: Circulating blood microRNAs are biomarkers for resilience or vulnerability to the effects of chronic social stress in rats

Authors: ***S. BELTRAMI**[1], R. CHEN[1], G. KELLY[1], A. SENGUPTA[1], W. HEYDENDAEL[1], B. NICHOLAS[2], S. LUZ[1], S. BHATNAGAR[1,3];

[1]Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Univ. of Pennsylvania, Philadelphia, PA; [3]Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: Small, noncoding RNAs, referred to as microRNAs (miR), regulate expression of a significant number of protein-encoding genes, generally repressing their expression. Circulating microRNAs have become well-validated biomarkers of immune and cardiovascular diseases. More recently miRNAs been identified as non-invasive biomarkers for several diseases of the central nervous system, including Multiple Sclerosis and Alzheimer's Disease. However, much less is known about circulating miRNAs and psychiatric illnesses. Symptoms of psychiatric illnesses such as anxiety and depression can be precipitated or exacerbated by stressful life events. Some individuals are more vulnerable to these effects of stress while others are more resilient. Identifying non-invasive biomarkers of resilience or vulnerability to the effects of stress would provide valuable information for the prevention and/or treatment of stress-related diseases. To investigate the utility of microRNAs as biomarkers of resilience or vulnerability to stress, adult male Sprague Dawley rats were subjected to chronic social defeat using the resident-intruder paradigm with exposure to an aggressive resident rat for 30min per day for 7 days. In previous work (Wood et al., 2010), we showed that rats vulnerable to chronic stress are rapidly defeated by the resident rat and exhibit increased anxiety- and depressive-type behaviors and neuroendocrine dysfunction. In contrast, rats that are resilient to chronic stress resist being defeated and do not exhibit behavioral or neuroendocrine dysfunctions. Circulating blood microRNAs were isolated from these rats and a group of control rats prior to the start of 7 days of defeat and at 24h after the last defeat and were analyzed on Affymetrix GeneChip microRNA 3.0 arrays, encompassing all known rat microRNAs. Prior to onset of social defeat, expression of miR-24-2-star, miR-27a, miR-30e, miR-362-star, miR-3590-3p, miR-532-5p was reduced in rats that later became vulnerable to stress compared to control rats. In contrast, after 7 days of defeat, resilient rats displayed reduced expression of miR-139-5p, miR-28-star, miR-326, and miR-99b compared to controls. These results provide proof-of-principle that assessment of circulating microRNAs may be useful in identifying individuals that are vulnerable to future stress or individuals that have become resilient to ongoing stress.

Title: Identifying alterations in gene regulatory networks in Post-Traumatic Stress Disorder: Evidence from preclinical models

Authors: *K. SMITH[1], D. A. CRUZ[2], B. C. BINGHAM[3], D. A. MORILAK[3], D. E. WILLIAMSON[2];
[2]Psychiatry, [3]Pharmacol., [1]Univ. of Texas Hlth. Sci. Ctr. San Antonio, San Antonio, TX

Abstract: Ongoing research by our group involves interrogating the genetic mechanisms underlying post-traumatic stress disorder (PTSD). Using a whole-genome microarray approach, we previously examined mRNA in the medial orbital frontal cortex (OFC) of human postmortem brain samples and observed 51 genes differentially expressed in PTSD subjects compared to controls. This study further examined these genes in a rat preclinical model of PTSD, the Chronic plus Acute Prolonged Stress (CAPS) model that has been shown to induce PTSD-like behavioral changes. In addition, we subjected rats to a session of fear extinction training following CAPS treatment to model prolonged exposure therapy, an effective form of cognitive behavioral therapy for PTSD in humans. Of the top 45 genes that showed differential expression in the human postmortem OFC, only mitochondrial ribosomal protein S9 (Mrps9) was differentially expressed in the OFC of CAPS-stressed rats compared to controls following treatment. Further, while human MRPS9 showed increased expression in the OFC of PTSD subjects, we found that the expression of this gene was reduced in the OFC of rats that had undergone fear extinction training following CAPS treatment. These preliminary results suggest that cognitive treatment indexed by fear extinction may reverse changes in the expression of gene networks observed in human PTSD. Future studies will investigate the effects of CAPS treatment alone (i.e., without fear extinction) on gene expression compared to unstressed controls. Additionally, work is currently underway to examine whole-genome changes in mRNA in the rat model of PTSD to identify other changes in gene expression immediately following exposure to the traumatic stress procedure. Understanding how changes in gene expression converge between human clinical PTSD and preclinical models of PTSD will ultimately aid in uncovering the root causes of this debilitating condition, and may suggest potentially novel therapeutic targets.

Abstract: A single-nucleotide polymorphism (rs2230912) in the purinergic P2X7 receptor (P2X7R) gene leading to a glutamine (Gln) by arginine (Arg) substitution at codon 460 (Gln460Arg) has been associated with mood disorders in many but not all human genetic studies. Therefore, we conducted a meta-analysis taking into account all published studies that consider association between case-control status and the P2X7R-Gln460Arg polymorphism. We found a significant effect of rs2230912 on case-control status, which can be explained by a dominant or a heterozygote disadvantage model. This finding supports a contribution of the P2X7R Gln460Arg polymorphism to increased susceptibility for the development of mood disorders. In contrast to the many loss- and gain-of-function polymorphisms that have been identified, seemingly the mood disorder associated P2X7R-Gln460Arg variant is not compromised in its activity. However, we could demonstrate at molecular and cellular level that hetero-oligomerization between human wild-type P2X7R (hP2X7R-WT) and hP2X7R-Gln460Arg impairs normal receptor function, which depends on direct physical interaction of the two P2X7R isoforms. To

further investigate the functional significance *in vivo*, we generated mice expressing hP2X7R-WT and hP2X7R-Gln460Arg, respectively. Under basal conditions humanized mice did not show any alterations in a battery of test assessing endophenotypes related to mood disorders. But interestingly, mice heterozygous for both variants showed signs of a pre-symptomatic disease stage as reflected by a decreased startle response and alterations in sleep quality and architecture. Along these lines heterozygote hP2X7R mice revealed an increased vulnerability to develop mood disorder-related endophenotypes in response to chronic stress. These results suggest that heterozygosity of wild-type P2X7R with P2X7R-Gln460Arg alters receptor function and thereby impacts the stress vulnerability. Taken together, these humanized mouse lines provide functional evidence supporting P2RX7 as a susceptibility gene of mood disorders.

Title: The 5-HTT genotype dependent effects of stressor controllability on dorsal raphe nucleus activation

Authors: *P. SCHIPPER, R. REINTJES, D. LOPRESTO, J. HOMBERG;
Donders Inst. For Brain, Cognition and Behavior, Nijmegen, Netherlands

Abstract: The 5-HTTLPR short allele, which affects serotonin homeostasis by reducing expression and function of the serotonin transporter (5-HTT), is well known for modulating the effects of stress on the pathogenesis of psychiatric disorders. The severity of a stressor's impact is strongly influenced by an individual's controllability of that stressor, with uncontrollable stressors having a much more detrimental effect on subsequent emotional behavior; these effects are known to be mediated by a serotonergic mechanism. Here, we subjected 5-HTT deficient rats and wild-type controls to a signaled active stressor avoidance behavioral paradigm, as well as a

yoked control experiment wherein the same stressors were given but the animals had no control over the stressor. Subsequently, the animals were sacrificed and serotonergic neuronal activation in the dorsal raphe nucleus (DRN) was assessed, as well as neural activation in the prefrontal cortex. We found that 5-HTT deficient rats acquired the task quicker than wild-types, resulting in lower response latency for this genotype. Whereas several effects of stressor controllability on serotonergic activation are seen throughout different regions of the DRN in the wild-type animals, few effects are seen in the 5-HTT knockout animals. Furthermore, escape latency correlated with DRN serotonergic activation in wild-types, but not in 5-HTT knockout animals. These findings indicate that the mechanisms directing the effects of stressor controllability on subsequent behavior are 5-HTT genotype dependent.

Abstract: Obsessive-Compulsive Disorder (OCD) is a complex neuropsychiatric disorder with an estimated lifetime prevalence of 2-3% worldwide. Neuroimaging studies have indicated that OCD individuals have decreased serotonin transporter (SERT) expression in the midbrain and brainstem. Moreover, Serotonin Reuptake Inhibitors (SRIs) are currently the only clinically effective medications for the treatment of OCD. The neurobiological substrates and cellular mechanisms by with SRIs produce therapeutic efficacy in OCD remain unclear. A rare single

nucleotide polymorphism, isoleucine to valine at amino acid 425 (I425V) in SERT is implicated in the pathogenesis of OCD, Tourette Disorder, alcohol abuse/dependence, anorexia nervosa and pervasive developmental disorders. However, the physiological effects of V425-SERT in serotonergic signaling and whether V425-linked dysregulation of SERT imposes behaviors contributing to OCD and possibly to other psychiatric disorders are unknown. To investigate this in a physiological context, we replaced isoleucine to valine at position 425 of exon 9 in the SERT gene (Slc6a4) and generated V425-SERT knock-in mice. The presence of the V425 mutation in SERT is confirmed by sequencing. V425-SERT mice have a birth rate consistent with Mendelian inheritance ratios, indicating that the V425 mutation in SERT did not create a trans-dominant lethal phenotype. Both male and female homozygous mice are viable, displayed no major developmental abnormalities and exhibit normal growth and size. As reported in human subjects, V425-SERT mice have reduced SERT expression and function in the midbrain and hippocampus but not in the cortex. Homozygous V425-SERT mice display elevated anxiety levels in open-field, elevated-zero maze and light-dark box tests. These results indicate that introducing naturally occurring OCD-associated human SERT coding variant leads to perturbations in normal SERT functional expression and subsequently altering serotonergic regulation of anxiety-related behaviors. Given the value of SERT offering a pharmacological target in the treatment of OCD as well as I425V association with OCD and TD, V425-SERT knock-in model provides a novel tool to further our understanding of the role of SERT in neuropsychiatric and developmental disorders. The knowledge we gain from such studies may aid in developing potential pharmaco-therapeutic strategies for the treatment of these disorders.

Title: Adolescent and female specific roles of RasGRF1 in the stress response

Authors: G. UZTURK[1], *L. A. FEIG[2];
[1]Tufts Univ., Boston, MA; [2]Tufts Univ. Sch. Med., BOSTON, MA

Abstract: Females and adolescents are both known to be particularly sensitive to stress. Studies have shown that this may be due, at least in part, to enhanced sensitivities of their HPA axis to stress, yet the molecular mechanisms underlying these differences are poorly understood. RasGRF1 (GRF1) and RasGRF2 (GRF2) form a family of calcium-activated guanine nucleotide exchange factors (GEFs) that activates Ras and Rac GTPases and regulates multiple forms of synaptic plasticity in the CA1 of hippocampus. GRF1 contributes to LTP mediated by calcium-permeable AMPA receptors and LTD mediated by NMDA receptors. Because the hippocampus is known to modulate the HPA axis that regulates the stress response, we tested the involvement of GRF1 in this process by comparing the response of GRF1 knockout (GRF1(-/-)) mice and control mice after exposure to short-term and chronic restraint stress. We found that enhanced 'risk taking' behavior in the elevated plus maze and open-field tests, as well as elevated corticosterone (CORT) levels that normally occur after chronic restraint stress (30 min/day for 7 days) are blocked in GRF1(-/-) mice in an age and sex dependent manner. In particular, these responses to chronic stress are blocked in adolescent female GRF1(-/-) mice, but normal in both their adolescent male and adult female GRF1(-/-) counterparts. Strikingly, the opposite phenotype is found after acute (a single 30 min restraint) and short-term (30 min/day for 3 days) stress, such that adolescent female, but not adolescent male or adult female GRF1(-/-) mice display enhanced CORT compared to their control counterparts. These results show that GRF1 plays an adolescent and female specific roles in the regulation of HPA axis that differs after exposure to short-term and chronic restraint stress. These observations may yield new insights into the mechanisms underlying stress induced activation of HPA axis that occurs in an age and sex dependent manner.

Title: Early life experience modulates the effects of unpredictable chronic mild stress during adolescence

Authors: *E. K. KIRSCHMANN[1,2,3], J. C. MAUNA[1,2], C. O'CONNOR[1], J. LU[1], E. C. DONNY[3,4], A. F. SVED[2,4], E. THIELS[1,2,3];

Abstract: Adolescence is a period of many neural, physiological, and behavioral changes, and may be a period of vulnerability to psychiatric disorders. Unpredictable chronic mild stress (UCMS) is a widely-used model for inducing depressive- and anxiety-like behaviors in adult rodents. We examined the effect of UCMS during adolescence on behavior, hypothalamic-pituitary-adrenal (HPA) axis function, and the brain of adolescent rats, and also tested whether early life experience (e.g., shipping conditions) influences experimental outcome. We ran 2 studies in parallel: 1) male rats weaned and shipped from the supplier on postnatal day 21 (p21; w/s condition); and 2) male rats shipped with a foster dam on p18 and weaned in-house on p21 (d/s condition). Starting at age p28-31, rats were exposed to 5 weeks of UCMS (n = 10 w/s, 9 d/s) or control conditions (Con; n = 10 w/s, 9 d/s), and we assessed effects on body weight, sucrose preference, activity in a 2hr open-field test (OF), and performance on the elevated plus maze (EPM). Rats were sacrificed at p62-65 for collection of trunk blood and brains, to examine levels of stress hormones in plasma and stress-relevant proteins in select brain regions. Prior to sacrifice, some rats were treated with saline/dexamethasone and exposed to an acute 5min swim stress, to assess HPA axis function. In the w/s condition, UCMS attenuated growth and resulted in a phenotype characterized by hyperactivity and reduced anxiety; total weight gain was significantly lower, whereas activity and time in the center of the OF arena and exploration of the open arms of the EPM were significantly higher in UCMS- compared to Con rats. Sucrose preference was significantly reduced after 1 week of UCMS, but rebounded by week 2. Plasma corticosterone levels were significantly blunted at baseline and after acute stress, and glucocorticoid receptor (GR) levels in the paraventricular nucleus were lower in UCMS- compared to Con rats. GR levels in the basolateral amygdala tended to be higher in UCMS rats. Results were very different for rats in the d/s condition. For all measures except OF locomotor activity, no differences emerged between UCMS and Con. This was not because the UCMS effect was blunted, but because the results of d/s Con and UCMS rats resembled those of w/s UCMS rats. The w/s controls, but not the d/s controls, had a phenotype similar to controls born in-house. Taken together, our findings suggest that: 1) UCMS during adolescence causes a hyperactive/risk-seeking phenotype, which is accompanied by decreased HPA axis function and changes in brain stress systems; and 2) shipping with a foster dam alters control phenotype, whereas rats weaned and shipped resemble in-house rats.

Title: Pre-pubertal ('juvenile') stress-induced susceptibility to PTSD, which is associated with selective alterations in GABAAR alpha1 subunit in the dentate and amygdala, is rescued by juvenile but not adulthood exposure to 'Enriched Environment'

Authors: *G. RICHTER-LEVIN[1], Z. ARDI[2], A. ALBRECHT[3], A. RICHTER-LEVIN[3]; [1]Univ. Haifa, Haifa, Israel; [2]Sagol Dept. of Neurobio., [3]Univ. of Haifa, Haifa, Israel

Abstract: Despite the intuitive association of Post-Traumatic Stress Disorder (PTSD) with an exposure to a trauma, most individuals are able to cope with it, and only a minority will exhibit prolonged maladaptive responses to the traumatic experience. Thus, the exposure to the trauma may be a necessary, but not a sufficient condition to induce PTSD. There must be additional factors that determine the outcome of the exposure to the trauma. Understanding the neurobiology of those risk factors holds great importance for understanding PTSD. We have developed an animal model of PTSD, which takes into consideration the exposure of rats to pre-pubertal (juvenile) stress, as a risk factor, and measuring behavioral and neurbiological outcomes one month after the adulthood trauma, to ensure the relevance of our findings to PTSD. We have demonstrated that exposure to juvenile stress is a significant risk factor for the development of PTSD (Horovitz et al, 2012; 2014). 'Enriched Environment' (EE) has been suggested to have the ability to rescue abnormal anxiety behaviors induced by stress in adulthood. In the current study we examined the ability of one month exposure to EE from juvenility to adulthood to prevent the effects of pre-exposure to 'Juvenile stress', and compared that to the ability of one month exposure to EE from after the exposure to the adulthood trauma to rescue PTSD-like symptoms following the exposure to the combination of 'Juvenile + adulthood stress'. Furthermore, we have analyzed hippocampal and amygdala tissue for correlated alterations in expression of proteins

associated with gultamatergic and GABAergic neurotransmission. Results indicate that exposure to EE from juvenility to adulthood could prevent the effects of pre-exposure to 'Juvenile stress'. In contrast, exposure to EE from after the exposure to the adulthood trauma failed to rescue PTSD-like symptoms following the exposure to the combination of 'Juvenile + adulthood stress'. In addition, we identified a selective increase in expression of GABAAR alpha1 subunit only in the basolateral amygdala and the ventral dentate gyrus, which was correlated with the PTSD symptoms. This increased expression of GABAAR alpha1 subunit was also prevented by EE from juvenility to adulthood. The results demonstrate the effectiveness of the 'Juvenile stress' model of PTSD as a platform for identifying target genes associated with PTSD psychopathology, but also with environmental risk factors for developing PTSD. In addition, the results point to selective alterations in GABAR subunit that may be part of the neurobiology of PTSD.

Title: Repeated exposure to threat in adolescence increases defensive behaviors, but decreases avoidance in highly arousing test conditions

Authors: *M. L. JACOBSON, J. LIEBMAN, N. ODYNOCKI, D. AWALT, Jr., P. PEDULLA, B. J. ANDERSON;
Psychology and Integrative Neurosci., Stony Brook Univ., Stony Brook, NY

Abstract: Stressors experienced in daily life may elicit responses that are adaptive in matched environments and maladaptive in mismatched environments. To help understand adaptations in different contexts, our lab has designed a rodent living environment that allows manipulation of threat prediction and control. When presenting repeated unpredictable threats (UT) without harm, rodents develop heightened responses to aversive stimuli, including potentiated defensive burying and sensitization of acoustic startle. These effects represent hyper-reactivity to threat and hypervigilance, two features of anxiety. Both effects are in response to stimuli that increase arousal, but there were no effects on passive avoidance in the elevated plus maze (EPM), a test

sensitive to anxiolytics and typically tested in neutral test conditions. To understand whether group differences emerge only in high arousal conditions or to focused threat, we retested avoidance of open arms in the EPM in highly arousing conditions. Rats were housed with resources (food and water) separated by a tunnel for three weeks. Simultaneous presentations of predator odor, abrupt lights and sound were presented randomly (p=.25) in the center of the tunnel during crossings in the UT condition, whereas control (CT) rats crossed without risk. After the condition, animals were tested in the EPM with wind and variable room noise. UT rats explored the open arms of the maze more than CT during the first five minutes of maze exposure, and the effect was not explained by differences in locomotion. Regardless of testing conditions, ambiguous or aversive, repeated threats failed to increase passive avoidance. In contrast, when tested in the Barnes maze, previous threat exposure impaired memory in tests of low arousal test conditions, but improved memory in highly arousing test conditions. The increase in entries into open arms of the EPM in aversive test conditions suggest that improved memory in identical aversive test conditions is not accounted for by motivation to avoid open spaces. In summary, exposure to repeated threats increases active defensive behaviors without increasing passive avoidance; therefore repeated threats produce behaviors that favor active over passive coping forms of coping, and match the positive symptoms of anxiety, but not negative symptoms. Future studies will investigate other symptoms of anxiety, including impaired safety learning.

Title: Changes to tyrosine hydroxylase activity in the adult medial prefrontal cortex following adolescent social defeat

Authors: *M. A. WEBER[1], J. L. SCHOLL[1], G. L. FORSTER[1], K. J. RENNER[2], M. J. WATT[3]; [1]Basic Biomedial Sciences, Univ. of South Dako, Vermillion, SD; [2]Biol., Univ. of South Dakota, Vermillion, SD; [3]Basic Biomed. Sciences, Univ. of South Dakota, Vermillion, SD

Abstract: Negative social experience in adolescence is associated with increased incidence of psychiatric disorders manifesting both acutely and later in life, which are characterized by deficits in cognitive processing. Such deficits may result from stress-induced disruption of the developing adolescent prefrontal cortex (PFC) dopamine (DA) system. We have shown that male rats exposed to repeated social defeat during adolescence exhibit decreased medial PFC (mPFC) DA activity in adulthood, along with associated behavioral changes such as impaired working memory. Here, we investigated whether mPFC DA hypofunction could result from reductions in activity of tyrosine hydroxylase (TH), the rate-limited enzyme in DA synthesis. Male rats were defeated daily for 5 days from postnatal days (P) 35-39 using a modified resident-intruder paradigm. Controls did not experience social defeat, but were exposed to a novel empty cage for the duration of each defeat trial. After maturing undisturbed to early adulthood (P56), rats received injections of either vehicle or the aromatic amino acid decarboxylase (AADC) inhibitor NSD-1015 (100 mg/kg, ip.), with accumulation of the DA precursor DOPA in the mPFC serving as a measure of *in vivo* TH activity. Subjects were decapitated 30 min after injection, and tissue content of mPFC DOPA quantified using HPLC with electrochemical detection. Inhibition of AADC resulted in greater DOPA accumulation compared to vehicle treatment. However, previously defeated rats showed significantly higher DOPA content 30 min following AADC inhibition than controls. Current studies are examining additional time points following AADC inhibition to determine if the time course of DOPA accumulation differs between defeated and control rats. Western immunoblots are also being used to measure expression of both total and phosphorylated TH as a complimentary analysis of changes to mPFC TH activity following adolescent defeat. Findings to date suggest that experience of social defeat in adolescence has long-lasting effects on mPFC TH activity, implying alterations to DA synthesis.

Title: Adolescent experience of food restriction results in delayed enhancement of spatial learning in female rats

Authors: *T. G. CHOWDHURY[1], A. A. FENTON[2], C. AOKI[2];
[1]NYU Ctr. For Neural Sci., New York, NY; [2]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Adolescence is a period of vulnerability to onset of psychiatric illnesses such as depression, schizophrenia, addictions, and eating disorders. We have shown that adolescence is a critical period for experience-dependent plasticity in the ventral hippocampus, a region important for regulation of anxiety. In the ventral hippocampus of female rats, we observed a transient increase in the number of apical dendritic branches and a steadily increased proportion of mature spines on CA1 pyramidal cells during the period between puberty and adulthood. These increases were followed by pruning of branches by adulthood with no change in the proportion of mature spines. These anatomical changes occurred precociously in animals that experienced activity-based anorexia (ABA), a rodent model of anorexia nervosa that combines the experience of food restriction and voluntary wheel-running exercise (Chowdhury et al., 2014). To study the effects of exercise and food-restriction separately, and jointly as ABA, on hippocampus-dependent behaviors, we tested spatial learning, anxiety, and cognitive flexibility. Four experimental groups of females were evaluated: CON (control rats with no running wheel experience or food restriction), ABA (housed with a running wheel from P36-44 and food restricted from P40-44), EX (housed with a running wheel from P36-44), and FR (food restricted from P40-44). Behavioral outcomes were measured at two ages: P47 and P53. We trained rats across two days in an active place avoidance task that requires persistent hippocampal synaptic plasticity (Pastalkova et al, Science, 2006). Day 1 included an open field test on the rotating circular arena in dim light and without shock, followed by three 10-min training sessions to actively avoid the zone of a 500 ms, 0.3 μA shock that stays stationary relative to room-based spatial cues. The day 2 retention test was followed by three conflict sessions with the shock zone in the opposite location to test cognitive flexibility. At P47, we found that EX and FR groups

entered the shock zone during the 2nd training session less than CON and ABA groups. EX and FR groups also entered less during the 1st conflict trial than CON and ABA groups. At P53, animals that experienced food restriction from P40-44 (ABA and FR groups) learned to avoid more rapidly than CON and EX groups. In the first two training sessions, ABA and FR groups had half as many entries as CON and EX groups. These results suggest that the experience of exercise during adolescence transiently improves spatial learning while food restriction improves learning through young adulthood. ABA has a delayed effect of improved spatial learning in young adulthood.

Title: Acute stress to adolescent rats reduces p-CREB in adulthood

Authors: *V. M. CHIU, B. K. YAMAMOTO;
Dept. of Neurosciences, Univ. of Toledo, Toledo, OH

Abstract: Early-life stress may cause long-term effects that are evident in adulthood. Previous studies have shown that repeated stress during adolescence decreases glutamate receptor expression in the prefrontal cortex. However, it is unknown whether acute traumatic stress during adolescence could alter transcription factors that may be associated with long term effects in adulthood. The current study exposed rats to acute traumatic stress during adolescence and examined the transcription factory, CREB in adulthood. An acute, single prolonged stress (SPS) paradigm was used that included restraint for 2 hours followed by forced swim for 20 min and anesthetization with isoflurane 15 min later. This paradigm has been used to model a stressful traumatic experience. Rats were exposed to SPS or no stress as a control at PND 28 and left undisturbed until adulthood and killed on PND 60. Preliminary results show that prior exposure to SPS, decreased phosphorylated cAMP response element-binding protein (p-CREB) by 20% ($p < 0.029$) and histone deacetylase 2 (HDAC2) by 40% ($p < 0.003$) in the frontal cortex compared to the no stress group when examined at 60 days of age. However, the above changes were not

observed in the dorsal hippocampus. These results suggest that the effects of early childhood stress persist for at least a month in a brain region dependent manner that may involve epigenetic mechanisms. Further experiments are needed to further examine the mechanisms underlying the protracted effects of adolescent traumatic stress that exhibit in adulthood.

Title: Social context differentially modulates neural Zif268 expression, behaviour, and endocrine function in response to acute and repeated stress in adolescent and adult male rats

Authors: *T. E. HODGES, C. M. MCCORMICK;
Psychology, Brock Univ., St. Catharines, ON, Canada

Abstract: Few studies have directly compared adolescent and adult hypothalamic-pituitary-adrenal (HPA) function in response to chronic stressors. In this experiment we manipulated stress history and social context: adolescent and adult rats underwent either acute (postnatal day 45; P45 or P85) or repeated (16 consecutive days from P30-45 or P70-85) one hr isolation (confined in a small ventilated container) after which they returned to either their original (familiar) or a new (unfamiliar) cage partner. Behaviour of rats upon return to the colony after isolation was monitored for 40 minutes. Blood samples and brains were collected either before the acute (baseline) or last repeated isolation, after isolation, or one hour after isolation after return to a familiar or unfamiliar cage partner for measurement of plasma corticosterone and testosterone using Elisa kits and for visualization of Zif268 expression by immunohistochemistry. Isolation stress increased in adolescent rats, and decreased in adult rats, affiliative behaviours irrespective of partner familiarity ($p<0.02$). In both adolescents and adults, there was no effect of stress history or partner familiarity on baseline corticosterone concentrations, and after 1 hr isolation, those that were undergoing their 16th isolation had lower corticosterone concentrations than those undergoing their first isolation (ps=0.01). After one hour of recovery, those with a familiar partner had lower corticosterone than did those with an

unfamiliar cage partner, irrespective of stress history. The only age difference in corticosterone was that adolescents had significantly higher corticosterone after a 16th return to an unfamiliar partner compared to a 1st return ($p=0.03$), whereas number of new partner pairings was not a factor for adults ($p>0.50$). Testosterone concentrations indicated that adult rat gonadal function was more responsive to isolation and social context than was adolescent gonadal function: adult testosterone increased after 1 hr isolation compared with baseline regardless of stress history and partner familiarity ($p=0.04$), and adult rats repeatedly paired with a familiar partner after isolation had lower testosterone concentrations compared with adult rats repeatedly paired with unfamiliar peers ($p=0.003$) and adult controls isolated for the first time ($p=0.002$). Further, adolescent and adult rats differed in Zif268 expression in a number of brain regions depending on stress history and partner familiarity. Differential responses to stressors between adolescents and adults may be based in age differences in sensitivity to social context rather than immaturity of the HPA axis.

Title: Adolescent CB1 receptor antagonism alters adult stress responsivity and emotional behaviour in male rats

Authors: *T. T.-Y. LEE[1], M. N. HILL[2], B. B. GORZALKA[1];
[1]PSYCHOLOGY, Univ. of British Columbia, VANCOUVER, BC, Canada; [2]Anat. and Cell Biol., Hotchkiss Brain Institute, Univ. of Calgary, Calgary, AB, Canada

Abstract: Previous work from our laboratory has reported dynamic and temporal-specific changes in anandamide (AEA) content and fatty acid amide hydrolase (FAAH) activity within corticolimbic structures throughout the peri-adolescent period. Moreover, CB1 receptor

expression has been reported to peak during early to pre-adolescence, which then decreases to adult levels. Together, these findings suggest that normative adolescent endocannabinoid signaling within the corticolimbic stress circuit may be vulnerable to perturbations such as stress or exogenous cannabinoids. Therefore, we sought to examine the role of adolescent CB1 receptor activation in the development of HPA axis stress responsivity and emotionality behaviour in male rats. Between post-natal days (PND) 35-45, animals were administered daily IP injections of CB1 receptor antagonist, AM-251 (5 mg/kg), or vehicle. Upon reaching adulthood (PND 75), endocannabinoid content, HPA axis stress reactivity and emotional behaviour were assessed. AM-251 treated males exhibited greater anti-depressive-like behaviour in the forced swim test and greater risk assessment behaviour in the elevated plus maze, with no significant differences in general motor activity. Preliminary results suggest that adolescent AM-251 treatment had no significant effect on HPA axis stress reactivity to restraint. The relatively modest long term behavioural effects of adolescent CB1 receptor antagonism also resulted in moderate changes to the adult endocannabinoid system, with no significant changes to 2-AG content, and a small but significant increase and decrease in the amygdala and hypothalamus, respectively.

Title: Programming grit: Prepubertal stress combined with social support promotes resilience even in the face of aging

Authors: K. E. MORRISON[1], *C. N. EPPERSON[2], T. L. BALE[1];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Psychiatry, Perelman Sch. of Med., Philadelphia, PA

Abstract: The prepubertal period represents a particularly sensitive window for adversity to precipitate adult affective disorders in women. In contrast, a supportive social environment following exposure to early life adversity is a strong predictor of long-term resiliency, or grit. A mild amount of stress during early life has been associated with improved coping skills in adulthood, suggesting that grit is a valuable characteristic aligned with future success. Affective disorders and cognitive deficits commonly emerge during aging, with many women reporting increased difficulty with emotional regulation as well as prefrontal cortex (PFC)-dependent executive functions. Risk factors for late-onset cognitive and affective disorders in women include prepubertal adversity, a time that coincides with PFC maturation. We have developed a novel mouse model to examine the interaction between prepubertal experience and age-related changes in cognition and stress regulation. Female mice were exposed to prepubertal chronic variable stress (CVS) from postnatal day 21-34 and either individually housed, to model stress susceptibility (CVS-S), or housed with social interaction, to model resiliency (CVS-R). One year following this stress, mice were examined in tasks to access their cognition and their HPA stress axis reactivity. We found that the aged females displayed significantly lower circulating estradiol than young controls, irrespective of prepubertal stress experience, indicating onset of reproductive senescence. To examine cognition, females were tested for spatial memory acquisition and reversal learning on a modified Barnes maze. Aged female controls displayed a deficit in reversal learning compared to young controls. Interestingly, aged CVS-R females displayed improved performance in reversal learning, suggesting that prepubertal stress with social support promotes resilience. As reversal learning is a PFC-dependent task, whole RNA was isolated from the PFC and gene expression was obtained via Affymetrix GeneChip microarray analysis. Statistical comparison revealed a subset of genes with expression patterns that reflect the findings in reversal learning, such that CVS-R females have differing expression compared to both control and CVS-S females. Prepubertal CVS did not alter stress responsivity in aged females, as assessed by both HPA stress axis responsivity and the acoustic startle response. These data suggest that prepubertal stress in the context of social support provides females with resilience to age-related cognitive decline and provides a novel mouse model for the examination of the mechanisms underlying this interaction.

Title: Developmental high-fructose diet consumption increases depressive-like and anxiety-like behavior and remodels the hypothalamic transcriptome

Authors: ***C. S. HARRELL**, J. BURGADO, S. D. KELLY, Z. P. JOHNSON, G. N. NEIGH; Emory Univ., Atlanta, GA

Abstract: Fructose consumption, which promotes insulin resistance, hypertension, and dyslipidemia, has increased by over 25% since the 1970s. In addition to metabolic dysregulation, fructose ingestion stimulates the hypothalamic-pituitary-adrenal axis resulting in elevated glucocorticoid production. Adolescents are the greatest consumers of fructose, and adolescence is a critical period for maturation of the hypothalamic-pituitary-adrenal axis. Repeated consumption of high levels of fructose during adolescence has the potential to promote long-term dysregulation of the stress response. Therefore, we determined the extent to which consumption of a diet high in fructose affected behavior, serum corticosterone, and hypothalamic gene expression using a whole-transcriptomics approach. In addition, we examined the potential of a high-fructose diet to interact with exposure to chronic adolescent stress in male Wistar rats. Rats fed the peri-adolescent high-fructose diet showed increased anxiety-like behavior in the elevated plus maze and depressive-like behavior in the forced swim test in adulthood, irrespective of stress history. They also showed elevated basal corticosterone but a blunted response to forced swim. These behavioral and hormonal responses to the high-fructose diet did not occur in rats fed fructose during adulthood only. Finally, rats fed the high-fructose diet throughout development underwent marked hypothalamic transcript expression remodeling, with 966 genes (5.6%) significantly altered and a pronounced enrichment of altered transcripts in the POMC pathway. Collectively, the data presented herein indicate that diet, specifically one high in fructose, has the potential to alter behavior, HPA axis function, and the hypothalamic transcriptome.

Title: Prepubertal adversity in females programs a blunted stress reactive maternal phenotype during pregnancy

Authors: *K. E. MORRISON, T. L. BALE;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: The prepubertal period of development represents a particularly sensitive window for adversity to precipitate later adult affective disorders in women. However, a supportive social environment is a strong predictor of long-term resiliency, and appears to ameliorate the detrimental effects of the stress. Periods of great hormonal flux across the female lifespan are associated with the precipitation of affective disturbances, including puberty onset, pregnancy, and menopause. This suggests that prepubertal adversity may program central pathways involved with regulation of or interaction with hormonal state to determine affective symptomology. We have developed a novel mouse model to examine the factors that determine risk and resilience to prepubertal adversity, and the mechanisms involved in stress pathway dysregulation that intersect with hormonal state. Female mice were exposed to chronic stress from postnatal days 21-34 while being either individually housed, to model stress susceptibility, or housed with social interaction, to model resiliency. We examined endpoints in adults related to stress pathway regulation. Female stress dysregulation, a key feature of affective disorders, was assessed both by HPA responsivity to an acute restraint stress and the acoustic startle response, prior to pregnancy, during early (E7.5) or late (E17.5) pregnancy. We found that prepubertal stress significantly blunted the acoustic startle response, irrespective of pregnancy state. As the acoustic startle response is an indicator of PFC function, these data show that adversity can alter PFC programming that is ongoing during the prepubertal window, and that this programming is independent of hormonal status. HPA dysregulation, via a blunted corticosterone response in prepubertal stress groups was evident only during pregnancy. This suggests that HPA programming intersects with the hormonal changes that occur during pregnancy. To better understand the mechanisms by which prepubertal stress interacts with pregnancy to produce stress dysregulation, regions relevant to the stress response, such as the prefrontal cortex, hypothalamus, and amygdala, were examined. Together, these studies confirm prepubertal stress as a risk factor for endophenotypes of affective disorders, particularly during later periods of hormonal flux across the lifespan and provide a novel mouse model for the examination of the mechanisms underlying this interaction.

Title: Social instability stress in adolescence alters social behaviour in a food competition task

Authors: M. J. CUMMING[1], M. THOMPSON[1], *C. M. MCCORMICK[2];
[1]Neurosci., [2]Brock Univ., Saint Catharines, ON, Canada

Abstract: Social instability stress in adolescence (SS; daily 1 h isolation + new cage partners postnatal days 30 - 45; thereafter with original cage partner, also in the SS condition) and control (CTL) rats competed for access to a preferred food (sweetened condensed milk) in 5 test sessions. As adults, all rats were habituated individually to the test apparatus in three 10 min sessions (adapted from Matalynska et al., 2007). In the first test session, SS pairs displayed more aggressive behaviour (frontal attacks, $p = 0.02$; rear attacks, $p = 0.03$), and were less likely to relinquish access to the food voluntarily ($p = 0.03$) and tended to spend more time at the feeder than CTL pairs ($p = 0.06$). Pairs were considered to have formed dominant-submissive relationships (DSR) if one rat spent significantly more time at the feeder than the other across the five sessions. A similar number of SS and CTL pairs displayed significant DSRs (8 of 12 pairs each). Analyses were conducted to investigate change in behaviour from the 1st to 5th session in SS and CTL rats based on DSR status (DSR pair, no-DSR pair). Aggressive behaviour increased from the 1st to 5th session ($p < 0.001$), was greater in no-DSR than DSR pairs ($p = 0.04$; consistent with the proposed adaptive value of forming DSRs), and was higher in SS than CTL pairs ($p = 0.057$). Time at feeder increased ($p < 0.001$) from the 1st to 5th session, but the three-way interaction was significant ($p = 0.009$) for number of bouts at the feeder: SS pairs had more bouts than CTL pairs on the first day ($p = 0.02$), and in the 5th session, SS pairs had fewer bouts than CTL pairs ($p = 0.04$) among the no-DSR pairs, and did not differ for the DSR pairs ($p = 0.53$). The percentage of voluntary retreats from the feeder decreased from the 1st to 5th session, and SS pairs tended to have a lower percentage of voluntary retreats ($p = 0.08$) than did CTL pairs. These results add to our previous findings that social instability stress in adolescence modifies the adult social repertoire of rats and highlight the importance of adolescent social experiences in adult behaviour.

Title: A critical period of vulnerability to adolescent stress: epigenetic mediators in mesocortical dopaminergic neurons

Authors: ***M. NIWA**, R. S. LEE, S.-I. KANO, A. SAWA;
Psychiaty and Behavioral Sci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Adolescence is a sensitive developmental period when environmental stressors can affect dynamic brain maturation, which in turn determines adult behaviors. The molecular basis of vulnerability to stress during the adolescent period is largely unknown. We recently reported that adolescent stress on a genetically vulnerable mouse model led to neurochemical abnormalities and behavioral deficits in adulthood via glucocorticoids (Niwa et al, Science 2013). In the present study, we identify potential molecular mediators that may play a role in stress-induced behavioral deficits. We report that three-week (five to eight weeks of age) adolescent stress in combination with *Disc1* genetic risk elicits alterations in DNA methylation of a specific set of genes, *Th*, *Bdnf*, and *Fkbp5*. The epigenetic changes in the mesocortical dopaminergic neurons are prevented when mice are treated with a glucocorticoid receptor (GR) antagonist RU38486 during the isolation period, which implicates the role for glucocorticoid signaling in this pathological event. We define the critical period of GR intervention as the first one-week period during the stress regimen, suggesting that this particular week in adolescence may be a specific period of maturation and function of mesocortical dopaminergic neurons and their sensitivity to glucocorticoids. Our study may provide insight into how and when individuals with genetic risk(s) may require early detection and prophylactic intervention to protect against risks of adolescent stressors.

Title: Voluntary wheel running exercise by female adolescent rats reduces GABAergic synaptic coverage of the CA1 pyramidal cell bodies and dendrites but the same exercise maintains GABAergic synaptic coverage and increases alpha4-GABARs at spines, if also exposed to and is resilient to food restriction-stress while evoking no change to alpha1-GABARs

Authors: *C. J. AOKI, K. TATEYAMA, I. YU, J.-Y. WANG, M. HSU, G. S. WABLE, T. G. CHOWDHURY;
Ctr. Neural Sci., New York Univ., NEW YORK, NY

Abstract: Physical exercise (EX) has many health benefits, including anxiolysis and the improvement of cognition and mood. These benefits are likely to be linked to cellular changes in the hippocampus, including angiogenesis, neurogenesis and the release of neurotrophins, but are also influenced by stressors that induce neurogenesis-dependent anxiety. For humans, dieting is one stressor that is often combined with EX. Another human condition in which stress frequently co-exists with EX is anorexia nervosa. We've shown that when food restriction (FR) is imposed upon rodents given access to a running wheel, many, but not all exhibit great increases in voluntary EX, causing them to lose more weight than by FR alone. Post mortem analysis

indicated that moderate exercisers (MEX) increase α4-containing GABA receptors (α4-GABARs) at dendritic spines of the hippocampus, while those that express life-threateningly high, i.e., excessive levels of EX (EEX) fail to up-regulate α4-GABARs (Aoki et al., 2014) and exhibit elevated anxiety (Wable et al, ms in prep). Here, we sought to determine (1) whether EX alone also induces α4-GABAR expression; (2) whether α1-GABAR expression is altered among the EEX; and (3) whether GABAergic innervation is altered by EX alone and differently, depending on whether the animal has become an EEX due to FR. Electron microscopy with a non-diffusible marker was used to probe for the presence and level of α4-GABARs and α1-GABARs at the plasma membrane, synapses and extra-synaptic sites and of the extent of GABAergic synapses formed on somatic and dendritic plasma membranes of the hippocampal CA1 of female adolescent rats. We compared the values among animals with EX only and also of those induced to become spontaneously EEX or MEX following 8 days of access to a running wheel plus 4 days of FR. We show that (1) the extent of voluntary running correlates negatively with α4-GABAR expression at excitatory axo-spinous synapses (R=-.65; p=.02) with or without FR, suggesting suppression of excitatory inputs within the MEX hippocampi that may underlie anxiolysis; (2) α4-GABARs at plasma membranes outside of axo-spinous synapses increase >100% among the MEX but not of those of EEX or EX alone (i.e., without FR); (3) α1-GABAR expression is unaltered by FR+EX; (4) GABAergic innervation is reduced ~25% by EX alone, through reduction of axon numbers at somata and shafts; (5) GABAergic innervation is also reduced by FR+EX, but only among those that become EEX. These findings indicate that EX exerts differential effects, depending on whether it is combined with FR and depending on individuals' response of becoming EEX and anxious or MEX and not anxious.

Title: Three weeks of maternal separation induced a long lasting changes in the plasticity of hippocampal neurons of offspring and mothers

Authors: *G. BIGGIO[1], P. P. SECCI[1], M. V. MELIS[1], M. C. MOSTALLINO[2];
[1]Dept. Life and Envrn. Sci., Univ. of Cagliari, Monserrato, Italy; [2]Inst. of Neurosci., Natl. research Council, Cagliari, Italy

Abstract: Neural plasticity is the capability of neurons to changes the structure, function and organization of neurons in response to new experiences. It specifically refers to strengthening or weakening nerve connections or adding new nerve cells based on environmental stimuli. These processes are responsible for physiological changes, learning and the formation of appropriate responses to external events. Neural plasticity is among the most important aspects of the field of modern neuroscience and its study is leading to a better understanding of brain development. In this study the expression levels of BDNF and Arc protein, the density of dendritic spines and the neurogenesis, were studied after a long-lasting stress, due to maternal separation Neuroplasticity was evaluated in controls (mother and offspring not exposed to maternal separation) and after the stress induced by maternal separation (3h at day from the 3rd to the 21st day after birth). The mothers were sacrificed 21 days after the birth and pups in three different age groups: 21, 30 and 60 days. In the hippocampus of non-stressed we found an increase in the expression levels of the protein BDNF and Arc, in the dendritic spines density and in the neurogenesis, a phenomenon still present at weaning (21 days postpartum). In contrast, opposite effect (decrease) was observed on all the neurogenesis parameters in the mothers separated of their pups for 3 h per day for 20 days. Similarly to the mothers, also in hippocampus of the pups separated from their mothers was present a reduction of BDNF, Arc, dendritic spines density and neurogenesis in all three ages studied (21, 30 and 60). These results demonstrate that stress due to separation in the postnatal period results in adverse effects on neuronal plasticity in the hippocampus of both mothers and offspring.

Abstract: We investigated gene expression in prefrontal cortex of mice subjected to acute and repeated social stress using microarrays. The most important finding was identification of hemoglobin genes (*Hbb-b1*, *Hbb-b2*, *Hba-a1*, *Hba-a2*, *Beta-S*) as potential markers of chronic social stress in mice. Expression of these genes was not altered by acute stress, but was progressively increasing in animals subjected to 8 and 13 days of repeated stress. Expression of hemoglobin genes was correlated with altered expression of *Mgp* (*Mglap*), *Fbln1*, *1500015O10Rik* (*Ecrg4*), *SLC16A10*, and *Mndal*. Chronic stress increased also expression of *Timp1* and *Ppbp* that are involved in reaction to vascular injury. Acute stress induced changes in expression of *Fam107a* (*Drr1*) and *Agxt2l1 (Etnppl*) that have been implicated in psychiatric diseases. The observed up-regulation of genes associated with vascular system and brain injury suggests that stress may affect brain function through the stress-induced dysfunctions of the vascular system.

Title: Chronic stress induces epigenetic modification to the mPFC, OFC, and HPC of adult rats

Authors: *B. E. KOLB[1], A. MUHAMMAD[1], S. ILNYTSKYY[2], R. MYCHASIUK[3];
[1]Canadian Ctr. Behav Neurosci, [2]Biol. Sci., [3]Univ. of Lethbridge, Univ. Lethbridge, Lethbridge, AB, Canada

Abstract: Chronic stress is associated with a multitude of cognitive symptoms including deficits in emotional regulation, diminished self-regulatory and attentional function, abnormal learning, memory, and executive function. Many researchers have demonstrated that the medial prefrontal cortex (mPFC), orbital frontal cortex (OFC), and the hippocampus (HPC) work in conjunction to mediate responses to stressful experiences and have also shown that changes in these brain regions may precede the cognitive impairments. Anatomical studies have identified consistent alterations in the neuronal morphology of these brain regions, specifically demonstrating that chronic stress reduces dendritic arborization and spine formation in the mPFC and HPC, but increases the same parameters in the OFC. Little is known, however, about how experiential stressors actually change the neuronal structure and function of these brain regions. The current study examined the epigenetic changes that occur in response to chronic stress, with a specific focus on the mPFC, OFC, and HPC. Adult male and female Long-Evans rats (P70) were exposed to an elevated platform stressor for 15 minutes, twice a day, for 14 consecutive days, given a 14 day withdrawal period, and then sacrificed. DNA from the mPFC, OFC, and hippocampus was used for global DNA methylation analysis and RNA from the same brain regions was examined with an mRNA biosequencing platform to ascertain changes in gene expression. Following the two week withdrawal period, we found that exposure to chronic stress was associated with increased methylation in the mPFC and OFC for both male and female rats ($p < .05$). There was an opposite effect in the HPC of male rats, decreasing global methylation ($p < .05$), but no effect in the HPC of female rats. When examining the RNA from the same brain regions, chronic stress exposure was associated with changes in expression of 58 genes in male rats (HPC:9, mPFC:17, OFC:32) whereas the same exposure in female rats was associated with changes in expression of 76 genes (HPC:17, mPFC:18, OFC:41). There was little overlap in gene expression by sex or region. (A full list of genes and function will be included with poster). This study demonstrates that the persistent epigenetic changes associated with chronic stress are region specific and differ in males and female. It also shows a much larger change in OFC than in either mPFC or HPC, suggesting that the OFC may play a larger role in chronic effects of stress than generally believed.

Title: Prefrontal cortex pituitary adenylate cyclase-activating peptide inhibits HPA axis responses to stress

Authors: *R. A. MAKINSON, M. SMELTZER, K. LUNDGREN, R. SAKAI, K. SEROOGY, J. HERMAN;
Univ. of Cincinnati, Cincinnati, OH

Abstract: Pituitary adenylate cyclase-activating peptide (PACAP) neuropeptide is implicated in a number of cellular processes and complex behaviors, including learning and memory, synaptic plasticity, neuronal homeostasis, neural protection and psychiatric illness. PACAP is robustly expressed in brain regions regulating hypothalamic-pituitary-adrenal (HPA) axis activation and fear conditioning, including the hippocampus, amygdala and medial prefrontal cortex (mPFC). This study explored the role of mPFC PACAP in regulation of acute stress responses. Adult male Sprague-Dawley rats received bilateral injections of PACAP in a volume of 0.5µl/side into the prelimbic (PL) and infralimbic (IL) junction of the mPFC. Five min after injection, rats were placed in a restrainer for 30 min and tail blood collected. At 120 min, rats were overdosed with pentobarbital and perfused with 4% paraformaldehyde. Rat brains were then removed and sectioned on a microtome to assess the impact of mPFC PACAP infusion on central Fos activation via immunohistochemistry. PACAP infusion decreased Fos activation within the paraventricular nucleus of the hypothalamus (PVN). PACAP also reduced peak corticosterone release at 30 minutes. Given this possible role in stress regulation, the expression of PACAP mRNA in the mPFC was evaluated following 14-day exposure to a chronic social stress regimen via the visible burrow system (VBS). Expression of PACAP mRNA within the PL and IL regions was assessed by semi-quantitative *in situ* hybridization. Analysis of the hybridization data indicated that neither dominance nor subordination affected PACAP mRNA in the IL or PL in this model. These data suggests that PACAP in the mPFC may have a buffering effect on HPA output to acute stress, perhaps by enhancing stress-inhibitory output from the PFC.

Title: Building prefrontal functional connectivity map at cellular resolution: Application to socially isolated mice

Authors: *A. Y. MOROZOV, C. FARNAN, B. PAUDEL, W. ITO;
Virginia Tech. Carilion Res. Inst., Roanoke, VA

Abstract: (Rationale) Connectivity between brain sites is described by two components: anatomical connectivity and functional connectivity. Popular functional MRI imaging in humans, primates and laboratory animals produces rich datasets of correlated neuronal activities across brain regions during specific behaviors or in mental disease. Nonetheless, there is a gap of knowledge in linking changes in macro-patterns of functional connectivity with alteration at the cellular, synaptic and molecular levels. Thus, description of functional connectivity at cell resolution is necessary. To that end, we began probing functional connectivity of neurons in dorso-medial prefrontal cortex by using local optogenetic stimulation followed by c-Fos mapping of neuronal activity at the targets inside and outside mPFC, investigating which cell-types are recruited in healthy and pathological brain. We use rodent social isolation as a disease model since it elicits behavioral traits relevant to several psychiatric disorders, including deficit in pre-pulse inhibition, which is characteristic of schizophrenia and is attributed to malfunction of the prefrontal cortex. Numerous alterations in molecular composition and morphology of the prefrontal neurons and glia have been documented. Yet, it remains unclear how such alterations affect functional connectivity of the prefrontal neurons within local microcircuits and towards remote targets throughout the brain. (Methods) At p21, mice receive prefrontal injections of adenoassociated virus expressing channelrhodopsin; at p50, optic fiber is implanted above the injected area. From p58 to p60 mice are habituated to optical stimulation setup. On p61, 2 mW

473 nm light stimulation in 2 s 10 Hz bursts repeated every 5 s for 30 min is delivered through the optic fiber. Animals are perfused 90 min after beginning of stimulation, followed by c-Fos analyses of activated areas. For socially isolated mice, animals are singly housed from p21, whereas controls are housed four animals per cage. (Results) Preliminary analyses suggests that post-weaning social isolation increases excitability of neurons in dmPFC and alteres patterns of neuronal activation among cortical layers within dmPFC, with greatest increase in neuronal activation in layer 2/3. In addition, it differentially altered proportion of c-Fos positive cells among distinct subtypes of GABAergic neurons, which suggests reorganization of local dmPFC network and its output to remote targets.

Title: Reduced glutamate outflow from infralimbic prefrontal cortex inhibits depression-like behavior and prevents the behavioral consequences of chronic stress

Authors: *B. MYERS[1], J. M. MCKLVEEN[1], W. BEISCHEL[1], J. R. SCHEIMANN[1], R. MORANO[1], S. P. WILSON[2], M. B. SOLOMON[1], J. P. HERMAN[1];
[1]Psychiatry and Behavioral Neurosci., Univ. of Cincinnati, Cincinnati, OH; [2]Pharmacology, Physiology, and Neurosci., Univ. of South Carolina, Columbia, SC

Abstract: Altered activity of ventromedial prefrontal cortex (vmPFC) correlates with depressive illness in humans. Additionally, studies utilizing electrical or optical stimulation techniques suggest that vmPFC regulates despair-like behavior in rodents. Our previous studies have isolated the infralimbic portion of the vmPFC as key regulator of neuroendocrine responses to

stress. However, despite significant implications for understanding affective disorders, the importance of glutamate outflow from infralimbic cortex for the behavioral consequences of chronic stress is unknown. In the current study, we utilized a lentiviral-packaged gene construct coding for a vesicular glutamate transporter 1 (vGluT1) siRNA. This approach permits the long-term knockdown of glutamate packaging at infralimbic synaptic terminals. Two separate cohorts of rats each received injections of the vGluT1 siRNA-expressing lentivirus or a GFP control virus and were then divided into two groups per cohort that received chronic variable stress (CVS) or remained as unstressed controls. One cohort was assessed for immobility behavior in the forced swim test (FST) prior to stress exposure while a second cohort received the FST after 14 days of CVS. Additional behavioral assays were carried out during the first three and last three days of CVS in each cohort to query the role of infralimbic output in the behavioral changes associated with chronic stress. Our results indicate that knockdown of infralimbic output reduced indices of depression-like behavior in the FST compared to GFP controls, both in animals exposed to chronic stress as well as previously unstressed animals. Further, the effects of CVS to reduce exploratory behavior in the open field test, novel object interaction, and elevated plus maze were prevented by treatment with the vGluT1 siRNA. The effects of vGluT1 knockdown on behavioral responses to CVS were not related to learning deficits, as all groups demonstrated effective associative learning during classical conditioning. These data point to the importance of infralimbic glutamate outflow for regulating depression-related behavior, as well as the behavioral changes associated with chronic stress. These findings, coupled with previous findings related to the role of the infralimbic cortex in physiological responses to stress, identify this area as a potential nexus for chronic stress-related pathologies.

Title: BAG-1 levels alter stress-induced gene expression in the prefrontal cortex

Authors: *T. G. RUBIN, J. D. GRAY, B. S. MCEWEN;
Rockefeller Univ., New York, NY

Abstract: Bcl-2 associated athanogene-1 (BAG-1), an established anti-apoptotic chaperone, binds the glucocorticoid receptor (GR) to alter GR-dependent signaling and therefore may serve as a novel molecular switch between GR-dependent and NFkB-dependent gene transcription. While BAG-1 has been shown to directly interact with the NFkB transcription factor p50 in hippocampus, this has not been demonstrated in the prefrontal cortex (PFC). Stress-induced neuroplasticity in the PFC, a region essential for executive cognitive functions, has been observed in rodent models of chronic stress and these changes parallel those observed in patients with stress sensitive mental health disorders. Understanding how BAG-1 levels and stress alter gene expression in the PFC will provide important insight into the molecular mechanisms associated with certain mental illnesses. The present study will characterize the effects of stress on gene expression using transgenic mice overexpressing BAG-1 (BAG-1 TG) and BAG-1 heterozygous knockout (BAG-1 KO) mice, which have been previously shown to have altered stress reactivity. Adult BAG-1 TG, BAG-1 KO, and wild type (WT) littermates were subjected to a 21 day chronic restraint stress (CRS) and sacrificed 24 hrs following the final stress. Brains were quickly removed and the PFC was dissected and flash frozen. RNA was extracted from the tissue and a cDNA library was generated for qRT-PCR analysis. Immunoprecipitations were performed on PFC tissue to probe for an interaction between BAG-1 and NFkB gene products. qRT-PCR revealed BAG-1 KO mice had significantly increased basal GR levels, whereas BAG-1 OE had unchanged basal GR levels compared to WT controls. Further, GR levels in both transgenic lines appeared insensitive to the effects of CRS, suggesting BAG-1 levels may impact stress-induced neuroplasticity in the PFC. Immunoprecipitations indicated BAG-1 interacts with the p50 subunit of NFkB in the PFC. These results suggest that BAG-1 can alter the gene expression response to stress by modulating GR levels, but that it may also act through the NFkB pathway and other pathways to modulate stress reactivity. High throughput analysis of the gene expression networks in BAG-1 mutant mice would identify changes in these other pathways and elucidate possible therapeutic targets for stress-related mood disorders. Studies using the BAG-1 mutant mice to assess the effect of BAG-1 levels on stress-induced morphological neuroplasticity are underway. Future studies will also seek to characterize epigenetic mechanisms that might underlie these stress-induced transcriptional changes.

Title: Acute stress-induced prefrontal cortex dysfunction is mediated by the CRH-CRHR1 system

Authors: *A. URIBE, B. SOLFRANK, G. BALSEVICH, C. DOURNES, S. SANTARELLI, M. MASSANA, D. HARBICH, A. CHEN, M. V. SCHMIDT;
Max Planck Inst. of Psychiatry, Munich, Germany

Abstract: The prefrontal cortex (PFC) plays a fundamental role in adaptive responses and has been ascribed to the cognitive hallmarks that characterize different psychiatric disorders. Furthermore, stress has been shown to affect the function of the PFC and is also associated with neuropsychiatric conditions such as depression. Among numerous candidates CRH, through the activation of CRH receptor 1 (CRHR1), constitutes one of the main effector systems by which stress unchains deleterious effects upon different brain regions. However, the contributions of this system to the effects of stress in the PFC are still unclear. The present project aims to characterize the role of the CRH-CRHR1 system on the impact of stress in the PFC. In all experiments, C57Bl6 mice were employed. In experiment 1, animals underwent acute social defeat stress and were tested 8 hours later either in a temporal order memory task (TOM) or a reversal learning test. In experiment 2, animals were submitted to a single episode of social defeat stress and 8 hours later were sacrificed. PFC sections of these animals were submitted to an *in situ* hybridization protocol to assess changes in CRHR1 mRNA levels. In experiment 3, a guide cannula was implanted in the PFC and animals received intra-PFC microinjections of either vehicle or CRH, and 8 hours later were submitted to either the TOM or reversal learning task. In experiment 4, CRHR1lox/lox mice received intra-PFC microinjections of either empty-AAV or Cre-AAV to induce a PFC-specific CRHR1 KO. One month later, they were submitted to an acute social defeat stress and after 8 hours were tested in either the TOM or reversal learning tasks. The results obtained show that a single episode of stress impaired cognitive flexibility and the recognition of objects with different recency. Also, significant increases in CRHR1 mRNA levels were observed in different subregions of the PFC 8 hours after stress. In addition, acute-stress induced prefrontal cortex-mediated cognitive dysfunctions were mimicked by intra-PFC CRH microinjections. Moreover, the CRHR1 knockout in the PFC completely reversed the effects of acute stress in these prefrontal cortex dependent tasks. Taken together, our results suggest a molecular mechanism that links stress to behavioral dysfunctions, thereby opening new intervention strategies for patients suffering from stress-related diseases, such as depression.

Title: Modulation of medial entorhinal cortex layer II principal cell circuitry by glucocorticoids

Authors: *J. HARTNER, L. A. SCHRADER;
Tulane Univ., New Orleans, LA

Abstract: Previous research has shown that stress impairs rodent performance on spatial memory tasks, but the underlying mechanisms are unclear. Spatial memory processing is mainly localized to a loop between the hippocampus and the entorhinal cortex. Stellate cells in layer II of the medial entorhinal cortex (MEC - LII) are spatially-tuned and necessary for establishing an internal grid-like representation of the environment. Our preliminary data show that chronic stress causes dendritic atrophy of stellate cells of layer II, suggesting that stress may functionally modulate these cells. MEC - LII is also composed of pyramidal cells, which are anatomically organized in grid-like fashion around the stellate cells and have a seemingly distinct network of inputs and inhibition. The functional interaction between these two principal cells' networks and modulation of these networks by environmental factors, such as stress, are not studied to date. Here we use stereotaxic injection of fluorescent retrograde tracers into the dentate gyrus and contralateral MEC as a means of real-time identification of MEC - LII principal cell type. We also use whole-cell patch clamp electrophysiology of MEC slice preparations in mice, paired with stimulation of inputs to MEC - LII from the parasubiculum, to elucidate the functional connectivity of MEC - LII principa l cells implicated in spatial processing. We test synaptic changes of layer II principal cells in response to bath application of dexamethasone, a synthetic glucocorticoid, and show that synaptic activity may be differentially affected by dexamethasone application based on cell type.

Abstract: Psychological stress activates the hypothalamic-pituitary-adrenal (HPA) axis to produce glucocorticoids which mobilize energy for the organism to attend to the stressor. Circulating glucocorticoids act through both rapid and prolonged mechanisms to alter neuronal properties in the hippocampus. Exposure of male rodents to chronic variable stress induces depressive-like symptoms, including anhedonia, increased circulating glucocorticoids, weight loss, and impairments in spatial memory. In contrast, acute stress can facilitate the formation of spatial memory, but impairs working memory and memory recall in male rodents. Fewer studies investigate the effects of acute and chronic stress in female rodents, and varying results are reported. A wealth of literature focuses on molecular and cellular plasticity caused by stress and sex related hormones in the hippocampus; however, the effects of these hormones in the entorhinal cortex, the primary excitatory input into the hippocampus, have been largely unexplored. In this study, we used Golgi Cox impregnation to visualize camera lucida reconstructions of pyramidal and stellate neurons in layer II of the entorhinal cortex. Following exposure to two weeks of chronic variable stress we observed a reduction in dendritic complexity in stellate cells in stressed male rats. Additionally, we investigated the molecular cascades in homogenate from the entorhinal cortex following a 30 minute exposure to acute predator odor (trimethylthiazoline or TMT) in intact male and female rats. We found that TMT exposure caused a rapid decrease in ERK/MAPK activation and increased PKA activity in male, but not female rats. Our results suggest that the entorhinal cortex exhibits structural plasticity in response to chronic variable stress, and that acute stress alters canonical signaling cascades in a sex-

dependent manner. These findings implicate the entorhinal cortex as a brain region in which plasticity may mediate some of the cognitive changes caused by both acute and chronic stress. Future studies will investigate the specific role of corticosterone and estradiol on the structure and function of the principal cells of the entorhinal cortex.

Title: SIRT1 activity affects granule cell excitability and synaptic activity in the dentate gyrus of mouse hippocampus

Authors: *D. YU, L. A. SCHRADER;
Tulane Univ., New Orleans, LA

Abstract: The sirtuins are a family of NAD+ dependent protein deacetylases that are involved in metabolic processes and have various functions in neurons, such as DNA repair, stress resistance, and neuronal survival. Recent research indicates that Sirtuin 1 (SIRT1) may also play a critical role in hippocampus function, particularly learning and memory. Our lab and others have shown that chronic stress affects hippocampus structure and function, including causing memory impairments. We found that chronic stress significantly increased SIRT1 activity in the dentate gyrus (DG) of chronically stressed rats. Direct infusion of sirtinol, a SIRT1 and 2 inhibitor, into the DG prevented CVS-induced memory impairment and depressive-like behavior. The specific function of SIRT1 in the DG, however, is unknown. We hypothesized that SIRT activity may affect intrinsic properties or synaptic inputs of the DG granule cells. In this study, we investigated effects of pharmacological activation and inhibition of SIRT1 on the electrophysiological properties of granule cells of the DG. Whole-cell patch-clamp recordings were made from granule cells in acute mouse hippocampus slices. We found that both activation and inhibition of SIRT1 increased granule cell excitability. Analysis of spike properties of granule cells showed that both threshold and afterhyperpolarization (AHP) of spikes significantly

decreased, which led us to focus our future study on modulation of potassium channels. In addition, we found that SIRT1 inhibitor can increase spontaneous excitatory postsynaptic current (sEPSC) frequency in the DG granule cells with no effect on sEPSC amplitude. Further study indicated that this effect was action potential-dependent as miniature EPSC frequency, recorded in tetrodotoxin, was not affected by SIRT1 inhibition. We are now testing the effect of SIRT1 on ATP-dependent potassium channels (K (ATP) channels), A-type potassium current and delayed rectifying potassium current, respectively. In addition, future studies will investigate SIRT1 function in chronically stressed mice. These studies suggest a novel, rapid mechanism for SIRT1 effects in DG neurons.

Title: High cortisol levels are associated with atrophy of cingulate and middle frontal gyrus in healthy men and women

Authors: *A. STOMBY[1], C.-J. OLSSON[2], A. NORDIN[3], L.-G. NILSSON[6], R. ADOLFSSON[3], T. OLSSON[1], L. NYBERG[4,5];
[1]Dept. for medicine, [2]Ageing and Living Conditions programme, [3]Dept. of Clin. Sci., [4]Integrative Med. Biol., [5]Umeå Ctr. for Functional Brain Imaging, Umeå Univ., Umeå, Sweden; [6]Dept. of Psychology, Stockholm Univ., Stockholm, Sweden

Abstract: Glucocorticoids causes dendritic atrophy and decrease plasticity in the hippocampus (HC) and prefrontal cortex (PFC). Our hypothesis was that circulating cortisol levels are associated with HC and PFC volumes in men and women without cognitive impairments. Individuals from the population based Betula prospective cohort study of memory and aging in Umea were included. The sample consisted of 102 men and 103 women with a mean age of 67 years (range 55-80) and a mean score of 28 on the Mini Mental State Examination. A MRI scan of the brain with volumetric analyzes of PFC and HC regions was performed. Cortisol levels in 4 saliva samples collected at 0700, 1100, 1600 and 2300 h during one day were analyzed with a

Chemiluminescence immunoassay. Episodic memory, verbal fluency, visuospatial ability and working memory were tested and participants were asked about diseases and drug use during the preceding 5 years. Multivariable linear regression analyses were used to test whether cortisol levels at 2300 h and area under the curve (AUC) for cortisol levels in all 4 saliva samples were associated with brain volumes and cognitive functions. Age, gender, total intracranial volume and level of education were used as covariates. In the multivariable analysis AUC for cortisol levels in saliva was negatively associated with volume of the left cingulate gyrus (b=-0.15, p=0.011), right cingulate gyrus (b=-0.11, p=0.045), left middle frontal gyrus (b=-0.16, p=0.012) and right middle frontal gyrus (b=-0.20, p=0.001). There were no significant associations between AUC for cortisol levels and volume of superior frontal gyrus, inferior frontal gyrus or the HC in neither hemisphere. Cortisol level at 2300 h was not associated with brain area volumes. There were no significant association between cortisol levels and cognitive measures. Performance on the visuospatial task was positively associated with volume of left middle frontal gyrus (b=0.19, p=0.008) and cingulate gyrus in left (b=0.24, p=0.002) and right (b=0.27, p<0.001) hemisphere. In addition, performance on the 2-back test of working memory was positively associated with volume of right cingulate gyrus (b=0.18, p=0.046). The association between AUC for cortisol and right middle frontal gyrus as well as visuospatial ability and right and left cingulate gyrus remained significant after Bonferroni correction while the other associations became non-significant. Our results add to the growing amount of data suggesting that the association between cortisol levels and brain volume is stronger for PFC than HC brain areas. It is unclear whether the observed brain atrophy is a cause or consequence of increased cortisol levels.

Title: The impact of chronic stress on the rat brain lipidome

Authors: *T. G. OLIVEIRA[1], R. B. CHAN[2], F. V. BRAVO[1], A. MIRANDA[1], B. ZHOU[2], F. MARQUES[1], V. PINTO[1], J. J. CERQUEIRA[1], G. DI PAOLO[2], N. SOUSA[1];

Abstract: Chronic stress is a major risk factor for several human disorders that affect modern societies. The brain is a key target of chronic stress; in fact, there is growing evidence indicating that exposure to stress affects learning and memory, decision making and emotional responses, and may even predispose for pathological processes, such as Alzheimer's disease and depression. Lipids are a major constituent of the brain, and specifically signaling lipids have been shown to regulate brain function. Here, we used a mass spectrometry-based lipidomic approach to evaluate the impact of a chronic unpredictable stress paradigm and chronic administration of exogenous corticosterone (CORT) on the rat brain in a region-specific manner. We found that the prefrontal cortex (PFC) was the area with the highest degree of changes induced by chronic stress. Specifically, sphingolipid metabolism was profoundly affected, showing an increase in ceramide and a decrease in sphingomyelin and dihydrosphingomyelin levels. Furthermore, the fatty acyl profile of phospholipids and diacylglycerol revealed that chronic stressed rats had higher 38 carbon(38C)-lipid levels in the hippocampus and a decrease in 36C-lipid levels in the PFC. Finally, lysophosphatidylcholine levels in the PFC were found to be correlated with blood CORT levels. In summary, lipidomic profiling of the effect of chronic stress allowed for the identification of dysregulated lipid pathways, revealing putative targets for pharmacological intervention that may potentially be used to modulate the stress-induced deficits.

Title: Locally synthesized growth hormone enhances spine density in the amygdala

Authors: *B. GISABELLA[1,2], J. YAO[1,2], K. A. GOOSENS[1,2];
[1]MIT, Cambridge, MA; [2]McGovern Inst. for Brain Res., Cambridge, MA

Abstract: Growth hormone (GH) exerts strong trophic effects in multiple tissues of the body. Although GH is synthesized by the pituitary gland, where it is released into the circulating bloodstream, it is also synthesized within limbic brain areas such as the amygdala, a brain region that regulates emotional memory. However, very little is known about the role of locally synthesized GH in regulating emotional processing. Our recent studies show that chronic stress increases GH protein expression in the basolateral complex of the amygdala (BLA) and is both necessary and sufficient for chronic stress-related enhancement of fear memory in rodents, an animal model of post-traumatic stress disorder (PTSD). Others studies have shown that chronic stress enhances spine density in the BLA (Vyas et al., 2002). We hypothesize that stress-related changes in GH may drive the morphological changes observed in the BLA following stress exposure. Here, we characterize the distribution of GH and its receptor (GH secretagogue receptor, or GHS-R) in the rat BLA using florescent *in situ* hybridization. Our preliminary findings suggest that GH and GHS-R are widely expressed in neurons of the BLA, demonstrating that GH is poised to exert potent and widespread effects. To explore the hypothesis that GH regulates neuronal morphology, we used an adeno-associated viral vector to overexpress either GH with green florescent protein (GFP) or GFP alone in the BLA in rats. Dendritic spine density was quantified by combining confocal imaging with three-dimensional dendritic analysis. We find that GH overexpression dramatically enhances spine density on both the primary and secondary branches of BLA pyramidal neurons. These findings support the idea that chronic stress may produces vulnerability to enhanced fear via GH-driven changes in neuronal morphology.

Abstract: Neuropsychiatric disorders are often associated with abnormal glucocorticoid receptor (GR) and neurotrophin signaling. Current knowledge suggests reciprocal actions of glucocorticoids and brain-derived neurotrophic factor (BDNF) on neuronal growth, survival and behavior that suffers from a lack of mechanistic understanding. We report that priming BDNF signaling at the time of glucocorticoid exposure contributes to neuronal allostasis to stress by way of phosphorylation of the glucocorticoid receptor. Manipulations aiming at blocking BDNF-induced GR phosphorylation *in vivo* prevent the allostatic overload of stress on post-synaptic dendritic spine plasticity in a cortico-cortical network. Mechanistically, BDNF-induced GR phosphorylation did not alter GR nuclear translocation, turnover or DNA-binding, but rather fosters cofactor recruitment to promote a novel gene expression signature involved in cellular networks (Lambert et al. MCB 2013). We further assess the allostatic functions of two of these genes using gain- and loss-of-function in *in vivo* experiments. We find at least one of these genes is critical for dendritic spine plasticity to stress in a mouse cortico-cortical network, and ectopically expressed in human BA9-10 cortex as a function of age and cognitive impairment. Thus, we report that glucocorticoid actions may diverge as a function of BDNF signaling to serve allostatic functions at least in cortical networks.

Title: Epigenetic alterations in rats with traumatic stress exposure treated with oxytocin prior to reinstatement of methamphetamine-seeking

Authors: *C. L. FERLAND, J. F. MCGINTY;
Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Previous research has shown a strong link between post-traumatic stress disorder (PTSD) and substance abuse disorders (SUD). In individuals diagnosed with PTSD, the incidence of SUD is higher than in the general population and treatment outcomes for individuals with co-morbid SUD and PTSD are generally poorer. Moreover, traumatic stress exposure independent of PTSD development can precipitate relapse to abuse in recovering SUD individuals. While alterations in several neural systems are implicated in increased vulnerability to SUD following traumatic stress exposure, the endogenous oxytocin system is regulated in response to both stress and substance use. The goal of these studies is to examine whether stimulating the endogenous oxytocin system attenuates methamphetamine (Meth) seeking in a preclinical model of traumatic stress. We examined (1) reinstatement of Meth-seeking induced by cues or the predator odor, trimethylthiazoline (TMT) paired with Meth self-administration (SA), in rats injected with 1.0 mg/kg, i.p. oxytocin (OXT) or saline 30 min before reinstatement and (2) neuroendocrine alterations and mRNA expression in the dorsomedial prefrontal cortex (dmPFC) and the paraventricular nucleus of the hypothalamus (PVN). TMT-pretreated animals injected with saline exhibited increased lever pressing to both cues and stress (TMT) compared to vehicle-pretreated animals injected with saline. In contrast, OXT treatment suppressed cue or TMT-induced Meth-seeking in both control and TMT-exposed rats. After reinstatement, a significant decrease in *Oxt* and *OxtR* mRNA was seen in the PVN of TMT-pretreated animals compared to saline-pretreated controls. OXT prevented the decrease in *Oxt* mRNA and resulted in a trend toward an increase in *OxtR* mRNA in both control and TMT-exposed animals. In the dmPFC after reinstatement, TMT-pretreated rats treated with saline showed a significant reduction in the epigenetic mark *Hdac5* and a corresponding increase in *Bdnf*IV mRNA compared to saline-pretreated animals. OXT attenuated the *Hdac5* decrease and normalized *Bdnf*IV mRNA in the dmPFC of TMT-pretreated rats. The results from these studies could represent a novel therapeutic strategy for SUD with concurrent with PTSD. Supported by T32 DA07288 and DoD W81XWH-11-1-1245 Subaward 803-237

Title: Effects of chronic stress on methamphetamine-stimulated behaviors and striatal dopamine release in female rats

Authors: *E. M. ANDERSON, M. MCWATERS, L. MATUSZEWICH;
Psychology, Northern Illinois Univ., Dekalb, IL

Abstract: Previous research in humans and animals suggests that exposure to chronic stress alters the susceptibility and behavioral responses to drugs of abuse, such as methamphetamine. Our lab has found that male rats exposed to chronic stress showed an increase in locomotion and dopamine release in the striatum following an acute injection of methamphetamine or cocaine, compared to unstressed control rats (Matuszewich & Yamamoto, 2004; Moenk & Matuszewich, 2012). Interestingly, sex differences have been reported in response to stress and stimulants. Non-stressed female rats exhibited an increase in locomotion and stereotypy following a single injection of methamphetamine compared to male rats (Milesi-Halle et al., 2007). These findings indicate that females may be more sensitive to the effects of stimulants and supports a growing literature characterizing sex differences in stimulant use. Therefore, we were interested in determining whether prior exposure of female rats to chronic unpredictable stress would potentiate methamphetamine-stimulated behaviors and dopamine release in the dorsal striatum compared to unstressed female rats. Female rats were exposed to unpredictable stress or no stress (control) for 10 days and then tested either in the open field or had extracellular dopamine measured through microdialysis two weeks later. In the open field, females that had received unpredictable stress showed an increased response immediately following an injection of methamphetamine as measured by distance traveled ($p=.045$) and speed ($p=.045$) compared to control rats, but had lower distance and speed at later time points. Stereotypy scores showed no differences between rats exposed to stress and rats not exposed to stress following an injection of methamphetamine. Preliminary microdialysis data suggest that rats exposed to chronic unpredictable stress have an increased dopamine response following an injection of methamphetamine compared to non-stressed female rats. Taken together, these findings indicate that chronic stress sensitizes the behavioral and dopaminergic response to an acute methamphetamine injection in female rats similar to the effects of chronic stress in male rats. Where sex differences have been observed in the magnitude of the change following stimulant exposure (Milesi-Halle et al., 2007; Anderson et al., 2014), stress acts in a similar manner to potentiate the response to an acute methamphetamine injection.

Title: Effect of heat acclimatization on monoaminergic neurotransmitters in the caudate putamen in rats

Authors: *H. NAKAGAWA[1], T. MATSUMURA[2], K. SUZUKI[2], C. NINOMIYA[2], S. YANAGITA[3], H. HASEGAWA[4], T. ISHIWATA[2];

Abstract: Brain monoaminergic neurotransmitters, such as serotonin (5-HT), dopamine (DA), and noradrenaline (NA), play crucial roles in several physiological functions and behavior including exercise. In addition, it has been reported that levels of neurotransmitters are rapidly changed by various thermal conditions. Although many studies have observed heat acclimatization in rats, few studies have assessed neurotransmitters in brain areas that participate in exercise during chronic thermal exposure. The present study was designed to determine changes in the levels and balance of 5-HT, DA, and NA in the caudate putamen (CPU) after heat exposure using homogenate techniques. In addition, we observed core body temperature (Tc), heart rate (HR) and locomotor activity (Act) in order to determine the timing of heat acclimatization. Firstly, we observed physiological indices of the rats. Male Wistar rats (250-300 g body weight) were implanted with a telemetry device. Rats were kept under normal conditions for 1 week (temperature 23 ℃,humidity 50%, 12-h/12-h light/dark cycle with lights on between 6:00 and 18:00 h) , and were then kept in a heated room for up to 4 weeks (temperature 32 ℃ and humidity 50%) . They had free access to food and water. Although Tc and Act rapidly increased and decreased, respectively, after heat exposure, they both returned to control levels at two weeks. We concluded that this timing was due to heat acclimatization. Secondly, we determined the levels of neurotransmitters in the rat CPU after heat exposure for different periods. Male Wistar rats (250-300 g body weight) were kept in a heated room for 3 hours, 1 day, 1 week, 2 weeks, and 1 month. Each group consisted of 6 rats. After each specified period, the rat brains were quickly removed and sliced into 300-μm sections. Samples were cut using a disposable 1-mm-diameter micro-punch, homogenized, and deproteinated in 0.2 M perchloric acid. The levels of 5-HT, DA, and NA in the CPU were analyzed using high-performance liquid

chromatography. DA was decreased when rats were kept in the heated room for 1 day, 1 week, 2 weeks, and 1 month. 5-HT and NA were increased at 3 hours and 1 month. These results suggest that the activity of heat acclimatized rats was regulated not by DA, but by 5-HT and NA.

Title: Distribution of mineralocorticoid and glucocorticoid receptor immunoreactivity in a songbird brain

Authors: ***M. R. HASSTEDT**[1], S. A. MACDOUGALL-SHACKLETON[2];
[2]Psychology, [1]Univ. of Western Ontario, London, ON, Canada

Abstract: Stress affects numerous aspects of physiology, brain and behaviour. In birds, stress research has focused on seasonal changes in the stress response, chronic stress, and the effects of stress on breeding. In addition, recent studies have documented the effects of developmental stress on song learning and hippocampal-dependent spatial cognition. Despite this, there is little research examining where corticosterone (CORT) binds in the brain. CORT binds to two receptor subtypes, mineralocorticoid (MR) and glucocorticoid (GR) receptors with high and low affinity respectively. In the brain these receptors are thought to have opposing effects on the stress reaction. It is thus important to know where in the brain these CORT receptors are located. Previous studies have looked at receptor distribution in the brain but have only looked at glucocorticoid receptors or only the song control nuclei. In this study we have documented the distribution of both GR and MR throughout the entire songbird brain. Four European starling (Sturnus vulgaris) brains were cut coronally at 40um and stained in alternating series for MR and GR using immunohistochemistry. Areas implicated in stress response and regulation in mammals showed immunoreactivity for GR including: hippocampus, hypothalamus and nucleus taenia (avian homolog to amygdala). MR immunoreactivity was seen in several song-control regions though darkest staining occurred in the hippocampus. GR immunoreactivity was more ubiquitous

throughout the brain but was strongest in areas involved in negative feedback in mammals. This distribution of GR and MR is critical for our understanding of how CORT is having its effect on bird behavior and physiology.

Title: Memory for multiple associations in early visual cortex

Authors: ***S. E. BOSCH**, C. F. DOELLER;
Donders Institute, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: During successful recall, the hippocampus is thought to interact with the cortex to support mnemonic reinstatement. Previous work in our lab showed that the identity of two recalled associations could be predicted from the activity pattern in early visual cortex. The strength of this reinstatement in visual cortex was further modulated by hippocampal BOLD activity. In the current study, we go beyond this simple two-association paradigm by using multiple associations and parametric behavioural measures to reliably assess variability in memory performance. We combined fast functional magnetic resonance imaging, multivariate analyses and a cued recall paradigm to rigorously investigate how early visual cortex and the hippocampal formation support mnemonic reinstatement. Human participants learned tone-grating associations and subsequently performed a recall task in which they were cued with tones and adjusted a line to match the remembered orientation of the associated grating. Analyses of behavioural data indicate that there is considerable variability in memory performance between different associations within as well as across participants. To examine memory-specific reinstatement in visual cortex we developed an analysis approach employing a forward modelling framework, in which hypothetical orientation channels, weighted by data from an orthogonal task, can be used to predict voxel responses in early visual cortex during recall. In

ongoing analyses, this approach allows us to link fine-grained behavioural measures and neural estimates of the participants' mnemonic representations.

Title: Single-unit activity in the human medial temporal lobe during an episodic memory task and subsequent sleep

Authors: *J. NIEDIEK[1], T. REBER[1], H. GAST[1], J. BOSTRÖM[2], V. A. COENEN[2,3], C. E. ELGER[1], F. MORMANN[1];
[1]Dept. of Epileptology, [2]Dept. of Neurosurg., Univ. of Bonn, Bonn, Germany; [3]Dept. of Stereotactic and Functional Neurosurg., Univ. of Freiburg, Freiburg, Germany

Abstract: Episodic memory can be defined as our ability to mentally recall personal experiences, including contents, time, and place of experienced events. Lesion studies, as well as extensive research using functional MRI, have shown that the hippocampus is a necessary structure for the encoding of episodic memory, but the mechanisms by which neuronal ensembles enable episodic memory processes remain unknown. One hypothesis is based on research in rodents, where place-cells (spatially selective cells) in the hippocampus have been found to contribute to spatial memory: Sequences of place-cell activity during slow-wave sleep resemble sequences of place-cell activity during previous exploration of an environment. Experimental disruption of these re-activations severely impairs spatial memory. Our current research focuses on "semantic neurons" in the human medial temporal lobe (MTL). These neurons are tuned to semantic concepts: They respond to the presentation of different pictures or

the written name of, for example, a certain celebrity, but not to any other pictures or names. It has been speculated that these neurons constitute a more abstract version of rodent place-cells, representing semantic concepts instead of locations. We hypothesized that the mechanism by which semantic neurons in the human MTL contribute to episodic memory resembles, to a certain extent, the re-activation of place-cell firing sequences in rodents. We recorded single- and multi-unit activity from different subregions of the MTL of 20 epilepsy patients who had been implanted with intracerebral electrodes for presurgical monitoring. The patients learned a simple story, involving up to 10 concepts for which semantic neurons had previously been identified. These concepts were represented in the stories both as pictures and as written names. Learning consisted of several re-iterations of reading and free recall. Similar to previous findings, we observed internally generated activations of semantic neurons during recall prior to vocalization. Furthermore, we used polysomnography to identify sleep stages. We found increased activity of semantic neurons during slow wave sleep compared to REM sleep. Furthermore, reactivations of semantic neurons were linked to sharp-wave ripple activity. These findings give first, indirect evidence in favor of the hypothesis that semantic neurons contribute to episodic memory.

Title: The schema effect and sleep-dependent memory consolidation

Authors: N. HENNIES, *M. LAMBON RALPH, J. COUSINS, P. A. LEWIS;
Univ. of Manchester, Manchester, United Kingdom

Abstract: Objectives The acquisition of knowledge is more effective if the new information can be incorporated into an associative schema. This advantage for schema-linked learning is thought to be driven by accelerated consolidation mechanisms. Whether or not sleep-dependent consolidation is involved in this process remains unclear. Here, we explore the interaction between sleep-dependent consolidation and schema-linked learning. Methods After establishing a schema over several days, participants encoded new facts that were either related to the schema (schema memories) or unrelated (non-schema memories). The encoding was done in two

sessions, 24 hours apart (consolidated and unconsolidated memories). Overnight sleep was polysomnographically monitored, and memory was tested in an MRI scanner directly after the second encoding. Results Participants showed a greater advantage for schema-linked learning after consolidation (p=0.003). Interestingly, this interaction between schema and consolidation correlated positively with the spindle density (r=0.6, p=0.006), and negatively with the percentage of stage 4 (S4) sleep (r=-0.62, p=0.003). A median split analysis further suggested that the spindle density was associated with the retention of schema memories (p=0.003), while S4 sleep was associated with the retention of non-schema memories. Functionally, we observed two separate clusters in the left medial temporal lobe, including hippocampus and parahippocampus, where the interaction between schema and consolidation was predicted by spindle density and time in slow wave sleep. Conclusion Our results provide initial evidence for an association between schema-linked learning and sleep-dependent memory consolidation, and suggest that deep sleep and sleep spindles may play differential roles.

Title: Grid cell representations in humans align to a common reference frame

Authors: ***T. NAVARRO SCHROEDER**, C. F. DOELLER;
Donders Institute, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: Since the seminal discovery that entorhinal grid cells fire at lattices of a triangular grid in freely-moving rodents, the common notion had been that the orientation of the grid is relatively stable within animals, but random between animals. Recently, Stensola et al. [1] reported non-random grid-orientations across rats in a square environment. Currently, it remains elusive what the underlying mechanisms of this effect are and whether it would generalize to

non-square environments. In the present study, we sought to test if human six-fold symmetrical grid-representations align to a common reference frame in circular environments. By combining fMRI proxy-measures of cellular activity and navigation in virtual environments with well-controlled visual cues, we investigated grid-cell representations in humans. We observed an alignment of grid-representations in entorhinal cortex to a common reference frame in a circular virtual environment. Furthermore, we replicated this alignment effect in a second scanning session with the same participants and also in a different group of participants in a modified virtual environment with a different reference frame. The present finding of a common alignment of grid-representations in humans might suggest that, under specific environmental conditions, visual information is being used for grid formation in a stereotypical manner. This could be an important constraint for computational models of spatial navigation and could help to elucidate the network mechanisms leading to stable representations of spatial context. [1] T. Title: Domain sensitive responses in medial temporal lobes examined with a large stimulus set

Authors: ***B. B. HARRY**[1], K. UMLA-RUNGE[2], K. GRAHAM[2], P. DOWNING[1];
[1]Sch. of Psychology, Bangor Univ., Bangor, United Kingdom; [2]Sch. of Psychology, Cardiff Univ., Cardiff, United Kingdom

Abstract: Representational models of medial temporal lobe (MTL) function propose that different sub-regions within the MTL are differentially sensitive to stimulus content. Evidence of domain sensitivity has been shown in cortical medial temporal regions, with object sensitivity found in the perirhinal cortex and scene sensitivity in the posterior parahippocampal gyrus. However, to date, sensitivity to stimulus content in medial regions has been demonstrated in studies that presented only a small number of categories (e.g., scenes and faces). The aim of the

present study was to measure MTL activity evoked by stimuli drawn from a broad range of categories to better characterise content sensitivity in this region. We measured brain activity with fMRI while participants (N = 20) performed a one-back task on stimuli from 20 categories in an event related design. A separate odd-one-out task consisting of faces, scenes, objects and shapes was used to localise category selective voxels in the occipito-temporal and medial temporal lobes, independently of the main experimental scans. We compared the response profile for the perirhinal cortex with category specific regions in the occipito-temporal cortex with multidimensional scaling to examine whether the responses observed in the medial temporal regions were typical of other category specific regions. All face and object sensitive regions - including the fusiform face area, occipital face area, lateral occipital, perirhinal cortex and amygdala - clustered together, whereas scene selective regions - including the parahippocampal place area and retrosplenial cortex - formed a separate cluster. To follow up recent reports that the perirhinal cortex may also respond to scenes (e.g., Preston et al., 2009), we analysed all voxels within a perirhinal mask (Holdstock et al., 2009). Face and object selective voxels (as defined in the localiser) showed the strongest response in the main experiment to faces and to other objects, respectively. In contrast, scene selective perirhinal cortex voxels (as defined in the localiser) did not show the strongest response to scenes in the main experiment, indicating that previous reports of scene selectivity in the perirhinal cortex may have been the result of using a restricted stimulus set. Specifically, these results provide a richer characterisation of category-related responses in MTL than previous work, and favour a model in which perirhinal cortex processes objects and faces (but not scenes) in concert with similar inferotemporal regions.

Title: Investigating the spatio-temporal organization of episodic memory within a virtual world

Authors: *L. DEUKER, J. BELLMUND, T. NAVARRO SCHROEDER, C. F. DOELLER; Donders Institute, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: Both time and space are defining characteristics of everyday experience, and the question how spatial and temporal aspects are represented in episodic memory has been the focus of intensive research in recent years. While it has long been known that the local environment is encoded by spatially tuned cells in the hippocampal formation, specialized hippocampal neurons have been recently discovered in rodents, which seem to encode the temporal properties of specific episodes ("time cells"). However, it remains unclear how spatial and temporal information is integrated in the human brain. To investigate this, we created a novel complex virtual reality environment of the size of a downtown city area. In this virtual world, participants encountered several everyday objects as they repeatedly navigated along a predefined route. Critically, we dissociated the temporal distance between objects (how long it took participants to navigate from one object to the next) and the spatial distance between objects (how far objects were apart in the city). This allowed us to investigate the impact of spatial and temporal context on memory performance in a 2-by-2 design, with factors spatial distance (high vs low) and temporal distance (high vs low). Preliminary behavioural results indicate that participants were able to learn the routes and the locations of the objects with ease and could reproduce the relative spatial and temporal distance between pairs of objects in a subsequent memory test. Furthermore, in a free recall test, the order in which objects were reproduced reflected knowledge about the routes in the virtual environment. In a next step, simultaneously acquired fMRI data will be analysed with respect to the spatial and temporal structure of the newly formed episodic memories.

Title: Functional parcellation of the human entorhinal cortex

Authors: *N. I. ZARAGOZA JIMENEZ, T. NAVARRO SCHROEDER, E. VAN OORT, C. F. BECKMANN, C. F. DOELLER;
Donders Institute, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: The entorhinal cortex (EC) is the interface between the hippocampus and the neocortex. Since the discovery of grid cells in the rodent medial EC, it has been recognized as a crucial hub for spatial coding and navigation in rodents. Traditionally, the EC has been subdivided into a medial (MEC) and a lateral (LEC) portion. Postmortem comparative anatomical evidence, however, suggests broader subdivisions among rodents, non-human primates and humans. Cytoarchitectonically, up to nine subdivisions of the human EC have been distinguished. Several cytoarchitectonic features also suggest a modular arrangement, such as periodic bundling of pyramidal cell dendrites and axons. Furthermore, tract tracing studies in rodents and non-human primates suggest a wide range of projections along the EC, with medial portions of the EC projecting to the temporal portion of the hippocampus, while lateral and caudal portions connected to the septal hippocampus. Differential connectivity pattern of EC subregions could thus lead to distinct intrinsic signal fluctuations, visible to functional magnetic resonance imaging (fMRI) at high spatial resolution. However, knowledge about the fine-grained, in-vivo fMRI-based parcellation of the EC has been scarce. Here, we aimed to parcellate the human EC based on its intrinsic signal fluctuations during a virtual navigation task combined with high-resolution, submillimetre fMRI at 7T. We generated a functional parcellation of the EC by leveraging a novel instantaneous correlation analysis approach, termed instantaneous connectivity parcellation (ICP) [1]. ICP provides information on how the functional connectivity within a region evolves over time. Subsequently, independent component analysis (ICA) was used across subjects to create three-dimensional parcellations of the EC based on its intrinsic functional properties. The resulting parcellations showed strong correspondence to topographies from postmortem cytoarchitectonic studies. These findings allow us to test connectivity fingerprints of human EC subregions *in vivo* and could open up the possibility to investigate neural mechanisms of spatial cognition at an unprecedented level of detail. Title: Prospective event representation in the hippocampus depends on contextual certainty and time

Authors: *P. W. SMULDERS, B. MILIVOJEVIC, S. E. BOSCH, F. P. DE LANGE, C. F. DOELLER;
Donders Institute, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: Recent evidence from single cell recordings in rodents and neuroimaging work in humans suggests that the hippocampus represents events in a prospective manner. However, it remains unclear on what temporal scales prospective events are coded by the hippocampus and whether such prospective coding can facilitate decision making. Here, we used functional MRI to record brain activity while participants viewed pictures of faces, houses and objects during three experimental phases. During a learning phase, participants performed an object-categorisation task in which stimuli were organized into triplets so that a face or a scene was always preceded by two objects: the context. The contextual pairs of objects were either fully predictable of the upcoming 'final' stimulus (predictable context) or they created uncertainty as to whether the upcoming stimulus would be a face or a scene (uncertain context). Before and after the learning phase, participants viewed the same images in a random order. We hypothesized that neural-pattern similarity between the 'final' item and the 'context-defining' items would change as a consequence of learning to discriminate between the predictable and uncertain contexts. Over the course of learning, we found that reaction times decreased for the critical 'final' item in predictable contexts compared to uncertain contexts indicating that participants were able to successfully use context to facilitate their behavioural responses. Hippocampal activity gradually increased from the onset of the first item in the triplet to presentation of the 'final' item for predictable but not uncertain contexts. Using representational similarity analysis, we compared neural-pattern similarity before and after learning and found an increase in similarity between the predictable 'final' item and the 'context-defining' items and a decrease in similarity between the uncertain 'final' item and the 'context-defining' items in the medial temporal lobe and the striatum. Furthermore, we found that association between the 'final' item and the preceding context depended on time whereby posterior hippocampus represented associations on shorter timescales (i.e. between the second 'context-defining' item and the 'final' item) while anterior hippocampus was sensitive for the association on longer timescales (i.e. between the first 'context-defining' item and the 'final' item). These preliminary

data suggest that the hippocampus uses contextual information to represent upcoming events simultaneously at multiple timescales resembling a well-known gradient in the representation of spatial distance along the long-axis of the hippocampus in rodents.

Title: Dynamic representation of multi-event narratives in the medial temporal lobe

Authors: *S. H. COLLIN, B. MILIVOJEVIC, C. F. DOELLER;
Donders Institute, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: One of the key features of episodic memory formation is the integration of multiple events and experiences into coherent mnemonic representations. We have previously shown that linking two events into one narrative is accompanied by increased neural pattern similarity in the hippocampus and medial prefrontal cortex, which suggests the formation of a shared memory representation coding for linked events. However, it remains unclear how flexible and malleable these novel narrative representations are. In the current fMRI study, we aimed to address this outstanding question by extending the narratives. To do so, we presented the participants with three-event narratives, which were sequentially built up over time, as well as control events that were never integrated into the narratives. Behavioural results show that participants are able to make direct associations between the events with high accuracy. Based on evidence for anatomical and functional specialization within the medial temporal lobe, we hypothesized that the resolution of narrative representations would differ within the medial temporal lobe. Preliminary results of multi-voxel pattern analyses indicate that the representation of direct associations between events, and the representation of the entire multi-event narrative coexist in the medial temporal lobe. These findings suggest that episodic memories might be organized

hierarchically, with representation of individual associations and multi-event narratives co-localized within the hippocampal formation.

Title: Hippocampal-prefrontal theta oscillations support memory integration in humans

Authors: ***A. R. BACKUS**[1], S. SZEBÉNYI[1,2], J. M. SCHOFFELEN[1,3], S. HANSLMAYR[4,2], C. F. DOELLER[1];

Abstract: The integration of separate memories forms the basis of inferential reasoning - an essential cognitive process that enables complex behaviour. Considerable evidence from lesion studies in rodents and neuroimaging studies in humans suggest that both the hippocampus and medial prefrontal cortex play a crucial role in memory integration. Although electrophysiology indicates that theta oscillations govern the communication between hippocampus and prefrontal cortex, the oscillatory mechanism underlying memory integration in humans remains elusive. To bridge this gap, we recorded magnetoencephalography data while participants performed an associative inference task. Source power analyses suggest that theta oscillations in medial temporal lobe during encoding predict subsequent memory integration. Moreover, we observe increased encoding-related theta coherence between hippocampus and medial prefrontal cortex for later successfully integrated associations. In sum, our preliminary results suggest that integrated memory representations arise through theta oscillations that engage the medial temporal lobe and might help to orchestrate communication with the medial prefrontal cortex.

Title: Brain regions supporting memory processes: using voxelwise lesion-symptom mapping to identify the neural correlates of performance on neuropsychological tests of memory

Authors: *D. E. WARREN[1], J. BRUSS[1], J. GLÄSCHER[2], D. TRANEL[1];
[1]Neurol., Carver Col. of Medicine, Univ. of Iowa, Iowa City, IA; [2]Dept. of Systems Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Declarative memory for facts and events depends on the medial temporal lobe (MTL) and hippocampus, but the degree to which specific, widely-used neuropsychological tests of memory are specifically related to MTL or other brain damage has not been conclusively established. Drawing on the Iowa Neurological Patient Registry, we applied voxelwise lesion-symptom mapping (VLSM) in order to identify the neural correlates of performance on common neuropsychological tests of memory in a large sample of patients with focal brain injury (max N=450, with sample size varying somewhat by test). The Registry contains data for patients with focal, stable brain lesions who have undergone neuropsychological testing at least 3 months after symptom onset. Brain lesions were identified using structural neuroimaging (CT or MRI) and mapped in a common template space using the MAP-3 method. These lesion maps, along with memory test performances, were submitted to VLSM analysis. Several distinct memory processes were probed including semantic memory (Wechsler Adult Intelligence Scale, Vocabulary and Information subtests; Wide Range Achievement Test, Spelling subtest), short-term visual memory (Benton Visual Retention Test), delayed visual memory (Complex Figure Task, recall), short term verbal memory (Rey Auditory Verbal Learning Task, trial 1), and delayed verbal memory (Rey Auditory Verbal Learning Task, delay). Composite memory indices from the Wechsler Memory Scale (e.g., General Memory Index, Immediate Memory

Index, Delayed Memory Index) were also analyzed. Our results reinforce the critical role of the MTL and hippocampus in supporting the declarative memory operations exercised by these neuropsychological tests, and also demonstrate significant lateralization of function within that region while highlighting the importance of other brain regions for normal memory processes. These findings provide important insight into the relationship between neuropsychological tests of memory and the necessity of certain brain regions by contributing empirical support to the validity of widely-held assumptions about behavior, cognition, and brain injury in the domain of memory. This work should positively impact clinical practice by further informing brain-behavior relationships.

Title: Investigating the relationship between head direction representations and spatial cognition

Authors: ***J. BELLMUND**, L. DEUKER, T. NAVARRO SCHROEDER, C. F. DOELLER; Donders Institute, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: In order to be able to successfully navigate its environment, an organism requires information about its location and orientation. While place cells code for location, head direction cells provide information about the animal's spatial orientation in the environment. In rodents, head direction cells have been found throughout Papez circuit and recent recording work demonstrates that the firing of head direction cells directly impacts spatial behaviour. Despite previous evidence for head direction representations in humans during scene viewing and virtual navigation, the behavioural relevance of the head direction system in humans remains elusive. To investigate this, we combined fMRI with a virtual reality (VR) task in which participants freely navigated a virtual arena with a circular layout and learned the locations of objects over multiple trials. Here, we show that entorhinal cortex exhibits heading direction specific

representations during virtual navigation. Furthermore, the strength of this directional effect was predictive of spatial memory performance. Our preliminary findings shed light on the relationship between head direction representations and spatial cognition in humans. In an ongoing follow-up study, we investigate the relationship between head direction related fMRI responses and a continuous measure of directional behaviour in a realistic, large-scale VR city. Preliminary behavioural results show that participants successfully represented directions between different locations of the VR environment.

Title: Opposing effects of negative emotion on item and associative memory are predicted by activity in amygdala and hippocampus

Authors: ***J. A. BISBY**[1,2], A. J. HORNER[1,2], L. D. HORLYCK[1], N. BURGESS[1,2]; [1]UCL Inst. of Cognitive Neurosci., London, United Kingdom; [2]UCL Inst. of Neurol., London, United Kingdom

Abstract: The formation of associations between items in memory is thought to rely on hippocampal-dependent mechanisms which go beyond those supporting memory for a single item. Whilst memory for emotionally negative items is enhanced, associative memory can be reduced (e.g., Bisby & Burgess, 2014, Learning & Memory, 21:760-6). Enhanced memory for negative items is thought to rely on amygdala-dependent processes, but the way in which negative emotion affects hippocampal-dependent associative memory remains unclear. We aimed to further understand the contributions of the amygdala and hippocampus to item and associative memory, and the effect on these of negative affect. Using fMRI, we examined encoding and retrieval of paired associates of neutral and negative images. At encoding,

participants viewed pairs of images presented as pure pairs (neutral-neutral or negative-negative) or mixed pairs (neutral-negative). At test, participants were cued with one image and instructed to retrieve the associated (target) image. All combinations of neutral and negative cue and target items were used. Results showed enhanced memory for negative images and reduced associative memory for pairs that included a negative image. Subsequent memory for items was correlated with amygdala activity during encoding, while subsequent associative memory was associated with hippocampal activity during encoding. We also saw a reduction in hippocampal activity in the presence of a negative image compared to viewing neutral images, during encoding trials and during correct associative retrieval trials. Finally, our results showed increased activity in the amygdala for correctly retrieved negative images, even when cued by a neutral image. Our findings suggest negative emotion can enhance amygdala-dependent item memory but disrupt hippocampus-dependent associative memory.

Title: Memory formation in figure-noun association increased functional connectivity between the hippocampus and inferior frontal gyrus

Authors: *K. LIANG[1], Y.-W. WANG[1], J.-H. CHEN[2], T.-L. CHOU[1];
[1]Dept. of Psychology, [2]Dept. of Electrical Engin., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Formation of declarative memory may alter connectivity in the cortical network and such change could be initiated by influence from the medial temporal lobe, particularly the hippocampal formation. To detect functional connectivity changes in the memory network

during human verbal learning, we examined the neural correlates of memory formation for figure-word pairs in human participants by functional magnetic resonance imaging (fMRI) and resting-state functional connectivity. Sixteen participants were recruited to learn 24 pairs of figure-noun associations and the retention was tested by recognition 24 hours later. The participants were subjected to brain scans before, during and after the acquisition trial in the following order: a pre-learning baseline resting-state scan, the paired association learning along with fMRI scan, an interpolated task, and a post-learning resting-state scan. During the resting-state scans, all participants were instructed to close their eyes but remain awake and think of nothing. The learning task required participants to memorize 24 pairs of Fourier figure-Chinese noun association while they underwent fMRI scans. The interpolated task was an attention task that lasted for 1 hour in order to prevent participants from active rehearsal of the learned materials during the memory formation period. Two major findings came out from analyses of the available data. First, learning figure-word association was accompanied with greater bilateral activation in the visual cortices and inferior frontal gyrus (IFG), which was presumably related to the stimulus processing. Second, a contrast of the post-learning resting scan versus the pre-learning resting scan revealed an increase in the functional connectivity between the hippocampus and the right IFG and also between the hippocampus and left inferior parietal lobule (IPL). These findings of increased resting-state functional connectivity suggest the presence of an interaction between the hippocampus and certain cortical areas during the memory formation period. This increased functional connectivity may play a critical role for the hippocampus to modulate memory formation in the neocortex.

Title: Sleep interruptions impair learning in a virtual navigation task

Authors: ***Y. YANG**[1], K. KONISHI[2], R. GRUBER[2], V. D. BOHBOT[2];
[1]McGill Univ. Douglas Hosp., Verdun, QC, Canada; [2]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada

Abstract: Aim: Researchers have established a relation between sleep, and learning and memory. In the rodent hippocampus (HPC), the same group of place cells activated in a navigation task were reactivated during sleep (Wilson and McNaughton, 1994). In humans, sleep was shown to reorganize brain activity such that spatial memory was mediated more by the striatal network than HPC structures (Orban et al, 2006). Sleep deprivation, as well as stress, impairs HPC-dependent memory. Interestingly, stress hormones impair memory only during sleep but improve memory in the wake state (Kelemen, et al, 2014). In this study, we studied the relation between sleep and navigational strategies dependent on the hippocampus and caudate nucleus. Methods: We tested 20 healthy older adults on a 4-on-8 virtual maze (4/8VM) designed to differentiate between the two strategies. Each trial consisted of 8 arms branching out from the center. Participants must retrieve objects at the end of the arms. In part 1 of the learning stage, 4 arms were blocked, and objects were located in the open arms. In part 2, all arms were open and participants had to retrieve objects from the 4 previously blocked arms. A probe trial was administered after participants reached the criterion in the learning stage. The criterion was making zero errors on part 2 of a trial. In the probe, all landmarks were removed allowing for the dissociation of the two strategies. The sleep data were obtained with an Actiwatch that detected counts of body motion in two separate nights. The metrics included duration of sleep/wake period, the ratio of sleep/wake duration over the entire rest period, wake time after sleep onset (WASO), and the time spent before sleep onset. Results: WASO was significantly correlated with the number of trials needed to reach the criterion on the 4/8VM ($r=.49$, $p < .05$), indicating that the more people woke up after sleep, the more trials they needed to reach the criterion. No significant differences were found between the two strategies at $p <.05$ level on any measures of sleep. As per our previous findings (Iaria et al, 2003), spatial learners required more trials to reach the criterion and made more errors in both the learning stage and probe trial. Conclusion: Consistent with previous studies, sleep seems to be associated with general learning ability. Sleep interruptions were associated with slower learning on a navigation task.

Title: Pattern completion for episodic events in the human hippocampus

Authors: *A. J. HORNER[1,2], W.-J. LIN[1,2], J. BISBY[1,2], N. BURGESS[1,2];
[1]UCL Inst. of Cognitive Neurosci., London, United Kingdom; [2]UCL Inst. of Neurol., London, United Kingdom

Abstract: The multiple elements of episodic events, represented in distinct neocortical regions, are thought to be bound into coherent 'event engrams' by the hippocampus (Damasio, 1989; Tulving, 1983). These engrams should allow for the retrieval of all event elements via pattern completion, resulting in their 'reinstatement' in the neocortex (Marr, 1971). We have previously shown behavioural dependency between retrieval of different elements of the same event (Horner & Burgess, 2013). For example, for location-person-object events, if we remember the location of a specific event we should be more likely to remember the person and object from that same event. We have further shown that this behavioural dependency is due to pattern completion at retrieval, rather than fluctuations in encoding strength (Horner & Burgess, 2014). Thus, pattern completion was seen even when the overlapping pairwise associations comprising an event were presented separately, but was only seen when all possible within-event pairwise associations were encoded, forming a 'closed-loop' associative structure, but not when incomplete 'open-loop' sets of associations were encoded. Here we asked whether pattern completion is related to hippocampal activity and whether it results in the reinstatement of event elements in the neocortex. In an fMRI experiment, participants learned events consisting of multiple distinct elements (locations, people and objects/animals) via separate presentation of the pairwise associations. At retrieval, all pairwise associations from each event were tested. During encoding of paired associates from the closed-loop condition, hippocampal activity predicted subsequent memory performance for all within-event elements, supporting the idea that the hippocampus binds the multimodal elements of events into event engrams. During retrieval of a paired associate hippocampal activity was greater for 'closed-loop' relative to 'open-loop' events, and correlated with reinstatement activity corresponding to all within-event elements in the neocortex. Thus, we provide evidence for the reinstatement of event elements in the neocortex following hippocampal pattern completion.

Title: The BDNF val66met polymorphism is associated with decreased use of landmarks and decreased fMRI activity in the hippocampus during virtual navigation

Authors: *K. KONISHI[1], R. JOOBER[1], J. BREITNER[2], V. D. BOHBOT[1];
[1]Psychiatry, Douglas Mental Hlth. Univ. Institute, McGill Univ., Verdun, QC, Canada; [2]Dept. of Psychiatry, McGill Univ., Ctr. for Studies on Prevention of Alzheimer's Dis. (StoP-AD), Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada

Abstract: Aim: People can navigate in a new environment using one of two strategies. A series of studies have dissociated between hippocampus-dependent "spatial" navigation and habit-based "response" learning mediated by the caudate nucleus. The val66met polymorphism of the brain-derived neurotrophic factor (BDNF) gene leads to decreased secretion of BDNF in the brain, including the hippocampus. In young adults the BDNF val66met polymorphism is associated with the decreased use of spatial strategies during virtual navigation and decreased fMRI activity in the human hippocampus. Here, we aim to investigate the role of the BDNF val66met polymorphism on virtual navigation behaviour and brain activity in healthy older adults. Methods: 139 healthy older adult participants (mean age=65.8 ± 4.4 yrs) were tested in this study. Blood samples were collected and BDNF val66met genotyping was performed. Participants were divided into two distinct genotype groups: val/val and met carriers. The 4on8 Virtual Maze (4/8VM) consists of an 8-arm radial maze, in which 4 arms are accessible and 4 are blocked. Participants have to retrieve objects located at the end of the 4 accessible arms. Then, all 8 arms become accessible and participants have to retrieve objects now located in the 4 arms that were previously blocked. After participants have learned the task, a probe trial is given in which all landmarks are removed. The probe trial allows us to dissociate spatial and response learners, as spatial learners make more mistakes compared to response learners. A subset of the participants (n=66) were scanned in a 3T MRI scanner while engaging in a virtual navigation task called the Concurrent Spatial Discrimination Learning Task (CSDLT). The CSDLT is a virtual 12-arm radial maze in which participants have to learn the location of objects within 6 pairs of arms. Results BDNF val/val individuals made more errors on the probe trial of the 4/8VM compared to BDNF met carriers, confirming that val/val individuals relied more on landmarks to remember target locations (i.e. increased use of the spatial strategy). Additionally, BDNF val/val individuals had more fMRI activity in the hippocampus compared to BDNF met carriers during performance of the CSDLT. Conclusion: Our results are consistent with findings in young adults, showing that, even with aging, the BDNF val/met polymorphism is associated with dysfunction of the hippocampus.

Title: Non-depressed older adult response learners score slightly but significantly lower than spatial leaners on a depression scale

Authors: *Z. K. CHAUDHARY[1], K. KONISHI[2], V. D. BOHBOT[2];
[1]Psychiatry, McGill Univ., Montreal, QC, Canada; [2]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada

Abstract: Aim: People spontaneously use different strategies when they navigate in an environment and these strategies rely on different memory systems. The spatial strategy involves remembering the locations of objects in relation to landmarks in the environment, while the stimulus-response strategy, relies on making a series of stimulus-response associations (e.g., right/left turns). These strategies depend on the hippocampus and the striatum, respectively. The use of these strategies has implications for other cognitive processes. Namely, the use of striatum-dependent response strategies is associated with an increased use of drugs of abuse and alludes to heightened sensitivity to reward. Given their reward-seeking tendencies, we asked whether non-depressed response learners would also have more positive affect compared to spatial learners. Methods: 139 healthy older adults (mean age: 66.4) completed the Geriatric Depression Scale (GDS), a self-report questionnaire used to assess depression in the elderly. They were also tested on the 4-on-8 virtual maze, a task that requires remembering the locations of 4 objects in an 8-arm radial maze. Participants retrieved objects located at the end of four accessible arms in a landscape embedded with an array of landmarks after which they were instructed to avoid these previously visited paths to retrieve the objects among eight accessible arms. They completed this task until they reached criterion (100% accuracy) for at least one trial and moved onto a probe trial in which landmarks were removed, rendering spatial learners more prone to making errors. Participants' spontaneous navigation strategies were then assessed and they were classified as either spatial or response learners using both probe trial errors and verbal reports. Results: When differences in scores on the GDS were compared across navigational

strategies, response learners (mean = 2.61) had significantly lower scores compared to spatial learners (mean = 3.66; t = 2.34, p = 0.021). Conclusions: GDS has been shown to correlate inversely with positive affect and to correlate directly with negative affect. Furthermore, there is a distinction between two clusters of depression-related symptoms (increased negative affect, decreased positive affect), and these are mediated primarily by different neurotransmitter systems (serotonergic and dopaminergic, respectively). It is then possible that a disparity in the level of positive affect between spatial and response learners could reflect: a) their previously reported differential reward seeking tendencies and b) tendencies towards different personality traits among spatial and response learners.

Title: Luteal phase of the menstrual cycle positively correlates with use of a spatial strategy in a human virtual navigation task

Authors: ***S. HANAFI**[1], D. HUSSAIN[2], K. KONISHI[1], W. BRAKE[2], V. D. BOHBOT[1]; [1]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada; [2]Concordia Univ., Montreal, QC, Canada

Abstract: Aim: People spontaneously use a spatial or response strategy when learning to navigate in an environment. These strategies depend on the hippocampus and the caudate nucleus, respectively. Estrogen (E) is known to enhance dendritic spine density in hippocampal CA1 pyramidal cells (Gould, et al., 1990). Furthermore, in women, concentrations of E flux in a regular manner over the course of the menstrual cycle. Notably, there is a surge of E during the second half of the cycle (i.e. the luteal phase). In addition, the hippocampus has been shown to undergo an increase in gray matter as women progress from the late-luteal (low E) to late-follicular (high E) phases of the menstrual cycle (Protopescu et al., 2008). Thus we hypothesized that women tested during the luteal phase of their menstrual cycle would be more likely to use a spatial strategy on a virtual navigation task, as previously found in rodents (Korol, 2004).

Methods: We tested 44 young women (ages 18-35) on the 4-on-8 virtual maze (4/8VM). Participants were grouped for phase of menstrual cycle on the date of testing based on data gathered via a questionnaire. Eighteen participants were in the luteal phase and 26 participants were in the follicular phase of their menstrual cycle. The 4/8VM consists of an 8-arm radial maze, in which 4 arms are accessible and 4 are blocked. Participants have to retrieve objects located at the end of the 4 accessible arms. Then, all 8 arms become accessible and participants have to retrieve objects now located in the 4 arms that were previously blocked. Participant's strategies are assessed with a verbal report and a probe trial whereby all landmarks are removed, leading to errors only in participants who had previously used these landmarks. Results: As per our hypothesis, 66.7% of women tested during their luteal phase used a spatial strategy in contrast to only 38.5% of women tested during their follicular phase. Consistent with our previous work showing that spatial strategies are more cognitively demanding (Iaria et al., 2003), women tested during their luteal phase required significantly more trials to reach criteria and made more errors when compared to women tested during their follicular phase. Conclusion: We concluded that the luteal phase, during which E is high, is associated with increased use of a spatial navigational strategy. This is congruent with Qiu et al. (2013), who found that hippocampal volume in rats increased during the proestrus (i.e. high E) phase, and that these increases were positively correlated with the use of a spatial strategy on a dual solution T-maze. This evidence suggests that the association of phase and navigational strategy may be due to elevated E levels.

Title: Patients with mild cognitive impairment show increased fMRI activity in the hippocampus following a spatial memory intervention program

Authors: *D. SODUMS[1], K. KONISHI[1], V. NAIR[1], H. CHERTKOW[2], S. GAUTHIER[1], L. KOSKI[3], L. BEHRER[4], V. D. BOHBOT[1];

Abstract: Aim: Atrophy of the hippocampus has been observed in patients with Mild Cognitive Impairment (MCI) and has been shown to be associated with an increased probability of conversion to Alzheimer's disease (AD). Hence, it is relevant to explore methods that could stimulate the hippocampus and potentially delay the onset of dementia among people who are at a high risk of developing AD. Previous research in our laboratory has shown that healthy participants spontaneously use different strategies when navigating in a virtual environment. More specifically, the use of spatial memory strategies has been found to be associated with increased activity and grey matter in the hippocampus while the use of stimulus-response strategies has been found to be associated with increased activity and grey matter in the caudate nucleus. Since AD affects the function and volume of the hippocampus, we developed a computerized spatial memory intervention program (SMIP) to specifically stimulate this region. This program, developed and validated over the course of 5 years, has been designed to promote extensive use of spatial memory strategies, taking particular attention to minimize the use of stimulus-response strategies. Methods: MCI participants underwent the SMIP. Each participant underwent a functional Magnetic Resonance Imaging (fMRI) scan before and after the SMIP. During this scan participants performed a virtual navigation task, called the Concurrent Spatial Discrimination Task (CSDLT), to assess potential change in fMRI activity in the hippocampus. The CSDLT is a virtual 12-arm radial maze in which participants have to learn the location of objects within 6 pairs of arms. The SMIP is comprised of 16 one-hour spatial memory training sessions administered to participants twice a week during the course of eight weeks. The participants navigate in 46 different virtual environments that vary in size and complexity in which the relative positions of objects, landmarks, or rooms need to be learned. Results: After intervention, there was a significant increase in the functional activity in the hippocampus during the first experimental trial of the virtual navigation task, consistent with early activity in the hippocampus established in previous studies. Conclusion: The results suggest that promoting spatial strategies leads to increased fMRI activity in the hippocampus during virtual navigation tasks. Though these results are preliminary, they are promising and suggest the potential effectiveness of SMIP restoring function in the hippocampus of patients at risk for AD.

Title: Assessing navigation performance in virtual environments on mobile devices

Authors: L. HONG[1], L. DAHMANI[2], V. D. BOHBOT[2], *N. C. SCHMITZER-TORBERT[1]; [1]Psychology, Wabash Col., CRAWFORDSVLLE, IN; [2]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada

Abstract: Aim: Navigation paradigms are useful for the study of memory in non-human animals, and virtual navigation tasks have allowed for comparative and neuroimaging studies in humans. However, virtual navigation tasks typically collect data using desktop and laptop computers, while mobile devices and tablets are becoming increasingly prevalent. The aim of this study was to assess navigation performance using standard virtual navigation tasks adapted for mobile devices. **Methods:** A set of virtual navigation tasks (Barnes maze, Morris water maze, and radial maze task) were developed for Android tablets. The tasks were released as a game in an online store. Upon the first use after installation, participants were randomly assigned to a Barnes maze, Morris water maze, or the 4-on-8 virtual radial maze (based on Iaria, Petrides, Dagher, Pike, Bohbot, 2003). More participants were assigned to the Barnes maze task than to the other tasks. After the first attempt, users could select additional tasks to complete. Participants were also asked to submit their sex and age after each task. **Results:** A total of 10,973 installations of the game were obtained. From all of the installations, 10,490 Barnes maze sessions, 819 water maze sessions, and 652 radial maze sessions were submitted. A total of 5,721 sex responses and 5,255 age responses were submitted. Each task included a probe trial, used to assess spatial learning (water maze), or the use of spatial versus response strategies (Barnes and radial maze). Behavioral performance across the tasks was not well related, with some exceptions. Across all three tasks, reaction times on the probe trial and the trial preceding the probe were more consistently related than other measures. Also, participants who made fewer errors on the radial maze task probe trial were also more likely to use a response strategy on the Barnes maze probe. In the water maze, men had better performance than women early in the

task. However, sex was not associated with performance or strategy on the Barnes or radial maze. Additionally, age was associated with longer latencies in the water maze, and with the use of response strategies on the Barnes maze probe trial. Data were also collected using a desktop version of the task under controlled laboratory conditions, and largely replicated the findings in the mobile sample. **Conclusion:** While these mobile tasks are currently being validated against standard virtual navigation tests, our results demonstrate the utility of remote data collection from mobile devices, and the potential of such devices to collect data from large samples for clinical and epidemiological studies.

Title: Higher dietary vitamin K intake is associated with increased use of the spatial strategy in healthy older adults

Authors: *N. ANDRUCHOW[1], K. KONISHI[2], B. SHATENSTEIN[3], V. D. BOHBOT[2]; [1]Dept. of Psychiatry, Douglas Mental Hlth. Univ. Institute, Dept. of Psychiatry, McGill Uni, Verdun, QC, Canada; [2]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada; [3]Inst. universitaire de gériatrie de Montréal, Univ. de Montréal, Montreal, QC, Canada

Abstract: Aim: Vitamin K deficiency potentially plays a role in Alzheimer's disease (AD) pathology. Vitamin K can improve survival of neurons and has important functions such as preventing apoptosis of neurons in the brain (Allison, A. C. 2001). In AD, the hippocampus is one of the first structures to degenerate. We previously demonstrated that healthy participants spontaneously use different strategies to navigate an environment. Spatial memory strategies are associated with increased activity and grey matter of the hippocampus, while stimulus-response strategies are associated with increased activity and grey matter in the caudate nucleus (Iaria et al., 2003; Bohbot et al., 2007). Thus, we investigated the relationship between dietary vitamin K intake and navigational strategies in healthy older adults. Methods: We administered the Food

Frequency Questionnaire (FFQ), validated by Shatenstein et al. (2005), which assesses participants' regular diet over the past year, to a group of healthy older adults (N = 53, mean age = 65.96 ± 4.5 yrs). Participants were also administered the Concurrent Spatial Discrimination Task (CSDLT). The CSDLT is a virtual 12-arm radial maze in which participants have to learn the location of objects within 6 pairs of arms. After participants learn the location of the objects, a probe trial is administered where the arms are recombined but the reward contingency remains the same. Performance on the probe trial indicates whether participants learned the position of the objects in relation to environmental landmarks (i.e., using a spatial strategy), which results in few errors. Results: We found a positive correlation between dietary vitamin K intake and probe scores on the CSDLT ($r = 0.289$, $p < 0.05$), indicating that increased dietary vitamin K intake is associated with increased use of the spatial strategy. Conclusion: Prior studies have shown a relationship between vitamin K and AD. In rats, lifetime vitamin K deficiency leads to impaired spatial memory performance on the Morris Water Maze (Carrie et al, 2011) and in healthy older adults, higher vitamin K concentrations correlate with better verbal episodic memory and free recall (Presse et al, 2013). Here, our results suggest that dietary vitamin K is associated with increased use of spatial strategies and may be protective against degeneration of the hippocampus. In fact, in rodents, it has been shown that vitamin K increases the survival of embryonic hippocampal neurons grown in serum-free medium (Nakajima, 1993). Therefore, the current results suggest that a diet higher in vitamin K may contribute to healthy aging.

Title: Navigational strategies in young and older adult Inuit hunters

Authors: ***V. D. BOHBOT**[1], I. DEMACHEVA[2], L. DAHMANI[3], E. CHACHAMOVICH[4]; [1]Douglas Mental Hlth. Univ. Institute, Dept. of Psychiatry, McGill Uni, Verdun, QC, Canada; [2]Dept. of Psychiatry, McGill Univ., [3]Integrated Program of Neuroscience, McGill Univ., [4]Div. of social and transcultural psychiatry, Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada

Abstract: Aim: Inuit hunters exhibit exceptional navigational skills. For centuries, they have found their way through seemingly homogeneous landscapes without using maps or navigation devices (Aporta, 2009). Although researchers have described the ways in which Inuit hunters navigate, we do not know the specific cognitive strategies that they use to find their way. They use a variety of environmental features to navigate, including the direction of winds, stars, landmarks, and snowdrifts. The fact that they use these ever-changing features implies that they are constantly forming spatial relationships between their current location, these environmental features, and their destination. This process is the hallmark of the "spatial strategy". Different strategies can be used to navigate, but we hypothesized that Inuit hunters use the spatial strategy to a greater extent. We also hypothesize that young Inuit hunters, because they rely more on technology, use the spatial strategy to a lesser extent than older Inuit hunters. Methods: Nine healthy older Inuit men hunters (mean age: 60.13 yrs) and 7 healthy young Inuit men hunters (mean age: 30.86 yrs), tested in Igloolik, Nunavut, took part in the 4-on-8 virtual maze. The task consists of an 8-arm radial maze, in which 4 arms are accessible and 4 are blocked. Participants have to retrieve objects located at the end of the 4 accessible arms. Then, all 8 arms become accessible and participants have to retrieve objects now located in the 4 pathways that were previously blocked. Spatial learners use landmarks to learn the location of the objects in the maze, while response learners use a sequence of right and left turns from a given starting position or stimulus. Results: As per our hypotheses, 87.5% of the elderly Inuit participants used a spatial strategy in contrast to only 39% of Southern Canadians. Further, elderly Inuit participants used spatial strategies to a greater extent than young adult Inuit hunters. Interestingly, the proportion of spatial learners was the same (50%) in young adult Inuit hunters and young adult Southern Canadians. Conclusion: Traditional occupations such as hunting seem to promote hippocampus-dependent spatial memory in the Inuit, a strategy associated with healthy cognition. Further research is needed in order to expand these results in a larger sample, balanced for sex, profession, and environment. Interestingly, contrary to our findings in southern Canadians whereby there is a decrease in the use of spatial strategies with age, older Inuit use spatial strategies to a greater extent than young Inuit, suggesting that growing up in a traditional environment increases the use of spatial strategies.

Title: Structural development of hippocampal subfields is related to statistical learning and inference

Authors: *M. L. SCHLICHTING[1], K. F. GUARINO[1], A. C. SCHAPIRO[2], N. B. TURK-BROWNE[2], A. R. PRESTON[1];
[1]Univ. Texas Austin, Austin, TX; [2]Princeton Univ., Princeton, NJ

Abstract: Recent work suggests that the hippocampus undergoes protracted structural development, which may explain developmental changes in learning and memory. However, the hippocampus is a heterogeneous system comprising several subfields that differ in cellular makeup, anatomical connectivity, and hypothesized function. Little is known about how these subfields develop or how their development relates to behavior. Although the hippocampus is primarily known for its critical role in the encoding and retrieval of individual episodic memories, it has also been implicated in coding relationships that span experiences. For instance, the hippocampus is involved in a form of statistical learning, extracting temporal regularities from the environment by generalizing across events. The hippocampus has also been implicated in novel inference judgments that require consideration of the relationships among multiple episodes. In the present study, we investigated the relationship of individual differences in hippocampal subfield anatomy to statistical learning and inference abilities from ages 6-30. Participants performed statistical learning and associative inference tasks that have previously been shown to require hippocampal function. We then acquired high-resolution T2-weighted structural MR images oriented perpendicular to the main hippocampal axis to quantify changes in subfield volumes across the age range. We found reduced behavioral performance among children relative to adults in both statistical learning and associative inference tasks. Consistent with the notion that hippocampal structures continue to mature into adolescence, we also observed that hippocampal volumes decreased over development, which was primarily driven by changes in the CA fields in the head of the hippocampus. Moreover, after accounting for age effects, we found relationships between hippocampal volumes and behavioral performance on both statistical learning and inference tasks. These results paralleled the volume decreases we observed over development, with smaller CA3 subfield volumes linked to superior behavioral performance. These data show that hippocampal structure relates to individual differences in the ability to integrate related experiences across time. Moreover, our findings suggest that the ability to derive knowledge across learning episodes may not reach maturity until adulthood.

Title: Habitual action video game playing is associated with caudate nucleus-dependent navigational strategies

Authors: *G. WEWT[1], B. DRISDELLE[2], K. KONISHI[3], M. DIARRA[2], P. JOLICOEUR[2], V. D. BOHBOT[4];
[1]Psychology, Univ. of Montreal, Outremont, QC, Canada; [2]Univ. of Montreal, Montreal, QC, Canada; [3]McGill Univ., Montreal, QC, Canada; [4]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada

Abstract: Aim: Action video games are associated with increased grey matter and activity in the striatum (Kuhn et al., 2011; Tanaka et al., 2013). Studies in humans and rodents have shown an inverse relationship between grey matter in the striatum and hippocampus. Therefore, we investigated whether habitual action-video game playing is also associated with increased use of response strategies, known to be dependent on the caudate nucleus of the striatum. Methods: Seventeen action video game players (VGPs) and 18 non-action video game players (NVGPs) were administered the 4-on-8 virtual maze (4/8VM), a virtual navigation task aimed to dissociate between spatial and response navigational strategies. The 4/8VM consists of an 8-arm radial maze, in which 4 arms are accessible and 4 are blocked. Participants have to retrieve objects located at the end of the 4 accessible arms. Then, all 8 arms become accessible and participants have to retrieve objects now located in the 4 arms that were previously blocked. To find the rewarded arms, spatial learners used environmental landmarks, while response learners used a pattern of open and closed arms from a given position. After participants have learned the task, a

probe trial is given in which all landmarks are removed, whereby spatial learners make more errors than response learners, indicating reliance on external landmarks. In addition to this, we used an event related potential (ERP) target detection task to measure group differences in stimulus-response orienting. Results: We found that VGPs had a significantly higher likelihood of using a caudate nucleus-dependent response strategy (83.33%) compared to NVGPs (50%). In contrast, NVGPs used spatial and response strategies in similar proportions to what was observed in past young adult studies using the 4/8VM (Iaria et al. 2003). Further, VGPs showed a larger N2pc component for targets that were furthest away from fixation, consistent with prior studies. Conclusion: Increased use of the response strategy in VGPs is consistent with previously observed increases in striatal volume in VGPs. Response strategies are associated with decreased grey matter in the hippocampus, which, in turn, is associated with increased risk of neurological and psychiatric disorders. While VGPs may have been predisposed to action video game playing due to genetic and experience dependent factors such as early adversity (Schwabe et al., 2011), recent evidence suggests a correlation between time playing action video games and atrophy of the entorhinal cortex (Kuhn and Gallinat, 2013). As such, these results suggest that playing action video games may have an impact on long-term cognitive health.

Title: EEG-Theta modulation is greater in spatial learners than response learners: A scalp-EEG study in young adults tested on a virtual navigation task

Authors: ***T. H. FALK**[1], H. J. BANVILLE[1], S. BISHUNDAYAL[2], R. CASSANI[1], E. CHAN[3], A. CLERICO[1], L. DAHMANI[3], R. GUPTA[1], A. RATHARAJAH[2], N. PHILLIPS[2], V. D. BOHBOT[3];
[1]Energy Materials Telecommunications, Inst. Natl. De La Recherche Scientifique, Montreal, QC,

Canada; [2]Concordia Univ., Montreal, QC, Canada; [3]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada

Abstract: Aim: Using spatial memory when navigating is known to elicit hippocampal function, which in turn activates theta frequency electroencephalography (EEG) modulation for spatial coding purposes. The virtual navigation tasks developed by Bohbot have been shown to correlate with hippocampal fMRI activity for both young and older adults. Previously, hippocampal activity was detected using intracortical EEG. Our aim was to detect hippocampal activity with scalp EEG, which is non-invasive. We tested both spatial and response learners and hypothesized that spatial learners would show more theta EEG activity than response learners. Methods: We performed a pilot experiment with 10 young adults (5 women, 5 men; 3 spatial and 7 response learners). We used the 4-on-8 virtual maze to investigate EEG activity during virtual navigation. Participants performed a series of control and experimental tasks. The task consists of an 8-arm radial maze, in which 4 arms are accessible and 4 are blocked. In the experimental trials, participants have to retrieve objects located at the end of the 4 accessible arms. Then, all 8 arms became accessible and participants had to retrieve objects now located in the 4 pathways that were previously blocked. After the task was learned, a probe trial was given in which all landmarks were removed. The probe trial allows us to dissociate spatial and response learners, as spatial learners make more mistakes then response learners. In the control trials, participants explored the virtual environment while counting down by 3 from 1000. The experimental task is known to elicit fMRI activity in the hippocampus relative to the control task. We recorded 64-channel EEG; amplitude modulation and cross-frequency interaction analysis was performed. Results: A pair-wise comparison test showed that theta amplitude modulation was significantly higher for the spatial learners during the experimental task compared to the control task, response learners in the experimental task, and lastly response learners in the control task. Conclusion: Theta activity, an EEG band previously shown to be associated with hippocampal function, is differentially modulated in spatial vs. response learners. These preliminary findings suggest that the proposed EEG features are sensitive to hippocampal function. Interestingly, the control condition of the spatial learners elicited greater theta than the experimental condition of the response learners. Assuming that theta rhythm is associated with spatial learning, these results suggest that spatial learners have a general brain state or readiness for acquiring spatial information that is not as present in response learners.

Title: Focusing on what matters: Modulation of the human hippocampus by relational attention

Authors: ***N. I. CORDOVA**, M. ALY, N. B. TURK-BROWNE;
Princeton Univ., Princeton, NJ

Abstract: Relations are essential for long-term memory, helping us remember where and when things occurred within past episodes. The hippocampus is known to play a critical role in such relational memory. However, relations are also important over much shorter time periods, when perceiving the current environment. For example, how do we see the relative positions of objects, or their temporal order, or the relationship between their features? Here we investigate the role of the hippocampus in such online relational processing by manipulating visual attention to different kinds of relations in a dynamic display. During high-resolution fMRI, participants were presented with a series of trials in which two images appeared very rapidly. Orthogonally, the images differed in relative spatial position, temporal onset, and size; in addition, each of the images was rotated independently of the other on a subset of trials. Afterwards, a post-cue appeared that pointed to the location of one image. This enabled four tasks: (1) spatial task: was the cued image to the left or right of the other image? (2) timing task: did the cued image appear before or after the other image? (3) size task: was the cued image smaller or bigger than the other image? (4) tilt task: was the cued image tilted or not (irrespective of the other image)? The spatial, timing, and size tasks oriented attention to the corresponding relations between the images, while the tilt task provided a control in which attention was oriented to an individual image and between-image relations were task-irrelevant. Critically, we used a staircasing procedure to equate behavioral performance across tasks (i.e., by changing the spatial, temporal, and size offsets, and amount of tilt), eliminating explanations of the neural data based on task difficulty. We examined attentional modulation in three hippocampal subfield regions-of-interest: CA1, CA2/CA3/dentate gyrus, and subiculum. All subfields showed reliable deactivation across tasks, but deactivation was greater when participants attended to relational vs. item information. This effect was most strongly driven by attention to temporal relations. One possible interpretation is that this deactivation simply reflects disengagement of the hippocampus. To investigate this possibility, we performed pattern similarity analyses, with the idea that disengagement would reduce information content and result in noisier and less reliable patterns of activity. Instead, pattern similarity was robust over runs of the timing task, and

stronger than in any other task. These findings suggest a general role for human hippocampus in the rapid online extraction of relational information.

Title: Neural correlates of dynamic emotional facial expressions in infants

Authors: ***N. ROTEM-KOHAVI**[1,2], A. ROSE[4], C. G. E. HILDERMAN[3], T. F. OBERLANDER[6], N. VIRJI-BABUL[3,5];

Inst., Vancouver, BC, Canada; [6]Univ. of British Columbia, Pediatrics, Child and Family Res. Inst., Vancouver, BC, Canada

Abstract: Infants' ability to discriminate between different facial expressions is necessary for social and emotional development. Recognizing facial expressions supports the detection of another person's emotional state, and provides cues on how to respond in different social situations. Simulation theories for the perceptual processing of emotional faces assert that in order to recognize the emotions and infer the feelings of others, observers recruit the neural circuitry involved in creating their own emotional facial expressions. The electroencephalography (EEG) mu rhythm is a sensorimotor oscillation hypothesized to index the activation of the mirror neuron system. The mirror neurons have been shown to fire during both action performance and during action observation. Recently, it was suggested that observing emotional faces involves simulation of the emotional facial expression, which may elicit mu rhythm desynchronization. However, to date, the EEG mu response to viewing different facial expressions, in infants has not been studied. In this study we recorded EEG responses in 8-10 month old infants (n=11) while they observed dynamic facial expressions of neutral, sad, pain and happiness. Mean mu desynchronization was calculated for each expression in the central brain regions. The response to all expressions was significantly greater than zero ($p<0.001$ for all of the expressions). Our data show that the magnitude of mu desynchronization in response to observing pain was significantly larger than for happy and sad facial expressions in the left

central regions (p=0.038, and p=0.021 respectively). Our preliminary results suggest that between the ages of 8-10 months infants respond differentially to dynamic facial expressions and that the perception of painful expressions may evoke a stronger response. These results may provide insights into the developmental processes associated with empathy.

Title: Involvement of bilateral inferior frontal gyri in emotional recognition with social context: A TMS study

Authors: ***Y. YAMASHITA**[1,2,3], H. MAESHIMA[2,4], M. ABE[1,6], M. HONDA[1], M. OKADA[2,5], K. OKANOYA[2,3,4];

Sch. of Frontier Sci., The Univ. of Tokyo, Kashiwa, Japan; [6]Dept. of Neurology, Sch. of Med., Fukushima Med. Univ., Fukushima, Japan

Abstract: In order to investigate the involvement of both left and right inferior frontal gyri (IFG) in emotional recognition with social context, we developed a novel behavioral task to quantitatively measure an effect of contextual information on the recognition of facial expression changes. Then, by applying repetitive transcranial magnetic stimulation (rTMS) over left and right IFG, we examined whether these brain regions are critically involved in the processing of emotional context. The task trial consisted of sequential presentation of three pictures of a pre-face, a context scene, and a post-face, selected from the facial expression continua that were morphed in 6 steps from happy to fearful faces of a same model identity. Inserted scene images

were pleasant, unpleasant scenes describing social context, and meaningless images were used for control conditions. The participants were asked to discriminate quickly and accurately the direction of facial expression changes (positive/negative) from the pre-face to the post-face. The behavioral experiment demonstrated that the detection of subtle facial expression change was highly sensitive to the context scene. That is, when a facial expression change was "compatible" (i.e. direction of a change in facial expression was consistent with the context stimulus), subjects were able to recognize significantly more precisely than "incompatible" changes of facial expressions (context effect). In addition, when pairs of the pre and the post faces belonged to different emotional category, subjects were able to recognize significantly more quickly and precisely than those from same category (category effect). Eighteen subjects, in whom the left IFG was successfully identified using TMS-induced speech arrest (SA) method, participated in the rTMS experiment. Fifteen minute-rTMS of 1Hz was applied to the left and right IFG to interfere cortical functions of these areas and the performances of the above task were measured before, immediately after and 30 minutes after the rTMS. As a result, the context effect was affected by the TMS applied over both the right and the left IFG. That is, TMS temporarily increased the error rate for the contextual trials, but not for the control, suggesting that bilateral IFG may be critically involved in the processing of emotional context. By contrast, the category effect was selectively affected by the TMS applied over the left IFG, which increased response latencies for the different category trials but not for the same category trials. This suggests that the left IFG plays a critical role in the categorical perception of emotional facial expression.

Title: Different widespread networks are activated by musical prosody: An EEG and subjective evaluation study

Authors: ***M. CASTRO GONZÁLEZ**[1], B. CORONA-DZUL[1], M. CORSI-CABRERA[1], E. FLORES-GUTIÉRREZ[2,3];

[1]Lab. de Sueño, Posgrado, Facultad de Psicología, Univ. Nacional Autónoma De México, México, Mexico; [2]Inst. Nacional de Psiquiatría Ramón de la Fuente Muñíz, México, Mexico; [3]Escuela Nacional de Música, México, Mexico

Abstract: Musical prosody communicates different emotional feelings, when melody is influenced by consonant or dissonant chords, and major or minor chords. The aim of this study was to analyze brain response to musical prosody in conjunction with subjective ratings of feelings expressed by music. We used ten musical pieces, each one in four piano versions: major consonant, minor consonant, major dissonant and minor dissonant (40 pieces in total). Musical pieces (about 16 s each) were presented in a classical block design alternating white noise in four counterbalance runs, one for each group of musical version. After each run subjects (n = 20) rated the subjective feelings communicated by the music (Likert scales). Spectral power (1-50 Hz) and current density sources were obtained. Significant differences were found between music and noise and between musical pieces depending on their musical structure and feelings expressed by them. Music compared to noise, induced higher theta and alpha absolute power over widespread brain regions of the two hemispheres and decreased beta and gamma mainly in the right hemisphere. Significant differences in current source density and spectral power were found between consonance and dissonance that were also different for major and minor modes involving alpha, beta and gamma frequencies in the right hemisphere in frontal lobe, orbitofrontal, cingulate, insular and superior and middle temporal cortex. The left hemisphere showed only higher alpha current density in orbital and cingulate gyrus and higher gamma in superior parietal lobule, superior temporal lobe, angular gyrus and precunneus. Alpha, beta2 and gamma current densities were higher for major consonant compared to major dissonant pieces in right frontal lobe and lateral orbital region. Feelings communicated by musical pieces, pleasant for consonants and major, and unpleasant by dissonant and minor, were corroborated. The right hemisphere responds stronger to musical prosody, and the left for consonance and major mode only in posterior regions fast frequencies.

Title: Is the cognition of emotional face expression influenced by menstrual cycle?

Authors: *M. YAMAZAKI[1], S. SUZUKI[1], K. TAMURA[1], Y. UGAWA[2];
[1]Hlth. Sci., Daito Bunka Univ., Saitama, Japan; [2]Dept. of Neurology,, Fukushima Med. Univ., Fukushima, Japan

Abstract: Women in reproductive age experience dynamic changes of sexual hormones level and also serotonin which influences emotion and mood with their menstrual cycle. However, it remains still poorly understood that whether the brain response in face processing is affected by the menstrual cycle or not. The purpose of this study was to investigate the influence of the menstrual cycle and gender on the emotional face cognition. We employed event-related potentials (ERP) with scalp 19channels during a judgment task of emotional expression (happy or fear) / non-emotional expression (neutral) selected from the Karolinska Directed Emotional Faces (KDEF). Twenty (10 males and 10 females) university students were participated in this study. Female subjects were examined during both the preovulatory (high estrogen) stage and premenstrual (low estrogen) stage. We analyzed the peak amplitude, latency of ERP components and the scalp topographies of the ERP. The fear expression elicited higher amplitude in premenstrual stage females compared to men and preovulatory stage females. Scalp topographies showed gender difference female but not in menstrual stage. The present data suggest that we should take account of the influence of the menstrual cycles when we discuss the gender differences in emotional face cognition, such as the emotional content of stimuli.

Title: Common network for the processing of dynamic emotional bodies contains information to discriminate individual basic emotions

Authors: *J. JASTORFF[1,2], M. A. GIESE[3], M. VANDENBULCKE[1];
[1]Res. Group Psychiatry, [2]Res. Group Neurophysiol., KULeuven, Leuven, Belgium; [3]Dept. of Cognitive Neurol., Univ. Clin. Tübingen, Tübingen, Germany

Abstract: Mechanisms underlying the processing of basic emotional expressions have been proposed to reside in distinct gross anatomical locations. Recent meta-analytical studies, however, provide conflicting results with some in favor (Vytal & Hamann 2010) and others disagreeing (Lindquist et al. 2012) with this proposition. Here, we used dynamic stimuli of emotionally expressive gaits to address the question whether common or distinct networks subserve processing of different emotions displayed by human bodies. Furthermore, instead of relying on general activation differences between emotions, we investigated which regions contain information to reliably discriminate between different emotions. Stimuli were generated from a motion capture database of actors performing neutral and emotionally expressive (anger, happiness, sadness, fear) gaits. A custom-built volumetric avatar model was used for animation. This procedure has been shown to result in highly recognizable emotional stimuli (Röther & Giese 2009). Six stimuli of each of the four emotions and the neutral gaits were selected for the event-related fMRI experiment, resulting in 30 stimuli. These were presented twice within one run (8 & 5 vis. degrees respectively) for two consecutive gait cycles in a pseudo-random order. To identify regions commonly activated by all emotions, we contrasted each emotion individually with the neutral condition and selected voxels significantly activated in all 4 contrasts. These were located in the posterior STS, the temporal poles, posterior, middle and anterior cingulate cortex, the left parahippocampal gyrus and the medial orbitofrontal cortex. Investigating the information present in these ROIs, SVM classification showed above chance performance for at least 3 out of the 4 emotions in the left posterior STS, left parahippocampal gyrus, medial orbitofrontal cortex and middle cingulate cortex. Contrasting each emotion separately with the three others did not yield any significant voxels common to all 3 contrasts. Furthermore, information about the specific emotion was not limited to the emotion network, but was also present in the posterior MTG, left inferior frontal sulcus, and the fusiform gyrus; all parts of the action observation network. We did not obtain evidence for discriminable brain correlates of individual basic emotions. Nevertheless, several regions commonly activated for all emotions also contained information about the specific emotion displayed. In our ongoing work, including patients with neurodegenerative diseases, we intend to identify the contribution of the localized emotion network for the processing of emotional body expressions.

Title: Infants' brain responses to subliminal emotional eyes

Authors: *S. JESSEN, T. GROSSMANN;
Max Planck Inst. For Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: Emotion perception is a fundamental aspect of social interaction and as such operates extremely fast and efficient. Increasing evidence suggests that emotional information can influence neural and behavioral responses even in the absence of conscious awareness. While this subliminal emotion perception has been studied extensively in adults, its development in ontogeny is poorly understood. The present electroencephalographic (EEG) study therefore investigated the brain responses to subliminally presented eyes in 7-month-old infants. Infants were presented with fearful and happy eyes, as well as a polarity-inverted version of these stimuli. All stimuli were displayed for 50 milliseconds, which is well below the perceptual threshold established for this age group, and followed by a mask consisting of a neutral facial expression. We observed differential brain responses for fearful and happy eyes within 200 milliseconds at occipital electrodes, suggesting an emotional distinction early in visual processing. Furthermore, neural response at frontal electrodes clearly differed between happy and fearful eyes from 400 milliseconds onwards, which points to an influence of subliminal emotional content on the allocation of attention. Crucially, both effects were only observed for the original stimuli and not for the polarity-inverted control condition. Our results therefore highlight the role of eyes in emotion perception by showing that they are sufficient to elicit emotion specific neural activations, even when not consciously perceived. The present study is the first to show that this mechanism operates not only in adults, but that differential brain responses to subliminal emotional stimuli can already by observed in infants.

Title: Power spectral analysis of EEG from emotional auditory stimuli

Authors: *H. LEE[1,2], R. DU[1];
[1]Computer Sci. & Engin., Chonbuk Natl. Univ., Jeonju, Jeonbuk, Korea, Republic of; [2]Ctr. for Advanced Image and Information Technol., Jeonju, Korea, Republic of

Abstract: Purpose: Many researchers have investigated various psychological and physiological phenomena because of the importance of emotions. Emotion recognition process is the important part in the auditory BCI system. Power spectral analysis is a useful way to investigate the emotional information from EEG signals. The purpose of this abstract is to explore cortical oscillation properties in the emotional auditory experiment by analyzing the significant effects of the power spectrum. Method: We have collected the 18 channel EEG signals over 30-male subjects under the standard. International affective digitized sounds clips are classified in three emotional states, happy, neutral and fear. Power spectrum were calculated from the four frequency bands namely theta (4-8 Hz), alpha (8-13 Hz), beta (13-30 Hz) and gamma (30-50 Hz). In order to discover significant effects, a significance level of $p < 0.01$ is combined with the power spectrum to analyze the data. Repeated measures ANOVA with Bonferoni correction were employed to analysis. Results: The results showed only three bands have the significant relations between power and emotion. High alpha band waves ranged 10.9 and 12.2 Hz showed differences with significant effects in the prefrontal, central, temporal and parietal regions. Power differences of beta band between 13.7 and 29.6 Hz were found in the all cerebral areas except prefrontal region. In addition, the gamma band has one narrow band between 30.2 and 38.6 Hz with power differences in the frontal and central regions, and another narrow band between 40 and 46.8 Hz in the parietal and occipital regions. Conclusion: Interesting findings are 1) there had no significant effects of response in the theta band. 2) the narrow frequency bands between 10.9 and 12.2 Hz showed differences in the prefrontal, central, temporal and parietal regions. 3) the whole beta band ranged 13.7 and 29.6 Hz was found in all cerebral areas except prefrontal region. 4) gamma band have the narrow bands of 30.2-38.6 Hz with power differences in the frontal and central regions.

Title: Decoding music-evoked emotions from brain activity

Authors: *L. ROGENMOSER, S. ELMER, L. JÄNCKE;
Dept. of psychology, Div. neuropsychology, Univ. of Zurich, Zurich, Switzerland

Abstract: Music contributes enormously to our daily emotional experiences. Nevertheless, relatively little is known about the underlying mechanisms. Hindering factors are, on the one hand, the complexity and the length of the researching stimulus and, on the other hand, the individuality of the subjects' preferences. The present study aims to investigate the underlying mechanisms of music-evoked emotions in an ecologically valid manner by taking these hindering factors in consideration. To address this, we recorded the electroencephalography (EEG) in 20 subjects. For each subject, 24 excerpts (60 sec) were individually selected, based on their previous ratings, and were presented in the EEG session. Independent component (IC) analysis, spectrogram and IC clustering were applied. Specific ICs with specific spectra were linked to the valance (happy vs. sad) and the arousal experienced during music listening.

Title: Perception of happiness affected by exposure to the life histories of others

Authors: *K. MOGI;
Fund Res. Lab., Sony Comp Sci. Lab., Shinagawa-Ku, Japan

Abstract: The elucidation of cognitive mechanisms involved in the perception of happiness has recently become an important research topic (Lyubomirsky & Lepper 1999, Diener 2000,

Killingsworth & Gilbert 2010). Subjects are known to assume that their perceived happiness is influenced by a certain set of elements, when in fact the perceived utility is determined by a broader set of parameters (Kahneman et. al 2006). It is an interesting question, from scientific and practical points of view, to study how people can be induced to break free from the cognitive bias of anchoring (Wilson et al. 1996), to arrive at a balanced assessment of their own happiness. Evidence suggests that prefrontal areas are involved in the formation of cognitive bias (Podell et al. 1995, Browning et al. 2010). Activities in the ventral mesial frontal cortex correlate with positive emotions (Lane et al. 1997), while greater left superior frontal activation has been associated with higher levels of perceived well-being (Urry et al. 2004). These results suggest the possibility that we may be able to change a subject's perception of happiness through a manipulation of the bias parameters and contexts. Here I study how the exposure to descriptions of the life history of other subjects with similar or different backgrounds lead to a "defocusing" of the focusing illusion (Kahneman et. al 2006). Subjects were recruited to give estimates of their individual happiness, together with elements of life that they consider are important in determining the measure of happiness. In addition, the subjects were asked to provide generic and anonymous descriptions of the conditions in their lives they consider are important in determining happiness. Changes in the subjects' perceived levels of happiness after exposure to life accounts of subjects with backgrounds of various similarities are analyzed. Personal connection to other people is known to enhance the level of perceived happiness (Diener & Seligman 2002). Based on the results, I discuss how the perception of happiness can be made more robust through the exchange of life history accounts with other people.

Title: Intertwined affective and semantic representations of the world around us: Applying voxel-wise encoding models to studying the cortical representation of emotional natural images

Authors: *S. A. ABDEL-GHAFFAR[1], A. G. HUTH[2], D. E. STANSBURY[3], A. S. COWEN[1], S. J. BISHOP[1,2];
[1]Psychology, [2]HWNI Neurosci., [3]Vision Sci., UC Berkeley, Berkeley, CA

Abstract: It has been argued that emotional stimuli receive prioritized processing. This is especially held to be the case for 'biologically prepared' stimuli. Prior fMRI studies have investigated the brain circuitry that encodes image affective value, but there has been little investigation of how this interacts with image semantic content. Regions throughout occipital and temporal cortex are known to be highly selective for semantic categories such as faces, bodies, and places. If these regions also store information as to the affective value of stimuli, this might enable quick identification of prepared stimuli. This raises the questions: Is there representation of image affective content within these regions? How does this interact with semantic tuning? To address these questions, we used voxel-wise encoding models (Naselaris, Kay, Nishimoto, Gallant, 2011) to investigate the brain-based representation of complex emotional images. Participants viewed a large set of emotional images (>1500), categorizing each image by valence (negative, neutral, or positive). Post scan ratings of image arousal and the emotion engendered by each image were also acquired. Encoding models of image structural properties, semantic and affective content were used to predict the BOLD response to new images from a held out 'validation' data set. In line with prior findings, a gabor model best predicted the BOLD response in early retinotopic visual regions, while semantic models predicted well in anterior occipital and ventral temporal regions. An interaction model (semantic category x emotional valence x arousal level (high, low)) significantly improved BOLD response prediction accuracy across anterior occipital, ventral temporal and other cortical regions. A principal components analysis was conducted upon the features weights from this model. The first 3 components explained >50% of variance across voxels, primarily encoding animacy, emotional intensity (arousal) and negativity, respectively. Plotting each voxel's response as characterized within this PC space onto flat maps of each subject's brain showed a similar structure across hemispheres, as well as certain commonalities between subjects. Within semantically selective regions, we find additional tuning for image valence and arousal, with voxel response profiles varying in a smooth and consistent manner across both hemispheres. These maps allow us to visualize the complex interactions between semantic and affective value encoded within visual cortex. Similarities across subjects may reflect common representations allowing for fast recognition of high survival-value stimuli.

Title: Different empathic responses to painful expressions versus needle-pricked body parts: Evidence from behavioral and electrophysiological study

Authors: *Y.-B. SUN, J.-Y. WANG, F. LUO;
Inst. of Psychology, Chinese Acad. of Scienc, Beijing, China

Abstract: Empathy, a basic social cognitive function, plays an vital role in everyone's daily life. Two kinds of stimulus materials (painful facial expressions and body parts receiving painful stimulation) are widely used as representations of other's pain in these research. However, what is always ignored by previous studies is that the two kinds of stimuli may result in different psychological processes of the observers, e.g., one may imagine he himself in pain when viewing injured body parts while do not implicate himself when seeing painful faces. The present study focused on the differences between empathic responses elicited by painful expressions and needle-pricked body parts. Highly ecological validity video clips were prerecorded depicting people being injected (n=10, 4 males). The videos were split and trimmed into two different clips, consisting of faces and injected arms respectively. The control video clips were recorded from additional 10 subjects showing neutral expressions with arms being wiped by a Q-tip. A total of 28 video clips are assigned to 3 blocks. Thirty-six graduate and undergraduate subjects (males 12, age 22.0±1.8) participated in this experiment. Facial EMG and pulse rate were recorded to assess the emotional responses elicited by visual stimuli. Subjective ratings of pain intensity and unpleasantness as well as IRI were measured after the termination of video stimuli. The results showed that, compared to the neutral videos, viewing pain videos elicited more corrugator activity, lower pulse rate, and higher pain ratings. Further more, stronger empathetic reactions (more corrugator activity, lower pulse rate, and higher pain ratings were also found when watching arm-pain videos than face-pain ones. These results suggest that observing injured body may lead to more self involvement relative to observing painful faces. Using the event-related potential approach, we examined the differences between brain responses elicited by visual images of painful faces versus needle-pricked arm. The time-course of empathic reactions to painful condition and nonpainful condition was investigated and compared. The preliminary data showed face-locked ERP components (N1, P2 and N2) recorded at electrode site Cz. The arm-locked ERPs displayed longer latency and lower amplitude as compared to the face-locked

ERPs. Painful faces elicited N1 and P2 of greater amplitude than neutral faces. Further analysis of electrophysiological data is being done relating to the late, emotion-related components as well as the source location.

Abstract: In adults and children, sleep loss is associated with affective dysregulation and increased reactivity to negative stimuli (Franzen et al., 2009, Walker & van der Helm, 2009; Legenbauer et al.2012; Berger et al., 2011). Adult functional neuroimaging (fMRI) studies have also demonstrated associations between sleep deficits and increased activation in the amygdala and reward systems when viewing emotional picture and face stimuli (Yoo et al, 2007; Gujar et al., 2011). However, few studies have examined the associations between sleep and emotional reactivity in school-aged children and no studies have investigated this relationship using fMRI. In the current study, we examined the relationship between sleep quality in pre-adolescents and fMRI responses to emotional faces. Fifteen male child subjects (ages 7-11) were recruited from a larger study (N=88) investigating fear processing and child behavior problems (Sylvers et al., 2011). Information about child sleep duration was collected via maternal report. Children were scanned with fMRI in an event-related paradigm in which they viewed and made perceptual judgments about negative, neutral, and positive emotional faces. We predicted that shorter sleep duration would be associated with increased activation in the amygdala and other regions

associated with emotional response, in line with prior studies in adults. Neuroimaging results revealed that when viewing negative (i.e., fearful, disgust) vs. neutral emotional faces, shorter sleep duration was associated with increased activation in the bilateral amygdala, left insula, and left temporal pole ($p<.05$, corrected for multiple comparisons). Additionally, shorter sleep duration was associated with increased right orbitofrontal and bilateral prefrontal activation when viewing disgusted vs. neutral faces, as well as increased bilateral orbitofrontal, right anterior cingulate, and left amygdala activation when viewing happy vs. neutral emotional faces. In contrast, as predicted, longer sleep duration was not specifically associated with increased activation in emotion-related brain regions. Taken together, these findings indicate that among school-aged children, shorter sleep duration may contribute to neural alterations of circuitry involved in the regulation of emotion and reward processing. Future studies should extend this work to examine the relationship between child sleep deficits and emotion regulation on both neural and behavioral levels.

Title: Variability in human anterior insula gray matter volume predicts awareness for perithreshold backward masked fearful faces

Authors: *R. TORRENCE, J. CARLSON;
Psychology, Northern Michigan Univ., Marquette, MI

Abstract: The threshold for conscious perception of stimuli within the environment varies from individual to individual. For example, behavioral research has noted that when administering an awareness task with fearful vs neutral faces to normal healthy individuals, some perform above chance level indicating that they have better perceptual awareness. Functional neuroimaging studies suggest that the anterior insular cortex (AIC) positively correlates with perceptual awareness. However, few have examined the structural differences among individuals. The purpose of this study is to examine neural differences in perceptual awareness. This study hypothesizes that there will be a positive correlation with AIC gray matter volume and scores on

the awareness task. The awareness task was designed to assess awareness for the presence and location of backward masked fearful and neutral faces, masked with neutral faces. The participants responded by indicating on which side the masked fearful face appeared, or whether there were two neutral faces. The task included a total of 60 trials. T_1-weighted magnetic resonance images were collected to measure gray matter volumes. A whole brain threshold of $p < .001$ and 20 voxels were used with the insular as the regions of interest. In SPM8, a regression analysis was used with awareness as the predictor variable, gray matter as the dependent variable, and age and total gray matter volume as the control variables. The results indicated that there was a relationship between greater awareness and greater gray matter volume in bilateral AIC: left ($t(38) = 3.85$, $p < .001$), $k = 21$ and right ($t(38) = 4.49$, $p < .001$), $k = 108$. Individuals that were more aware of backward masked fearful faces had greater gray matter volume in their AIC. Future research could examine if practicing tasks that require greater perceptual awareness causes structural differences in the brain.

Title: Individual differences in detecting changes in face identity and emotional expressions depend on two distinct mechanisms

Authors: *A. L. ACHAIBOU, S. J. BISHOP;
Dept Psychology, UC Berkeley, UC Berkeley, Berkeley, CA

Abstract: Despite the importance of detecting changes in our environment, people often fail to notice changes when they occur after a brief visual disruption. In an early fMRI study, Beck and colleagues showed that change detection was associated with increased activity in fronto-parietal networks and category selective areas of the ventral visual stream, concluding that these activations indexed awareness of change (Beck et al., 2001). However, a subsequent EEG study revealed that frontal activity associated with change detection actually occurred prior to the change itself, suggesting that this prefrontal activity may reflect preparatory attentional function

as opposed to conscious change detection (Pourtois et al., 2006) Faces convey information not only about identity but also expression. It has been suggested that processing of these two aspects of faces are relatively independent from one another (Bruce & Young, 1986) and that fearful facial expressions are processed via a fast subcortical thalamo-amygdala pathway (de Gelder, 2011), and may facilitate 'bottom-up' stimulus driven attention. Here, we adapted Beck's change detection paradigm to investigate the hypothesis that detection of changes in identity would be associated with increased prefrontal activity (presumed to index preparatory activity), but that successful detection of changes in expression (from neutral to fearful) would be primarily linked with amygdala activation. Participants saw two consecutive displays, separated by 1s, each with two faces or two houses either side of fixation presented for 250 ms, and reported if there was a change on the left side or right side or if no change had occurred. Morphing was used to create both small and large identity and expression changes. After controlling for general change detection ability (indexed by performance on house trials), we found that there was no relationship between performances on identity and expression change trials but strong commonality in performance within each type of change condition (but across difficulty levels). FFA activity tracked change detection regardless of conditions. In contrast, increased activity in ventro-lateral prefrontal cortex was associated with detection of identity changes, but not expression changes, while amygdala activity was associated with performance on expression change but not identity change trials. Overall, our results support the idea that the ability to detect changes in face identity and emotional expressions depends on two distinct neural mechanisms.

Title: Sustained, not habituated, activity in the human amygdala during threat-elicited attention

Authors: *M. A. WEBER, W. RIZER, K. MORROW, K. KANGAS, R. TORRENCE, J. M. CARLSON;
Northern Michigan Univ., Marquette, MI

Abstract: The human amygdala processes conscious and nonconscious fearful facial expressions and directs spatial attention to these faces. Additional research has shown that amygdala activity decreases or habituates after repeated exposure to fearful faces in passive viewing tasks. However, it is unclear to what extent the amygdala habituates during biologically relevant amygdala-mediated behaviors such as the orienting of attention to environment threat signals. This study investigated amygdala habituation to backward masked fearful faces compared to neutral faces when attention is directed and undirected. Participants performed a dot probe task while amygdala activity was recorded using functional magnetic resonance imaging (fMRI). The dot-probe task required participants to locate a dot either to the left or right of a fixation cross after two face stimuli were presented. Directed attention trials consisted of one fearful and one neutral face equally appearing the left or right visual field followed by a neutral mask. Half of these trials were congruent (fearful face-dot) or incongruent (neutral face-dot). Subject response times to dot location were significantly faster for congruent than incongruent trials because attention was oriented to that location, $p = 0.006$. Undirected trials consisted of two fearful (FF) or two neutral (NN) faces presented to either side of the fixation cross followed by a neutral mask. Subject response times were not different between FF and NN trials because attention is equally divided across the two visual fields ($p > 0.1$). Sustained and habituation amygdala activity was analyzed in SPM8 by looking for elevated activity across the task or for a relative decline in activity across the task. There was significant sustained activity in the left amygdala for directed attention (vs. NN, $t = 3.34$, $p = 0.004$, $k = 78$) and undirected attention (FF vs. NN, $t = 3.08$, $p = 0.006$), but no overall habituation pattern was observed for directed ($p > 0.05$) or undirected ($p > 0.05$) attention. This study suggests that the amygdala does not habituate during the presentation of backward masked fearful faces during dot-probe task. The findings suggest that the demand for attention and action during the task leads to sustained, rather than habituated, amygdala activation.

Title: Gender and task-context modulate the LPC amplitudes related to facial preference

Authors: *S. KIM[1], J.-H. KANG[2], S.-P. KIM[4], Y. CHO[3];
[1]Korea Univ., Korea, Republic of; [2]Brain and Cognitive Engin., [3]Cognitive Psychology, Korea Univ., Seoul, Korea, Republic of; [4]Design and Human Engin., Ulsan Natl. Inst. of Sci. and Technol., Ulsan, Korea, Republic of

Abstract: A great number of previous works with various research methods has been conducted on the topic of facial attractiveness or preference (Johnston & Oliver-Rodriguez, 1997; Werheid et al., 2007, Zhang et al., 2011). Specifically, in the ERP studies, Late Positive Complex (LPC) is one of the representative components sensitive to the attractiveness of face stimulus in latency after 400 ms. Here, we investigated the effect of facial preference on LPC component with two different tasks. Participants were to perform a passive viewing task and an active choice task with the same face images sequentially. In the first passive task, each face stimulus was presented one at a time and participants simply looked at the face stimuli without any explicit response. After a few minute breaks, a pair of same-gender face images, which were used in the passive viewing task, was presented sequentially and participants were asked to actively choose one image among the two, within the context of preference, "which face do you prefer more?" On the basis of the behavioral data from the second task, the face images were classified into three preference groups, "preferred" (33%), "neutral" (33%), "non-preferred" (33%) groups and ERP analyses were conducted based on this preference categorization. The LPC time range was 600-1,000 ms after the onset of a stimulus and the ERP waveforms were acquired from the parietocentral site (Pz). There were significant different patterns of LPC among three preference groups in both tasks. Non-preferred images elicited the lowest positivity. The LPC amplitude gradually increased with the level of preference. In the passive task, participants' gender differences was observed. Female participants showed the greatest mean LPC amplitude toward preferred images than the other images, whereas male participants showed the lowest mean LPC amplitude toward non-preferred image and no difference between preferred and neutral images. In the active choice task, both genders of participants showed the greatest LPC amplitude to preferred images than the other images, suggesting that the preference related a neural component could possibly be modulated by the participants' gender and task context. Also, both genders of participants had a tendency to show greater LPC amplitudes toward preferred "female" faces than preferred male faces, suggesting that people react somewhat more sensitively and are more likely to be tuned toward attractive female faces.

Title: Effects of inconsistency between facial and verbal expressions on degree of trust and brain activity

Authors: *S. MORIOKA[1], M. OSUMI[1], M. OKAMOTO[2], M. HIYAMIZU[1], H. MAEOKA[1], Y. OKADA[1], A. MATSUO[1];
[1]NeuroRehabilitation, Kio Univ., Kitakatsuragi-gun/Nara, Japan; [2]Rehabil., Kitade Hosp., Gobo, Japan

Abstract: [Objective] Social communication is performed smoothly using both verbal and non-verbal language. The present study aims to determine the degree of trust and brain activity when verbal and facial expressions are inconsistent. [Methods] The subjects were 14 healthy volunteers (age: 21.7±0.8). The task used photographs of 8 people with pleasant expressions (smile) or unpleasant expressions (frown). For verbal expression, the 2 most positive and 2 most negative expressions were chosen from 50 sentences in a preliminary experiment; rescuing a child from a fire and keeping a promise with a friend were considered positive, whereas running over and killing a friend and bullying a friend were considered negative. A verbal [positive/negative] and a facial [smile/frown] expression were combined in each trial. Four types of representative images were randomly shown 80 times on a PC screen. Verbal expressions were initially presented alone for 5 s, followed by verbal expressions and photographs concurrently for 2 s. A donation was established as an index for the degree of trust: subjects were asked how much they would offer (amount of offer) when told the person in the photograph was troubled financially. Positive emotions and degree of trust were evaluated using the visual analogue scale (VAS). Using electroencephalography (EEG), event-related potentials (ERPs) were obtained by averaging the wave patterns appearing 170~240 ms after viewing the photograph. From these ERPs, the area of brain activity during inconsistency conditions was identified using standardized low-resolution brain electromagnetic tomography (sLORETA). One-way analysis of variance, multiple comparison tests, and Pearson's correlation were used for statistical analysis (significance level 5%). [Results] The VAS scores for positive emotions and degree of trust for [positive × smile] were significantly higher than those for the other conditions($p < 0.05$). Positive correlations were seen between all positive emotions and degree of trust ($r = 0.54$~0.84, $p < 0.05$). The amount of offer was significantly lower for inconsistencies between verbal and facial expressions, particularly for [negative × smile]. EEG showed more activity in the parietal lobe (BA7) with [inconsistency] than with [consistency]. [Conclusion] A negative verbal expression with a positive facial expression [negative × smile] elicited the least positive emotion, degree of trust, and amount of offer. Also our result indicated that parietal lobe

was activated in inconsistency of sensory information in social communication. It was suggested that this activity was a base of mentalizing.

Title: The emotional response to social gaze is a domain specific cognitive mechanism

Authors: *N. LAPOLLA[1], B. BISHOP[1], J. CIBOTTI[1], S. STEDNITZ[1], E. GAHTAN*[2]; [2]Psychology, [1]Humboldt State Univ., Arcata, CA

Abstract: Eye contact with another person (social gaze) reliably produces an emotional response, accompanied by amygdala and autonomic nervous system activation, which is measurable using the skin conductance response method (SCR). While social gaze is known to produce an SCR, we investigated whether 'self-gaze' (gazing at one's own eyes in a mirror) also elicits an SCR. In cognitive psychology, domain specific cognitive mechanisms have narrow responses properties and domain general mechanisms have broad response properties, and this difference has implications for understanding how diverse cognitive functions evolved. We reasoned that if SCRs were different on social gaze trials relative to self-gaze trials that would support a domain specific model of the social gaze response mechanism. We compared SCRs between episodes of social gaze and self-gaze in 40 Humboldt State University student pairs. Each participant engaged in ten, 20 second eye contact trials, alternating between social gaze and self-gaze. Stimuli were presented using an automated panel on which a mirror (for self-gaze trials), open window (for social gaze trials), or opaque panel (for inter trial intervals) could be displayed. SCR data was collected using an ADInstruments amplifier and stainless steel finger electrodes. Self-gaze was found to elicit SCRs, however social gaze produced significantly larger responses compared to self-gaze, ($p<.001$). SCRs decreased across trials ($p=.021$), suggesting habituation. Eye contact between opposite sex partners was predicted to yield larger SCRs, but this effect was not found. These results suggest that the social gaze response mechanism is domain specific and evolved for social communication outside of the mating domain.

Title: Sensory evidence is predictive of certainty in perceptual decisions

Authors: ***G. A. BUZZELL**[1], D. M. ROBERTS[1], J. R. FEDOTA[2], E. P. SHAW[1], C. G. MCDONALD[1];
[1]George Mason Univ., Fairfax, VA; [2]NIH/NIDA, Baltimore, MD

Abstract: Human perceptual decision-making is a complex process involving attention, the accumulation of sensory evidence, the comparison of this evidence, and ultimately the arrival at a decision outcome. In addition, stochastic variations in this process invariably lead to variations in both the accuracy of discriminations, as well as the subjective experience of certainty associated with a given response. A longstanding body of research within primate models has elucidated a general process by which decision-making is achieved, and recent neuroimaging work has begun to extend this work to humans. Nonetheless it remains unclear exactly how and when uncertainty arises in the decision-making process. In the present study, we recorded EEG while participants performed a difficult perceptual decision-making task and rated their subjective certainty of stimulus identity following each trial. In this way, we were able to investigate the neural changes that give rise to uncertainty when participants respond correctly, but are uncertain of their response. Critically, sensory evidence was assessed by comparing the occipital-temporal N1 component for correct, sure trials to those in which participants were correct, but unsure. In addition, pre-stimulus attentional state was assessed by measuring oscillations in the alpha band of the EEG, and confidence in the outcome of the decision was assessed using the P3 component, in addition to behavioral measures. Our data suggest that in a difficult perceptual decision-making task uncertainty arises from a cascade of events, beginning with reduced attention prior to stimulus onset (indexed by increased pre-stimulus alpha), which leads to impoverished sensory evidence (indexed by a reduced N1 component). These events were predictive of a reduction in the P3 component and slower response times. Our findings

demonstrate that when perceptual decisions are difficult uncertainty detected later in the processing stream can be attributed to lapses in proactive executive control that lead to impoverished sensory representations.

Title: Transcranial direct current stimulation over ventro-medial prefrontal cortex changes human value-based decision making: A computational neurostimulation study

Authors: ***D. HAEMMERER**[1,2], M. KLEIN-FLÜGGE[3,4], J. BONAIUTO[4], M. BIKSON[5], S. BESTMANN[4];
[1]Inst. of Cognitive Neurosci., London, United Kingdom; [2]Lifespan Psychology, MPI for Human Develop., Berlin, Germany; [3]Wellcome Trust Ctr. for Neuroimaging, [4]Inst. of Neurol., Univ. Col. London, London, United Kingdom; [5]Biomed. Engin., The City Univ. of New York, New York, NY

Abstract: When deciding between options with different expected outcomes, the ventromedial prefrontal cortex (vmPFC) tracks the value of the expected net gain from this decision. Mechanistically, value tracking is conceived as a competition between neural populations coding for the value of individual options via mutual inhibition. However, this assumption is largely based on correlational evidence. Here we asked how causally influencing neurotransmission in vmPFC through non-invasive brain stimulation (NIBS) impacts decision making. We used a novel computational neurostimulation approach to generate behavioural predictions for transcranial direct current stimulation (tDCS) of vmPFC. Neural activity during decision making was modelled in a well-established and biophysically realistic model of recurrently connected spiking neurons that predicted choices by competition via mutual inhibition. We then fit the

choice predictions of the biophysical model with a simplified reinforcement learning (RL) model. Simulated anodal stimulation in this model reduced the inverse temperature parameter (a measure for the impact of value expectations on choices) but had no effect on learning rate. To test these model predictions, we used tDCS with the anode over medial or lateral PFC during value-based decision making. Current modelling confirmed induced current peaks at target site. The same RL model was used to fit subject's behavioural data. In line with model predictions, stimulation over vmPFC reduced the inverse temperature parameter but not learning rates. Stimulation over lateral PFC had no such effect. We demonstrate that a causal manipulation of the vmPFC activity pattern impairs value choice processes but not learning. Importantly, modelling suggests that this is caused by depolarization of response-specific neural populations and a hyperpolarization of their mutual inhibition via interneurons. Behaviorally, this resulted in a shift from selecting the option that has the highest expected value to selecting options more randomly. This novel computational neurostimulation approach outlines how mechanistic predictions about the consequences of NIBS in value-based decision making can be obtained, with relevance for applications that seek to augment cognitive function through NIBS.

Title: Predicting the behavioral impact of tDCS on perceptual decision making with computational neurostimulation

Authors: ***J. J. BONAIUTO**, A. DE BERKER, S. BESTMANN;
Sobell Dept of Motor Neurosci. and Movement Disorders, Univ. Col. London, London, United Kingdom

Abstract: Transcranial direct current stimulation (tDCS) allows for non-invasive and reversible modulation of neural activity in widespread cortical and subcortical networks. These network changes can generate both beneficial and detrimental changes in behavior, depending on the

specific placement of electrodes on the scalp and stimulation parameters. However, there are currently no mechanistic frameworks capable of predicting or explaining these behavioral changes. Here we introduce a computational neurostimulation approach in which we use a theoretically established computational network model that generates realistic behavior in the random dot kinetogram (RDK) task, a classic perceptual decision making test. We then perturb various parameters in this biophysically realistic model of recurrently connected populations of spiking neurons to generate principled predictions about the behavioral impact of tDCS. Specifically, we simulated the effects of tDCS on the model by altering the resting membrane potential of its neurons based on values suggested by an *in vitro* study of the effects of transcranial stimulation on sensory evoked potentials (Molaee-Ardekani, 2013). These simulations predict that anodal stimulation decreases and cathodal stimulation increases reaction times (by -20.2% and 60.6% respectively), but importantly that both forms of stimulation reduce the accuracy of performance by 12.3- 25.9% on difficult trials. We then tested the behavioral predictions of the model in healthy human subjects performing the task. tDCS was applied over dorsolateral prefrontal cortex (dlPFC), thought to integrate sensory evidence for decision making independent of response modality (Heekeren, 2006). Finite element modeling of current flow was used to guide electrode placement such that induced currents peaked in left dlPFC. The size of the model effects scales with the intensity of the simulated stimulation, however ongoing analyses show the qualitative changes in response time and performance predicted by our model match those observed in human subjects: anodal stimulation over dlPFC improves reaction time on the RDK task but at the cost of decreased performance, with ongoing testing for cathodal stimulation. Our model suggests that this is due to an increase in pyramidal cell firing coupled with a decrease in inhibitory interneuron firing, which results in task options being less differentiable but causing the network to reach the response threshold faster. More generally, our novel computational neurostimulation approach demonstrates how one can obtain mechanistic predictions about the consequences of tDCS at the appropriate level of description.

Title: Characterizing functional brain networks associated with speed vs. accuracy emphasis in simple decision-making

Authors: *A. S. WEIGARD[1], S. WILSON[2], C. HUANG-POLLOCK[2];
[2]Psychology, [1]The Pennsylvania State Univ., University Park, PA

Abstract: When engaging in simple cognitive tasks, individuals can choose to emphasize either response speed or accuracy depending on individual characteristics, instructions on performance strategies, and/or the specific demands of the task. This function been explained in the context of formal models of decision-making as changes in response threshold, or the amount of evidence an individual deems appropriate to make a decision (Brown & Heathcote, 2008). Recent research on the neural basis of this function has supported the "striatal hypothesis", which contends that response thresholds are modulated when cortical regions involved in motor control (e.g., the pre-SMA) increase activity in the striatum to disinhibit the motor system under speed emphasis (Bogacz et al, 2010, Forstmann, et al, 2010; 2008). However, the role that other top-down control regions (DLPFC, ACC) play in this process, and whether the same connections between the striatum and pre-SMA are essential for cautious responding that emphasizes accuracy, as well, is not currently known. The current study aims to use unified structural equation modeling (uSEM) approach for directed functional connectivity analysis, which can indicate both contemporaneous and time-lagged connections between regions (Gates & Molenaar, 2012), to further clarify this. It is predicted that, when speed is emphasized, the DLPFC and ACC will display functional connections with the pre-SMA, which will, in turn, be related to increases in striatal activity. In contrast, when accuracy is emphasized, DLPFC activity will be negatively associated with baseline striatal activity. In an ongoing study, young adult participants (target N = 20) are asked to complete a simple perceptual decision-making task while fMRI data were collected, in which they must decide whether a briefly presented letter is a vowel ("A", "U", "E") or a consonant ("P", "H", "F") under speed or accuracy instructions. Behavioral analyses on data already collected (N=6) indicate that, as expected, individuals were significantly faster during the speed emphasis condition, $t(5)=3.595$, $p=.02$, and displayed a non-significant trend toward being less accurate in this condition, $t(5)=1.190$, $p=.29$. Neuroimaging analyses will be presented, which will utilize peak coordinates from prior studies to select ROIs for the DLPFC, pre-SMA, ACC and striatum. Functional connectivity between these ROIs will be estimated using the GIMME model (Gates & Molenaar, 2012), a technique that can identify group-level connectivity maps using uSEM while incorporating individual variation into these estimates.

Title: Cortical representations of confidence in a visual perceptual decision

Authors: *L. ZIZLSPERGER[1], T. SAUVIGNY[2], B. HÄNDEL[3], T. HAARMEIER[1]; [1]Dept. of Neurol., RWTH Aachen Univ., Aachen, Germany; [2]Dept. of Neurosurg., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [3]Ernst Strüngmann Inst. (ESI) for Neurosci. in Cooperation with Max Planck Society, Frankfurt, Germany

Abstract: Neuronal recordings in behaving monkeys and rats have detected representations of decision formation and the degree of certainty in it. Surprisingly, to date there is little electrophysiological evidence on human choice certainty. To dissociate electrophysiological representations of objective performance and subjective confidence, in a first experiment we asked one group of subjects to indicate the perceived direction of moving random dots and the confidence in that perceptual decision while stimuli were cued validly and invalidly. In the second experiment we did not cue selective attention but the motor effector to identify electrophysiological correlates of decision confidence in motor preparation. Motion stimuli, i.e. moving random dot patterns of varied coherence levels, were presented and subjects indicated global motion direction in a 4-alternative forced-choice design and the confidence in their decision via 4 numerical certainty ratings using a 4-button controller. We demonstrate electrophysiological correlates of choice certainty that evolve as early as 300 ms after stimulus onset and resemble the primary visual motion representations in early visual cortex. These correlates do not emerge unless or until the subject unambiguously knows which of the competing visual stimuli is actually relevant to behavior. They extend beyond stimulus presentation up to the motor response but are independent of the motor effector. Our findings suggest that perceptual confidence evolves in parallel with representations of stimulus properties and is dedicated to one specific aspect of the visual world. Its electroencephalographic correlates can be disentangled from representations of sensory evidence, objective discrimination performance, and overt motor behavior.

Title: The salience network in multisensory perception

Authors: *B. LAMICHHANE[1], M. DHAMALA[1,2];
[1]Physics and Astronomy, [2]Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Recent evidence suggests that the anterior insula (AIN) and the dorsal anterior cingulate cortex (dACC) are a part of "salience network (SN)". dACC is known to play a role in detecting interference between competing responses and in selecting appropriate behavioral responses. AIN is known to be involved in accumulating sensory evidence in perceptual decision independent of the motor response. How these nodes in SN contribute to the decision process from segregation of stimuli to the generation of appropriate behavioral response remains to be understood. Here, we performed functional magnetic resonance imaging (fMRI) experiments and fMRI data analysis using the dynamical causal modeling (DCM) to investigate the functional relationship between the activity of SN and the audiovisual-asynchrony perception. Thirty-three subjects were scanned in fMRI and asked whether the presented pairs of a brief tone and a flash were synchronous or asynchronous. Response time was observed in asynchrony percepts were longer compared to the time in synchrony percepts. Synchrony and asynchrony percepts both resulted strong activation in the SN. Brain activation of asynchrony percept was found significantly higher compared to synchrony percept in SN. The DCM analyses determined that the input into SN is most likely via the right insula (RI) and found to be intrinsically connected with the other nodes of SN. The dACC received causal inputs from both the left and right insula. These results suggest that INSs might provide perceptual evidence and trigger dACC for detecting interference between competing responses to generate an appropriate response.

Title: Cortical network oscillations during perceptual decision-making of visual objects

Authors: *G. CHAND[1], B. LAMICHHANE[1], M. DHAMALA[1,2];
[1]Physics and Astronomy, [2]Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Previous neuroimaging studies have shown that perceptual decisions of human-faces and houses involve distributed brain networks that include the ventral temporal cortex and prefrontal cortex. The field still lacks a systematic investigation of how perceptual decisions are formed and related to the large-scale brain networks and network activity. We monitored brain activity with millisecond time resolution by recording electroencephalographic (EEG) responses while participants decided whether the presented picture was human-face or house. We found that the peak activity appeared in the areas of ventral temporal cortex and in the prefrontal cortex at latencies ~130-180 ms and ~190-220 ms respectively. We found that the beta and gamma-band oscillatory networks and their network activity were at work to carry out perceptual decisions. These findings suggest that beta and gamma band oscillatory networks coordinate activity between cortical regions mediating sensory and cognitive processing to arrive at perceptual decisions of visual objects.

Title: Prior expectations modulate hemodynamic activity before and during perceptual decisions: Evidence from diffusion modeling and fMRI

Authors: *M. E. WHEELER[1], K. E. DUNOVAN[2], J. J. TREMEL[2];
[1]Psychology, Georgia Inst. of Technol., Atlanta, GA; [2]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: As we gather noisy sensory information from the environment, prior knowledge about can be leveraged to facilitate recognition. However, when violated by observed evidence, strong prior beliefs can lead to errors in perceptual judgment and delay the recognition of unexpected stimuli. In the present study we probed the underlying dynamics of perceptual expectation biases using a combination of diffusion modeling and functional magnetic resonance imaging (fMRI). Human subjects performed a noisy face/house discrimination task in which each stimulus was preceded by either a predictive or neutral cue indicating the likelihood of the upcoming stimulus being a face or house. Predictive cues were valid on 80% of trials, and "catch trials" were included to separate cue-related and decision-related activity in "pre-stimulus" and "post-stimulus" epochs, respectively. Each subject performed the task while whole-brain activity was recorded using fMRI. As expected, face/house decisions were faster and more accurate when cued expectations matched the stimulus category. Behavioral data were modeled as a bounded drift-diffusion process in which cued expectations biased the prior starting-point (i.e., pre-stimulus baseline) and the drift-rate of evidence accumulation (i.e., post-stimulus sensory gain). Critically, this approach allowed us to quantify subject-specific biases and observe their effects on fMRI activity during isolated components of the decision process (i.e. pre- and post-stimulus epochs). Imaging results showed a clear mapping between diffusion model bias estimates and activity in category selective regions of inferotemporal cortex as well as domain-general regions within the frontoparietal decision-making network during pre- and post-stimulus epochs. Furthermore, effects of prior expectation were more apparent for face than house stimuli. These findings highlight a specificity in the effectiveness of perceptual expectations, and provide new insights into how top-down and bottom-up sources of information converge over the course of a decision.

Title: Neural correlates of evidence accumulation in perceptual and memory-based decision making

Authors: *M. A. BEULEN, N. A. TAATGEN, M. K. VAN VUGT;
Artificial Intelligence, Univ. of Groningen, Groningen, Netherlands

Abstract: Decision making is well described by evidence accumulation models. This class of mathematical models states that decisions are made by accumulating evidence for each available option until a threshold is reached, at which point the corresponding response is executed. We have previously found that oscillatory activity in the theta band (4-9Hz) in occipitoparietal brain areas shows a ramping pattern of activity during decision periods, consistent with such accumulation models. Most studies so far have focused on perceptual decision making tasks, ignoring the role of additional cognitive processes like memory retrieval in many real-world decisions. However, in a recent intracranial EEG study, we have shown that a similar evidence accumulation process takes place during recognition memory decisions, and that in addition to the previously observed posterior theta oscillations, gamma activity (48-90Hz) in dorsolateral prefrontal cortex also shows dynamics consistent with evidence accumulation. It is unclear, however, whether this result generalizes to scalp EEG, and whether the crucial difference with earlier work is indeed the memory demands of the task. We therefore created a perceptual discrimination task and a recognition memory task that are matched on stimulus material and task difficulty. Using both scalp EEG and intracranial EEG, we investigated the neural correlates of the evidence accumulation process in these matched tasks. This allows us to see whether and how the addition of memory retrieval to the decision process impacts the brain regions accumulating evidence for the decision, and the pattern of accumulation itself. We replicated our earlier finding of a ramping activity pattern in low-frequency oscillations during decision periods. The sets of channels exhibiting this ramping activity was similar between the perception and memory conditions. In contrast to our previous EEG experiments, we also saw ramping activity in 14-28Hz beta oscillations, and this was carried by posterior channels for the perception task and more central channels for the memory task.

Title: Online behavioral readouts in an auditory perceptual decision making task

Authors: R. MEDINA, J. L. PARDO-VAZQUEZ, *A. RENART;
Champalimaud Neurosci. Programme, Champalimaud Ctr. for the Unknown, Lisbon, Portugal

Abstract: The behavioral evidence typically used to infer the mechanisms underlying decision processes consists of reaction time (RT) and choice, which reflect only the output of the decision process, and is therefore only indirectly informative on the decision process itself. In order to gain more direct access to the decision process from behavior, we have set-up an auditory 2AFC perceptual decision-making with two online behavioral read-outs: motor output and pupil size. In the task, human subjects have to decide whether the overall lateralization of a time-varying white-noise stimulus is left or right. Lateralization is controlled using the inter-aural level difference (ILD) of the stimulus delivered through headphones. The instantaneous ILD is chosen with a given probability every 15-25 ms from a set of ILD values, and the overall difficulty is controlled by rigidly moving this probability function. Depending on the shape of this probability we can alter the temporal correlations in the ILD stream. Subjects report their choices by moving a joystick-controlled dot in a computer screen to either of two lateral locations and are free to move the joystick throughout the stimulus presentation. Pupil size is monitored through the experiment. Stable psychometric functions confirm that the subjects can reliably perform this task. Mean RTs are in the range of 1-2 s, and increase with difficulty. Interestingly, behavioral reverse correlation shows that the subject's strategy seems to change with the stimulus correlation time, with choices relying on evidence accumulation vs. detection of sustained ILD transients for temporally uncorrelated vs. correlated stimuli respectively. Joystick trajectories can be classified into stereotyped (ST) and non-stereotyped (NST). ST trajectories are the majority (75-85%) and consist of a ballistic movement to either of the choice targets. In NST trials displayed large amplitude movements before choice. The proportion of NST trials increases with both difficulty and with the temporal correlations in the stimulus. We have so far been unable to find statistically significant trial-by-trial correlations between the stimulus sequence and the joystick trajectory in NST trials, but the speed of the choice response becomes slower in ST trials as stimulus difficulty increases, consistent with previous work (Selen et al., J. Neurosci., 2012). Preliminary analysis of pupil dynamics shows pupil size increases towards the moment of choice, at a rate which depends on stimulus difficulty. We are currently exploring modifications in the task that will increase the number of NST trials and facilitate their interpretation.

Title: New predictions and experimental tests of scale invariance in a diffusion decision/timing model

Authors: *P. A. SIMEN, K. Y. VLASOV, S. PAPADAKIS;
Neurosci., Oberlin Col., Oberlin, OH

Abstract: Weber's law is the canonical scale invariance law in psychology: when the intensities of two stimuli are scaled by any value k, the just-noticeable-difference between them also scales by k. A diffusion model approximating a Poisson spike counting process accounts for Weber's law (Link, 1992), but there exist surprising corollaries of this account that have not been previously described or tested. We show that: 1) the Poisson counting model predicts time scale invariant decision time distributions in perceptual decision making, and time scale invariant response time distributions in interval timing; 2) for two-choice perceptual decisions, the model predicts equal accuracy but faster responding for stimulus pairs with equally scaled-up intensities; 3) the coefficient of variation (CV) of decision times should remain constant across average intensity scales, but should otherwise decrease as a specific function of stimulus discriminability and speed-accuracy tradeoff; 4) for timing tasks, response time CVs should be constant for all durations, and the skewness of response time distributions should always equal 3 times the CV. We tested these predictions using visual, auditory and vibrotactile decision tasks and visual interval timing tasks in humans. The data conformed closely to the predictions in all cases. These results support a unified theory of decision making and timing in terms of a common, underlying Poisson spike counting process, compactly represented as a diffusion process.

Title: Probing a model of self-consistent perceptual decision making

Authors: *A. STOCKER;
Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Human perception is context-dependent. The interpretation of sensory information is shaped and biased by the context within which the information is presented to the observer. We have previously conjectured that context can also include preceding decisions of the observer when performing a task sequence involving the same sensory evidence (Stocker and Simoncelli 2008). This hypothesis can be formulated as a probabilistic observer model that performs optimal inference about a stimulus parameter based on sensory uncertainty and prior beliefs, yet is conditioned on the observer's preceding decision. We refer to this as a "self-consistent" observer model. We tested the model using the following psychophysical experiment: After being presented with two orientation stimuli, subjects were asked to judge whether the orientation of the second stimulus was clockwise or counter-clockwise relative to the first one. After the response, a third stimulus was presented, and the subjects were then asked to judge the orientation of the third stimulus relative to the second one. The "self-consistent" model predicts that a subject's first decision reshapes their probabilistic representation of the second stimulus' orientation such that the probability for any orientation that is inconsistent with the first decision is set to zero. Thus, a subject would be more likely to respond "counter clockwise" in the second task after having responded "clockwise" in the first task, and vice versa. This leads to characteristics distortions and shifts of the psychometric functions. In contrast, an "optimal" model assumes that both decisions are performed independently, and thus does not predict any change in subjects' psychometric functions. By measuring subjects' individual sensory uncertainties in a separate discrimination experiment, we were able to make quantitatively predictions for their behavior in the sequential decision task for each of the two models. We found that the data is very well predicted by our "self-consistent" model, including a characteristic distortion and shift of the psychometric curve while the optimal model provided rather poor predictions. We conclude that perception follows a self-consistency principle that guarantees a robust and stable interpretation of the world.

Title: A common frontoparietal network underlying categorization and perceptual decision-making

Authors: *S. SHANKAR[1], A. S. KAYSER[2];
[1]Ernest Gallo Clin. & Res. Ctr., Emeryville, CA; [2]Neurol., Univ. of California, San Francisco, San Francisco, CA

Abstract: Perceptual decision-making in the laboratory setting typically involves choosing between two or more discrete stimuli. Choice behavior in perceptual decision-making depends to a great extent on stimulus strength (perceptual uncertainty), and activity in the frontoparietal decision network reflects this sensitivity. In comparison, categorization involves a more abstract choice between two or more discrete categories of stimuli in accordance with some rule. Categorization too can be difficult when stimuli are noisy, but it is also affected by proximity of the stimulus to category boundary (categorical uncertainty). In addition, these two kinds of uncertainty can interact to decrease the efficacy of categorization. Previous categorization studies in macaques have revealed category related activity in posterior parietal cortex and lateral prefrontal cortex. Human studies have also implicated prefrontal cortex participation in coding uncertainty. These studies have, however, primarily modulated ambiguity in only one of the domains. To characterize uncertainty effects more completely and to assess the role of the frontoparietal decision network in categorization, we trained subjects to categorize dot motion as left or right of a pre-defined boundary, an oblique line inclined at either 45° or 135° from the horizontal. Perceptual ambiguity was introduced by changing the percentage of dots moving coherently while categorical ambiguity was manipulated by setting motion direction to different distances from the category boundary. The two types of ambiguity were independently modulated on each trial and their levels (4 perceptual, 5 categorical) were determined to provide a consistent set of accuracy levels across subjects, from 50% (chance) to 100%. Subject accuracy and response times varied as a function of not only perceptual and categorical uncertainty but also their interaction; within a given uncertainty level in either domain, performance declined as ambiguity increased in the other domain. Whole brain BOLD data revealed that a frontoparietal network active during categorization was similar to the one recruited in perceptual decision-making. This network showed parametric modulation to dot-motion coherence as well as distance from category boundary. Additionally, it appears to encode an interaction of uncertainties; as a function of distance from category boundary, the parametric effect of coherence seems to change qualitatively in amplitude and/or sign. Further analyses using regions

of interest and timecourses therein will help ascertain the robustness of these results and better characterize the categorization network.

Title: Neurophysiological correlates of the incorporation of prior information into decisions under perceptual versus temporal demands

Authors: ***S. KELLY**[1], R. G. O'CONNELL[2];
[1]Neurosci., City Col. of New York, NEW YORK, NY; [2]Psychology, Trinity Col. Dublin, Dublin, Ireland

Abstract: Given prior information that one of two alternatives is more likely, observers will respond faster and exhibit a choice bias for perception of the more likely event. In most mathematical models of decision making based on sequential sampling, priors are incorporated by shifting the starting point of a decision variable (DV) closer to the more likely of two opposing boundaries. Little neurophysiological work has been done to directly test this. Here we test the idea that prior information is incorporated in different ways depending on the conditions under which the observer is compelled to utilize it. We exploited a recent finding that supramodal decision formation can be traced in a centro-parietal positivity (CPP) on the human scalp (O'Connell et al 2012). Observers discriminated the motion direction of random dots in discrete trials, with trial-randomized color changes preceding evidence onset indicating whether leftward or rightward were more likely (75% validity) or neither (50%, neutral). This task was performed under three blocked conditions: Easy blocks allowed 1600 ms to discriminate motion at 20% coherence; Low-coh blocks had the same deadline but reduced coherence (7-11% individually titrated); and Deadline blocks had 20% coherence but a strict individually set deadline of 400-500 ms. The nine observers run so far show strong effects of informative pre-cueing on reaction time (RT) and choice bias in both the Low-coh and Deadline conditions. The Easy condition showed weak if any such behavioral effects, and event-related potentials (ERP)

locked to evidence onset were similarly unmodulated. In the Deadline condition, the CPP decision signal reached a higher amplitude at the time of a correct decision report for invalidly cued motion compared to neutral, and reached a lower amplitude for valid trials, consistent with shifting decision bounds. In contrast, in the perceptually demanding Low-coh condition, prior information modulated build-up dynamics in a distinct way that is consistent with selective attentional enhancement of early motion detectors to facilitate perception. ERPs to cue onset showed no trace of a shift in CPP starting point prior to evidence onset according to prior information, but did show interesting differences in anticipatory frontal and occipital signals across blocked conditions: a frontocentral negativity was significantly stronger when a strict Deadline was imposed, whereas anticipatory negative potential over visual cortex was stronger for the Low-coh condition. This work stands to illuminate context-specific modulations and parameter adjustments that enable advantageous information integration.

Engin., City Col. of the City Univ. of New York., New York, NY; [4]Trinity Col. Inst. of Neurosci. and Sch. of Psychology, Trinity Col. Dublin, Dublin, Ireland

Abstract: The P300 component of the human event-related potential has been the subject of intensive experimental investigation across a five-decade period, drawing enduring interest for

its apparent role in a range of cognitive operations and its sensitivity to brain disorders. Yet, its exact contribution to cognition remains unresolved in the absence of conclusive empirical data linking the P300 to a specific neural mechanism. Here, a new analysis of ERPs elicited by auditory and visual targets, combined with computational simulations, reveals that, rather than being the culmination of a unitary neural event, the P300 is a dynamically evolving process that triggers action upon reaching a stereotyped level and whose rate-of-rise determines reaction time at the single-trial level. Thus, the P300 exhibits the critical properties of the theoretical 'decision variable' signals predicted by sequential sampling models and directly observed in monkey neurophysiology. In identifying the P300 as a decision variable signal we place it at the heart of a well-established, explanatory framework that should facilitate more mechanistically principled investigations of sensorimotor transformations in both the typical and atypical human brain.

Title: Perceptual task difficulty and inhibitory control during a Go-NoGo task: An event-related potential study

Authors: D. W. SHUCARD[1], R. CHIN[2], T. J. COVEY[1], *J. L. SHUCARD[1];
[1]Neurol., [2]Psychol., Univ. At Buffalo, BUFFALO, NY

Abstract: Cognitive control mechanisms such as conflict monitoring and inhibitory control are dynamic neural processes that can be influenced by variations in task difficulty. The N2 and P3 components of the event-related brain potential (ERP) are thought to be influenced by these neural processes. One hypothesis is that N2 is an index of conflict monitoring (e.g., the monitoring of competing response options), while the P3 reflects inhibitory processes (e.g., the inhibition of specific response options). Several studies have manipulated task difficulty, most often using speed of response, to examine the independent contributions of the N2 and P3 components during response inhibition tasks. The findings regarding the roles of N2 and P3 have been mixed. The present study, unlike previous studies, used perceptually ambiguous stimuli to evaluate the underlying functional significance of N2 and P3 ERP components in relationship to

conflict monitoring and response inhibition. Eleven healthy adults completed two visual Go/NoGo continuous performance tasks (A-X CPT), the first with regular letters (unambiguous, easy task) and the second with degraded letters (ambiguous, difficult task). ERPs to regular and degraded Go and NoGo stimuli were obtained using a dense-electrode array recording system. Behavioral measures of reaction time (RT) and accuracy were also recorded during both tasks. During the Go condition, RT was slower for degraded compared to the regular stimuli. Both N2 and P3 latencies were longer for the degraded compared to the regular stimuli. The P3 component showed the classic frontocentral maximum amplitude for NoGo trials and a parietal maximum amplitude for Go trials. These P3 findings were present regardless of whether the stimuli were regular or degraded. Thus, the amplitude of the P3 was influenced by the need to carry out or inhibit a response, but not by the perceptual integrity of the stimulus. When greater conflict was introduced by increased perceptual ambiguity of the stimuli, a more prominent frontal-N2 response was elicited compared to the regular stimuli. This greater N2 negativity to degraded compared to regular stimuli was present for both the Go and NoGo conditions. Thus, the N2 negativity was influenced by the conflict created during the evaluation of perceptually ambiguous stimuli and not by the response properties of the stimuli (i.e., the necessity to carry out or inhibit a response; Go or NoGo, respectively). These findings support the notion that P3 amplitude is an index of inhibitory control and that N2 reflects conflict monitoring. This ERP approach may be useful in understanding inhibitory mechanisms in clinical and at-risk populations.

Title: Relating a spiking neural network model and the diffusion model of decision making to investigate neural mechanisms of speed-accuracy tradeoffs

Authors: *A. UMAKANTHA[1], B. A. PURCELL[2], T. J. PALMERI[1];
[1]Vanderbilt Univ., Nashville, TN; [2]New York Univ., New York City, NY

Abstract: Speed-accuracy tradeoffs (SAT) involve strategic adjustments of decision-making processes to optimize desired outcomes. The drift-diffusion model [1] explains decision making as the integration of perceptual evidence over time for alternative choices until a response boundary is reached. According to this model, SAT is commonly implemented through adjustments of a single parameter, the response boundary. The neural circuits underlying decision-making are likely more complex than the elements assumed by this abstract model, and recent neurophysiology suggests that SAT may involve multiple changes to the networks that underlie decision making [2]. Indeed, any single diffusion model parameter could potentially be implemented by many neural mechanisms. To explore the potential neural mechanisms of SAT and related decision-making processes, we simulated perceptual decisions using a biophysically-plausible spiking neural network model [3], and then fit the diffusion model to the simulated data just like we would fit the model to human or animal data. If variation in diffusion model parameters are necessary to explain behavior, then what can we conclude about variation in the underlying neural processes based on diffusion model fits? We systematically examined how variation of a number of spiking neural network parameters cause variation in the best-fitting parameters of the diffusion model. As expected, variation in the baseline firing rate and the response boundary of the spiking neural network were captured by variation in the diffusion model response boundary, implementing SAT as traditionally assumed. More surprisingly, we found that variation in the strength of recurrent excitation as well as variation in NMDA, AMPA, and GABA conductances were also captured by variation in in the diffusion model boundary. This demonstrates how a single psychological phenomena, SAT, captured by a single diffusion model parameter, response boundary, can be implemented by multiple - and sometimes unanticipated - neural processes. This also demonstrates how parameters and mechanisms of complex spiking neural network models can be non-uniquely identifiable based on their predictions of behavior as many different low-level neural changes can all produce the same behavioral change. Title: Learning expectations about changing environments for optimal inference

Authors: *C. M. GLAZE, J. I. GOLD;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Many decisions depend on the accumulation of noisy evidence that arrives sequentially over time. The dynamics of this process can include perfect, leaky, and/or bounded evidence accumulation to identify stable signals and differentiation to detect abrupt signal changes. We recently developed a normative model that naturally encompasses all of these different dynamics. The model is derived from the Bayes-optimal solution to evidence accumulation in environments subject to unpredictable changes that occur at a constant hazard rate. A key feature of the model is that the expected hazard rate governs decision dynamics. When perfect stability is expected, evidence is accumulated perfectly. Otherwise, however, evidence is accumulated with a leak and a bound that both depend on subjective hazard rate. We have previously shown that, for two separate tasks, human subjects can adapt to different objective hazard rates and use decision dynamics prescribed by the model. However, little is known how these dynamics are learned. To address this issue, we used a task in which subjects made trial-by-trial choices about which of two spatially separated triangles on a computer screen was the source of noisy samples of data. The correct source changed at a hazard rate (0.05-0.95) that was constant within a block of trials but varied across blocks. Model fits suggest that subjects were able to effectively adapt to different generative hazard rates when given trial-by-trial feedback on the correct answer, but with a bias towards a prior hazard rate. In sessions without any feedback, subjects showed less learning and more bias towards their prior hazard rate. For sessions in which the presence of feedback was alternated across blocks of trials, hazard rates learned in the presence of feedback were maintained over hundreds of non-feedback trials but slowly drifted back in the direction of the prior. Overall, the data suggest that humans have subjective prior expectations about rates of change that can be adapted to the environment when given appropriate feedback.

Title: Self-consistent inference explains bias in sequential perception

Authors: *L. LUU, A. A. STOCKER;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: The perceived motion direction of a random-dot kinematogram is systematically biased when probed in the context of a fine discrimination task (Jazayeri and Movshon, 2007). This bias was thought to represent the combined result of a noisy sensory representation and a neural decoding strategy that uses a weighting profile optimized for the discrimination task. The task-dependent nature of the decoding strategy predicts that no perceptual bias would occur if the discrimination task was omitted or modified such that the optimal strategy does not induce any preferential weighting. We conducted two psychophysical experiments to test this hypothesis. Experiment 1 was aimed to replicate the results of the original study for a different visual stimulus. A white ellipse (length of long axis: 5 degs) was presented at the center of the screen along with black reference marks indicating a reference orientation. Subjects were instructed to indicate whether the orientation of the ellipse was clockwise (CW) or counter-clockwise (CCW) relative to the reference orientation. Subsequently, they were asked to provide an estimate of the ellipse's orientation. For each trial, the reference orientation was randomly chosen and the ellipse's orientation was within +/- 10 degs of the reference orientation. We used three different aspect ratios for the ellipse (1.1, 1.2, and 2) to modulate sensory uncertainty. We found that subjects' orientation estimates were systematically biased away from the reference orientation, and that the bias increases with increasing stimulus uncertainty. Our results confirm the findings of the original study. Experiment 2 was identical to Experiment 1 except that i) subjects were given the categorical information (CW/CCW) before the stimulus was presented, and ii) subjects performed an orthogonal color discrimination task before estimating stimulus orientation. Specifically, the categorical information was provided with a colored (red/green) arc extending 90 degs from the reference mark; and subjects had to discriminate the arc's color that was randomly picked on each trial. We found perceptual biases that were similar to those found in Experiment 1. We conclude that the bias cannot be the result of a task-dependent neural weighting profile. Instead, we show that the results of both experiments are in agreement with a "self-consistent" Bayesian observer model which assumes that subjects' orientation estimates are the result of an inference process that is conditioned on the (given or self-made) categorical decision (Stocker and Simoncelli, 2008).

Title: Role of Attention in Perceptual Decision-Making

Authors: *G. TAVARES, P. PERONA, A. RANGEL;
Caltech, Pasadena, CA

Abstract: When faced with a value-based decision, humans tend to fixate on the items presented to them in order to compare their values and make the best possible choice. Previous work using food items has shown that patterns of fixations have an important role in this type of decision process. In particular, choices and reaction times in binary value-based decisions can be quantitatively described by a modified version of the drift decision model (called the aDDM), in which the value comparison process depends on the pattern of fixations among the two items, and in which relative visual attention have a sizable effect on choices. Here we investigate whether the same mechanism applies to perceptual decision making. Our experiment consists of a simple binary perceptual choice task. On each block of trials, subjects are first trained to recognize a target, which is a bar oriented at a certain angle. Then, on each subsequent trial, they are shown two different bars on the screen, and must decide which of the bars has an orientation closest to the target. During trials we recorded both choices and reaction times, and used an eye-tracking device in order to obtain the subjects' patterns of fixations. We collected data from 25 different subjects (10 female; mean age 23±4), and each one of them completed a total of 1,344 individual trials. Our preliminary data analysis shows several choice biases that are predicted by the aDDM. First, our data shows a last-fixation bias, meaning that subjects are more likely to choose the last item that was fixated in that particular trial. Second, subjects are also more likely to choose items that have been fixated for a longer period of time during the trial. Finally, the first item fixated in a trial does not influence that trial's final choice. Additional investigation with this data will allow us to estimate the parameters of the model at both individual and group levels, then use the estimated parameters to predict choices and reaction times. Our results will generalize the validity of the DDM to perceptual decisions, providing additional evidence of this model's capability to explain the role of attention in a wide range of decision situations.

Title: Differential MEG activity patterns for congruent and incongruent spatial relational judgments

Authors: N. M. SCOTT[1], M. SERA[2], *A. P. GEORGOPOULOS[3];
[1]Ctr. for Cogntive Sci., [2]Inst. of Child Develop., Univ. of Minnesota, Minneapolis, MN;
[3]Neurosci, Univ. Minnesota, MINNEAPOLIS, MN

Abstract: Children learn above/below relational judgments earlier than right/left judgments, but there is no explanation for this phenomenon. Relational judgments may exhibit congruency effects and this may complicate learning. For example, encoding above is easier at the top part of the screen than at the bottom - where it is incongruent. Incongruent trials, like right and left judgments, may require inhibition of a prepotent response or additional processing. We investigated the neural correlates of encoding and maintaining spatial relations for 3 seconds in working memory in 20 adults using magnetoencephalography (MEG). When comparing the MEG signal for above/below vs. right/left judgments over the period of stimulus presentation, we found the greatest difference in activity in the left temporal-parietal-occipital junction, right temporal cortex and cerebellum. Similar differential activation was observed during the working memory phase. When comparing congruent to incongruent trials, we found differential neural activity only in left frontal areas. Congruent-incongruent comparisons in working memory indicated differential activity bilaterally in frontal and temporal areas, including the same left frontal area indicated in the encoding phase. These findings are consistent with the idea that right/left relations are represented differently than above/below during both encoding and working memory phases.

Title: Geometrical concepts in the brain: An fMRI study on figure dependency

Authors: *T. CHIANG[1], C.-J. WU[2], D. ANSARI[3];
[1]Univ. of Western Ontario, London, ON, Canada; [2]Dept. of Educational Psychology and Counselling, Taipei, Taiwan; [3]Brain and Mind Inst., London, ON, Canada

Abstract: What kinds of representations are stored in the brain for geometrical concepts we have learnt in the primary school? We can speak out without a second thought some geometrical concepts such as 'triangle inequity theorem'. However, some theorems require more time to respond, such as 'In a triangle, the longest side is across from the largest angle', or 'the opposite sides of a parallelogram are parallel'. To what extent of differences in the brain to deal with the two types of known concepts? Two experiments were executed to clarify the issue. The first experiment was a behavioural study to differentiate the two types of learnt concepts by a priming paradigm in which a congruent/incongrount/no_precue geometrical figure was presented before a math question. In control of background knowledge, subjects were separated from science and arts groups. Math questions were selected for the analysis when the accuracy is above 85% in the group. Ccorrect RTs in 3 precue conditions were cluster axises and the results showed 2 distinctive types of questions, one was primed by geometrical figures, called 'figure questions'; the other was immune from the influence of geometrical figures, called 'rule questions'. The fMRI study selected some of more distinctive questions in the 'figure' and 'rule' category based on the 1st experiment. The contrast, 'figure questions' vs 'rule questions', showed activation in the right angular gyrus, and LOC areas. Meanwhile, the questions with the accuracy above 0.75 activated bilateral hippocampus, bilateral IFL, left angular gyrus, left IPL/IPS, anterior cingulate cortex, compared to the extremely difficult questions with the accuracy below 0.4. The results verifies 2 corresponding systems in the brain and also shed a light on Neuroeducation.

Title: Differential load- and performance-related brain activity during spatial working memory in preadolescent children

Authors: *A. S. HUANG, A. SMALL, A. S. LEE, D. KLEIN, H.-C. LEUNG;
Psychology, Stony Brook Univ., Stony Brook, NY

Abstract: Spatial working memory is commonly associated with activity in a set of frontal and parietal regions, including the dorsolateral prefrontal cortex and posterior parietal cortex, which typically show increasing activity with load in young adults. Children show similar activation of these prefrontal and parietal regions during working memory tasks in comparison to baseline tasks with no memory requirements. However, working memory load effects in the prefrontal cortex were not consistently found in studies using spatial tasks, but were more consistently observed in studies using verbal or visual tasks. These inconsistencies may result from large individual differences between children. Recent studies showed correlations between visual working memory task performance and activity in frontal and parietal regions in children. Here we conducted an fMRI study to examine individual differences in spatial working memory performance and brain activity. We hypothesize that activity in frontal and parietal regions increases with memory demand, and that load-related difference in activity predicts performance. Using a 3 T Siemens Trio system, we collected structural and functional images from 36 preadolescent children (9-12 years old, 16 female) . The children performed a 1-back task where they keep track of either 1 spatial location (Load 1), or 3 spatial locations (Load 3). The two load conditions were presented in blocks of 5 trials. The order of the two load conditions was counterbalanced across two runs, each lasted 4 min 7 sec and contained 4 blocks of each load with 13-sec of fixation in between. During each block, the participants made button presses on each trial to indicate whether any location differed from the previous trial. There was a variable delay of between 2.3 to 4.8 seconds between each trial. Children performed worse on the Load 3 condition compared to the Load 1 condition. Our fMRI data revealed greater activity in the

dorsolateral prefrontal cortex, superior parietal lobule, inferior parietal lobule and intraparietal sulcus in Load 3 compared to Load 1. There was greater activity in the precuneus and supramarginal gyrus in Load 1 compared to Load 3. Activity differences in the supramarginal gyrus comparing Load 3 versus Load 1 is positively correlated with performance differences between the two load conditions across subjects. In sum, our results show load-related increases in brain activations and deactivations in preadolescent children similar to the patterns documented in previous studies of young adults. Further, the differences in load-related activity mainly correlate with individual differences in performance in this age range.

Title: GABA alterations in the NF1 brain: A multimodal 11C-flumazenil pet and MRS study

Authors: *I. R. VIOLANTE[1], M. PATRICIO[2], I. BERNARDINO[1], J. REBOLA[1], A. J. ABRUNHOSA[3], N. C. FERREIRA[3], M. CASTELO-BRANCO[1];
[2]Lab. of Biostatistics and Med. Informatics, [1]IBILI, Fac. of Medicine, Univ. of Coimbra, Coimbra, Portugal; [3]ICNAS, Univ. of Coimbra, Coimbra, Portugal

Abstract: Alterations in the push-pull mechanism regulating excitatory and inhibitory neurotransmission might underlie the cognitive deficits found in several developmental disorders. Neurofibromatosis type 1 (NF1) is a genetic disorder associated with cognitive dysfunction. Recently, using magnetic resonance spectroscopy (MRS), it was shown that GABA levels are decreased in the visual cortex of children with NF1. However, it is still to determine

whether GABAergic alterations are present in adults and whether GABA concentration deficits impact the distribution of GABA receptors. Here, we investigated GABA alterations in adult patients using a multimodal strategy combining MRS to determine GABA concentration and PET 11C-Flumazenil (FMZ) to investigate GABAA receptor binding. 14 patients with NF1 (35±7 yo.,4M) and 13 aged and gender matched controls (36±9 yo.,4M) performed PET and MRS in the same day. Our results show that: 1.Patients with NF1 have significantly less GABA+ than controls, $p<0.001$ in visual cortex, Fig1B. 2.Whole-brain analysis of FMZ BPND revealed decreased GABAA receptor binding in the left precuneus and right middle temporal gyrus, $p<0.001$ in patients, Fig1D. 3.We found no difference in GABAA receptor binding in the visual cortex between patients and controls. 4.There was no correlation between GABA concentration and FMZ BPND in the visual cortex, neither in controls nor in patients. In sum, adult patients with NF1 showed reduced GABA in the visual cortex, indicating that GABA deficits do not ameliorate with age. Whole-brain PET analysis revealed reduced FMZ BPND in the precuneus and middle temporal gyrus. Interestingly, precuneus is involved in visuospatial tasks, a hallmark deficit of NF1. Reduced GABA levels do not seem to impact the density of GABAA receptors, as we did not observe altered 11C-FMZ BPND in the visual cortex or a relationship between GABA levels measured by MRS and GABAA receptor density measured by PET. This result has important implications for understanding the disease mechanism, as it suggests that GABA alterations are predominantly pre-synaptic.

Title: Influence of Perioperative Hypnotherapy on Postoperative Improvement in Cognitive Performance (HYPNOC): preliminary results of a randomized controlled clinical trial

Authors: *C. A. IONESCU, F. BORCHERS, E. WEISS-GERLACH, K.-D. WERNECKE, C. SPIES;
Anesthesiol., Charite Berlin, Berlin, Germany

Abstract: Background: Every third patient develops postoperative delirium (POD) and postoperative cognitive dysfunction (POCD), respectively. POD and POCD increase postoperative morbidity and mortality as well as health care costs due to prolonged hospital stay. In previous studies, hypnosis has been shown to effectively reduce acute pain, stress, and anxiety; all of them contributing to the development of POD and POCD. The aim of this study is to evaluate the effect of perioperative hypnosis on the incidence of POD and POCD. Methods: In this ongoing RCT single center study 59 adult patients scheduled for cardiac surgery or spine surgery (mean age 61.6 years, 64.4% males) have been randomly selected to receive either hypnosis (3 sessions of 60 minutes, the first session 1 day preoperatively followed by 2 sessions postoperatively within 5 days) or to usual care. At baseline all patients were tested for suggestibility using the Stanford Hypnotic Suggestibility Scale. Patents with mild cognitive disorders (< 24 points in the Minimental State Examination, MMSE) or known dementia were excluded. POCD was diagnosed by using the CANTAB™ test battery (visual memory test, attention test, verbal learning test and Stroop colour test) on the day of discharge (primary endpoint) from hospital and three months after surgery. After surgery, patients were screened within the next 7 days for POD using validated delirium scores and the gold standard DSM-IV. In addition pain- and stress levels, emotional and functional status, sleep quality and time on ICU/in hospital were investigated as secondary endpoints. Statistics: Considering the low number of cases we performed a two-sided Fisher's-exact test to evaluate the influence of hypnosis on POCD. Results: POD occurred in 8 out of 59 patients. Three of those patients were in the intervention group and 5 in the control group (10.34% vs. 16.67%, p = 0.71). POCD occurred in 9 out of 59 patients. Three of those patients were in the intervention group and 6 in the control group (10.35% vs. 20.0%, p = 0.47). Conclusions: Preliminary results of this ongoing RCT did not show a significant reduction of postoperative cognitive dysfunction on discharge from hospital through hypnosis. Due to a remarkably low incidence of POCD, randomization of 409 additional patients (alpha error 5%; power 80%) is required.

Title: The development of hierarchical cognitive control and rule-guided behavior

Authors: *K. UNGER[1], D. AMSO[1], L. ACKERMAN[2], D. BADRE[1];
[1]Dept. of Cognitive, Linguistic, & Psychological Sci., [2]Brown Univ., Providence, RI

Abstract: As children transition from childhood to adolescence, they make gains in their ability to use abstract rules that define the relationship between context and classes of more concrete actions. For example, behavioral evidence has demonstrated that children have greater difficulty following progressively abstract rules, even when demands on competition and load are controlled (Amso et al., in press). Previous work in adults has indicated that increasing abstraction in rule-guided action recruits progressively rostral portions of lateral frontal cortex along a rostrocaudal axis. Importantly, the frontal cortex undergoes a protracted and heterogeneous developmental course, with different regions reaching maturity at different times. We hypothesized that the functional development of the frontal cortex, from middle childhood to adulthood will reflect the emergence of mature rule-guided behavior. Here, we tested children through young adults (ages 7-28 years) in a task that requires a high degree (3rd order) of rule abstraction, while separately manipulating competition among choice alternatives in working memory. We replicated previous observations that developmental change in rule-guided behavior was evident only in in rule abstraction, whereas increasing competition did not result in developmental differences in task performance. In adults, parametric variation of competition among abstract rule representations was reflected in the level of activation in the inferior frontal sulcus, consistent with prior observations. Preliminary fMRI data from children and adolescents suggest that abstract rule use is associated with less focal activation in lateral frontal cortex than in adults. This pattern is consistent with previous findings showing lower functional specialization in the fronto-parietal control network at younger ages, and may reflect qualitative differences in how children represent and follow abstract rules.

Title: Age-dependent sex-specific differences in the functional neuroanatomy of word processing

Authors: *O. A. OLULADE, J. S. NEIMAN, G. F. EDEN;
Georgetown Univ. - CSL, Washington, DC

Abstract: Studies have demonstrated sex-specific differences in behavioral performance on cognitive tasks (Kimura, 1996), brain structure (Good et al., 2001), and brain function (Shaywitz et al., 1995). Differences in language and reading have been of special interest, given the sex-specific differences in rate of language (Ozçalişkan and Goldin-Meadow, 2010; Eriksson et al., 2012) and reading (Wolf and Gow, 1986) acquisition and the higher incidence of language-based learning disabilities such as dyslexia (Rutter et al., 2004) in males. Previous studies have addressed the role of age (Turkeltaub et al., 2003) and sex (Ihnen et al., 2009) on the functional anatomy of single word processing, but not concurrently. In this study, we examined the interaction of age and sex in modulating neural response to real word processing and to false font processing. Twenty-three children (13 Girls, 7-16 yrs; 10 Boys, 7-13 yrs) and 50 adults (21 Women, 19-30 yrs; 29 Men, 19-42 yrs) were matched on intelligence and reading (Full-scale IQ/WJ-III Word Identification mean ± std: Girls: 121 ± 15/117 ± 14; Boys: 118 ± 10/111 ± 13; Women: 123 ± 7/111 ± 8; Men: 119 ± 9/108 ± 11). fMRI whole-brain images were collected while participants performed feature detection of a tall character within visually presented real words (RW) or false font strings (FF). Analysis was performed using SPM8. Following pre-processing, images were submitted to a whole-brain statistical ANOVA with Sex and Age Group as between-subject factors, and Task as a within-subject factor. Significant clusters emerging from the three-way interaction (Sex x Age Group x Task; $p < 0.005$; $k>30$) were extracted using MarsBar. For each subject, mean percent signal change was computed for each task relative to

baseline, and subsequently averaged for each of the four groups to determine the direction of observed effects. The three-way ANOVA yielded a significant cluster within the left supramarginal gyrus. This area is known to be activated in normal readers during reading and phonological tasks (Pugh et al., 2001) and gray matter volume here is correlated with reading ability (He et al., 2013). We found that Girls had lower activation for RW than for FF, while Women had greater activation for RW than for FF. The opposite trend was observed for males: Boys had greater activation for RW than for FF, while Men had lower activation for RW than for FF. Our results present evidence for age-dependent, sex-specific differences that are specific to word processing.

Title: Neuro-Electrical bases during encoding and calculation phase of arithmetic Sequential: An electroencephalography investigation

Authors: *E. T. MULUH[1], E. MULUH[2], L. JOHN[3];
[1]9 Cumnor Court, 292 Main Road Kenilworth, Cape Town, South Africa; [2]Cape Peninsula Univ. of Technol., Cape Town, South Africa; [3]Univ. of Cape Town, Cape Town, South Africa

Abstract: Objective: The study investigated the encoding and subsequent calculation cognitive processes when arithmetic problem are presented in different formats (3 + 4, 3 x 4, three + four, three x four, /three/ + /four/, and /three/ x /four/). Method: Electroencephalography (EEG) data were collected from seventeen first year University students while they mentally process addition and multiplication problems presented in Arabic, audio and word formats. Early and late event-related potentials (ERPs) components where analyzed for the presentation-format effect (PFE), problem-size effect (PSE) and arithmetic-operation effect (AOE) using an exact-statistical method. Results: The PFE, PSE and AOE were observed both at the encoding and calculation phases of problems. Interactions of presentation-format with problem-size and arithmetic-operation at parietal electrode locations were associated with shift in calculation strategies in the

various formats and operations. ERPs latencies where shortest with operand where presented auditory while Arabic operands took intermediate position between auditory and word operands. Conclusion: Results suggests that the effects of auditory versus Arabic or word formats on ERPs components substantially reflect format-related shifts in the use of procedural strategies or codes that contribute to given tasks as early as the encoding phase of problems and continue to calculation phase. Significance: These findings will add insight into how the human brain performs the everyday activities that require mental calculation.

Title: Electrophysiological investigation of number and area comparison abilities in children

Authors: *D. SANTANA[1], R. A. ABREU-MENDOZA[2], N. ARIAS-TREJO[2], R. HARO VALENCIA[3];
[1]Hosp. Gen. De Mexico, Mexico, Mexico; [2]Facultad de Psicología, UNAM, México, Mexico; [3]Clínica de Trastornos del Sueño, División de Posgrado, Facultad de Medicina, UNAM-Hospital Gen. de México, México, Mexico

Abstract: The salience of number over other magnitudes has been proved across several infant studies. Seven-month-olds are better at discriminating smaller ratio changes in number than area (Libertus et al., 2013). However, this salience tends to disappear: adults are equally good at discriminating number than area (Lourenco et al., 2012). Importantly, number but not area comparison abilities have been explored by means of electrophysiological techniques. Positive amplitudes behave according to the ratio: increased amplitudes for smaller ratio changes than for larger changes (Hyde and Spelke, 2011). The current study aims to contrast the accuracy of

children in discriminating area and number while brain activation was recorded. 19 children participated in two tasks: a Number Comparison Task (NCT) and an Area Comparison Task (ACT). In the first task, children had to decide whether the first or second stimuli had a larger number of dots_the surface area of the stimuli was held constant. In the second, they had to decide whether the first or the second stimuli had bigger or smaller dots_the number of dots was held constant. Children responded by pressing a left button if the first stimulus was larger or bigger and a right button if it was the second. Accuracy across tasks was analyzed by means of a 3x2 repeated measures ANOVA with Ratio (3:4, 5:6, 7:8) and Task (NCT & ACT) as within-subjects factors and mean correct responses as the dependent measure. The analysis only yielded a significant effect of Ratio ($F(2,32)= 10.49$, $p < .001$, $n2 =.39$). Post-hoc analyses indicated that children were better at discriminating 3:4 than 5:6 ($p = .05$) or 7:8 ratio changes ($p < .001$). Visual inspection of the grand average Event-Related Potentials waveforms showed a positive amplitude between 210-310 ms at P3 electrode that behaved accordingly to the ratio changes of number of dots; while a negative amplitude between 100-200 ms at P3 that only behaved according to the ratio changes of area. This was confirmed in two 3x2 repeated measures ANOVAs with Ratio (3:4, 5:6, 7:8) and Task (NCT & ACT) as within-subjects factors, one with the negative amplitudes and another with the positive amplitudes as dependent measures. The analyses yielded significant interactions of Ratio and Task for both measures (Negative $F(2,32)= 4.26$, $p < .05$, $n2 =.21$; Positive amplitudes $F(2,32)= 4.54$, $p < .05$, $n2 =.22$). The Ratio effect was illustrated by positive amplitudes for the number ratio changes, while the Ratio effect in negative amplitudes for area changes. These results indicate that, even though children had the same accuracy in discriminating number and area changes, these two magnitudes are processed differently in childhood.

Title: Neural substrates of numerical processing develop independent of visual experience

Authors: *S. KANJLIA, C. T. LANE, L. FEIGENSON, M. BEDNY;
Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: The ability to perform symbolic math is linked to a primitive number sense. Human adults, infants and other animals rapidly estimate the number of items in a visual array. Adults who are better at estimating numbers of dots score higher on tests of mathematical ability, such as the SAT (Libertus et al, 2012, Acta Psyc). Symbolic and non-symbolic numerical processing depends on the same region in the inferior parietal sulcus (IPS) (Piazza et al., 2007, Neuron). We asked whether visual experience with numerical sets is necessary for the development of cortical circuits involved in numerical processing. Congenitally blind and sighted participants underwent fMRI while solving simple algebra equations. Participants heard pairs of equations (e.g. X-2=5, X-4=3) and judged whether the value of "X" was the same. Half of the equations were simple (single-digit e.g. X-2=5) and half were complex (double-digit e.g. X-12=15). In control task, participants judged whether pairs of sentences had the same meaning. Half of the sentences were syntactically simple (subject-relative clause) and half were syntactically complex (object-relative clauses). fMRI data were motion-corrected, temporally filtered, mapped to the cortical surface, smoothed and fit with a GLM using FSL and Freesurfer. Replicating prior studies, we find that the IPS of sighted adults is 1) more active during a symbolic math task than during sentence comprehension, 2) responds more to complex than simple math equations and 3) is insensitive to syntactic complexity. Critically, we observed the same functional profile in the IPS of congenitally blind adults (group-by-condition ANOVAs main effect of math difficulty $F(1,13)=6.77$, $p=0.02$; group-by-condition interaction $F(1,13)=0.27$, $p=0.61$; main effect of syntactic complexity ROIs ($F(1,13)=0.96$, $p=0.35$; group-by-condition interaction $F(1,13)=1.46$, $p=0.25$). The functional selectivity of the IPS is similar in congenitally blind and sighted individuals. These results suggest that neural structures supporting numerical processing develop independently of visual experience.

Title: Different strategy for movement imitation in ASD

Authors: *M. KAWASAKI[1,2], H. KOMEDA[3], T. MURAI[3], Y. FUNABIKI[3];
[1]Univ. of Tsukuba, Ibaraki, Japan; [2]RIKEN Brain Sci. Inst., Saitama, Japan; [3]Kyoto Univ., Kyoto, Japan

Abstract: One character of autism spectrum disorder (ASD) includes a problem of overlap between physical and visual representations in movement imitation. It is not clear about what are the differences between the ASD and typical development (TD) subjects in such imitations. To address the issue, we compared the performance, strategy, and neural mechanisms between them, by using a movement imitation task during electroencephalograph (EEG) and near infrared spectroscopy (NIRS) measurements. Eighteen TD and 18 ASD subjects took part in the experiments after they gave written informed consent. The ASD was assessed by the MSPA (Multi-dimensional scale for PDD and ADHD) and ADOS (Autism Diagnostic Observation Schedule). In the movement imitation tasks, both right and left hands were presented from top, right, left or bottom in PC display. Either right or left hand tapped a key, and then subjects were asked to imitate the movement as soon as possible. Each subject completed 3 sessions. In the first session, they performed the task without the instruction of the strategy. After that, we interviewed the strategy with the subjects. In the second and third sessions, they performed the task with the same strategy and the different strategy from the first session, respectively. The results of the interviews showed the different strategy between the ASD and TD subjects in the movement imitation. Most ASD subjects used mental rotation where they rotated the PC's hands and superimposed them with the self-hands in their minds. In contrast, most TD subjects used perspective taking where they superimposed the self-representation to the PC's hands in their minds. The different strategy is correlated with the scores of the MSPA and ADOS. Moreover, the ASD subjects' performance were degraded when they were asked to use the different strategy (i.e. third session), in comparison to the case of using the same strategy (i.e. second session), whereas the differences were not found in the TD subjects. The EEG and NIRS results showed the modulations of the frontal activity in the ASD subjects, which suggested the possibility that the frontal executive systems would be related to the ASD subject's different strategy in the movement imitations.

Title: Developmental changes of short-term special memory of children assessed in the inverted delayed response test

Authors: *N. CHKHIKVISHVILI[1], M. DASHNIANI[1], T. NANEISHVILI[2];
[1]I.Beritashvili Ctr. of Exptl. Biomedcine, Tbilisi, Georgia; [2]St.Andrew the first-called Georgian Univ. of Patriarchy of Georgia, Tbilisi, Georgia

Abstract: Formation of the mechanisms for evaluation of the object's location in the space and of spatial memory occurs in the human postnatal development in a certain sequence. In our investigation, in order to determine the egocentric and allocentric systems' formation in the spatial short-term memory of the children of various ages, the Inverted Delayed Response test has been implemented, in which location of an object presented prior to the delay, is assessed by the subject following 1800 rotation. Total of 119 children of either sex aged 18-96 months were participating in the experiments. All of these attended a kinder-garden or school. The work complies with the ethical guidelines for human research. According to the data obtained, children aged 18-24 months, localization and retention in the memory of an item perceived, fulfill via the egocentric mechanism of spatial memory. In the landmark-poor environment correct solution of the above task begins in children since 24-36 months of age, which should be attributed to perfection of egocentric spatial memory. At this age the dead reckoning mechanisms, based on the afferent information concomitant to displacement, should be formed. Investigations of regularities of the inverted delayed response task performance, in conditions of functional blockage of sensory afferent systems in the children of various ages, have revealed that the above mechanisms function more perfectly in the children of 60+4 months, than in those of 40+4 months. The children of 7-8 years, unlike the children of 60+4 months, can determine location of an item perceived before the displacement in the inverted delayed response task just according to the surrounding landmarks (distant signals), without the sensory information accompanying the displacement. The data obtained provide for outlining the stages of the spatial short-term memory system's formation in the children.

Title: Six-year longitudinal growth-curve modeling of functional brain changes during problem solving in children

Authors: ***C. J. BATTISTA**, T. M. EVANS, T. J. NGOON, T. CHEN, V. MENON; Psychiatry, Stanford Cognitive and Systems Neurosci. Lab., Palo Alto, CA

Abstract: Cross-sectional studies of cognitive development and problem solving have shown a general shift from frontal to parietal activity over time. Examination of short-term changes associated with problem solving have found linear increases in parietal and lateral occipital cortex activation between ages 7-8.4, with no evidence for decreases (Rosenberg-Lee et al., 2011). Long-term changes between ages 9-18 have been shown to manifest linear decreases in diffuse prefrontal and temporal lobe activation accompanied by linear increases in focal dorsal parietal and lateral occipital cortex activity (Rivera et al., 2005). Here we use growth curve analysis of functional brain changes associated with arithmetic problem solving in children who were tracked longitudinally from the ages of 7.74 and 13.9 at roughly one-year intervals, with each child contributing at least 2 and at most 4 data points. At each visit participants underwent a 3T fMRI scan, during which they performed single-digit addition, single-digit subtraction, and number identification tasks. Interestingly, linear growth-curve models provided the best fit for the addition task, whereas both and linear and quadratic models fit the subtraction task. During the addition task activity in the left superior parietal lobe (SPL), the anterior intraparietal sulcus (IPS), the posterior right parahippocampal gyrus, and the posterior cingulate cortex (PCC) increased linearly over time. Linear decreases in activity over time were observed in multiple prefrontal areas, including the bilateral insula, superior frontal gyrus, and the anterior cingulate cortex. In the subtraction task, linear increases in right posterior IPS activity were observed, whereas linear decreases were seen in right prefrontal cortex and the supplementary motor area. Notably, a quadratic inverted U-shaped profile was observed in the PCC whereas the bilateral insula showed a U-shaped profile. Our findings provide the first evidence for longitudinal

developmental shifts from prefrontal to parietal cortex during childhood. Importantly, neurodevelopmental profiles depend on the complexity of problems, and are characterized by both linear and nonlinear changes. Critically, more difficult problems showed prominent nonlinear changes in the PCC and insula, pointing to a dynamic role for default mode and salience network hub regions in cognitive skill development during childhood.

Title: Cognitive function can be affected by the physical properties of dietary lipids in early life

Authors: A. L. SCHIPPER[1], L. M. BROERSEN[2], M. LOOS[3], A. J. W. SCHEURINK[4], G. VAN DIJK[4], *E. M. VAN DER BEEK[5];
[1]Nutricia Res., Danone Nutricia Early Life Nutr., Utrecht, Netherlands; [2]Nutricia Res., Advanced Med. Nutr., Utrecht, Netherlands; [3]Sylics, Amsterdam, Netherlands; [4]Dept Neuroendocrinology, Univ. Groningen, Groningen, Netherlands; [5]Nutricia Reseach - Danone Nutricia Early Life Nutr., Singapore, Singapore

Abstract: Cognitive development in infants can be positively influenced by the mode of feeding in early postnatal life. The duration of breastfeeding as well as differences in dietary lipid quality between Breast Milk (BM) and Infant Milk Formula (IMF) may contribute to this effect. Indeed, alterations in the dietary supply of omega 3 fatty acids (FA) early in life affect adult cognitive function. We studied whether another aspect of lipid quality, i.e. physical properties of lipid globules, may also contribute to cognitive development. We developed an IMF containing a complex lipid matrix (CLM) which more closely resembles the physical properties of lipid globules in BM (i.e. larger lipid droplets coated by phospholipids), without changing omega 3 and 6 FA composition. Healthy male C57Bl/6j mice were subjected to rodent diet containing either CLM or Control lipid composition (CTR) between 16 and 43 days of age. Thereafter regular rodent chow was fed until dissection (day 101). During adolescence and adulthood all mice were subjected to a test battery targeting various cognitive domains including novel object recognition and T maze spontaneous alternation. Biochemical analyses (e.g. lipid profile) were

performed in fresh collected brain material at dissection. In adolescence, CLM fed mice showed a higher preference for novel objects (day 35) and significantly better short term memory performance in the T maze (day 36) compared to CTR. Spatial reference memory in the Barnes maze (day 41) was not affected. In adulthood (day 78), after five weeks on regular rodent chow, preference for novel objects in the CLM fed group was significantly higher compared to CTR, but the improved short term memory performance in T maze test did not persist into adulthood (day 79). Reference and working memory in the 8-arm radial maze (day 101) remained unaffected. In conclusion, dietary exposure between postnatal day 16 and 43 (directly following lactation), to a chow containing a lipid structure closer to BM lipid globules improved attention and working memory in healthy mice without altering their spatial reference memory. These effects were sustained into adulthood. Further analyses of brain material to elucidate possible mechanisms underlying the observed behavioral changes are ongoing.

Title: Brain injury and cognitive dysfunction secondary to severe and recurrent hypoglycaemia

Authors: ***G. PITTS**[1], A. KUMARAN[2], J. BULLOCK[4], K. HUSSAIN[2], D. GADIAN[3], F. VARGHA-KHADEM[1];
[1]Cognitive Neurosci. and Neuropsychiatry Section, UCL Inst. of Child health, London, United Kingdom; [2]Clin. and Mol. Genet. Unit, [3]Imaging and Biophysics Unit, UCL Inst. of Child Hlth., London, United Kingdom; [4]Great Ormond Street Hosp. for Children, London, United Kingdom

Abstract: It is well established that patients who experience severe and recurrent episodes of hypoglycaemia early in life are at risk of brain injury, yet the late effects of such insult are not well documented. Here we report the pattern of brain abnormality associated with hypoglycaemia in relation to cognitive and motor performance. We selected 28 patients with a history of severe and recurrent hypoglycaemia sustained below the age of 5 years, and assessed them along with a group of 28 age- and sex-matched controls (patients mean age= 9.9yrs, sd= 2.15; controls mean age= 10.1yrs, sd=1.9yrs). Analysis of total grey matter (GM) and white matter (WM) volumes indicated a global increase in GM ($p=0.002$) and a reduction in WM ($p=0.025$). These were accompanied by regional abnormalities as indicated by Voxel Based Morphometry (Ashburner & Friston, 2000). Specifically, patients had a regional reduction of GM volume in the left inferior frontal gyrus ($p<0.05$, FWE corrected), and an increased GM volume in bilateral temporal regions ($p<0.05$, FWE corrected). In addition, patients showed reduced WM volume in bilateral occipital and temporal regions, as well as left parietal regions ($p<0.05$, FWE corrected). Manually measured hippocampal volumes were lower on each side in patients relative to controls ($p<0.05$). Neuropsychological test results revealed significantly lower scores relative to controls on working memory, processing speed, academic attainments, attention and motor skills. Although the patient group as a whole was not impaired on measures of long term memory, there was variability in performance with some individuals showing memory deficits. In addition, immediate and delayed recall scores correlated positively with hippocampal volumes ($p<0.01$). Consistent with the frontal GM and posterior WM abnormality, patients were most impaired in the domains of executive function, attention and motor performance. This is the first study documenting the pattern of hypoglycaemia-induced brain abnormality using quantitative whole brain analyses. This abnormality is characterised by a global increase in GM volume and a decrease in WM volume. While damage to WM in posterior areas has been reported previously, the pattern of GM abnormality reported here is novel and warrants further investigation to establish its link with cognitive profiles. The variability in cognitive outcome in the patient group raises the possibility that factors other than hypoglycaemia, such as the timing of brain insult or the presence of hypoglycaemic seizures, may influence long-term outcome.

Title: Development of a pattern recognition System using an artificial neural network for the rehabilitation of children with dysgraphia

Authors: *H. J. PELAYO[1], J. LOPEZ-MARTINEZ[2], J. CASTRO-MANZANO[3], V. REYES-MEZA[4], V. ZANELLA-PALACIOS[2];

Abstract: A Pattern Recognition System (PRS) is used to identify specific features of an environment or object. We have developed a PRS to detect and identify the patterns specified by the following pairs: (d, b) and (p, q). The system has a high reliability because it is built upon three artificial neural networks with different data inputs based on the same pattern, thus giving three resolutions about such pattern. The PRS discrimination is done because those graphemes (i.e., patterns) are misperceived by children with Dysgraphia, a pathology that increases the risk of failure and children desertion at school. Therefore, new methods to reduce this problem have to be developed, and stimulating tools could be a solution. Our PRS is part of a tool, videogame-inspired, where the player's goal it is to reach a high score by writing down the letters correctly. Additionally, it gives positive or negative feedback strongly indicating if the letter is wrong or well written, stimulating the player by a reward system in order to improve his writing skills and trying to help him with his dysgraphia problem. The preliminary results, from 20 regular students, support previous findings showing that children are highly motivated to work with the system. Financial support from UPAEP 30108-1030.

Title: Electrophysiological measures of functional connectivity and their relationship with working memory capacity in childhood

Authors: *J. BARNES, D. E. ASTLE;
MRC Cognition & Brain Sci. Unit, Cambridge, United Kingdom

Abstract: Functional connectivity enables neurally encoded information to be communicated between different brain areas, and this communication is likely to be highly important for particularly complex aspects of cognition, such as when regions involved in cognitive control need to communicate fluctuating task goals to lower order, functionally specific regions. Some of these functional connections are identifiable even at rest, and are typically observed with fMRI, a method that is limited by its use of indirect measures of neural activity and thereby is insensitive to the rich neurophysiological information conveyed via functional connections. We used magnetoencephalographic (MEG) recordings, projected into source space, to demonstrate that brain networks in childhood have electrophysiological underpinnings that are evident in the spontaneous fluctuations of oscillatory synchronisation and desynchronisation. Using the temporal structure of these oscillatory patterns we were able to identify a number of functional networks, such as resting state networks that have previously been characterised in adults. Importantly, we did not provide any spatial specifications, with the spatial distribution of the networks across cortex being an emergent property of the common underlying temporal pattern of the electrophysiological activity. We also demonstrated that inter-subject variability in these electrophysiological measures of functional connectivity are related to individual differences in cognitive ability: the strength of connectivity between fronto-parietal cortices and lower-level sensory areas at rest corresponded to memory capacity, as measured outside the scanner with educationally-relevant standardised assessments working memory. This study represents an important advance in understanding the electrophysiological mechanisms underpinning functional connectivity at a level of cortex in childhood, and the extent to which characteristics of these functionally connected networks reflect cognitive ability.

Title: Domain specific higher-cognitive responses in “visual” cortex of blind adults

Authors: C. LANE, S. KANJLIA, A. OMAKI, *M. BEDNY;
Johns Hopkins Univ., Baltimore, MD

Abstract: Early blind individuals activate "visual" areas of the occipital lobe during a variety of verbal and non-verbal cognitive tasks. Are these plastic responses non-specific or are they selective by cognitive domain? We acquired fMRI data from early blind and sighted adults while they performed three kinds of tasks: sentence comprehension, solving simple algebra equations and remembering sequences of non-words. In Experiment 1, participants listened to sentences of high and low grammatical complexity and answered yes/no questions about them. The high complexity sentences involved a long-distance “movement” dependency. In a control task, participants performed a match to sample task with lists of non-words. In Experiment 2, participants heard pairs of sentences and judged whether they had the same meaning. In a numerical control task, participants heard pairs of spoken equations and had to decide if the value of a variable “X” was the same in both (e.g. X-4=5; X-6=3). Equations were either simple (single digit) or complex (double digit). Prior to fitting a GLM, fMRI data were motion corrected, high pass filtered, mapped to the cortical surface and smoothed using FSL and Freesurfer. Functional ROIs were defined in occipital cortex of blind participants: 1) lateral occipital ROIs responsive to sentences>equations and 2) occipital pole ROIs responsive to equations>sentences. We extracted parameter estimates for orthogonal contrasts. We observed a double dissociation in the functional response of different occipital areas. Regions that responded more to sentences than equations 1) responded more to sentences than sequences of non-words 2) showed greater responses to syntactically complex sentences, and 3) were insensitive to math complexity. By contrast, occipital areas that responded more to math equations than sentences 1) responded more to complex than simple math equations, and 2) were insensitive to syntactic complexity. We conclude that early blindness leads to development of functionally specialized higher-cognitive responses in “visual” cortex.

Title: Evidence for state-dependent high frequency power changes in human neonatal EEG

Authors: ***M. E. CANO**[1], R. KUPERMAN[3], K. L. ANDERSON[2], R. T. KNIGHT[2,1];
[1]Helen Wills Neurosci. Inst., [2]Psychology, UC Berkeley, Berkeley, CA; [3]Pediatric Epilepsy Program, Children's Hosp. and Res. Ctr. Oakland, Oakland, CA

Abstract: High frequency brain oscillations (high gamma; HG: 70-200 Hz) have been shown to reliably track many cognitive functions and can be used as a measure of neuronal firing. HG activity cannot typically be recorded using scalp EEG due to the 1/f power law and signal attenuation by the skull. Thus, human HG is generally studied using invasive surgical techniques. However, human neonates have thinner skulls than that of adults. Additionally, they have “soft spots”, or fontanelles, where the skull has not yet fused. Accordingly, we hypothesized that it might be possible to detect higher frequency brain oscillations from neonates using noninvasive scalp EEG. High frequency EEG (1000 Hz sampling rate) was continuously recorded from healthy neonates (n=14; 1-4 months) undergoing outpatient EEG monitoring for a possible seizure. Recordings were obtained from 11 electrodes placed according to the 10-20 system. All neonates were developmentally normal, and did not have any epileptic activity in their EEGs. High gamma power (75 - 150 Hz) was extracted from data acquired during both sleep and awake recording periods. We found enhanced high gamma power when the infants were awake compared to when sleeping ($p<0.05$). Additionally, we observed increased beta-high gamma phase-amplitude coupling in the awake periods compared with sleep ($p<0.05$). These findings were evident across almost all electrode sites. To address the possibility that any differences seen between sleep and awake states could be due to muscle artifact, we analyzed event-related activity from three neonates undergoing photic stimulation. We found HG power changes that reflected the stimulation frequency, such that HG power increased following photic stimulation.

The results from both naturalistic sleep state changes as well as event-related visual responses to photic stimulation provide evidence that high frequency activity can be recorded from the scalp of neonates. These findings provided evidence for a potential metric for developmental studies in health and disease in neonates.

Title: Dynamic neural network reorganization associated with improvement of prospective metacognition

Authors: *C. HOSODA[1], K. OKANOYA[1], M. HONDA[2], R. OSU[3], T. HANAKAWA[2]; [1]Univ. of Tokyo, Tokyo, Japan; [2]NCNP, Tokyo, Japan; [3]ATR, Kyoto, Japan

Abstract: A number of scientific neuroimaging studies have begun to characterize development of the gray matter (GM) in correlation with various human abilities. Recent studies found that GM volume in the frontal polar cortex (FPC) was correlated with various kinds of retrospective metacognition capacity, i.e., how well one's confidence ratings after a task distinguish between correct judgment and incorrect judgment (Flemming et al, 2010, 2012, McCurdy et al, 2013). However, it remains unclear whether FPC also concerns prospective-type metacognitive capability or not. Additionally, one important question is whether GM volume correlated with those metacognitive capabilities can develop through learning that induces plastic changes of the brain. To address these issues, we implemented 2-month training program for visuo-motor association learning (VML). Forty right-handed participants (31 male and 9 female, aged 21.4 ± 3.2 years) underwent a 10-week computer-based training in which they were required to learn and recall tapping sequences on a trial-and-error basis every weekday. The participants predicted

the time for completing a daily assignment and reported it before learning everyday. The difference between the predicted time and real learning times yielded an index of prospective metacognitive ability. We obtained structural magnetic resonance imaging (MRI) before and after the training intervention. The whole-brain analyses of MRI before the training identified that participant with more accurate prospective metacognition had greater GM volume in the FPC ($p<0.05$, FEW correct). This result indicates that FPC also mediates a metacognitive ability about future. Moreover, we found improvement of the prospective metacognitive ability after the training, and this change was correlated with plastic development of FPC GM volume. No correlation was found between the learning time and the change of FPC GM volume. These findings provide compelling evidence for the improvement of prospect metacognition associated with experience-dependent plastic changes of GM in FPC.

Title: Early brain structure and later behavioral outcomes in fragile X syndrome

Authors: ***J. BRUNO**[1], A. STARK[1], A. A. LIGHTBODY[1], H. C. HAZLETT[2], J. PIVEN[2], A. L. REISS[1];
[1]Ctr. for Interdisciplinary Brain Sci. Research, Dept. of Psychiatry, Stanford Univ., Stanford, CA; [2]Carolina Inst. for Developmental Disabilities, Univ. of North Carolina, Chapel Hill, NC

Abstract: Fragile X syndrome (FXS) is associated with behavioral, cognitive and neurological deficits attributed to limited or lack of the fragile X mental retardation protein (FMRP). One

particularly maladaptive behavioral feature is the presence of restricted and repetitive behaviors also associated with autism spectrum disorder (ASD). Neuroimaging indicates regional alterations in caudate morphology are significantly correlated with these behaviors in early life. The relationship between early brain measures and behavioral outcomes in later development may help us understand the mechanism by which FMRP influences behavior and could aid in the design of target treatments. We sought to elucidate the predictive power of early brain structure on later behavioral outcomes among boys with FXS and a developmentally matched comparison group. Using T1-weighted MRI, we scanned 116 boys aged 1-3 years (52 FXS, 64 ASD/developmental delay). Bilateral caudate volumes, extracted using FreeSurfer, were adjusted for total brain volume. We assessed behavioral outcomes (age 8-14) via the Autism Diagnostic Observation Schedule (ADOS-2), a structured behavioral assessment including a restricted/repetitive behavior subscale. Behavioral outcomes were collected for 25 boys thus far in this ongoing longitudinal study. We performed within group correlations to determine if caudate volume in early life predicted later ADOS scores. Within the FXS group, bilateral caudate volumes were significantly positively related to ADOS restricted/repetitive behavior subscale scores in later childhood. In the comparison group only left caudate volumes were significantly positively related to behavior. Total brain volume was not a significant predictor of behavioral outcome in either group. These results indicate a positive predictive relationship between caudate volume measured early in life and restricted repetitive behaviors measured in later childhood. Relationships were present, in at least one hemisphere, for both groups. The relationships were positive; larger volumes were associated with more restricted/repetitive behaviors. Predictive relationships with the caudate were significant after adjusting for total brain volume, suggesting the caudate may play a unique role in the development of restricted/repetitive behavior. Caudate volumes measured early in development could be a useful biomarker in FXS and, potentially, in idiopathic neurodevelopmental disorders. These relationships further elucidate the neurobiological basis of restricted/repetitive behavior and may aid in development of more targeted interventions.

Title: Visuospatial working memory assessed by Corsi Block Tapping Task: changes with aging

Authors: *J. C. HEVIA, M. GUEVARA, M. HERNÁNDEZ GONZÁLEZ, L. RIZO MARTÍNEZ, M. ALMANZA SEPÚLVEDA;
Univ. De Guadalajara, Guadalajara, Mexico

Abstract: It has been postulated that the execution of working memory is in direct correspondence with the maturation of the prefrontal cortex (PFC) which reaches maturity around the third decade of life. This work was developed in order to explore changes in the performance of working memory in relation to some critical stages of maturation of the CPF through the implementation of the backward Corsi Block Tapping task. Participants were 36 men divided into 3 groups (n = 12), group 1 (G1): 11-13 years, group 2 (G2): 18 -20 years and group 3 (G3): 26 to 30 years old. The G2 and G3 had a greater number of correct trials and more elements retained in memory with respect to G1. However, only the G3 showed a lower total runtime compared to G1. These results provide further evidence that the proper execution of cubes Corsi is reached early adulthood, while efficiency in visuospatial working memory is obtained until the end of the third decade of life. These findings are in agreement with the theory of development executive functions in relation to the maturity of the CPF.

Title: Increased daily cortisol secretion and aging are associated with smaller amygdala volume

Authors: *E.-M. QUINTIN[1], G. E. ENNIS[1], K. M. KENNEDY[2], J. SHIN[1], C. K. HERTZOG[1], S. D. MOFFAT[1];
[1]Georgia Inst. of Technol., Atlanta, GA; [2]Univ. of Texas at Dallas, Dallas, TX

Abstract: Many studies have reported that high levels of cortisol, a stress hormone, are associated with measures of cognitive aging but the relationship between cortisol and structural brain aging has not been studied extensively. In animals, glucocorticoid receptors are abundant in the hippocampus, amygdala, and frontal and cingulate cortex (Kolber et al., 2009) and chronic exposure to high levels of corticosteroids is associated with decreased hippocampal volume (Landfield et al., 1978). In humans, there is evidence that higher cortisol levels are associated with thinner frontal and anterior cingulate cortex (Kremen et al., 2010). Atrophy of the frontal cortex, hippocampus, and amygdala is also associated with normal aging. In the present study, we investigated the association between cortisol secretion and age and volume of neuroanatomical regions of interest. Participants were healthy community-dwelling volunteers (N = 36; Mean age = 64, range 42-83) who had both cortisol and MRI data available. Salivary cortisol was collected 7 times per day over 10 days. Cortisol measures have been previously described (Scott al., 2013) and included cortisol awakening response, total daily secretion (area under the curve [AUC]), and daily slope, all averaged over the 10 days. MRI scans (3T Siemens; MPRAGE) were conducted approximately two years following cortisol data collection. ROIs, as computed from Freesurfer and expert operators, were used as outcome measures (ROIs: hippocampus, amygdala, and the frontal and anterior cingulate cortices). All ROIs were adjusted for total intracranial volume. Older age was significantly associated with smaller volumes for all ROIs. Higher daily secretion of cortisol AUC and older age were significantly associated with smaller amygdala volume. Cortisol AUC was not significantly related to the volume of the other ROIs. Thus, cortisol levels may have a specific effect on amygdala integrity which appears to be independent of brain aging. Results will be discussed within the framework of the amygdala response to threatening stimuli as well as how cortisol may impact circuits including the amygdala that play a role in human behavior and cognition.

Title: Age differences and longitudinal changes on diffusion tensor imaging measures

Authors: V. K. VENKATRAMAN[1], C. E. GONZALEZ[1], *B. A. LANDMAN[2], J. O. GOH[3], S. M. RESNICK[1];
[1]Natl. Inst. of Aging, Natl. Inst. of Hlth., Baltimore, MD; [2]Vanderbilt Univ., Brentwood, TN; [3]Grad. Inst. of Brain and Mind Sci., Natl. Taiwan Univ. Col. of Med., Taipei, Taiwan

Abstract: Diffusion tensor imaging (DTI) has been used extensively to investigate age effects on white matter tracks and tissue microstructure. Studies have shown age differences in white and gray matter integrity in normal aging (Bennett et al 2010) and in relation to behavioral measures (Madden et al 2009). Previous studies have also shown that these measures can detect age-changes over a short follow-up period (Charlton et al 2010). In this study we use a large longitudinal sample with regional gray and white matter diffusion measures to investigate the regions that are most sensitive to estimates of cross-sectional age differences and longitudinal age changes over time, after controlling for scanner field strength. DTI MRI scans from the Baltimore Longitudinal Study of Aging were analyzed for this study (545 subjects; 800 visits; mean baseline age = 68.54 ± 12.66 years; mean follow-up interval = 0.86 years). All participants included in this study were cognitively normal and the data was acquired on 1.5T Intera and 3T Achieva scanners. DTI processing followed standard practice for tensor fitting and quality assessment (Lauzon et al 2013). The regional DTI outputs, mean diffusivity (MD) and fractional anisotropy (FA), were obtained from the BrainColor and EVE labels for gray and white matter regions, respectively. The MD and FA from gray and white matter regions were modeled as dependent variables in a mixed-model approach with subject-specific intercept and slope as random effects. Baseline age, follow-up interval, scanner field strength and longitudinal age effect (age*interval) were independent variables. The results indicate greater cross-sectional age is associated with significantly ($p < .05$) greater MD across gray and white matter regions and significantly lower FA in most white matter regions. FA showed significant decreases over time across gray and white matter regions, except medial superior frontal gyrus, superior and posterior corona radiata. MD increased over time across gray and white matter regions such as bilateral hippocampus and corpus callosum. Baseline age affected rates of change in several regions. FA in left superior longitudinal fasciculus, posterior and superior corona radiata, showed significant longitudinal decline which decelerates with increasing baseline age. Higher baseline age was associated with accelerated longitudinal increases in MD in gray (bilateral hippocampus, precuneus, amygdala) and white matter (bilateral superior longitudinal fasciculus, posterior corona radiata, left anterior and superior corona radiata). Overall, the cross-sectional and longitudinal age effects seem to be detectable in a consistent manner.

Title: Predicting age from surface-based morphometry data via support vector regression

Authors: *F. LIEM, S. MÉRILLAT, L. BEZZOLA, S. HIRSIGER, L. JANCKE;
Univ. of Zurich, Zurich, Switzerland

Abstract: Introduction Recently published work by Franke et al. demonstrated how a subject's age can be predicted solely based on brain imaging data (Franke et al., 2010; 2012). Via voxel-based morphometry (VBM) and machine learning algorithms, these authors made brain-based age predictions on a single subject level. The present work is based on the work of Franke et al. but further develops these authors' approach by extending it to data resulting from surface-based morphometry. As compared to voxel-based morphometry, surface-based morphometric analyzes allow for a more elaborate description of cortical anatomy (Winkler et al., 2010). As, for instance, cortical thickness and surface area differentially change with age (Hogstrom et al., 2013), using those metrics separately should give more accurate age-predictions. Methods T1w images (1x1x1mm) were obtained from 220 healthy subjects (age between 64 and 87 years; M = 70.4, SD = 4.9). Measures of cortical thickness, surface area and volume were computed via Freesurfer (Fischl, 2012). To predict age, these data were fed into a support vector regression (SVR) (Ben-Hur et al., 2008), in a 10-fold cross validation approach. The SVR implementation of scikit-lean was used (Abraham et al., 2014) with a linear kernel. The mean average error (MAE) and the correlation between the real age and the predicted age were taken as indicators of prediction success. Results MAE for cortical thickness was 3.09 years (correlation between predicted an real age: $r = 0.64$, $p < 0.001$). Similar results were found for cortical surface area (MAE = 3.48; $r = 0.50$, $p < 0.001$), and cortical volume (MAE = 3.55; $r = 0.43$, $p < 0.001$). Conclusion We demonstrated that surface-based morphometry data allow for a good brain-based prediction of a subject's chronological age. Furthermore, brain-based predictions are not only restricted to age. They also might aid, for instance, in predicting future cognitive abilities of children (Ullman et al., 2014), or in predicting conversion rates from mild cognitive impairment

to Alzheimer's disease (Gaser et al., 2013). References Abraham, A. et al. (2014) Front Neuroinform 8. Ben-Hur, A. et al. (2008) PLoS Comput Biol 4. Fischl, B. (2012) NeuroImage 62. Franke, K. et al. Title: Absolute cellular composition of the human cerebral cortex is preserved for neurons but not for non-neuronal cells during aging

Authors: *E. CASTRO-FONSECA[1], C. GOMES DA SILVA[1], C. H. ANDRADE-MORAES[1], V. CARDOSO DE OLIVEIRA[1], A. T. ALHO[2], R. E. LEITE[2], R. E. FERRETTI-REBUSTINI[2,3], J. M. FARFEL[2], C. K. SUEMOTO[2], C. A. PASQUALUCCI[2], W. JACOB-FILHO[2], L. T. GRINBERG[2,4], R. LENT[1,5];

Abstract: In the nervous system, the different cognitive functions of the cerebral cortex (CC) such as memory, attention and executive control can be altered during aging process. Since brain cells (and synapses) are the processing units underlying these functions, we studied the quantitative cell composition of the CC in post-mortem brains of people without cognitive impairment. Four regions of interest (frontal, parietal, temporal and occipital) were dissected using principal anatomic landmarks: central, lateral, parieto-occipital sulci and pre-occipital notch. We used the isotropic fractionator for cell quantification, based on nuclei identification by immunocytochemistry in representative aliquots of an isotropic nuclei suspension obtained from the original region. To date, we have studied five female subjects split into two groups: from 20 to 40 years and 70 to 90 years. We found an average of 10.4 ± 0.6 billion neurons in the whole cortex, of which approximately 38% are in the frontal lobe, 19% in the temporal, 24% in the parietal and 19% in the occipital. We observed that neuronal density has an inverse profile: greater in the posterior lobes than in the anterior ones; 25.1 ± 7.3 million/g in the frontal lobe and 31.8 ± 5.2 million/g in the occipital. Comparing the two age groups, we found no significant difference ($p < 0.05$) in the number of neurons or in the neuronal density neither for any particular lobe nor for the entire cortex. However, a lower number of non-neuronal cells in the entire cortex was found for the older group ($p= 0.0243$). Our results suggest that during normal aging (NA) there is a preservation of the number of neurons in female CC, which may explain the absence of cognitive decline in this population. In a previous study of our group, neuronal loss and an increase in the number of non-neuronal cells were found in cases with diagnosed Alzheimer´s Disease with dementia. This is probably associated with inflammatory reactions as shown in other works. Since these cells represent mainly glia, our hypothesis is that in NA the decrease in non-neuronal cells may exert a protective role to avoid inflammatory pathways and the consequent degeneration of neuronal cells, a possible cause associated to dementia. The absence of brain inflammation in the course of NA must be explored. This hypothesis can justify the preservation of neurons, the decrease in non-neuronal cells and the absence of cognitive decline found in NA. Despite the currently low n in our sample, these results serve as a baseline for quantitative composition of cerebral normal aging and can be useful to compare them with different neurological entities such as other neurodegenerative diseases.

Title: Profiles of age-related structural decline and stability in neuroanatomical systems supporting vocal emotion processing

Authors: *C. F. LIMA[1,2], N. LAVAN[3], S. EVANS[1], Z. AGNEW[4], P. SHANMUGALINGAM[1], J. WARREN[5], S. CASTRO[2], S. SCOTT[1];

Abstract: Humans use several cues to infer others' emotional states, such as facial expressions, body postures, or vocal information. Being effective at perceiving these cues is crucial for interpersonal functioning. Although a number of studies report age-related decrements in emotion recognition accuracy, most of these studies resort to facial expressions. Much less is known about the auditory expression of emotions and, crucially, it remains to be determined whether and how behavioural decrements in emotion recognition result from age-related grey matter loss. In this study, we focussed on nonverbal vocalizations, such as laughs, screams and sighs, and examined how the processing of these emotion signals change across the adult life span at behavioural and neuroanatomical levels. A cross-sectional sample of 61 healthy adults aged between 20 and 81 years was tested. Participants were also assessed for hearing thresholds and general cognitive functioning. The emotional stimuli consisted of a set of vocalizations previously validated to communicate two positive emotions, amusement and pleasure, and two negative ones, disgust and fear. A multidimensional rating procedure was implemented in which participants rated how much each vocalization expressed the intended emotion as well as all the other emotions. As expected, increasing age was associated with decrements in ratings and in a derived measure of accuracy. These decrements were similar across positive and negative emotions, and they were not mediated by hearing and cognitive losses. Participants also underwent a magnetic resonance imaging (MRI) scan; T1-weighted volumetric images were acquired in a Siemens Avanto 1.5 Tesla system, including 32-channel head coil. Voxel-based morphometry was performed and multiple regressions were conducted to assess the relationships between individual differences in grey matter volume, ageing, and individual differences in emotion recognition (statistical maps were thresholded at $p < .005$, cluster corrected with Family Wise Error correction of $p < .05$). Age-related grey matter decrements in the right middle temporal gyrus and in the left middle orbital gyrus were found to mediate behavioural decrements in emotion recognition. On the other hand, clusters in the left and right inferior frontal gyri, right hippocampus, right amygdala, and left inferior parietal lobe correlated

negatively with behavioural performance in emotion recognition similarly in younger and in older adults. These results are discussed in relation to theoretical perspectives on emotional ageing, particularly positivity effects, general cognitive decline, and neurocognitive decline.

Title: Age effects on self-reported navigation ability are mediated by regional brain volume

Authors: ***N. LUCENA**[1], T. L. S. BENZINGER[2], D. HEAD[3];
[1]Psychology, Washington Univ., St Louis, MO; [2]Neuroradiology, Washington Univ. Sch. of Med., St. Louis, MO; [3]Psychology, Radiology, Washington Univ. in St. Louis, St. Louis, MO

Abstract: Existing research indicates age-related differences in experimental tasks of spatial navigation ability, and these deficits have been associated with regional brain volumes. Although a substantial proportion of older adults do also report difficulty finding their way in unfamiliar places, there has been minimal research devoted to specifying the navigational skills and strategies that older adults report using in their daily lives. Furthermore, no studies have examined the neural correlates of self-reported navigational skills in older adults. The goals of the current study were to: a) assess the reliability of self-report measures of navigation skills in older adults, b) assess whether brain volumes of regions known to be involved in navigation are related to self-report measures of navigation, and c) assess whether regional brain volumes mediate age effects on self-reported real world navigation skill in older adults. Three self-report measures of navigation skill and previously collected structural imaging data were obtained from 70 cognitively normal older adults (Mage=71 (range: 66-83 yrs, 35 females) enrolled in studies at the Knight Alzheimer's Disease Research Center. Self-report scales of navigation skill generally evidenced adequate reliability (Cronbach's α range=0.51-0.86). Age effects on self-reported navigation were characterized by increased reliance on navigational aides and dependence on landmark use. General sense of direction showed the strongest brain-navigation

associations, and was positively correlated with prefrontal, parietal, and medial temporal gray matter volumes. Further, dorsolateral prefrontal and supramarginal gray matter volumes mediated the association between age and landmark use. These regions are associated with spatial working memory, body-centered coding of spatial layouts, and disambiguating previously learned routes from new routes. The current results provide initial evidence that quickly administered, self-report surveys could serve as valid measures of navigation skill in older adults. These easily obtained measures of navigation skill can be successfully used in conjunction with biomarker data (e.g., structural brain data) to investigate mechanisms leading to navigation difficulties in older adults.

Title: Cardiorespiratory fitness mediates the effect of age on mean cerebral blood flow in the gray matter of the visual cortex

Authors: *B. ZIMMERMAN[1], B. P. SUTTON[2], K. A. LOW[2], C. TAN[2], M. A. FLETCHER[2], N. SCHNEIDER-GARCES[2], E. L. MACLIN[2], G. GRATTON[2], M. FABIANI[2];

Abstract: Cognitive declines especially in fluid, online processing, are associated with normal aging, and are likely to be linked to age-related changes in cerebrovascular health. In order to gain a better understanding of the relationships between age, cardiorespiratory fitness (CRF), and cerebral blood flow, arterial spin labelling (ASL), a functional magnetic resonance technique, was used in a study of mean cerebral blood flow in healthy older adults ranging in age from 56-88. Previous research in our lab using the same method found that estimated CRF fully mediated the age effects on mean cerebral blood flow over frontal and parietal cortices. Here we present an

extension of this analysis to the visual cortex, using data collected on a subset of the participants in the first study one year later. We found that estimated CRF was positively correlated with gray matter mean flow in the visual cortex. Additionally, we found that CRF fully mediated the effects of age on mean cerebral blood flow in the gray matter of the visual cortex. These results indicate that the impact of CRF on age-related declines in blood flow is relevant across the brain, even in areas that are thought to be less affected by normal aging, such as the visual cortex. In the future, we will integrate these findings with additional aspects of cerebrovascular health to build a stronger understanding of the complex relationship between age, fitness, cerebrovascular health, and cognitive decline.

Title: Differential effects of cardiovascular and motor fitness on grey matter volume

Authors: *C. VOELCKER-REHAGE, C. NIEMANN, B. GODDE;
Jacobs Univ. Bremen, Bremen, Germany

Abstract: It has been demonstrated that cardiovascular fitness may counteract age-related brain volume loss in several cortical and sub-cortical regions. Less is known whether also motor fitness (i.e., fitness components based on information-processing like balance, speed, and coordination, see below) benefit brain volume and whether fitness effects differ with regard to the type of fitness (cf.[1]). In the current study we were interested in the association of fitness with volume of cortical brain regions. We obtained data from 79 healthy older adults between 65 and 82 years of age. cardiovascular fitness was measured and a heterogeneous motor test battery consisting of nine tasks measuring balance performance, action speed, reaction speed, and fine

coordination was applied to calculate a motor fitness index. Separately for both types of fitness, a median split was used to split the sample into low and high performing older adults. T1-weighted anatomical brain scans were collected within a 3-Tesla MR Scanner. Voxel-based morphometry (VBM8) with fitness levels as between factors was conducted to calculate brain volume differences separately for low vs. high cardiovascular fitness (analysis 1) and low vs. high motor fitness (analysis 2). Age was included as a covariate in the analyses. Analysis 1 revealed that cardiovascular high fit participants had larger brain volumes in the anterior cingulate gyrus as well as the lingual gyrus of the left hemisphere. Analysis 2 revealed that highly motor fit participants showed larger brain volumes in the right cingulate gyrus and right fusiform gyrus as well as the left postcentral gyrus and the left posterior cingulate. Findings suggest that both, higher cardiovascular fitness and higher motor fitness are associated with larger brain volumes in the cingulum as well as other distributed brain regions. Both types of fitness might prevent brain volume loss that goes in line with aging. Whether larger brain volumes in these areas go also in line with better cognitive performance in high fit older adults as compared to their low fit counterparts needs to be tested. Title: Brain responses reflecting age-related differences in perceptual experience of cosmetic cream

Authors: R. LEE[1], M.-J. KANG[1], M.-J. CHOI[2], J. BAE[2], J. NAM[1], S. KIM[1], Y. KIM[1], M. LEE[1], S.-A. LEE[1], D. CHOI[2], S. KIM[2], *C.-Y. KIM[1];
[1]Dept. of Psychology, Korea Univ., Dept. of Psychology, Korea Univ., Seoul, Korea, Republic of; [2]R&D Center, AMOREPACIFIC Corp., Seoul, Korea, Republic of

Abstract: Background: Perceptual sensitivity tends to decline with age (Cain & Gent, 1991; Sekuler et al., 1980), which seems to be accompanied by changed neural responses in relevant

brain areas (Moscovitch, 1982; Wang et al., 2005). For the tactile modality, this tendency has been shown by exploiting vibrotactile (Verrillo, 1980), thermal (Kenshalo, 1986), and grating stimuli (Tremblay et al., 2003). However, little is known about age-related differences associated with experience of cosmetic product on skin. In the present study using fMRI, we investigated whether brain activity reflects age-related differences in perceptual experience of cosmetic cream. Methods: Behavioral and fMRI data were collected from twelve young adult females in their 20's and twelve elderly females in their 50's-60's. We manipulated absorption rate (A_fast vs. A_slow) and oil content (O_high vs. O_low) of a basic mosturizing cream prescription, which yielded a total of four stimulus conditions. The stimulus formulations were designed by using Cetyl Ethylhexanoate, coconut oil, Caprylic/Capric Triglyceride, Cyclopentasiloxane, and Cyclohexasiloxane to manipulate oil content, and silica or cellulose gum to control absorption rate. The fMRI scanning session consisted of five functional runs each of which repeated four stimuli five times in a pseudo-randomized order. In each trial, the stimulus was applied to the back of the participant's left hand for 4 seconds. After 4 seconds of stimulus removal, there was a 2-second interval prior to the next trial. Participants underwent a bahavioral testing including preference rating outside the scanner. Results: According to stimulus conditions, significant differences in BOLD signal were observed between age groups in several brain regions. In the absorption rate condition, the left angular gyrus showed such difference; greater BOLD signal was associated with A_fast compared to A_slow stimulus only in the elderly group. In the oil content condition, those regions included the precentral and supramarginal gyri and the insula in the right hemisphere. Specifically, BOLD signal was greater in response to O_high than to O_low stimulus in the supramarginal gyrus of the elderly group, whereas in the precentral gyrus and the insula of the young group, BOLD signal was greater in response to O_low than to O_high stimulus. Behavioral preference response buttressed the fMRI results; the elderly group tended to prefer A_fast to A_slow and O_high to O_low stimulus. Conclusion: These results imply that elderly females differ from young adult females in their experience of cosmetic cream, which was reflected in differential brain activation patterns.

Title: Hippocampal volume is associated with verbal memory performance in older, but not younger, adults

Authors: *M. F. SCHMIDT[1], M. E. GRISWOLD[2], K. B. FREEMAN[3], T. H. MOSLEY[4]; [1]Program in Neurosci., [2]Biostatistics, [3]Psychiatry and Human Behavior, [4]Med. (Geriatrics), Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: The hippocampus plays a key role in memory storage and retrieval. Over the adult lifespan, hippocampal volume (HV) declines, accelerating in dementia. Relationships between HV and memory have been widely reported in the elderly and in neuropsychiatric disorders, eg. dementia, major depressive disorder, and schizophrenia. This relationship remains poorly understood in normal populations, particularly African Americans. We utilized the Genetic Epidemiology Network of Arteriopathy (GENOA) study, whose participants are members of sibships in which at least one sibling had essential hypertension diagnosed prior to age 60 to determine associations between HV, measured by Freesurfer 5.3 segmentation of 1.5T T1 SPGR images, and verbal memory (VM), measured by the Rey Auditory Verbal Learning Test (RAVLT). We included participants who underwent MRI and cognitive testing between 2001 and 2006, resulting in a sample of 634 African Americans (AA) (68% Female, aged 40 to 91) in 342 sibships and 667 non-Hispanic Whites (NHW) (61% Female, aged 37 to 83) in 305 sibships. Those with possible dementia (MMSE < 24; n = 94) were excluded. We used linear regression with Generalized Estimating Equations (GEE) to estimate slopes (β) while accounting for sibship clustering and adjusting for age, intracranial volume, education, gender, and race; robust Huber-White variances were employed. The mean HV (left + right) was 7.9cm3 (SD=0.9) and the mean RAVLT was 8.0 words recalled (SD=3.6). Overall, a 1cm3 increase in HV was associated with an additional β=0.23 words recalled (p=0.102, n=1200). Assessing left and right hippocampi individually, a 1cm3 increase in HV was associated with β=0.40 (p=0.121) on the left, and β=0.41 (p=0.109) on the right. Splitting the cohort into subsamples, a stronger relationship between HV and VM was found in females (β=0.51, p=0.001, n=776) compared to males (β=-0.18, p=0.366, n=424), in AA (β=0.40, p=0.020, n=545) compared to NHW (β=0.04, p=0.834, n=655), and in older participants (≥70 years: β=0.86, p=0.000, n=225) compared to younger (<70 years: β=0.02, p=0.901, n=975). These data support the hypothesis that hippocampal

atrophy contributes to memory loss in advanced age, but relationships between HV and VM are weak or nonexistent in younger populations.

Title: Model for aging and cognitive decline

Authors: *M. P. HENDERSON;
Physics, Drexel Univ., Philadelphia, PA

Abstract: A population of neurons in the cerebral cortex of humans and other mammals organize themselves into vertical microcolumns perpendicular to the pial surface. Anatomical changes to these microcolumns have been correlated with neurological diseases and normal aging, and in particular in area 46 of the rhesus monkey brain the strength of microcolumns was shown to decrease with age. We have previously developed a model to simulate aging brains by constructing a microcolumnar network of neurons and allowing the neurons to undergo Brownian motion while being constrained by a harmonic force that weakens as a function of age. Now, we expand on this model by constructing and simulating the generated neural networks. By generating a young neural network from strong restorative forces, one can create an initial distant dependent connectivity. Then, we age these networks and presume that connectivity between neurons either weakens or severs as a function of neural displacement from initial neuronal positions. We aim to show that older networks are unable to efficiently shift between different firing regimes, providing a potential mechanism for loss of information processing in relation to microcolumnar structure.

Title: Hippocampal activation in the older brain

Authors: *L. L. BEASON-HELD[1], J. O. GOH[2], J. A. ASH[1], S. M. RESNICK[1];
[1]NIA/NIH, BALTIMORE, MD; [2]Natl. Taiwan Univ. Col. of Med., Taipei, Taiwan

Abstract: The hippocampus is a critical component of the medial temporal lobe memory system, and is a site of early pathologic change in aging and age-related disease. Because patterns of memory decline may be related to the progression of hippocampal dysfunction with increasing age and disease, the goal of this study was to determine a robust functional MRI (fMRI) task for assessing functional integrity of the entire hippocampus. We performed 3 pilot studies that tested several tasks and scan designs to assess the extent of hippocampal activation elicited by each task. 17 volunteers participated in the pilot studies (7F, 10M; mean age= 57). In each pilot study, participants underwent fMRI scanning while performing 2 tasks. The first pilot study assessed Indoor/Outdoor scene and Scrambled Images encoding tasks (Binder et al., 2005), the second pilot compared a Water/No Water scene encoding task (Liu et al., 2013) with the Indoor/Outdoor scene task, and the third pilot compared a Face/Name encoding task (Putcha et al., 2011) with our own Face/Place encoding task. Scanning was performed on a Philips 3T scanner. The tasks were administered using blocked, event-related, or mixed block/event scan paradigms. Brain activation during task performance was compared to a fixation condition. Hippocampal activation of anterior, middle and posterior regions was assessed for each task. We found that anterior to posterior activation can be achieved with a scene encoding task. In the first two pilots, the Indoor/Outdoor scene task evoked more extensive hippocampal activation compared to either the Scrambled Images task or the Water/No Water task, especially when using a blocked scan paradigm. For pilot 3, the Face/Place task evoked more robust hippocampal responses than the Face/Name task when using a mixed block/event design. Overall, the most extensive pattern of hippocampal activation was seen with the Face/Place task using a mixed event/block design. These results show that variations in the type of episodic encoding stimuli and scan paradigms used are critical considerations for assessing hippocampal functional integrity.

Title: Meditation for improving cognitive functions in age related cognitive decline-a systematic review

Authors: *G. B. PATRUDU;
Andhra Med. Col. & King George Hosp., Visakhapatnam, India

Abstract: Many previous studies showed that meditation practice improves cognitive functions in a wide range of age groups .To assess the current evidence on the effect of Meditation on age-related cognitive decline, a search was performed in PubMed, Embase, &Google Scholar. A total of nine studies were found and all of them showed a better performance on attentional , executive & memory tasks in elderly subjects who practiced meditation compared to elderly subjects with no meditation practice. Gard etal (2014), showed that Fluid intelligence declined slower in yoga practitioners and meditators combined than in controls. Prakash etal (2012),found that elderly regular meditators performed better than elderly controls on tests of short term memory, executive skills , perceptual speed & attention . Nguyen & Kruse (2012), found that Elderly subjects when given Tai Chi (with meditation component) practice, showed better performance on Trail making test than elderly controls . Newberg etal (2010),found that Elderly subjects with age-related memory loss showed improved cortical blood flow & performance on tests of verbal fluency, Trails B & logical memory after 8 weeks of meditation . Kampanaros etal (2010), found that Elderly subjects when given body-oriented meditation showed improvement on fluid & crystalline intelligence. Van leeuwen etal (2009),found that ,Elderly mindfulness practitioners performed better than elderly controls on attentional blink task . Pagnoni & Cekic (2007),found that Elderly, Zen meditators performed better on a sustained attention task than elderly controls and didn’t show age-related decline in grey matter volume .Lazar etal (2005),

showed that Elderly regular Insight meditation practitioners showed less age-related cortical thinning and increased thickness in areas sub serving attention , interoception & sensory processing . Alexander etal (1989),found that Elderly subjects when given Transcendental Meditation or Mindfulness practice performed better on paired associate learning, tests of cognitive flexibility and word fluency than elderly controls. Overall, the current evidence shows that meditation has a beneficial effect on age-related cognitive decline ,however more studies involving standardized meditation techniques are needed as the current studies on meditation vary widely on the type of meditation studied.

Title: Cerebrovascular reactivity and cardiovascular disease in older adults: Results from an fMRI breath-hold hypercapnia task

Authors: *N. F. SCHWARZ[1], J. D. LUKEMIRE[1], U. S. CLARK[2], H. H. RISKIN-JONES[3], X. XU[4], D. LABBE[5], B. E. HAWKSHEAD[1], S. W. LIEBEL[1], L. H. SWEET[1];
[1]Psychology, The Univ. of Georgia, Athens, GA; [2]Mount Sinai Sch. of Med., New York, NY; [3]VA Greater Los Angeles Healthcare, Los Angeles, CA; [4]Idaho State Univ., Pocatello, ID; [5]Warren Alpert Sch. of Med. of Brown Univ., Providence, RI

Abstract: Functional magnetic resonance imaging (fMRI) is frequently used to investigate the neurophysiological changes that underlie cognitive decline in older adults (OA). Decline in cognitive performance is not only associated with advanced age but also with cardiovascular disease (CVD). FMRI blood-oxygenation-level-dependent (BOLD) signal is sensitive to changes in cerebral hemodynamics, which are modulated by neural activity. Relatively little is known about how changes in cerebrovascular reactivity resulting from normal aging and CVD affect the BOLD response. Dissociating cerebrovascular from neural contributions to the BOLD fMRI signal is critical in determining whether the BOLD signal is providing valid information with regard to underlying cognitive performance-related neurophysiology. We examined

cerebrovascular components of the BOLD signal by acquiring echoplanar fMRI data during a blocked breath-hold hypercapnia paradigm in a group of ten healthy OA (age: mean=67 years, SD=8; 6 females) and ten OA with CVD (age: mean=69 years, SD=8; 2 females). Based on previous findings in healthy OA, we hypothesized that the BOLD signal in OA with CVD would exhibit greater delay and variability in comparison to the control group. A conventional GLM was used to determine hypercapnia effects versus normal breathing. Replicating previous results, we observed that the BOLD response was delayed in both populations. Four prefrontal regions (left anterior cingulate, bilateral medial frontal and right middle frontal gyri) showed significant group differences in the magnitude of percent signal change observed during breath-hold blocks compared to baseline resting states ($p<.001$, corrected), where the control OA group showed less negative percent signal change during breath-hold than did the OA group with CVD. The percent signal change was expected to be negative as the BOLD response was delayed with respect to a standard response model convolved with our boxcar design. Furthermore, the BOLD response was significantly more variable in three out of the four regions in the CVD group. These results indicate that cerebrovascular reactivity differs in frontal regions between healthy OA and those with CVD. Accounting for cerebrovascular reactivity may provide a more sensitive characterization of the BOLD response in fMRI studies of brain function in OA and may be especially useful in those with CVD.

Title: The influence of demographic and disease risk factors on paired associates learning in an internet recruited cohort of over 29,000 individuals

Authors: *A. L. SINIARD[1,2,3], I. SCHRAUWEN[1,2,3], J. J. CORNEVEAUX[1,2,3], J. PEDEN[1], M. N. TURK[1,2,3], M. D. DE BOTH[1,2,3], R. F. RICHHOLT[1,2,3], M. MUELLER[4], J. LANGBAUM[2,5], E. REIMAN[2,5], R. CASELLI[6], P. COLEMAN[3,7], C. BARNES[2,3,8], E. GLISKY[2,3,8], L. RYAN[2,3,8], M. J. HUENTELMAN[1,2,3];

Abstract: There is significant interest in understanding the health and disease risk factors that influence cognition. However, most studies performed to date are underpowered to detect all but the factors that exert the largest effect. To address sample size concerns and to power our study to examine even those risk factors with minor influences on cognition, we developed a web-based task that examines paired associates learning (PAL). At www.mindcrowd.org we have studied the performance of over 29,000 individuals on the PAL task. This large data set and the nature of the recruited cohort, which spans the age spectrum from 18 to 85 years, uniquely powers us to identify even subtle factors that may influence PAL across the lifespan. The MindCrowd PAL task consists of 12 word pairs that are presented sequentially to the test taker. From all completed tests we applied several demographic filters to select a final cohort for analysis, including filters to remove duplicate test takers and those subjects who didn't understand the rules of the task. This yielded a final cohort size of 19,202 subjects between the ages of 18-85. A multiple regression model was fitted with the PAL results as the dependent value and all of the demographic, health/disease risk factor, and reaction time main effects as independent values. Of all the demographics tested, we found that Handedness ($p = 5.9 \times 10\text{-}4$, Right Handedness; $r = 1.66\%$) Marital Status ($p = 1.71 \times 10\text{-}4$, Single vs Married $r = 1.32\%$) and Race ($p = 2.71 \times 10\text{-}9$) significantly influence PAL performance. High Blood Pressure significantly affects PAL performance but only when present in individuals under the age of 35 (Age:HighBloodPressure interaction $p = 0.003$; <35 years of age, $p = 0.002$, $r = -4.37\%$). Smoking affects PAL performance in females only (Smoking:Gender $p = 0.004$; Females $p = 0.01$; $r = -2.00\%$; Males $p = 0.626$). There was no effect of Drug/Alcohol abuse, Diabetes, Dizziness, Heart Disease, Loss of Consciousness, Seizures and Stroke on PAL performance after correcting for all other demographics. We identified novel demographic and health risk factors associated with PAL performance in humans using a large web-recruited cohort. Previous studies examining hypertension status and cognitive task performance have mainly focused on older age groups and our data demonstrates that the largest effect is found in young adults. Limitations of our study include the fact that it is a cross sectional study and the potential for biased recruiting and/or PAL test taking through the use of the internet. Web-based recruitment and testing of a large and demographically diverse sample is both feasible and can uncover novel associations with cognitive task performance.

Title: MindCrowd: Web-Based paired associates testing of 19,202 individuals demonstrates significant main effects of chronological age, gender, education, and Alzheimer's disease family history on performance

Authors: *M. J. HUENTELMAN[1,2,3], I. SCHRAUWEN[1,2,3], J. CORNEVEAUX[1,2,3], A. SINIARD[1,2,3], J. PEDEN[1], J. LANGBAUM[2,4], E. REIMAN[2,4], R. CASELLI[5], E. GLISKY[2,3,6], L. RYAN[2,3,6];

Abstract: It is well documented that many aspects of human cognitive performance are influenced by both a heritable and non-heritable component; however, most studies of these components are largely underpowered to detect all but those that exert large effects on the cognitive task of interest. To address these sampling and cohort diversity concerns, we created a web-based (at mindcrowd.org) paired associate learning task (PAL) in an attempt to interrogate a large cohort of individuals that span a more complete range of genetic, demographic, and health risk factors. The MindCrowd PAL task consists of 12 word pairs that are presented sequentially to the test taker. We applied several demographic filters to select a final cohort for analysis, including approaches to remove duplicate test takers and those subjects who didn't understand the rules of the task. This yielded a final cohort size of 19,202 subjects between the ages of 18-85. Regression analysis demonstrated significant PAL performance differences, after correction for all other factors, for chronological age ($p<2.2 \times 10\text{-}16$, r=4.4% performance decline every decade), gender ($p<2.2 \times 10\text{-}16$, r=5.4% lower scores in males), education level ($p<2.2 \times 10\text{-}16$, r=4.4/7.8/11.2% increased performance versus 12 years or less of education for 14/16/20 years of education respectively), marital status (p=0.0002, r=1.3% higher performance in single individuals), handedness (p=0.0006, r=1.7% higher scores in right handed subjects), and the presence of a first-degree relative diagnosed with Alzheimer's disease (AD, p=0.002, r=1.3% higher performance in individuals without a first degree relative with AD). Chronological age, gender, and education have the most significant statistical associations with PAL performance. In

this study we extend the gender differences on PAL to even the youngest participants. The age:gender interaction for PAL performance becomes most noticeable near the average age of menopause onset suggestive of a potential link between sex hormone levels (either natural decline and/or hormone replacement therapy decisions) and PAL performance. AD first degree relative family history also has a significant effect on PAL performance. This effect is enhanced when individuals under the age of 42 are analyzed separately from those over 42. This finding suggests that heritable factors associated with first degree AD risk exert an effect on cognitive performance even in healthy individuals at young adult ages (note the significant effect of AD first degree relative status is evident in the 20s). Our results demonstrate the effectiveness of web-based recruitment for the study of cognition across a diverse cohort.

Title: Age differences in brain response to cues that signal the value of to-be-remembered information

Authors: *M. S. COHEN[1], J. RISSMAN[1], N. A. SUTHANA[1,2], A. D. CASTEL[1], B. J. KNOWLTON[1];
[1]Dept. of Psychology, [2]Dept. of Neurosurg., UCLA, Los Angeles, CA

Abstract: People often need to selectively remember important information. This skill is particularly important for older adults who must be efficient at directing limited encoding resources to important items. We tested 20 young adults and 17 older adults in a value-directed remembering paradigm (Castel et al., 2002) adapted for fMRI. Participants were presented with 5 lists of 24 words each. Each word was preceded by a numeric value cue (half high-value and half low-value) indicating how many points could be earned if that item was later recalled. Here, we examined how BOLD signal during the cue period preceding each word differed for high vs. low-value cues. We defined sets of ROIs based on automated meta-analyses obtained from the Neurosynth database. In young adults, activity was greater for high-value cues in a number of regions, including the "semantic" and "reward" networks defined from Neurosynth, but greater value-related increases in brain activity during the cue period were not associated with better subsequent memory or selectivity. In these subjects, memory selectivity was strongly related to value-related differences in activation while the words were being encoded, particularly in brain regions associated with semantic processing (see Cohen et al., 2014, CABN). Older adults showed a similar pattern of value-related activation as young adults while the to-be-remembered words were present, with value-related differences in activity in semantic processing regions during word encoding correlating with selectivity. However, during the cue period, we find a main effect of age on the degree of value-related modulation of brain activity. Unlike young adults, older adults did not show a significant overall increase in activity during high-value cues in semantic processing regions, in reward-sensitive regions, nor in other prefrontal regions sensitive to value cues in young adults. Individual differences in the degree to which value modulated older adults' cue period activity were, however, positively associated with later recall of valuable items. These data suggest that it may be beneficial to proactively engage brain areas that can strengthen memory encoding. Young adults seem to generally respond proactively to value, selectively engaging these regions prior to encoding regardless of their eventual performance, while many older adults do so only reactively, after the word appears. When older adults do engage these regions selectively prior to encoding, however, it was beneficial, suggesting a possible means by which older adults can learn to improve their cognitive performance.

Title: Long-term cortisol variability predicts Alzheimer's Disease risk

Authors: *S. D. MOFFAT[1], G. E. ENNIS[1], Y. AN[2], S. M. RESNICK[2], L. FERRUCCI[2], R. J. O' BRIEN[3];
[1]Psychology, Georgia Inst. of Technol., Atlanta, GA; [2]Natl. Inst. on Aging, Baltimore, MD; [3]Johns Hopkins Univ., Baltimore, MD

Abstract: Elevations in central and peripheral measures of cortisol and hypothalamic-pituitary-adrenal (HPA) axis dysregulation are recognized features of Alzheimer's Disease (AD) (e.g., Armanini et al., 2003; Giubilei et al., 2001; Näsman et al., 1995, Peskind et al., 2001). Whether cortisol dysregulation is a cause or consequence (or both) of AD, however, is not known. We used data from the Baltimore Longitudinal Study of Aging (BLSA) to examine whether longitudinal measures of urinary free cortisol: creatinine ratio (UFC/Cr), collected from 24 hour urine samples over an average interval of 8.17 years, was related to risk for AD. We also investigated apolipoprotein E, ε4 allele, a known genetic risk factor for AD, as a moderator of the relationship between UFC/Cr and AD risk. When examining continuous and trichotomized measures of UFC/Cr level, slope, and variability (i.e., within-person standard deviation) as predictors of AD risk, we found that UFC/Cr level and variability were significantly related to AD risk rate. Specifically, moderate UFC/Cr level and variability were related to a reduced AD risk compared to high level and high variability. The relationship between UFC/Cr moderate variability and AD risk was further moderated by APOE-e4 carrier status. APOE-e4 non-carriers with low and high UFC/Cr variability had an increased AD risk relative to those with moderate variability. UFC/Cr variability did not influence risk in APOE-e4 carriers. Cortisol dysregulation as manifested by low and high UFC/Cr variability may be a causative factor or early prodromal marker of AD in APOE-e4 non-carriers.

Title: The polyphenolic and f1 fractions isolated from butea frondosa ameliorates learning memory disruption in the laboratory animal models

Authors: *G. A. DESHPANDE[1], S. MENGI[2];
[1]Bharti Vidyapeeth Deemed Univ., Pune India, India; [2]Pharmacol., C.U.Shah Col. of Pharm., Mumbai, India

Abstract: Background: Butea frondosa is commonly used herb in Ayurvedic medicine. In the present study a systematic pharmacological and phytochemical investigation is performed. we examined *in vivo* nootropic activity of isolated polyphenolic (15, 30 and 60 mg/kg p.o) & F1 fraction (20, 40 and 80 mg/kg p.o) of the plant leaves. Methods: *In vivo* nootropic activity was investigated using exteroceptive, interoceptive and chronic stress induced memory models. The effects of both the fractions were measured during the acquisition/retention trials of exteroceptive models like elevated plus maze, shuttle box, cooks pole model. Fractions were also tested for diazepam-, scopolamine- and chronic stress-induced amnesia models. The putative biochemical markers of amnesia like cholesterol, glucose, total protein, corticosterone and hydrolyzed levels of acetylcholine were estimated spectrophotometrically. Statistical analysis was performed by using one way ANOVA. Result: In the exteroceptive models, the F1 fraction showed significant (*P<0.05) acquisition and retention ability. Chronic electroshock-induced retrograde- and scopolamine-induced amnesia was significantly reversed in a dose dependent manner by polyphenolic than F1 fraction during the acquisition/retention trials. Stress induced biochemical perturbations were significantly attenuated by both the fractions. Acetylcholine is reported to be a putative marker of cognition. Interestingly, we observed significant (*P<0.05) decrease in hydrolyzed levels of acetylcholine by both the fractions in a dose dependent manner. Conclusion: Both fractions show nootropic activity that may be applicable in treating cognitive and neurodegenerative conditions. Further studies will be required to elucidate the molecular targets of such conditions.

Title: A randomized, controlled trial investigating the psychopharmacological and cognitive enhancing effects of the herbal medicines Pycnogenol and Bacopa: The Australian Research Council Longevity Intervention (ARCLI)

Authors: M. P. PASE[1], A. SCHOLEY[1], K. SAVAGE[2], K. NOLIDIN[2], *C. STOUGH[2]; [1]Ctr. for Human Psychopharmacology, Swinburne Univ. of Technol., Hawthorn, Australia; [2]Ctr. for Human Psychopharmacology, Swinburne Univ., Melbourne, Australia

Abstract: Ageing is associated with cognitive decline, particularly in the domains of memory and processing speed. With the population ageing rapidly, it is important to elucidate ways to help the elderly remain as mentally healthy as possible. Certain dietary factors and even herbal medicine have been shown to have beneficial effects on cognitive performance and such interventions could be useful for ameliorating age-associated cognitive decline. For example, short term trials have shown that a special standardized extract of the Indian Herb Bacopa can improve verbal memory. The French Maritime Pine Bark extract Pycnogenol has also been shown to improve memory after three months of supplementation. The Australian Research Council Longevity Intervention (ARCLI) was developed to examine the effects of pharmacologically active supplements on cognitive performance. ARCLI is a randomized, placebo-controlled, double-blind, 4-arm clinical trial in which 465 participants are randomized to receive an extract of Bacopa monnieri (CDRI08 300 mg/day), Pycnogenol (150 mg/day), a micronutrient combination formula or a placebo daily for 12 months. Following baseline assessment, participants are tested after 3, 6 and 12 months of supplementation across an extensive battery of cognitive, neuropsychological and mood measures, cardiovascular (blood pressures and aortic stiffness), biochemical (inflammation, oxidative stress and safety) as well as genetic assessments (telomere length and several Single Nucleotide Polymorphisms). Neuroimaging is also performed in a subset of the sample before and after treatment. The primary aim is to investigate the effects of the supplements on cognitive performance. ARCLI represents one of the largest and most definitive clinical trials in which psychopharmacological

supplements are administered to elderly participants. To date, approximately 150 participants have been enrolled into ARCLI with just under 100 participants having completed the 12 month intervention. The study remains ongoing. This presentation will outline some of the preliminary results generated from ARCLI. The presentation will focus on the cognitive enhancing effects of both Pycnogenol and Bacopa.

Title: Mechanisms of music-induced neurophysiology - a proposed model for prescriptive listening applications in dementia patients

Authors: *L. E. MAGUIRE;
Johns Hopkins Univ., Baltimore, MD

Abstract: Studies in music-based interventions for Alzheimer's suggest physiological mediators as primary mechanisms to explain music's power in obtaining desired Mood, Cognitive and Behavioral (MCB) outcomes in Alzheimer's patients. Music reliably promotes healthy physiological outcomes including improved heart rate variability, blood pressure, oxygen saturation, lower cortisol levels and increases in melatonin, dopamine, immunoglobins and hormones (Fancourt et al, 2014) leading to positive MCB outcomes in most music-dementia studies (Guetin et al, 2013). Music appreciation is remarkably well preserved in Alzheimer's patients. Therefore, targeted, individualized therapeutic listening programs, created through development of computer-generated Prescription iPods, can ease both patient and caregiver burden in the medical field. The listening programs are based on clients' clinical baseline demographics, psychological profiles, cultural background, musical preferences, co-morbidities, best-case scenario prognostics and patient schedule of activities. The proposed medical music model produces computer-generated, individualized playlists using internal algorithms that draw

from an archive of refined, psychological and physiology-matched music recordings. Scheduled listening programs carry patients through longitudinal, multi-staged progressive musical programming levels that effectively escort and mediate improved MCB outcomes through physiologic mediation. The prototype model focuses on difficult afternoon hours (Alzheimer's "Sundowning Syndrome" between 1-5 pm) and uses music selections to escort function and redirect specific dysfunctional behaviors, cognitive distortions and emotional lability. Multiple weeks of varying, 20-50 minute, progressive music programming stages are created contingent on progressive clinical presentations, patient's response to music, scheduled activities and clinician/physicians' best-case prognosis. Unlike traditional music programming, prescriptive music programs introduce up to 90% novel (previously unheard but appealing) music programming to achieve intended outcomes. Personalized programs can automatically change, for example, every 10-14 days or adapt contingent on new clinical presentations. Ultimately, a field of expert musicians, performers, composers and musicologists who are also medically educated can potentially create, perform and deliver transformative, prescriptive medical music and new compositional designs intended for purposeful health entrainment in listeners of all kinds.

Title: Novel ROCK inhibitors developed for both cognitive enhancement and blockade of pathological tau phosphorylation

Authors: *M. TURK[1,2,4,5], M. D. ADAMS[2,4,6], T. WANG[3], T. DUNCKLEY[2], M. J. HUENTELMAN[2,4,5];
[1]Arizona State Univ., Phoenix, AZ; [2]Neurosci., [3]Translational Genomics Res. Inst., Phoenix, AZ; [4]Arizona Alzheimer's Consortium, Phoenix, AZ; [5]Evelyn F Mcknight Brain Inst. at the Univ. of Arizona, Tucson, AZ; [6]Midwestern Univ., Glendale, AZ

Abstract: Rho-associated protein kinase (ROCK) is an enzyme that plays important roles in neuronal cells including mediating actin organization, critical for cell migration and axon path-finding, as well as dendritic spine morphogenesis. The ROCK inhibitor (ROCK-i) Fasudil has

been shown to increase learning and working memory in aged rats, but another ROCK-i, Y27632, was shown to impair learning and memory in rats. These observations suggest different mechanisms of action for these two albeit structurally different inhibitors. Thirteen different ROCK-i, five of which are commercially available and eight of which were newly designed and synthesized for this study, were used to treat human neuroglioma cells overexpressing 4-repeat tau (H4-tau) across a 96-hour time course. The IC-10 dosage, at which 10% of H4-tau cells are no longer viable after 120 hours, was used and fresh drug-containing media was applied every 24 hours. The ratio of Serine 396 phosphorylated tau (p-tau) to total tau was measured using ELISA at each of 8 time points. All drug treatments were compared against the corresponding time point for vehicle-treated cells. Fasudil was the only commercial drug to decrease the p-tau total tau ratio ($p=0.0004$). Of note, Y27632 did not decrease this ratio ($p=0.218$). Several of the novel ROCK-i significantly decreased p-tau:total tau; of these, T343 had the greatest significance ($p=0.003$). T299, another newly designed ROCK-i, displayed no change in the p-tau:total tau despite its similarity to T343 in ROCK-I and ROCK-II inhibition. The results of these four drugs were replicated in H4-tau cells using the higher IC-50 dosage in order to ensure that the dose alone was not playing a significant role in the observed effect. While results of treatment with Fasudil, Y27632, and T343 at IC-50 were significant in the same direction of effect ($p=0.01$; 0.08; 0.003), T299 at the IC-50 dosage in contrast significantly increased the p-tau total tau ratio ($p=0.0009$). These findings detail several drugs with differential effects on tau. This presents a unique opportunity to utilize these molecules to dissect the changes associated with each, and perhaps further fine-tune the drugs to more effectively target p-tau. Of note, phosphorylation of tau at Serine 396 decreases tau mobility and the ability of tau to bind microtubules, contributing to the tauopathy of Alzheimer's disease. Further research is necessary to parse out whether the effects of Fasudil on learning and memory are mediated through changes in p-tau to total tau expression, or through other on- or off-target effects.

Title: Gene expression profiling of human astrocytes treated with bexarotene and related compounds shows increase in neuroprotective cytokine GMCSF

Authors: *R. RICHHOLT[1,2,3], I. PIRAS[4], A. M. PERSICO[4], M. J. HUENTELMAN[1,2,3];
[1]TGen Neurogenomics Div., Phoenix, AZ; [2]Arizona Alzheimer's Consortium, Phoenix, AZ; [3]Evelyn F. McKnight Brain Inst. at the Univ. of Arizona, Tucson, AZ; [4]Lab. of Mol. Psychiatry and Neurogenetics, Univ. Campus Bio-Medico, Rome, Italy

Abstract: Characteristic neuropathology of Alzheimer's disease (AD) includes the accumulation of extracellular amyloid plaques in the brain. These plaques are thought to be formed through an imbalance between beta-amyloid (Aβ) production and clearance. Recent studies in multiple AD mouse models show that treatment with the RXR agonist bexarotene (BEX) restores cognitive functions and in some models results in reduced soluble and oligomeric Aβ. These observations position BEX as a potential agent for AD prevention therapy. RXR and LXR activation has been shown to increase expression of the cholesterol transporters ABCA1 and ABCG1, as well as APOE. These increases in expression were attributed to the benefits of the BEX treatment on Aβ, but they also caused concern regarding its potential use in patients carrying the epsilon 4 allele variant of APOE. How these molecules facilitate Aβ clearance is not fully understood; therefore we utilized gene expression profiling to investigate BEX and related RXR/LXR agonists in human cells. Human primary astrocytes (Lonza) were treated for 48 hours with 100nM concentrations of the following RXR/LXR agonists - BEX, honokiol, and 9-cis retinoic acid (RA). Gene expression analysis was conducted with Illumina HumanHT-12 v4 BeadChips and differential expression was performed with the R package Limma. Hierarchical clustering and gene ontology analysis was performed. BEX and RA significantly upregulated ABCA1 and ABCG1 (P value < 0.01, validated by qRT-PCR), but APOE was unaffected by any of the three drug treatments. Cluster analysis identified a group of immune response genes that were upregulated at three hours by all drugs. Among these genes, BEX increased granulocyte-macrophage colony stimulating factor (GMCSF) (Log2 fold change 1.64, pvalue < 0.01), a cytokine that is known to be neuroprotective. Additionally, treatment of cultured human microglia with BEX demonstrated a significant increase in GMCSF across a similar time course. This study is the first to examine the molecular effects of BEX in human cells. Our results suggest that BEX treatment does not upregulate APOE expression and therefore should remain a strong candidate for anti-amyloid therapy in humans. Additionally, our results demonstrate that BEX may act at least in part via upregulation of GMCSF. Several studies demonstrate the importance of GMCSF in cognition and show that upregulation of GMCSF can reverse both cognitive impairment and amyloidosis. BEX likely represents a novel approach to upregulate GMCSF in the central nervous system and therefore warrants further investigation as a potential anti-amyloid agent in humans.

Title: Noncoding and micro RNAs associated with KCl-induced neuronal depolarization

Authors: *M. DE BOTH[1,2,3], A. SINIARD[1,2,3], J. CORNEVEAUX[1,2,3], H. ZHANG[4], J. COLEMAN[4], M. HUENTELMAN[1,2,3];
[1]Neurogenomics, Translational Genomics Res. Inst. (TGen), Phoenix, AZ; [2]Evelyn F McKnight Brain Inst. at the Univ. of Arizona, Tucson, AZ; [3]Arizona Alzheimer's Consortium, Phoenix, AZ; [4]Univ. of Florida, Gainesville, FL

Abstract: During new memory formation, the cellular constituents of the activated circuit undergo rounds of de novo transcription and translation. Characterizing and understanding these molecular changes are of great interest, because they may represent some of the most basic initial responses to activation. Because of that, they likely embody key points of intervention where memories could be enhanced or inhibited. Next-generation RNA sequencing (RNA-seq) provides the ability to digitally quantify transcript levels, construct an unbiased whole transcriptome map, and identify key transcriptional changes that are key to cell function and dysfunction. Here, we identify transcriptional changes following potassium chloride (KCl)-induced neuron depolarization *in vitro* in an attempt to characterize those transcriptional changes associated with neuronal cell activation. Cell cultures were initiated from the neocortex of E15 C57BL/6 mouse embryos. Neocortices were pooled, dispersed, and seeded on poly-L-lysine+laminin coated 6-well plates. After 20 days *in vitro* (DIV20), cells were silenced in 1 uM TTX + 100 uM AP5 for 24 hours. Depolarization was induced with 55 uM KCl for 0, 0.25, 0.5, 1, 6 and 24 hours, with RNA and protein collected at each time point. RNA was isolated using the RNeasy kit (Qiagen) and double stranded cDNA was synthesized using the Ovation RNA-Seq System (Nugen). NGS Libraries were prepped with the Encore Rapid Library Prep Kit (Nugen) and sequenced on the HiSeq 2500 instrument using paired-end 100bp chemistry (Illumina). RNA-reads were trimmed (AlienTrimmer), aligned (STAR), and quantified (HTSeq-count). The resulting raw counts were compared and analyzed in R for expression changes through the timecourse. We utilized custom pattern analysis to identify genes with interesting expression profiles, such as increasing or decreasing over various periods. Of the 174 transcripts that consistently increase expression over 24 hours, 37% are non-coding or miRNAs.

Additionally, of the 99 transcripts that consistently decrease over 24 hours, 41% are non-coding or miRNAs. Non-coding and miRNAs are a key class of transcripts that don't encode proteins directly but can significantly alter the expression of their targets and therefore, cellular physiology. Our results highlight that sustained transcriptional differences following neuronal depolarization are largely characterized by regulatory RNA molecules, suggesting that the action of this class of RNAs may play a key role in regulating the molecular process of learning and memory. Additional work is needed to explore this finding *in vivo*.

Title: Integrated approaches for analyzing u1-70k cleavage in alzheimer's disease

Authors: ***B. BAI**[1], P.-C. CHEN[1], C. M. HALES[2], Z. WU[1], V. PAGALA[1], A. A. HIGH[1], A. I. LEVEY[2], J. J. LAH[2], J. PENG[1];
[1]St. Jude Children's Res. Hosp., Memphis, TN; [2]Emory Univ., Atlanta, GA

Abstract: Protein cleavage is commonly discovered in the brain of neurodegenerative disease, leading to the accumulation of neurotoxic fragments. We have recently found in Alzheimer's disease (AD) the aggregation of U1 small nuclear ribonucleoprotein complex (snRNP) and abnormal RNA processing. The U1 snRNP subunit U1-70K (~70 KDa) is also cleaved into an N-terminal truncation (N40K, ~40 KDa). Here we present evidence to indicate that U1-70K cleavage frequently occurs in AD, and the N40K abundance is inversely proportional to the U1-70K level, implying that this cleavage event contributes to the loss of U1-70K function. To map the cleavage site(s) in U1-70K, we compared tryptic peptides of N40K and stable isotope labeled U1-70K by liquid chromatography-tandem mass spectrometry (LC-MS/MS). When equally mixed, shared peptides display approximately 1:1 ratio, but protein-specific peptides have large

ratio distortion, revealing that the proteolysis is located in a highly repetitive and hydrophilic domain of U1-70K, which is essentially not compatible with current LC-MS/MS settings. We then adapted high-resolution Western blotting to map the cleavage site(s) in multiple steps: (i) U1-70K and N40K proteins were demonstrated to share the same N-termini by MS; (ii) our high coverage MS analysis identified no major modification in N40K, otherwise the modification might alter protein migration; (iii) we matched N40K with a series of 8 recombinant U1-70K truncated proteins, determining the cleavage site(s) within a small region (Arg300 ± 6 residues). Since most proteases exhibit residue specificity, we considered all possible unique residues in the region (Ser295, Ala299, Arg300, Glu302, and Lys306) to make related recombinant proteins. Finally, these N40K proteins caused substantial degeneration of rat primary hippocampal neurons, suggesting that they were functionally indistinguishable. Our analysis combined multiple approaches for probing proteolytic site(s) in a difficult protein, and the results support that U1-70K cleavage and the N40K fragment may contribute to neuronal toxicity in Alzheimer's disease.

Title: Chronic life stress predicts decreased white matter volume in the prefrontal cortex among healthy older adults

Authors: ***G. L. MORENO**, J. BRUSS, N. L. DENBURG;
Neurol., Univ. of Iowa, Iowa City, IA

Abstract: Previous animal and human research has indicated that stress may have deleterious effects on the brain (Gianaros et al., 2007; Lupien et al., 2009). Surprisingly, several of the brain regions vulnerable to increased levels of stress, such as the hippocampus and prefrontal cortex, are also known to undergo disproportionate decline during normal aging. To gauge the integrity of brain regions involved in the stress response, we investigated whether chronic stress was

predictive of frontal and temporal lobe region volumes in healthy older adults. We hypothesized that older adults who evidenced more chronic stress would have decreased volumes in those brain regions involved in the stress response, namely prefrontal and temporal lobe regions. Structural MRI data and two measures of chronic stress, the UCLA Life Stress Interview (LSI; Hammen et al., 1985) and the Perceived Stress Scale (PSS; Cohen, Kamarck, & Mermelstein, 1983), were collected in 30 healthy, cognitively intact older adults (i.e., persons without overt neurological and psychiatric disease) between the ages of 65 and 90 years. As hypothesized, elevated chronic stress, as measured by both subjective (PSS) and objective (LSI) measures, was predictive of brain volume in temporal and frontal lobe regions, particularly in white matter. Notably, PSS predicted less white matter in the ventromedial prefrontal cortex bilaterally, the orbital gyri bilaterally, the dorsal lateral prefrontal cortex bilaterally, and the left ventrolateral prefrontal cortex. Our results suggest that elevated chronic stress is associated with a decrease in volume of specific brain regions; especially in those that are involved in the stress response and that are thought to be most vulnerable to age-related decline. These reductions in volume in relation to neuropsychological and cognitive measures, specifically in cognitive domains that are mediated by prefrontal and temporal lobe regions, will also be discussed.

Title: Elderly with high aerobic fitness maintain executive function predominantly by recruiting the primary hemisphere in the prefrontal cortex: A neuroimaging study with fNIRS

Authors: *K. HYODO[1], I. DAN[2], K. SUWABE[1], K. BYUN[1], G. OCHI[1], H. SOYA[1];
[1]Tsukuba Univ., Tsukuba, Japan; [2]Dept. of Integreated Sci., Chuo Univ., Tokyo, Japan

Abstract: Elderly adults with high aerobic fitness are known to have high executive function associated with the prefrontal cortex (PFC). Despite various research, the underlying neural mechanism for this remains unclear. With aging, pre-frontal activation during executive tasks shifts from predominant activation in the primary hemisphere to bilateral activation (i.e.,

hemispheric asymmetry reduction). Our previous studies have shown left-lateralized prefrontal activation in young adults compared to the bilateral prefrontal activation in elderly adults during color-word matching Stroop tasks (CWST) as observed using functional near infrared spectroscopy (fNIRS) (Hyodo et al., Neurobiol Aging, 2012; Yanagisawa et al., Neuroimage, 2010). Thus, In this study, we aimed to clarify whether the association between higher aerobic fitness and executive function would be mediated by lateralized PFC activity by using mediation analysis.To address this issue, 27 healthy elderly men (mean age 70.3 ± 3.5 years) participated in a graded exercise test using a recumbent ergometer, followed by a computer-based CWST. During the exercise test, respiratory gas was measured and ventilatory threshold (VT) analyzed to measure submaximal aerobic fitness. The CWST consisted of incongruent and neutral conditions, and the difference in reaction times between conditions (incongruent-neutral) was calculated as Stroop interference to determine executive control. Multichannel fNIRS was attached to the forehead during the CWST to measure task-related prefrontal activation. As the dorsolateral prefrontal cortex (DLPFC) is mainly associated with the CWST, this region was focused upon, and left-lateralized DLPFC activity (Left DLPFC - Right DLPFC) was calculated to evaluate activation laterality. Partial correlation analyses revealed that there was a significant relationship among higher VT, shorter Stroop interference time and greater left-lateralized DLPFC activity, with controlling age and years of education as covariates. Hierarchical linear regression and non-parametrical mediation analyses showed that the left-lateralized activity in the DLPFC significantly mediated the relationship between VT and task performance. CONCLUSION:Our results provide evidence validating the hypothesis that the elderly with high aerobic fitness maintain executive function predominantly by recruiting the primary hemisphere. Thus, lateralized brain activation during cognitive test could be a physiological indication for hyper executive functions.

Title: The effects of fitness on subcortical brain anatomy and cognition across the life span

Authors: *M. A. FLETCHER[1], K. A. LOW[1], C. TAN[1], T. KONG[1], B. ZIMMERMAN[1], N. SCHNEIDER-GARCES[1], K. E. MATHEWSON[2], C. R. BURTON[1], B. P. SUTTON[1], A. M. CHIARELLI[1], E. MACLIN[1], G. GRATTON[1], M. FABIANI[1];
[1]Beckman Institute, Univ. of Illinois, Urbana, IL; [2]Dept. of Psychology, Univ. of Alberta, Edmonton, AB, Canada

Abstract: Recent evidence suggests that fitness leads to cognitive and anatomical preservation, although the majority of these studies have examined these effects in adults over the age sixty (Voss et al., 2013). Here we examined the associations between age and fitness on the subcortical anatomy and cognitive performance of healthy middle-aged adults (N=31, ages 18-62). Participants underwent structural Magnetic Resonance Imaging and a battery of neuropsychological tests. Subcortical anatomy (normalized to estimated intracranial volume) was quantified using FreeSurfer©. Subjects were classified as highly active if they had a physical activity score (PAS) of four or five indicating that they participated in aerobic exercise for more than an hour each week (Jurca et al., 2005). Our results indicate that age has a significant impact on both brain anatomy and cognition. Specifically, age was associated with significant loss in most of the subcortical volumes studied. The largest volumetric losses with age were found in the nucleus accumbens, and in the mid-anterior and central corpus callosum. Running averages were suggestive of non-linear volumetric losses for the amygdala and nucleus accumbens, with the largest declines occurring after age 38 in these regions. Age-related volumetric losses were also examined separately for subjects reporting varying levels of weekly physical activity. Individuals with high and low PAS scores showed similar rates of atrophy in the hippocampus and basal ganglia. Subjects reporting higher weekly physical activity showed larger volumes in the anterior corpus callosum across the age range investigated in our study. The effects of age and physical activity on cognition were also examined. With age, participants experienced a large drop in performance on the operation span task and Raven's Progressive Matrices, and also committed more perseverative errors on the Wisconsin Card Sorting Task. In line with other studies, Shipley's Vocabulary scores increased with age. A two sided t-test (*$p<.05$) demonstrated that subjects with higher PAS had significantly higher scores on the CFL test, indicative of higher verbal fluency. These data supports the claim that fitness effects are already evident at a young age, and that fitness may provide a reserve against age-related volumetric and cognitive losses.

Title: Adult age differences in "online" learning from positive and negative probabilistic feedback

Authors: *R. B. SOJITRA, J. R. SIMON, M. A. GLUCK;
Ctr. for Mol. and Behavioral Neurosci., Gluck Lab. (Rutgers University), Newark, NJ

Abstract: Learning from probabilistic feedback requires using unreliable feedback (both positive and negative) from past experiences to inform future decisions. In general, studies show that older adults can learn from probabilistic feedback, but to a lesser degree than younger adults. However, previous conclusions may be limited for two main reasons. First, most task structures have not separated positive from negative feedback learning and therefore, it is not clear whether performance deficits are specific to one type of feedback. Second, other tasks rely on delayed tests to measure learning, and as a consequence, it is difficult to know whether the ability to learn declines with age or the ability to apply that learned information. To address these limitations, this study tested younger and older adults on a probabilistic category-learning task that dissociates positive (reward) from negative (punishment) feedback learning. Stimuli in the positive feedback condition gave either positive feedback or no feedback and stimuli in the negative feedback condition gave either no feedback or negative feedback; each type of feedback was reliable on 90% of trials. We examined "online" learning, as it was occurring, and found that older adults did learn from probabilistic feedback in both conditions, but not as well as younger adults. In addition, both age groups performed significantly better in the negative compared to the positive feedback condition. These results challenge the view that learning from negative feedback is preserved in healthy aging. Moreover, while previous work has shown that younger adults *prefer* positive feedback and older adults negative feedback, here we show that both age groups are better at *learning* from negative than from positive feedback.

Title: Cognitive performance in healthy elderly subjects with excess of electroencephalographic theta activity

Authors: *S. A. CASTRO-CHAVIRA[1], T. FERNÁNDEZ[1], C. ALATORRE[1], S. SÁNCHEZ MOGUEL[1], M. RINCÓN[2], T. HARMONY[1], J. SANDOVAL[1], M. ESPINO[3];
[1]Neurobiología Conductual y Cognitiva, Neurobiol Inst. UNAM, Querétaro, Mexico; [2]Facultad de Psicología, Univ. Autónoma de Querétaro, Querétaro, Mexico; [3]Ctr. Estatal de Salud Mental, Secretaría de Salud del Estado de Querétaro, Querétaro, Mexico

Abstract: Cognitive decline in elderly subjects can be predicted by the excess of electroencephalographic theta activity 7-10 years before its presentation (Prichep et al, 2006). NEUROPSI is a neuropsychological test normalized for the Mexican population that thoroughly explores cognitive functions for neuropsychological deficits. Twenty eight right-handed healthy subjects older than 60 years were selected. They had no neurological or psychiatric disorders. Their blood count, cholesterol test, triglycerides, glucose and TSH levels were normal, and their IQ was superior to 85. Their EEGs were recorded in the 19 leads of the 10-20 International System, considering the short-circuited earlobes as reference. Z values of Absolute Power corrected by Geometric Power were computed to separate the subjects into two groups: excess of theta (ET; n = 16) or theta between normal limits (NT; n = 12). Differences between groups in the NEUROPSI scores were analyzed using multivariate non-parametric permutation analyses (Galán et al., 1998). There were no differences between groups in the sepatared cognitive processes (attention, memory coding or retrieval, language, reading comprehension, writing, or executive functions). However, the ET group showed a significantly lower performance in the total score of the NEUROPSI test ($p = 0.05$). There were no significant differences between subjects with EEG risk to develop cognitive decline (ET) and without EEG risk (NT) for any of the individual cognitive processes evaluated. Furthermore, the subjects in both groups showed no cognitive deterioration. Even though the subjects with excessive EEG theta activity did not

express cognitive deterioration, their performance was poorer than the performance of the subjects with normal EEG.

Title: Impaired learning in multidimensional environments in healthy human aging

Authors: *R. DANIEL[1], A. RADULESCU[2], Y. NIV[2];
[2]Princeton Neurosci. Inst., [1]Princeton Univ., Princeton, NJ

Abstract: To flexibly and efficiently behave in rich multidimensional environments, we need to learn to focus only on the dimensions that are currently predictive of reward. This ability is relies on two core mechanisms: learning from trial and error, and selective attention. Unfortunately, both of these mechanisms are impaired in healthy human aging. We present an experiment in which we aimed to develop a precise understanding of the computational and neural mechanisms underlying the interaction between learning and attention in older adults, and how these differ from the mechanisms employed by younger adults. To this end, we acquired behavioral and fMRI data from 23 healthy older adults (M = 70.0; range = 61-80), and an equal number of young controls (M = 22.7; range = 18-35). Participants performed a bandit task in which they chose one of three stimuli that differed on three dimensions. Only one of those dimensions was predictive of reward within a given game. The task was presented in two variants: in the "simple learning" variant participants were informed about the relevant dimension. In the "attention learning" variant they had to learn this information from trial and error. Older adults showed worse performance on both tasks, with a trend towards an increased impairment in the attention learning variant. Neurally, in the attention learning task younger adults showed a correlation

between the width of the attentional filter as predicted by our reinforcement learning model, and activation in the right temporo-parietal junction (TPJ)/angular gyrus, an area that has been implicated in filtering task-irrelevant information. Older adults failed to show this correlation. We propose that overall lower task performance in older adults might be due to a failure to selectively engage TPJ during the learning process, resulting either in an impaired ability to search for the relevant dimension early in learning, or an impairment in suppressing task-irrelevant information later on, or both.

Title: Emotional recognition memory for faces and words in healthy young and older adults

Authors: ***C. SUMIDA**[1], L. J. ROTBLATT[1], S. N. GLUHM[1], D. M. SCHIEHSER[2,3], J. V. FILOTEO[2,3], P. E. GILBERT[1,4];
[1]Psychology, San Diego State Univ., San Diego, CA; [2]Dept. of Psychiatry, Univ. of California San Diego, San Diego, CA; [3]Veterans Admin. San Diego Healthcare Syst., San Diego, CA; [4]San Diego State University/University of California San Diego Joint Doctoral Program in Clin. Psychology, San Diego, CA

Abstract: Emotional enhancement of memory is a phenomenon whereby emotional information is remembered better than neutral information. Young adults have been reported to demonstrate a "negativity effect", such that negative stimuli are remembered better than positive stimuli. Older adults have been reported to show a "positivity effect", in which positive stimuli are remembered better than negative or neutral stimuli. These age-related differences in the enhancement of emotional memory comprise the Socioemotional Selectivity Theory. Age-related differences in emotional enhancement of memory may stem from functional and structural changes in the amygdala. However, some studies debate this theory and have shown that the pattern of memory

for emotional stimuli is similar in young and older adults. As a result, additional studies are needed to better understand the effect of emotion on recognition memory. The present study measured recognition memory for neutral, positive, and negative words and facial expressions in healthy young and older adults using d' as a sensitivity/discriminability index. The hit rate and false alarm rate are used to calculate d', whereby larger d' values indicate a better ability to discriminate "new" and "old" stimuli presented in a recognition memory test. During the study phase of the present task, participants were shown a series of either 24 target faces or 24 target words one at a time on a computer screen and were asked to rate the intensity of the stimuli on a seven-point Likert scale. For the recognition phase of each task, the participant was presented with the target faces or words amongst distractors and was asked to indicate if they had seen the faces or words during the study phase. Target and distractor faces were matched for valence, gender, approximate age, ethnicity, and facial hair. Target and distractor words were matched for valence, emotionality, imagery, concreteness, and frequency. Each participant completed each task, and the presentation of the faces task and words task was counterbalanced across participants. We found that d' scores were significantly higher ($p < .05$) in young adults compared to older adults for faces and words. However, no emotional enhancement was found in recognition memory for faces or words in either group. In contrast to the Socioemotional Selectivity Theory, we did not find a "negativity effect" in young adults or a "positivity effect" in older adults. However, the present findings are in accordance with other studies reporting that memory for emotional stimuli is similar in young and older adults.

Title: Effects of brain iron concentration on neural activity and memory performance in normal aging

Authors: *G. KALPOUZOS[1], B. GARZÓN[1], R. SITNIKOV[2], C. HEILAND[1], J. PERSSON[1], L. BÄCKMAN[1];
[1]Aging Res. Center, Karolinska Inst., Stockholm, Sweden; [2]MRI Res. Center, Clin. Neuroscience, Karolinska Inst., Stockholm, Sweden

Abstract: In the brain, non heme iron, stored in ferritin protein, is a fundamental mineral for cellular metabolism. However, free iron is highly toxic, inducing oxidative stress, cellular dysfunction, and cell death. Increased iron concentration has been shown in normal aging, notably in basal ganglia, and linked to lower cognitive performance. In the ongoing IRON project, we investigate potential associations between iron loading, brain activity measured with functional MRI, and cognition in 40 healthy adults aged 30 to 80 years old. The major aim is to examine whether higher iron loading can account for age-related differences in brain activity and cognition. Brain data are collected on a 3.0T GE MR scanner. A multiecho Gradient Recalled Echo (GRE) sequence with 8 echo times is used to calculate the mean transverse relaxation rate R2*, which has been shown to correlate strongly with iron concentration in brain tissue. In preliminary analyses including 12 men and women (age range = 34-72 years), we related age, R2* in basal ganglia, activity during a motor-imagery memory task where participants imagine and encode actions (e.g., playing tennis), and offline recall performance of the actions. Mean R2* values for caudate, putamen, and pallidum were determined. Regarding the functional MRI data, imagery blocks were contrasted against control blocks. R2* (reflecting increased iron concentration) increased with increasing age in right caudate and bilateral putamen ($.63 < r < .73$, $p \leq .01$), the relationship being marginal in left caudate ($r = .43$, $p = .08$). During the task, brain activity decreased with advancing age in caudate and putamen bilaterally ($r < -.71$, $p \leq .005$). Activity in these regions was correlated with the number of recalled actions ($r > .52$, $p \leq .04$) and with R2*, where higher values were related to lower activity, notably in bilateral putamen ($-.75 < r < -.62$, $p < .01$), and marginally in left caudate ($r = -.47$, $p = .06$). Interestingly, when controlling for age, the correlation in right putamen did not completely disappear ($r = -.47$, $p = .07$). Older subjects recalled fewer actions ($r = -.50$, $p = .05$), and R2* in left caudate and right putamen was negatively linked to recall performance ($r < -.50$, $p \leq .05$); when controlling for age, the correlation in left caudate was marginally significant ($r = -.47$, $p = .07$). These preliminary findings suggest an effect of increased age-related iron concentration in basal ganglia on local brain activity during cognitive task performance and on memory, and also a possible age-independent iron-activity-cognition relationship.

Title: Long-term memory guided attention in healthy ageing

Authors: *G. SALVATO[1], E. Z. PATAI[2], A. C. NOBRE[2];
[1]Dept. of Brain and Behavioural Sci., Univ. of Pavia, Pavia, Italy; [2]Dept. of Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom

Abstract: Recent progress in the study of cognitive decline in ageing has shown that the profile of the elderly is not consistent. Regarding implicit memory, contradicting accounts of the ability to utilize learned associations in ageing have been reported, with some groups showing intact cueing of attention through implicitly learned spatial configurations (contextual cueing - CC) (Howard, Howard, Dennis, Yankovich, & Vaidya, 2004), while others report deficits in CC with spared sequence learning (Smyth & Shanks, 2011). Additionally in the field of attention research, it has been shown that the elderly have an inability to prioritize information through endogenous (top-down) control and consequently to suppress distracting information (Bollinger, Rubens, Masangkay, Kalkstein, & Gazzaley, 2011; Gazzaley & D'Esposito, 2007; Gazzaley et al., 2008; Gazzaley, Cooney, Rissman, & D'Esposito, 2005; Zanto et al., 2011). Using a paradigm building on long-term memory guided attentional orienting, we investigated the ability of elderly participants to utilize encoded spatial locations of objects within complex scenes to deploy attention in order to optimize behavioural performance in a perceptual detection task. Our results show that over learning, older participants become faster at finding relevant targets, indicating a sparing of item-context association learning (linear contrast $F(1,17)= 156.6$; $p < .001$). Additionally, their memory for target locations and target identity was significantly above chance on a subsequent memory test ($p < .001$), and their self-rated confidence in their response is a valid reflection on their performance, indicating that these memories may be explicit in nature (linear contrast $F(1,17)= 403.2$; $p < .001$). Crucially, we found a significant effect of memory validity in the attention task: items that appeared in previously learned locations had faster RTs than items appearing in a novel location ($F(1,17)= 21.1$; $p < .001$). These results suggest that older adults are able to a) form robust memories of item-context associations, and b) exploit this information as top-down attentional cues. Our findings contribute to the understanding of memory and attention processes during healthy ageing, as well as the

interaction between these two systems, reflecting a non-uniform ability to apply top-down attentional cues depending on the source of the bias. Further research is needed to disentangle the contribution of implicit as opposed to explicit memory in this effect, as well as potential automaticity with which endogenous, long-term memory cues may incur a benefit on attentional guidance over explicitly directed top-down instructions.

Title: Investigating the neural correlates of spatial and temporal context memory across the adult lifespan

Authors: *E. ANKUDOWICH[1], D. KWON[1], D. MAILLET[1], S. PASVANIS[2], A. SWIERKOT[1], L. WALLACE[1], M. N. RAJAH[1];

Abstract: Healthy aging is associated with greater reductions in memory for context, or source, information compared to item memory. Previous functional neuroimaging studies have focused primarily on context memory in older compared to young adults, and have reported group differences in prefrontal and posterior visual areas during both encoding and retrieval. Although volumetric studies have reported decreases in prefrontal volume as early as midlife, little is known about the functional changes of prefrontal regions supporting context memory in middle-aged compared to young and older adults. The current study aimed to investigate group differences and similarities in the neural correlates of context memory across the adult lifespan. Using functional magnetic resonance imaging (fMRI), we compared young (20-35; n=27), middle-aged (40-56; n=22), and older (60-76; n=31) adults on context memory tests for the spatial and temporal details of face stimuli at both encoding and retrieval. Participants completed two versions of the task (easy and difficult) in order to characterize performance effects vs. age effects. Behaviorally, a Task (spatial, temporal) x Difficulty (easy, difficult) x Group (young,

middle, older) ANOVA yielded a significant Task x Group interaction on retrieval accuracy ($p<.05$). Although young adults outperformed both middle-aged and older adults on the temporal task, they performed no differently from the middle-aged adults on the spatial task. In addition, middle-aged adults outperformed older adults on the spatial task but not on the temporal task. We used multivariate partial least squares (PLS) analysis to identify whole-brain patterns of fMRI activity associated with successful context encoding and retrieval across age groups. We found age-related differences in lateral prefrontal recruitment during successful context encoding and retrieval, regardless of task type. We also found age-related changes in posterior cortical regions during encoding and retrieval. Our results suggest that age-related changes in the neural correlates of episodic memory occur as early as midlife.

Title: Effects of cognitive reserve and the BDNF Val66Met polymorphism on episodic memory, working memory, executive function and language processing in healthy older adults

Authors: *J. C. VICKERS[1], D. WARD[2], K. STUART[2], N. SAUNDERS[2], M. SUMMERS[2]; [1]Sch. of Med., [2]Wicking Dementia Res. and Educ. Ctr., Univ. of Tasmania, Hobart, Australia

Abstract: Objective. The Tasmanian Healthy Brain Project (THBP) is a long-term, longitudinal investigation into whether later-life tertiary education reduces ageing-related cognitive alterations and/or provides protection from dementia. Cognitive reserve (CR) has also been proposed to be protective for dementia, and brain derived neurotrophic factor (BDNF) has been implicated as having a significant role in mediating the effects of environmental enrichments in experimental studies. Method. We have investigated the THBP cohort at baseline to determine whether common allelic variation in BDNF Val66Met and APOE interact with CR to produce

cognitive outcomes. This study involved 433 participants (66.7% female), aged 50-79 years (M = 62.16, SD = 6.81). A measure of CR was established through a principal components analysis (PCA) of THBP study variables (WTAR IQ, prior education and the Lifetime of Experiences Questionnaire) previously shown to contribute to the construct. Composite variables of episodic memory, working memory, executive function and language processing were also derived through PCA, with the component accounting for the largest proportion of variance retained to represent that domain. Multivariate regression analyses then assessed the main and interaction effects for predictors: age; CR; APOE; and BDNF, for each cognitive domain separately. Results. This analysis demonstrated that: (1) CR was positively associated with each cognitive domain ($p < .05$) while age was negatively associated with each cognitive domain ($p < .05$), excluding language processing, (2) individual APOE and BDNF predictors were not associated with performance in any cognitive domain, (3) BDNF moderated the association between CR and executive function performance, in that BDNF Met carriers had a significantly reduced association when compared to Val homozygotes ($p < .05$). Conclusions. This study has shown that CR is associated with cognitive function in healthy older adults. In addition, BDNF Met carriers demonstrated a reduced ability to generate or access CR resources when compared to BDNF Met non-carriers with respect to executive function.

Title: Correlates of brain anatomy and cardiac function in healthy aging and atherosclerosis in mice

Authors: ***P. POULIOT**[1,2], P. AVTI[2], C. BOWEN[3], A. CASTONGUAY[1], M. TABATABEI[1], M. MOEINI[1], É. THORIN[4], F. LESAGE[1];

Abstract: Healthy aging is accompanied by broad and subtle anatomical and functional decline. Few MRI studies have correlated brain health measures with cardiovascular health measures in the same animals. 3 cohorts of mice (n=10 per group, age 4, 12 and 24 months) on a reduced-fat diet from the same C57/B6 lineage were imaged at 7T. Two LDLr−/−; hApoB+/+ (ATX) mice (aged 12 and 14 months), a mouse model that naturally develops atherosclerosis, were also scanned. Blood pressures were measured on 5 consecutive days and averaged. MRI scanning session durations were kept under about an hour with heart and brain scans done on different days. Brain scans consisted of 3D balanced TFISP with TR/TE=4.4/2.2 ms with 140 um isotropic resolution giving T2/T1 contrast, lasting 40 minutes. The cardiac scans were long axis (1 slice) and short axis (10 slices) CINEs with 16 frames, 156 um in plane resolution and 800 um thickness, lasting 35-40 minutes. Heart CINE scans were quantified with Segment (Medviso) to obtain ejection fraction and cardiac output. Brain scans were analyzed with Advanced Normalization Tools (ANTs). For each mouse, a brain mask was created; 16 TFISP scans were sum-of-square reconstructed and realigned, then N4 corrected and Otsu segmented into 3 tissue types. The cortical thickness was then estimated at each voxel. Its average value above the genu corpus callosum was extracted and was also measured graphically directly on anatomical images. Mean cortical thickness was 1.88 ± 0.09 mm, with no significant difference between groups while cortical thickness of the ATX mice was 2.0 and 3.6 sigma smaller. No significant correlation was found between cortical thickness and blood pressure.

Title: Relationships between longitudinal changes in functional brain activation, white matter integrity and cognitive performance in healthy older adults

Authors: *J. G. HAKUN, Z. ZHU, N. JOHNSON, B. T. GOLD;
Anat. & Neurobio., Univ. of Kentucky, Lexington, KY

Abstract: Three major neurocognitive variables affected by aging are prefrontal cortex (PFC) functional brain activation, white matter (WM) microstructural integrity, and cognitive task performance. However, our understanding of the inter-relationships between these neurocognitive factors has been inferred almost entirely from cross-sectional comparisons between young and older adults. Here we used a multimodal imaging approach to explore longitudinal change in PFC activation, PFC WM integrity, and task switching performance in eighteen healthy older adults. In support of a neural efficiency model of neurocognitive aging, we found that longitudinal increases in PFC activation were associated with longitudinal decreases in commissural microstructural integrity and increased response latencies during task switching. These findings provide the first evidence of correlated change in brain microstructural integrity and task-related PFC functional recruitment. In addition, the observed correlation between increased functional recruitment and increased response latencies serves as a challenge to compensation accounts of PFC over-recruitment in older adults. Overall, our study reveals a tight connection between brain structural integrity and functional activation that holds significant implications for brain imaging studies of cognition.

Title: White-matter integrity and cognitive flexibility in normal aging

Authors: *D. RINKER[1,2], C. FENNEMA-NOTESTINE[3], M. S. PANIZZON[3], D. J. HAGLER[4], C. FRANZ[3], P. M. THOMPSON[2], A. M. DALE[4], W. S. KREMEN[3];
[1]Univ. of Southern California, West Hollywood, CA; [2]Inst. for Neuroimaging and Informatics, USC, Los Angeles, CA; [3]Psychiatry, [4]Radiology, UCSD, La Jolla, CA

Abstract: The ability to switch between different attentional states is known as cognitive flexibility, and is a fundamental indicator of neurological health. As such, it is ubiquitously found in neuropsychological test batteries. Poor performance is associated with cognitive impairments, learning problems and can be an indicator of various diseases including Alzheimer's. Functional imaging has allowed researchers to study set-shifting *in vivo*, building on an existing body of lesion studies (Stuss & Levine, 2002). Most of the literature implicates the dorsolateral prefrontal cortex specifically superior and middle frontal gyri as essential in set-shifting (Zakzanis, et al., 2005). Many of these regions are important for sub-components of set-shifting, such as executive processing speed, motor tasks and visual scanning. Still, the neural recruitment of these diverse regions would suggest that a higher-level neural circuit contributes to set-shifting function. Association tracts in white matter (WM) facilitate neural communication between regions, forming functional neural circuits. Individual differences in WM integrity may explain some of the variance in corresponding cognitive tasks (Perry et al., 2009). Here we examined (1) set shifting, and (2) its role in cognitive and neurobiological aging. DTI and T1 data were obtained at 1.5T from 342 men (average age = 55.8 SD +/- 2.2), who underwent neuropsychological testing as part of the Vietnam Era Twin Study of Aging (Kremen, 2006). Images were processed with FreeSurfer and probabilistic tractography to define WM tracts. Time to completion on the shifting component of the Delis-Kaplan Executive Function System Trail-Making Test adjusted for sequencing components was used to assess cognitive flexibility, controlling for overall processing speed. FA for several tracts was significantly correlated with task performance ($P<0.05$), including: left fornix, bilateral inferior longitudinal fasciculus (ILF), and bilateral inferior occipitofrontal fasciculus (IFOF). MD was also was correlated significantly with task performance ($P<0.05$), in the bilateral cingulum, left uncinate, bilateral ILF, bilateral IFOF and left superior longitudinal fasciculus. These results mostly fit our a priori circuit hypothesis and were in the expected direction. While cognitive flexibility is often thought of as a frontal lobe function, our results suggest widespread networks are involved, and also give may indicate key tracts mediating the task.

Title: The operation of control devices in old age: A new approach to assess motor and cognitive performance during realistic working scenarios

Authors: *M. DALECKI[1], F. STEINBERG[2], M. KALICINSKI[3], O. BOCK[3];
[1]Sch. of Kinesiology & Hlth. Sci., York Univ., Toronto, ON, Canada; [2]Inst. of Sport Science, Dept. of Psychology, Johannes Guttenberg-University, Mainz, Germany; [3]Inst. of Physiol. and Anat., German Sport Univ., Cologne, Germany

Abstract: Cognitive and motor functions are known to degrade with advancing age, but it is unclear how these deficits - revealed by standardized laboratory tests - affect seniors' performance in everyday life. Unlike laboratory tests, realistic tasks include complex responses to complex environmental inputs, executed under varying levels of stress. The present study therefore compares the performance of young and older subjects in a complex process-control task.
We hypothesized that the elderly perform less well, and that their impairment is associated with cognitive and motor decline.
12 younger (mean age: 25 years) and 12 elderly subjects (mean age: 65 years) participated. They sat in front of a screen with multiple displays next to a working panel with multiple knobs and levers. Their task was to operate a simulated power plant by adjusting parameters such as temperature, fuel and power, for which they used the knobs and levers. Their earnings (proceeds minus costs) were presented continuously on the screen. Twenty-six work episodes of twenty seconds each alternated with short rest breaks. Gaze time on the screen and on the panel was recorded by an eye tracker (Tobii T60), and maximum force production on the knobs by force sensors (ATI Nano). Stress level was assessed by established questionnaires (NASA TLX), and

cognitive abilities (concentration, attention) by PC-based tests.
If compared to young subjects, elderly participants generated earnings at a lower rate (-73%), directed their gaze longer to the panel (+75%) and - accordingly - shorter at the screen, and applied higher grip forces to the knobs. Perceived stress didn't differ between age groups, but cognitive ability scores were significantly smaller in the elderly (-45%). There was a significant correlation between cognitive scores and magnitude of earnings.
We conclude that seniors' performance on a realistic process-control task is substantially degraded, possibly because elderly persons must focus more on their responses, thus missing important information presented on the screen. The deficit is not paralleled by an increased subjective stress level.

Title: Effects of aging on mnemonic discrimination of emotional information

Authors: *S. L. LEAL[1], M. A. YASSA[2];
[1]Psychological & Brain Sci., Johns Hopkins Univ., Baltimore, MD; [2]Neurobio. of Learning and Memory, Univ. of California, Irvine, Irvine, CA

Abstract: Episodic memory loss is one of the hallmarks of age-related cognitive decline and a major symptom of Alzheimer's disease. The persistence and strength of memories is determined by modulatory factors such as emotional arousal. Whether emotional memories are preserved with age or if these memories are just as susceptible to loss and forgetting is not well understood. We have recently shown that emotion alters how similar memories are stored using non-overlapping representations (i.e. pattern separation), in an emotional mnemonic discrimination task. Here, we extend this work to testing young and older adults at two time-points

(immediately after encoding and 24 hours later). Overall, older adults performed worse than young adults, a memory deficit that was not secondary to perceptual or attentional deficits. When tested immediately after the encoding session, older adults were impaired on neutral target recognition but intact on emotional target recognition. We also found that a pattern we previously reported in young adults (reduced emotional compared to neutral discrimination of similar items) was reversed in older adults. When tested after 24 hours, young adults exhibited less forgetting of emotional targets compared to neutral, while older adults exhibited more forgetting of emotional targets. Finally, discrimination of highly similar positive items was preserved in older adults. These results suggest that emotional modulation of memory interacts with age in a complex manner such that the emotion-induced memory trade-off reported in young adults is reversed in older adults. These findings shed light on how emotion and memory interact in the aging brain.

Abstract: More than 5.4 million of Americans suffer from AD. In Panama the geriatric population is gradually increasing as in the rest of the world. According to the census (2010), 7.4 % of Panamanian population is over 64 years of age. Dementia is among the diseases that primarily affect the elderly population. It is estimated that the rate of dementia increases with the increase in the rate of aging. Alzheimer's disease (AD) is the most common form of dementia. Among the primary risk factors for development of AD in Hispanics/Latinos are (1) age, life expectancy will be around 87 years by 2050, (2) low educational level and (3) vascular diseases together with high incidence of diabetes mellitus and other chronic diseases. The peculiar

characteristic about the Hispanics/Latinos is that they represent a wide mix of national origins, and the genetic complexity is greater compared with other ethnicities. We are conducting a biomarker based study to identify the risk and protective factors associated with cognitive function during aging in a sample of Panamanians over 64 years of age. To date, there are no published epidemiological surveys of aged individuals in Panama, placing our country among the least prepared to handle the boom in aging that is taking place. We report the results of a cross-sectional analysis of aged individuals (N=154). The following measures were obtained: (1) a medical history to identify diabetes mellitus, atherosclerosis, hypertension, and obesity, (2) blood samples for a biomarker profile (serum, plasma, and DNA), (3) cognitive function (Mini Mental State Examination, TMT A and B, and clock test), (4) muscle strength (dynamometer), (5) functional status (basic activities of daily living), (6) depression, and (7) telomere length measures. Preliminary results indicate that 63% of the sample shows no sign of dementia, 12% meet criteria for AD, 8% for mild cognitive impairment, 9% for vascular dementia, and 9% in other classifications. Also, 36% of the sample evidenced moderate to severe deficits in cognitive function according to the MMSE. Cognitive function (MMSE) and functionality (ABVD) showed a negative correlation. Lastly, 16% of the sample met the criteria for depression. This study is a first attempt to assess the factors associated with aging in Panama. Our aim is to establish the basis for future prospective studies.

Title: Dietary macronutrient composition is differentially associated with gray matter volumes of cortical and limbic regions in young and older adults

Authors: *S.-Y. YUAN[1], Y.-Z. TU[2], P.-Y. WANG[1], J. O. S. GOH[1,3,4];

Abstract: Energy and molecular substrates from dietary intake are important factors for neuronal structural development and function over the lifespan. There is limited information, however, on how human dietary macronutrient levels are associated with brain structure and function, particularly for those not affected by obesity or other dietary dysfunctions. We hypothesized that macronutrient intake levels in humans should have measurable associations with gray matter volume and cognitive ability even in individuals maintaining healthy dietary habits. Importantly, dietary-brain associations may differ across age due to differential nutritional requirements. 32 young (mean age (SD) = 23.3 (2.1) yrs) and 21 older (mean age (SD) = 70.2 (4.8) yrs) Taiwanese adults participated in (a) systematic dietary monitoring over 3 to 30 days, (b) neuropsychological tests of cognitive abilities, and (c) T1-weighted magnetic resonance imaging (MRI) of gray matter volumes (256*256 mm in-plane field of view, 1*1*1 mm3 voxels, TR = 2 s, inversion time = 0.9 s, flip angle = 9°). Participants were physically healthy at time of testing with no dietary dysfunction or neurocognitive counter-indications. Individual intake levels of calorie, carbohydrates, lipids, and proteins were scored based on the local food and drug administration database. T1 images were analyzed using Freesurfer software ver. 5.2.0 to parcellate regional gray matter volumes across the whole brain. We found no age differences in dietary macronutrient levels in this relatively healthy sample. Higher calorie and carbohydrate intake correlated with smaller orbitofrontal volumes in younger adults but larger volumes in older adults. By contrast, higher carbohydrate, protein, and lipid intake correlated with larger volumes in medial temporal and striatal regions in young adults, but smaller volumes in older adults. Adjusting for calorie intake revealed that higher percentages of carbohydrate levels correlated with smaller medial temporal and striatal volumes in young adults but either with larger or no difference in volumes in older adults. Higher percentages of protein correlated with larger hippocampal volumes in young adults but smaller volumes in older adults. Across these diet-sensitive regions, there were mixed correlations between brain volume and cognitive performances in older adults and minimal associations with young adult performances. Our findings demonstrate age-related differences in the association between dietary macronutrient intake and gray matter regional volumes. Age-related changes in nutritional requirements may modulate the effect of diet on brain and cognition.

Title: Locus coeruleus optoICSS: A role for selective noradrenergic activation in reinforcement

Authors: *K. SCHMIDT[1], C. KOLLER[1], E. VAZEY[2], I. WITTEN[3], C. BASS[4], G. ASTON-JONES[2], K. DEISSEROTH[5], D. WEINSHENKER[1];

Abstract: It is generally accepted that dopamine is the primary neurotransmitter of the brain's reward system. While accumulating data indicates that norepinephrine (NE) may also be important for some forms of reward and reinforcement, there are conflicting reports from the literature. For example, some groups found that electrical stimulation of the noradrenergic locus coeruleus (LC) could maintain operant behaviors, while others obtained the opposite result. Because these intracranial self-stimulation (ICSS) studies were limited by issues of electrode placement, could not discriminate between stimulation of LC cell bodies or fibers of passage, and likely resulted in collateral stimulation of non-noradrenergic cells in the area, a clear interpretation of these studies is elusive. We are taking an optogenetic approach to overcome these technical obstacles and conclusively determine how the LC fits into the brain's reward circuitry and whether noradrenergic activity can function as a reinforcer. We set out to use optogenetic techniques to selectively express channelrhodopsin (ChR2) in noradrenergic cell groups and assess the effects of their activation as a consequence of lever pressing behavior. We have tested the selective expression of ChR2 in the LC using two different viral systems: a Cre-dependent AAV-DIO in TH:Cre transgenic rats and a lentivirus driven by an LC-specific phox2b-dependent PRSx8 promoter. Because the PRSx8 had stronger expression in the LC, we have been using this system for our behavioral experiments. Preliminary results suggest that optogenetic stimulation of the LC can serve as a reinforcer to maintain lever-pressing behavior, implicating this noradrenergic nucleus as a component of the brain's reward system.

Title: The role of BLA rapid glutamate signaling in value-based decision-making

Authors: *M. MALVAEZ[1], A. M. YORITA[2], L. FENG[2], H. G. MONBOUQUETTE[2], K. M. WASSUM[1,3];
[1]Psychology, [2]Chem. Engin., UCLA, Los Angeles, CA; [3]Brain Res. Institute, UCLA, Los Angeles, CA

Abstract: Reward-seeking decisions are heavily controlled by the incentive value (i.e., desirability) of the reward they attain. This incentive value is acquired and continually updated through the process of instrumental incentive learning such that it tends to reflect the emotional response elicited during the most recent reward experience. Although the basolateral amygdala (BLA) has been implicated in the encoding and use of reward value information to guide decisions, the neurotransmitter processes within this structure mediating value-guided reward-seeking decisions are not well characterized. Recently, using a glutamate biosensor technology, we demonstrated a relationship between rapid BLA glutamate signaling and reward seeking; the frequency of rapid glutamate release events increases when rats are engaged in reward-seeking actions and the occurrence of these events positively predicts reward-seeking behavior. However, it remains unknown how these signals relate to the decision-making process and with which specific aspects of reward seeking they are associated. Therefore, we evaluated the hypothesis that transient glutamate release in the BLA tracks changes in reward value important for value-guided decisions. To examine the role of BLA rapid glutamate signaling in value-guided reward seeking, we used electroenzymatic biosensors to make near-real time measurements of BLA glutamate concentration changes during an incentive learning experience

and during the use of this updated information to guide reward-seeking decisions. We have found that BLA glutamate transient frequency is elevated during the experience of the reward in a novel, hungry state, but not during reward experience in the sated, control state. Moreover, the BLA glutamate transient frequency tracked reward seeking following instrumental incentive learning. These preliminary data suggest rapid BLA glutamate signaling may relate to the reward evaluation process that drive value-based reward seeking decisions.

Title: NMDA receptor regulation of prediction error in mice: Relevance for psychosis

Authors: *C. A. GIANESSI[1], S. L. QUICK[2], P. R. CORLETT[2], J. R. TAYLOR[2];
[1]Yale Interdepartmental Neurosci. Program, New Haven, CT; [2]Psychiatry, Yale Univ., New Haven, CT

Abstract: One hypothesis about the underlying mechanism of psychosis is that psychosis is caused by abnormal prediction error signals in the brain (Corlett et al., 2010). Prediction error is the difference between actual and expected events, and this calculation is used to update expectations to more accurately reflect the environment. Inappropriate prediction error signals would drive noticing coincident but random events in the environment, with delusions forming to explain the salience. Inappropriate prediction error related activity has been observed in the brains of first episode psychotic patients and psychiatrically healthy volunteers when administered sub-anesthetic doses of ketamine (Corlett et al., 2006, 2007). Results in human imaging studies are correlational, so the causal neural circuitry underlying anomalous prediction error related activity is not known. Here we used a Kamin blocking task and ketamine

administration in male C57/Bl6J mice to model the neurobiological underpinnings of prediction error deficits in schizophrenia. Blocking is a normal learning phenomenon, in which no learning occurs to redundant information. Animals learn to associate an initially neutral light with delivery of food. The second phase of learning consists of pairings of a novel tone together with the previously learned light with the same food delivery. This results in no learning about the tone. Learning to the tone is blocked because the light is already fully predictive of food, and there is no prediction error. We hypothesized that if ketamine produces altered prediction error signals then aberrant learning would result in an increased Pavlovian approach response to the tone. Preliminary data suggest that blocking is reduced after acute administration of 6 mg/kg (ip) ketamine given before each training session in the second phase of learning. The mice treated with ketamine mice show an increased Pavlovian approach response to the tone compared to animals treated with saline. Blocking is a behavioral and neural biomarker for delusions in human subjects that can be modeled in mice. This model can take full advantage of powerful neuroscience tools like transgenic mice to better understand what might underlie psychosis. This is a prelude to rationally developing novel therapies for psychosis that target the underlying pathophysiology based on empirical data rather than serendipity. These studies were supported by public health service grants: DA11717 (JRT), Kavli Fellowship (CAG), and PEO Scholar Award (CAG).

Title: Neural correlates of contingency in appetitive Pavlovian conditioning

Authors: *H. NASSER[1], J. AVILA[2], K. GILROY[3], P. SERRANO[2], A. R. DELAMATER[4]; [1]Sch. of Psychology, City Univ. of New York, Brooklyn, NY; [2]Hunter College-CUNY, Manhattan, NY; [4]Psychology, [3]Brooklyn College-CUNY, Brooklyn, NY

Abstract: The contingent presentation of cues via Pavlovian conditioning can affect synaptic plasticity and alter behavior. What neural mechanisms are reflected as a result of contingency are somewhat unknown. It is believed that the formation of associations is correlated with neural changes in the amygdala and nucleus accumbens. We were interested in measuring expression of postsynaptic density of the AMPA receptor subunit GluA2 in addition to nuclear expression of the immediate early gene c-Fos as a result of contingency manipulations. In this experiment, rats received appetitive Pavlovian conditioning with a tone stimulus and sucrose. Half of the rats received positive contingency training such that delivery of the sucrose was 100% contingent upon the presentation of the tone. The rest received zero contingency training, such that the delivery of sucrose was equally likely during each second of the session also known as a truly random control. Responding to the tone was then assessed in the absence of sucrose, at which point rats were sacrificed to measure expression of GluA2 and c-Fos. Results showed increased colocalized expression of GluA2 and post-synaptic density marker (PSD-95) in the nucleus accumbens core and a marginal increase in shell as a result of positive contingency training. These data are consistent with increases in GluA2/PSD-95 clustering observed after spatial learning and memory and now support a role for a similar mechanism in the nucleus accumbens during Pavlovian learning.

Title: Effects of delta-opioid receptor accumulation and internalisation in the nucleus accumbens shell on cue-guided choice

Authors: *A. K. MORSE[1], V. LAURENT[1], J. BERTRAN-GONZALEZ[2], B. BALLEINE[1]; [1]Brain and Mind Res. Inst., Univ. of Sydney, Camperdown, Australia; [2]Clem Jones Ctr. for Ageing Dementia Research, Queensland Brain Institute, The Univ. of Queensland, Brisbane, Australia

Abstract: Animals can use information extracted from their environment to guide their behaviour towards a desired outcome. In the laboratory, this critical ability can be studied through outcome-specific Pavlovian-instrumental transfer (PIT), in which a stimulus associated with a particular outcome biases response choice towards an instrumental action that earned that same outcome. Recent evidence from our laboratory indicates that expression of this bias requires the translocation of delta-opioid receptors (DOR) to the plasma membrane of cholinergic interneurons (mCINs) within the nucleus accumbens (NAc) shell. Interestingly, this plastic change in receptor expression occurs during Pavlovian training, in which specific and contingent stimulus-outcome associations are established. The present experiments examined behavioural and pharmacological manipulations of DOR expression, and their subsequent effects on specific PIT. Consistent with the literature, only manipulations of Pavlovian contingencies, degradation and non-contingent stimulus/outcome presentations, abolished specific PIT. Surprisingly, these procedures failed to reverse the DOR accumulation present after contingent Pavlovian training. DOR accumulation on mCINs within the NAc shell during Pavlovian learning therefore appears to be necessary but not sufficient for specific PIT. The effect of pharmacological DOR internalisation was also investigated to determine whether DOR accumulation triggered by Pavlovian learning changed receptor expression recovery following this internalisation. The specific DOR agonist SNC80, known to produce strong receptor internalisation, was administered to both trained and naïve mice. Although trained mice showed higher overall DOR expression, both trained and naïve mice given SNC80 has less DOR expression on mCIN than vehicle mice 24 hours after injection, consistent with previous findings. SNC80 administration 24 hours prior to test can therefore be used to investigate the effect of DOR internalisation on specific PIT. Disruption of DOR accumulation following Pavlovian learning may also disrupt specific PIT if animals are tested before this accumulation recovers.

Title: The role of d1 and d2 receptors in incentive value attribution

Authors: *J. J. CHOW[1], M. DARNA[2], J. S. BECKMANN[1];
[1]Psychology, [2]Pharmaceut. Sci., Univ. of Kentucky, Lexington, KY

Abstract: Reward-predictive stimuli compel some individuals to approach and interact with the stimulus (sign-tracking), while others approach the location of forthcoming reinforcement delivery (goal-tracking). Furthermore, rats that have a propensity to attribute incentive value to reward-related cues and display sign-tracking behavior are more susceptible to abuse-related behavior. It has been hypothesized that these different response types are mediated by different valuation systems. However, very little is known about the neural mechanisms that drive these proposed systems. Here we initially examined the role of the dopamine system in these different valuation systems with a single-stimulus, between-subjects Pavlovian conditioned approach (PCA) task using a D1 antagonist, SCH-23390 (0.01 and 0.03 mg/kg) and a D2 antagonist, eticlopride (0.01 and 0.03 mg/kg). The results indicated that at the 0.01 mg/kg dose, sign-tracking was suppressed by D1 antagonism, while D2 antagonism had no effect. The 0.03 mg/kg dose of both the D1 and D2 antagonists had non-specific effects. Next, we took advantage of the fact that different stimuli can specifically elicit different response types (lever for sign-tracking; tone for goal-tracking) to investigate the role of the D1 and D2 receptors on the relative valuation of a stimulus within-subjects. Sprague Dawley rats were trained on a 2-CS PCA task for fourteen consecutive days where a lever or a tone was presented for 8s and a food reward was delivered non-contingently. Rats were pretreated with either saline, SCH-23390 + eticlopride (0.01 mg/kg), SCH-23390 (0.01 mg/kg), or eticlopride (0.01 mg/kg) 15 minutes prior to start of each 2-CS PCA session. Following 2-CS PCA training, the valuation of the different stimuli was examined through extinction, conditioned reinforcement, and a novel choice procedure. Results from the 2-CS PCA task revealed that sign-tracking behavior was eliminated by D1+D2 antagonism, while goal-tracking behavior was mildly attenuated. However, when D1 and D2 receptors were individually examined, D1 antagonism eliminated sign- and goal-tracking behavior while D2 antagonism had no effect on sign-tracking behavior but did attenuate goal-tracking behavior. Furthermore, D1+D2 antagonism and D1 antagonism following the 2-CS PCA task also increased sign-tracking extinction rates, decreased conditioned reinforcement by the lever CS, and increased discounting of incentive value attributed to the lever CS. Overall, D1 and D2 receptor signaling seem to have differential roles in the attribution of incentive value to reward-predictive stimuli.

Title: Differential regulation of cue-induced incentive motivation by muscarinic and nicotinic acetylcholine receptors within the nucleus accumbens core

Authors: *A. L. COLLINS[1], I. XU[1], S. B. OSTLUND[2], K. M. WASSUM[1];
[1]UCLA, Los Angeles, CA; [2]UCI, Irvine, CA

Abstract: Reward-associated cues elicit excitation/arousal through association with an appetitive outcome and this excitation can act to enhance a non-selective range of reward-seeking actions: a process known as general Pavlovian-to-instrumental transfer (PIT). Evidence has implicated the nucleus accumbens core (NAc) in this cue-induced incentive motivation. Additionally, within the NAc, the two types of acetylcholine (ACh) receptors, muscarinic and nicotinic, have been demonstrated to distinctly modulate ACh and dopamine signaling, and reward-related behaviors generally. However, what remain unclear are the precise psychological processes modulated by NAc ACh signaling. Here we evaluate the hypothesis that muscarinic and nicotinic ACh receptors differentially modulate cue-induced incentive motivation. We utilized the PIT task in order to assess the role of NAc ACh receptors on Pavlovian cue-induced incentive motivation. In Experiment 1, we bilaterally infused a nicotinic antagonist, mecamylamine (10μg/0.5μl), a muscarinic antagonist, scopolamine (10μg/0.5μl), or equivalent volumes of ACSF in the NAc immediately prior to a PIT test. Under intra-NAc ACSF control conditions when the reward-paired cue was present rats invigorated their responding relative to the pre-cue periods and neutral cue presentations. This incentive motivation effect was blocked by intra-NAc antagonism of muscarinic receptors, while intra-NAc antagonism of nicotinic receptors enhanced the expression of PIT compared to ACSF-controls. In Experiment 2, we bilaterally infused either a nicotinic receptor agonist, nicotine (20μg/0.5μl), a muscarinic receptor agonist, pilocarpine (80μg/0.5μl), or equivalent volumes of ACSF within the NAc immediately prior to a PIT test. Either infusions of pilocarpine or nicotine attenuated the expression PIT relative to ACSF controls. In all groups, head entries into the food port were significantly elevated during the

reward-paired cue presentation relative to the pre-cue periods and neutral cue presentations indicating that these effects were unlikely due to general motivational or motor effects. These data indicate that alterations in NAc nicotinic receptor activity produces bidirectional effects on PIT, with enhanced signaling attenuating the impact of reward-paired cues on invigorating reward-seeking actions. Conversely, in either direction, modulating muscarinic receptors impaired PIT. Collectively, these data indicate distinct roles for muscarinic and nicotinic ACh receptors with the NAc in mediating the ability of reward-paired cues to generally invigorate reward-seeking actions.

Title: The effects of increased dopaminergic transmission on cognitive bias in mice

Authors: *R. A. CLIBURN, K. M. LOHR, T. S. GUILLOT, G. W. MILLER;
Emory Univ., Atlanta, GA

Abstract: Monoamines play a key role in regulating affective behavior. We and others have shown that mice with decreased vesicular monoamine transporter 2 (VMAT2) display decreased dopaminergic signaling and express a depressive-like phenotype (Taylor et al., J Neurosci, 29(25), 8103-8113, 2009). Furthermore, we show that mice containing a BAC-mediated overexpression of VMAT2 (Slc18a2) display enhanced levels of basal dopamine and dopaminergic transmission and exhibit significantly improved outcomes in tests of depressive- and anxiety-like behavior. This resilience to depressive-like behavior is gene-dose dependent: fewer copies of the VMAT2 gene result in a depressive affective state while multiple copies of the VMAT2 gene result in a positive affective state. This continuum of phenotypes seen in VMAT2 under- and over- expressing mice reflects the variation in human emotional states from depression to optimism. In order to further characterize the effects of VMAT2 levels in mice, we designed a novel cognitive bias test. Cognitive bias tests measure the tendency to interpret ambiguous stimuli more ‘positively’ or more ‘negatively.’ Our novel test for mice utilizes a modified t-maze protocol. Mice were trained with two distinct auditory cues predicting either food availability in one arm (positive reinforcement) or an aversive stimulus from which there

was shelter in the opposite arm (negative reinforcement). Cognitive bias is determined by playing intermediate tones and investigating whether the mouse interprets the ambiguous tone as a negative or positive cue. In this way, the reduced depressive- and anxiety-like behavior in VMAT-overexpressing mice, as evidenced by reduced immobility time in a forced swim test (21.7%) and fewer marbles buried in a marble burying assay (38.7%), could be further elucidated using a novel cognitive bias test.

Title: The reinforcement magnitude of flavored stimulus interferes with omission effects in rats

Authors: ***J. O. BUENO**, D. M. JUDICE-DAHER, H. G. DELIBERATO;
Univ. São Paulo, Ribeirao Preto, Brazil

Abstract: Reinforcement omission effects (ROEs) have been interpreted as behavioral transient facilitation after nonreinforcement induced by primary frustration, and/or behavioral transient inhibition after reinforcement induced by demotivation or temporal control. According to frustration theory, the size of the ROEs depend directly on the reinforcement magnitude: the behavioral facilitation after the reinforcement omission of larger magnitude should be greater than that observed after the reinforcement omission of smaller magnitude. However, studies involving operant paradigms have presented difficulty to demonstrate this relationship. Thus, the present study aimed to clarify the relationship between reinforcement magnitude and ROEs manipulating the magnitude linked to discriminative stimuli in a partial reinforcement fixed interval schedule. Rats were trained on a fixed-interval (FI) 12 s with limited hold 6 s signaled schedule in which correct responses were always followed by one of two reinforcement magnitudes (0.5 and 0.05 ml of a 0.15% saccharin solution). After acquisition of stable

performance, the training was changed from 100% to 50% reinforcement schedules. Data from acquisition training showed that there was a discriminative control during the signal, producing different response distributions depending on the reinforcement magnitude anticipated. The performance during the FI signaled by the Lm stimulus was more effective than that observed during the FI signaled by Sm stimulus. The response during FI Lm schedule was higher than during FI Sm schedule when recorded in the last seconds of FI, but smaller in the first seconds. Comparing the performance in the trials after nonreinforcement and after reinforcement, the results showed that there were ROEs: the response rates were higher after omission than after reinforcement delivery for both reinforcement magnitudes. Besides, data in the trials after nonreinforcement showed that the responding was higher after the larger reinforcement omission than the smaller one. Thus, the manipulation of reinforcement quality using the flavor of saccharin corroborates with the hypothesis that the reinforcement magnitude can operate in temporal discrimination and omission effect. But, it was not obtained any increase in the responding during trials after nonreinforcement compared with those immediately preceding ones, which did not support the behavioral facilitation approach of ROEs.

Title: Differential involvement of dopaminergic and beta-adrenergic receptors in the medial prefrontal cortex in latent inhibition of conditioned taste aversion after chronic consumption of sugar

Authors: ***S. CAYNAS**, G. RODRÍGUEZ-GARCÍA, M. I. MIRANDA;
Univ. Nacional Autonoma de Mexico - Inst. de Neurobiologia, Querétaro, México, Mexico

Abstract: Evidence suggests that the medial prefrontal cortex (mPFC) is a structure through which the taste system interacts with the reward and feeding system. For example, lesions,

catecholamine denervation and c-Fos studies have clearly established a role of the mPFC during conditioned taste aversion (CTA) acquisition, retrieval and extinction, and that acute sucrose intake increases extracellular levels of dopamine and noradrenaline in the mPFC. Recently, we have demonstrated significant changes in latent inhibition of CTA and a differential new aversive learning after chronic exposure to sugar. Accordingly, we evaluated if consumption of sugar solution during 14 days alters dopamine and noradrenaline systems in the mPFC, and if dopamine and noradrenaline activity may account for the increase in latent inhibition of CTA. Therefore, male rats were exposed during 14 days to 10% sucrose solution as the only liquid consumed ad libitum. After this chronic exposition, taste preference was measured and mPFC bilateral infusions of dopaminergic and beta-adrenergic receptors agonist and antagonist were made before CTA acquisition. Blockade of dopaminergic receptors and activation of beta-adrenergic receptors in the mPFC cortex prevented appetitive re-learning after chronic consumption of sugar, while the opposite treatment increases latent inhibition of CTA after acute consumption of sugar. These results suggest that, after chronic sugar exposure, the dopaminergic and beta-adrenergic receptors in the mPFC have a differential involvement during new aversive learning and re-learning of appetitive taste learning.

Title: Sex differences in conditioned orienting behavior and related phenotypes

Authors: S. M. LEWIS[1], M. E. OLSHAVSKY[1], E. S. SMITH[1], *H. J. LEE[2];
[1]Univ. of Texas at Austin, Austin, TX; [2]Psychology Dept, Univ. Texas, Austin, AUSTIN, TX

Abstract: Repeated pairings of light cues (Conditioned Stimulus, CS) followed by food pellets (unconditioned stimulus, US) in appetitive training provokes high conditioned orienting/rearing responses to the light in some male rats (Orienters) and less so in others (Non-Orienters). Our lab has shown that male Orienters tend to make more risky and impulsive choices in relation to male Non-Orienters, be more distracted in an attentional task, and to display more 50 kHz ultrasonic vocalization (USV) in response to amphetamine. Since this line of research has not yet been expanded to females, we investigated conditioned orienting behavior and related phenotypes in

female rats. We used intact females and ovariectomized females, either with estradiol replacements (OVX-E) or cholesterol control (OVX-C), alongside intact male rats. The rats received Pavlovian appetitive conditioning in which light presentation was followed by a grain pellet delivery. Then, they were tested in a dark-light open field (to measure baseline activity and preference for a novel/risky area), in an attentional shifting task, and for 50 kHz USV response to amphetamine. In appetitive training, all the female rats showed higher conditioned orienting compared to the male rats, but OVX-E females showed the highest levels of conditioned orienting behavior. During the dark-light open field test, the female rats were generally quicker to leave the dark and familiar area to enter the brightly lit and novel area compared to the male rats with OVX-E group being the quickest to enter the bright and novel area. In the attentional shifting task, all the groups showed comparable performance except OVX-E group that showed significant impairment. When the rats were injected with 2 mg/kg amphetamine, intact male and female rats displayed comparable 50 kHz USV while OVX-C and OVX-E groups showed lower levels of USV with OVX-E group showing the lowest level. Our study shows sex differences in conditioned orienting behavior and suggests related phenotypes might be partly influenced by different ovarian hormones.

Title: Inhibiting ventral pallidum with DREADDs impairs sign-tracking in rats

Authors: *S. E. CHANG, T. P. TODD, D. J. BUCCI, K. S. SMITH;
Dartmouth Col., Hanover, NH

Abstract: An environmental cue that predicts a rewarding event can capture attention and trigger pursuit of the cue itself due to the cue acquiring incentive salience, a process in which the cue acquires incentive value due to its association with the rewarding event (Berridge, 2004). The

phenomenon of autoshaping has been used to study the neural circuitry underlying the attribution of incentive salience, in which rats will approach, contact, and attempt to "consume" a lever conditioned stimulus (CS) that is paired with the delivery of a food unconditioned stimulus (US) upon retraction (sign-tracking). Previous studies have shown that the nucleus accumbens and its dopaminergic inputs are critical for the acquisition and expression of sign-tracking (e.g., Flagel et al., 2011; Saunders & Robinson, 2012). A region with bidirectional connections with accumbens is the ventral pallidum (VP), which has been shown to mediate reward processes including taste hedonics and salt appetite (Smith et al., 2009). The present study investigated the effects of inhibiting VP on sign-tracking using Designer Receptors Exclusively Activated by Designer Drugs (DREADDs), a technology that allows for repeated activation of engineered receptors by systemic injection of the otherwise inert ligand clozapine N-oxide (CNO). DREADDs are a particularly useful technology for repeated temporary inactivation of VP because lesions of VP abolish the motivation to pursue pleasant rewards (Cromwell & Berridge, 1993), and repeated inactivation using intracranial injections cause unwanted physical damage. Rats received surgery in which the hM4Di receptor was inserted into the VP through viral vectors. Rats underwent 12 days of training in which each session consisted of 25 CS+ and 25 CS- trials. CS+ trials consisted of insertion of one lever for 10 s that resulted in the delivery of a food US (2 grain pellets) upon retraction, while CS- trials consisted of insertion of another lever that was followed by nothing. In each session, the VP was inactivated in half of the rats with systemic injections of CNO, while the other half of rats received injections of distilled water (Control). Initially, both CNO and Control rats acquired sign-tracking at comparable rates, pressing more to the CS+ than the CS-. However, Control rats showed approximately double the levels of sign-tracking compared to CNO rats as training progressed, particularly over the last 4 days. In contrast, CNO and Control rats showed no differences in food cup behavior. These results demonstrate the utility of chemogenetics technology for studying mechanisms of incentive value and provide evidence that the VP is a critical region mediating this process.

Title: Decoding frontostriatal network activity during occasion setting

Authors: *J. L. SHOBE[1], L. D. CLAAR[2], K. I. BAKHURIN[2], S. C. MASMANIDIS[2]; [1]UCLA, IRVINE, CA; [2]UCLA, Los Angeles, CA

Abstract: The frontostriatal circuit is important for learning specific cue-reward associations in order to select among behaviorally appropriate responses. One prominent hypothesis suggests that neuronal activity within cortical and striatal structures make distinct contributions with respect to action selection and action value. However, a network-level understanding of how this contributes to these distinct components of learning remains unclear. As a general approach to address these questions, our laboratory has pioneered the development of large-scale multi-unit recording systems to sample spiking data from 512 channels simultaneously in multiple brain regions in awake, behaving mice. Animals are trained in a head-fixed preparation and perform appetitive Pavlovian olfactory discrimination tasks. Following a common two-odor discrimination task with an odor1-reward pairing (CS+) and an odor2 alone presentation (CS-), we observe distinct task modulated striatal activity during (i) CS onset, (ii) CS+ vs CS- epochs, and (iii) reward delivery, suggesting a robust encoding of these trial features (Bakhurin et al SFN 2013). However, these findings do not capture a critical hallmark of cognitive learning which requires that an animal understands the relationship between different cues (stimulus-stimulus interactions; S-S) to successfully perform the task. As an entry point to investigate this, we have utilized a feature negative discrimination task (occasion blocking) where a mouse learns that the presentation of odor1 alone is rewarded (CS+) but on a trial where odor1 (target) is preceded by odor2 (blocker) it is unrewarded (blocker-->target). Thus the mouse must perceive the relationship between the cues to resolve stimulus ambiguity (ie. odor1 only predicts reward 50% of the time). After several days of training, we found that mice are able to successfully discriminate between these trial types with near 100% accuracy (ie correctly respond on CS+ trials and correctly withhold on blocker-->target trials). We have also made a number of interesting preliminary physiological observations that fall outside the scope of the earlier hypothesis (i) many cells in both structures responded to both CS+ and the blocker cue suggesting that they encode for salience rather than action value and/or action selection and (ii) the blocker dramatically blunts neuronal activity during target presentations suggesting that it may cause a global downshift in task-modulated activity. We are currently analyzing the circuit and systems level connectivity between these brain regions to determine if this in combination with their spiking pattern is predictive of trial type.

Title: Signaling prediction for size versus value of rewards in rodent orbitofrontal cortex during Pavlovian unblocking

Authors: *N. LOPATINA[1], M. A. MCDANNALD[2], B. F. SADACCA[2], G. SCHOENBAUM[2]; [1]Dept. of Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Natl. Inst. on Drug Abuse, Intramural Res. Program, Baltimore, MD

Abstract: Modern reinforcement learning models and learning theories distinguish at least two different forms of reward prediction: specific features or properties of rewards, and value or general utility of rewards. Formation of specific goals requires intact prediction of reward features. Maximizing the value of these goals requires intact prediction of reward value. While reward size and reward value are inextricably linked, the changes of neural activity of individual units in response to rewards of different sizes can shed light on whether individual neurons' encoding reflects reward size or value. The current study examined changes in orbitofrontal cortex (OFC) neural activity using single-unit electrophysiological recording, measuring activity during a novel Pavlovian unblocking procedure that assesses excitatory and inhibitory cue learning driven by upshifts or downshifts in expected reward size. We have recorded hundreds of OFC neurons during the task. Preliminary analyses show that cue-related activity is regulated by the unblocking paradigm used, with findings of differential firing to blocked, size-downshift and size-upshift cues in individual neurons. A comprehensive analysis of these neural data will be presented.

Title: Selective loss of the rat nigral DA neurons needed for approach response to appetitive, but not aversive, stimuli and those needed for aversive, but not appetitive associative learning

Authors: *C. DA CUNHA[1], B. F. C. DE LIMA[1], A. GÓMEZ-A[1], S. L. BOSCHEN[1], J. K. BARBIERO[1], A. M. FIORENZA[1], D. L. ROBINSON[2], C. D. BLAHA[3];
[1]Univ. Federal do Parana, Curitiba, Brazil; [2]Dept. of Psychiatry and Ctr. for Alcohol Studies, Univ. of North Carolina, Univ. of North Carolina, Chapel Hill, NC; [3]Univ. of Memphis, Memphis, TN

Abstract: It is controversial whether different populations of midbrain dopamine (DA) neurons play a role in appetitive and aversive associative learning. Here, we show that partial bilateral lesions of DA neurons in the rat substantia nigra pars compacta (SNc) induced by 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP, 200 ug/side) or 6-hydroxydopamine (6-OHDA, 3 ug/side) impaired conditioned place avoidance (CPA) for an environment paired with quinine pellets without affecting conditioned place preference (CPP) for an environment paired with sucrose pellets. In addition, approach and consummatory responses to sucrose, but not to quinine, pellets were affected by the 6-OHDA, but not MPTP, treatment. Importantly, after tasting sucrose or quinine the MPTP and 6-OHDA rats presented facial expressions that were not different compared to the controls. Furthermore, no motor or emotional alteration was observed when the lesioned rats were tested in an open field. Reductions in issue content of DA in the striatum were similar in the MPTP and 6-OHDA lesioned rats, as shown by high performance liquid chromatography with electrochemical detection. Immunohistochemistry for tyrosine hydroxylase showed partial loss of DA neurons in the SNc, but not in the ventral tegmental area; no significant difference between MPTP and 6-OHDA rats or between anterior and posterior areas of the SNc was observed. Overall, these data suggest that: (i) there are different populations of neurons distributed in the SNc that encode incentive salience value and hedonic value for appetitive and aversive stimuli; (ii) such neurons differently impact associative learning involving rewarding and aversive stimuli; (iii) these different populations of DA neurons have different sensitivity to the toxic effects of MPTP and 6-OHDA, which makes them good tools to tease the DA populations apart. This finding has important implications in basic and applied

research of Parkinson´s disease, addiction, learning and memory, and other functions and diseases where striatal DA is implicated.

Title: Effects of phenotype and exercise on diet preference in a rat model

Authors: ***H. JOHNS**[1], K. PARKER[2], M. MCCABE[3], F. BOOTH[1], M. J. WILL[1];
[1]Univ. of Missouri, Columbia, MO; [2]Univ. of Minnesota, Minneapolis, MN; [3]Univ. of Vermont, Burlington, VT

Abstract: The obesity epidemic and associated diseases are a direct result of both diet choice and inactivity, as over-consumption of palatable foods and a sedentary lifestyle invariably precede the onset of weight gain. Our laboratory uses opioid activation of the nucleus accumbens to model hedonically-driven feeding of energy-dense palatable food in the sated condition, a behavior that typically precedes the onset of obesity. However, it is not clear how dietary choice and physical inactivity interact, and to what extent. The current study used two novel rat phenotypes, developed by selectively breeding for either high- or low-levels of voluntary running (HVR and LVR, respectively). As of the 10th generation, HVRs ran approximately 10-fold greater daily distances compared to the LVR rats, thus providing a unique model to examine cross-generational influence of inactivity on diet preference and overall feeding behavior. The current study sought to investigate the influence of voluntary exercise or forced sedentary conditions in HVR and LVR rats using an opioid feeding model choice task between either a low-fat/high-carb or high-fat/low carb diet. LVRs demonstrated a strong preference for the low-fat/high carb diet at baseline; this preference became further pronounced in a dose-dependent fashion following intra-Acb infusions of the mu opioid agonist DAMGO. HVR rats did not demonstrate a clear preference for either diet at baseline; however, their consumption of the high-fat/low carb diet increased dose-dependently following DAMGO infusions. Analysis of

low-fat/high-carb consumption revealed interactions between phenotype and baseline preference, as well as between phenotype, exercise condition, and DAMGO dose, suggesting differential opioid signaling across phenotype-by-exercise conditions.

Title: Effects of thiamine-deficiency on flavor consumption after flavor-thiamine pairings

Authors: D. KLAKOTSKAIA[1], R. RICHARDSON[1], M. MCCABE[1], E. WOODALL[1], C. WEINSTEIN[1], *T. SCHACHTMAN[2];
[1]Dept. of Psychological Sci., Univ. of Missouri, Columbia, MO; [2]Univ. of Missouri, COLUMBIA, MO

Abstract: Research has demonstrated that a specific flavor can come to be preferred if it is associated with a needed nutrient (e.g., thiamine). This study sought to demonstrate such a preference and show the dependence of this effect on the timing of the nutritional need. Flavor-thiamine pairings were administered to Sprague-Dawley rats, and then they were tested for flavor consumption. Flavor preference has been shown to be independent of nutritional need at the time of testing.

Title: Chronic ketamine pretreatment enhances the effects of pramipexole on contrafreeloading for water in rats

Authors: *C. SCHEPISI, S. DORONZIO, P. NENCINI;
Dept. of Physiol. and Pharmacology, Sapienza Univ., Rome, Italy

Abstract: INTRODUCTION Chronic treatment with the D3 agonist pramipexole (PPX) potentiates contrafreeloading for water (CFL), consisting in a biased selection of a contingent over a noncontingent access to water. CFL arises from an impairment of choice shifting between different options in conditions where behavioral cost is unbalanced. We provided preliminary evidence that the inability to switch to a more economical strategy depends on a loss of hippocampal control over behavior, and thus it could be sensitive to glutamatergic manipulation. **OBJECTIVES** We tested the effects of the full NMDA antagonist ketamine and of D-cycloserine (DCS), a partial agonist at the glycine binding site on NMDA receptor, on PPX induced CFL. **MATHERIALS AND METHODS** Rats were trained under a fixed ratio 3 (FR3) schedule of reinforcement for water. On days 1-6 (operant phase), water was only available through lever pressing while on days 7 to 14 (choice phase), choice between operant and free access was provided. In EXP 1, 15 mg/kg of ketamine or saline where intraperitoneally injected 30 minutes before PPX treatment (0.5 mg/kg). In EXP 2, DCS (15 mg/kg) or saline where administered in combination with PPX. **RESULTS** During the operant phase, PPX did not affect responding whereas it decreased drinking, resulting in a significant decreased in percentage of water consumed over that gained. Neither ketamine nor DCS modify the effects of PPX on contingent drinking. In condition of choice, PPX produced a significant preference for the contingent over the non-contingent access to water. Ketamine further boosted PPX effect on CFL by increasing the amount of water consumed through lever pressing. DCS was ineffective against PPX. Ketamine or DCS given alone did not induce any significant effect during both the operant and the choice phase. **DISCUSSION** The NMDA receptor antagonist ketamine worsens the effects of D3 stimulation on CFL. This finding suggests that blocking the NMDA component of glutamatergic transmission adds a further layer of dysfunction in the expression of PPX-driven inflexible behavior. However, facilitating NMDA transmission through DCS fails to restore adaptive drinking during PPX treatment. In conclusion, although NMDA inhibition is not necessary nor sufficient to elicit inflexible drinking, glutamatergic transmission is likely to be a target of PPX effects on compulsive behavior in CFL.

Title: Inbred mouse genetics approach yields novel genetic and genomic determinants of variation in appetitive reward-driven instrumental learning and motivation

Authors: *A. S. JAMES[1], B. M. SAFAIE[1], A. BAUTISTA[1], A. J. LUSIS[2], J. D. JENTSCH[3]; [1]Psychology, [2]Medicine, Cardiology, Human Genetics, Microbiology, Immunol. & Mol. Genet., [3]Psychology, Psychiatry & Biobehavioral Sci., UCLA, Los Angeles, CA

Abstract: Learning to exploit the environment in the pursuit of desired outcomes is a central to a wide array of behaviors that humans and other animals exhibit to achieve internal goals. In its extreme forms, variation in rates of learning about rewards, and motivation to seek them, may underlie psychiatric disorders (e.g., substance dependence), while in its normative forms, could influence aspects human behaviors that and mold our individual temperament and traits. However, little is known about the genetic markers that modulate these individual differences in reward-related behaviors. Therefore, we sought to ascertain novel genetic loci in control of variation in learning to perform an instrumental response to produce an appetitive outcome, and in motivation to perform this reward-seeking behavior. We performed a genome-wide association study of instrumental learning using the Hybrid Mouse Diversity Panel (HMDP) in concert with FaST-LMM (Lippert et al. 2011), which together offer substantial improvements in the domains of power, resolution, and type I error rate relative to traditional genetics approaches. We assessed spontaneous acquisition and performance of instrumental behavior in 70 strains (n = 2- 10 per strain) during three 8-hour daily sessions in which lever responses produced sucrose rewards under a schedule of reinforcement that gradually advanced from FR1 to VR5. Quantitative trait loci (QTL) for lever pressing behavior were identified on chromosomes 3, 11, and 19. We then used expression-QTL data and polymorphism effect prediction algorithms positional candidates. In conjunction, we applied weighted correlational techniques to gene

expression in the striatum of HMDP mice (Park et al. 2011) - a brain region critical for instrumental performance. In doing so, we were able to identify networks of highly co-expressed genes that associate with strain-level variation in instrumental reward-seeking. Ontology analyses of these gene networks and their highly intra-connected 'hub' genes, and analysis of the position of QTL candidates within these networks, further refined our QTL gene list. Importantly, because networks segregate a coherent set of signaling pathways, intra- and extra-cellular functions, and/or protein/cell interactions, we were able to uncover novel relationships between groups of RNA and protein regulatory mechanisms and reward-seeking behaviors. These data, therefore, can facilitate hypothesis generation for new neurobiological research of reward-seeking behaviors, while also guiding a fundamentally data-driven prioritization approach to performing causal studies of identified genes in the future.

Title: Isoflurane/nitrous oxide anesthesia during the first week of life can cause long-lasting cognitive deficits in rhesus monkeys

Authors: *M. G. PAULE;
Div. of Neurotoxicology, FDA's Natl. Ctr. For Toxicological Res., Jefferson, AR

Abstract: Isoflurane/nitrous oxide anesthesia during the first week of life can cause long-lasting cognitive deficits in rhesus monkeys M. G. Paule[1], M. Li[1], X. Zhang[1], S. Liu[1], J.P. Hanig[2], W. Slikker, Jr.[1] and C. Wang[1] [1]Division of Neurotoxicology, National Center for Toxicological Research, FDA, Jefferson, Arkansas, and [2]Center for Drug Evaluation and Research, FDA Previously our laboratory has shown that ketamine exposure (24 hours of clinically relevant anesthesia) causes significant increases in neuronal cell death and seemingly permanent cognitive deficits in rhesus monkeys. In the present study, eight monkeys were exposed on PND 5 or 6 to isoflurane (1%)/nitrous oxide (70%) anesthesia (ISO/N_2O; maintenance of a light surgical plane) for 8 hrs: eight control animals were unexposed. At 7 months of age all animals were weaned and began training to perform a series of cognitive function tasks as part of the

National Center for Toxicological Research (NCTR) Operant Test Battery (OTB). The OTB tasks used here included those for assessing aspects of learning, motivation, color discrimination, and short-term memory. Subjects responded for banana-flavored food pellets by pressing response levers and press-plates during daily (M-F) test sessions (50 min) and were assigned training scores based upon their individual task performance. Beginning as early as 8 months of age_and continuing for at least the following year--control animals earned more reinforcers in a task assessing appetitive motivation than animals exposed to ISO/N_2O (OTB assessments are continuing). At about 14 months of age, controls also began outperforming ISO/N_2O exposed animals in the OTB learning and visual discrimination tasks: exposed animals responded more slowly in the color discrimination task and completed less of the learning task--, responding more slowly and less accurately--and these effects have continued until the present (for at least six months). Performance in the short-term memory task is no different between the groups. These long-term cognitive impairments seen after an 8 hour exposure to ISO/N_2O, while slightly different from those noted in our previous ketamine studies, provide additional evidence that a single 8-hr episode of general anesthesia, occurring during a sensitive period of brain development, results in very long-lasting deficits in brain function in primates. Supported by CDER/FDA and NCTR/FDA.

Title: OpenMaze: A new resource for open source hardware and software for rodent behavioral neuroscience

Authors: C. O. LACEFIELD, *C. RODGERS, R. M. BRUNO;
Columbia Univ. Med. Ctr., New York, NY

Abstract: Neuroscientists have always needed to be creative in the construction of novel experimental apparatus. In the present day, however, most systems for behavioral experiments are costly and require extensive engineering and programming skills. Recently, a rich landscape of open-source hardware and software tools, requiring only minimal background in electronics and computing, has emerged. Devices such as the Arduino and the Raspberry Pi, essentially miniature computers, have been adopted by immense communities of users who maintain online forums dedicated to their operation. In addition, many devices have been designed to interface with these platforms, including low-cost sensors and motors. We have launched the OpenMaze.org website as a flexible platform to support and guide the easy construction of a diverse array of experimental apparatus. On the hardware side, the OpenMaze.org website contains tips and techniques for the construction of interactive behavioral apparatus. For instance, we have designed a series of attached prototyping boards, or "shields", for the Arduino microcontroller system that contain simple circuitry necessary for presenting simple sensory stimuli, controlling motors to alter the animal's environment, and reading out behavioral responses. These animal interaction boards are complemented by serial communication with more powerful processors such as the Raspberry Pi, which allow computer vision applications such as animal tracking, as well as more complex visual and auditory stimuli. On the software side, OpenMaze.org contains a repository of fully functional code for the Arduino, as well as additional applications in the Processing and Python programming languages. This code accommodates a variety of experimental paradigms, such as two-alternative forced choice, but can also be adapted to other tasks. Our current focus is on head-fixed mouse behavior, but the principles apply to other animal and even human models. We hope that the OpenMaze website and platform will help neuroscientists, even those with minimal technical background, take full advantage of the current rich landscape of open source hardware and software for the study of animal behavior. User contributions are highly encouraged.

Title: Learning and memory impairment in HIV-1-transgenic (Tg)26 mice: Potential regulation by Toll-Like receptors

Authors: *S. MOIDUNNY[1], M. A. BENNEYWORTH[1], T. MACHEDA[2], S. METZGER[2], U. SHARMA[2], J. MEINTS[2], M. J. THOMAS[2], S. ROY[2];
[1]Univ. of Minnesota, Minneapolis, MN; [2]UNIVERSITY OF MINNESOTA, Minneapolis, MN

Abstract: Toll-like receptors (TLRs) are a family of innate immune system receptors that respond to pathogen-associated and damage-associated molecular patterns. Recent evidence suggests that TLRs play a significant role in normal development of the central nervous system (CNS), and regulate neuroplasticity and behavior. We hypothesized that impaired memory associated with HIV-1 infection of the CNS is regulated by altered TLR expression. 18 weeks old littermate wild-type (C57BL6/J) and transgenic (Tg)26 mice, which express all viral genes that are known to mediate neuropathogenesis associated with HIV-1 infection, were assessed for altered behavior using Barnes maze test. We provide the first evidence that both male and female Tg26 mice show severe impairment in learning and spatial reference memory, compared to wild-type mice. Both Tg26 and wild-type males showed similar locomotor activity, whereas Tg26 females showed increased locomotor activity than the wild-type. Furthermore, preliminary data suggests an altered TLR expression in Tg26 mice brain, compared to wild-type. A detailed immunohistochemical, biochemical and molecular analyses would help us to understand the potential role of TLRs in impaired memory and synaptic plasticity associated with HIV-1 infection of the CNS.

Title: Sex differences in molecular mechanisms underlying consolidation of memory

Authors: *A. A. SCHMELING, I. C. SPEIRS, E. J. DONZIS, L. M. TURNBULL, N. C. TRONSON;
Univ. of Michigan, Ann Arbor, MI

Abstract: Molecular mechanisms of context fear conditioning have been well studied in male animals, however females have been largely overlooked. There is some evidence that males and females differ in both learning about context and context fear conditioning, with males exhibiting stronger memory than females. In contrast, other studies have observed no sex differences in fear conditioning. The few studies examining mechanisms of fear conditioning in both males and females have also demonstrated striking sex differences. Disruption of GluR1 and calcium calmodulin (CaM) signaling impair context fear conditioning in males but not females. In addition, activation of extracellular signal regulated kinase (ERK)/CREB signaling after fear conditioning differs between males and females. Here, we extended these findings by determining sex differences in multiple signaling cascades known to be important for consolidation of context fear conditioning in males. Female and male mice were conditioned across a range of shock intensities and either tested for freezing the following day, or brains were dissected for molecular analyses. To identify patterns of kinase activity in consolidation of fear-associated memory we used western blot analysis and immunohistochemistry to determine activation of ERK, AKT, mTOR, and CREB in males and females. Pinpointing sex differences in patterns of intracellular signaling will allow us to better understand how fear-associated memories are consolidated and modulated in females. These findings suggest the need for sex-specific strategies for treatment and prevention of memory-related disorders such as post-traumatic stress disorder.

Title: Single and double alternation in the adult female C57BL/6 mouse: Non-knockout versus estrogen receptor knockout

Authors: *J. D. ROWAN[1], M. K. MCCARTY[2], A. BAJRACHARYA[3], H. BOETTGER-TONG[4];
[1]Wesleyan Coll, MACON, GA; [2]Neurosci. Program, [4]Dept. of Biol., [3]Wesleyan Col., MACON, GA

Abstract: Studies of sequence learning dating back to the 1930s have repeatedly found that a single alternation pattern (SA) is more difficult to learn than a double alternation pattern (DA). Because these SA/DA task uses the same basic procedure while manipulating the complexity of the patterns, it could be an ideal for comparing deficits in cognitive function. Recent research has found that male rats learn structured sequences faster than females, indicating that estrogen may play an important role in rule learning. The goal of this study is to compare female C57BC/6 mice, with and without the gene knock (KO)-out for sensitivity of estrogen receptors, on acquisition of SA and DA patterns in an attempt to determine whether estrogen plays a role in rule learning. The subjects were 9 naïve female C57BC/6 mice (5 non-KO and 4 KO). The test chamber used was rectangular in shape (32.5cm x 23cm x 25.5cm) and was composed of clear Plexiglass walls and a floor of wire mesh. One wall of the chamber was equipped with 2 infrared emitter-detectors with a water delivery system. Before training, all mice required shaping for 3 days during which they repeated 120 nosepokes per day in only one of the locations. An indicator light in each nosepoke recess indicated the start of each trial. At the beginning of the experiment, all lights were illuminated. A correct response resulted in reinforcement with approximately 0.2 mL of water. All of the lights were then extinguished for 1 s and then again illuminated. When an incorrect response was made, all the lights were turned off except the correct one. After a correct response was made, the mouse was then reinforced with water. This procedure assured that the mice received feedback regarding the correct response on each trial. Each day, for 14 days, mice performed 10 repetitions of the SA pattern for a total of 160 correct responses per day. Using the same procedure, the same 2 groups of mice were then transferred to the DA pattern for an additional 14 days of acquisition. Analysis of revealed no differences in acquisition rates for the SA pattern, {$F(1, 13) = 1.45$, $p = 0.268$} and both groups were performing at below chance levels by Day 3 of the experiment. Interestingly, following the transfer to the DA patterns, the C57BC/6 Normal mice performed significantly fewer errors than the C57BC/6 KO group {$F(1, 13) = 8.8262$, $p = 0.035$}. On Day 14, the non-KO C57BC/6 mice generated 19.5% errors compared to the 42.5% errors of the KO group. These finding support the idea that estrogen plays an important role in learning patterned sequences. They also demonstrate the ability of the SA/DA task to identify deficits in cognitive functions such as simple rule learning.

Title: Dissociation of mechanisms underlying context fear conditioning and inhibitory avoidance

Authors: L. M. TURNBULL, I. C. SPEIRS, A. A. SCHMELING, N. NEVÁREZ, E. J. DONZIS, D. M. DUBOIS, *N. C. TRONSON;
Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Memory retrieval triggers a variety of active processes including reconsolidation to update or re-stabilize the memory, and extinction or learning about new stimulus contingencies. The precise mechanisms that mediate whether extinction or reconsolidation is engaged after retrieval remain unclear. Previous studies have demonstrated that contextual fear memory (CFC) but not inhibitory avoidance (IA) is sensitive to disruption of memory reconsolidation by propranolol. Given that both CFC and IA are examples of Pavlovian fear conditioning protocols with context acting as the conditioned stimulus, the difference in memory reconsolidation is somewhat surprising. In this study, we aimed to use this differential susceptibility to understand what mechanisms may trigger memory reconsolidation. To do this, we delineated molecular mechanisms after training and retrieval of several different fear conditioning protocols. C57Bl6 mice were trained on CFC or IA and brains were dissected post training or retrieval and immunoblotting and immunohistochemistry were used to examine the difference in circuits and molecular mechanisms activated after memory retrieval. We demonstrate that CFC and IA differentially activate ERK, EGR1, and pCREB activity, and that these differences occur across hippocampus, Anterior Cingulate Cortex and Nucleus Accumbens. These differences in circuit and mechanism active during retrieval may be key to understanding requirements for initiation of reconsolidation. Furthermore, these results suggest that what animals learn and what information is retrieved upon re-exposure to a conditioned context differs despite the similarity between fear conditioning protocols.

Title: HDAC3 in the dorsal hippocampus negatively regulates long-term memory consolidation for context fear

Authors: *J. L. KWAPIS, Y. ALAGHBAND, D. P. MATHEOS, R. M. BARRETT, A. SYLVAIN, A. E. CARL, M. A. WOOD;

Abstract: Understanding how aversive events are consolidated into lasting fear memory is a key step in treating anxiety-based disorders, including post-traumatic stress disorder. In rodents, aversive memory is often studied using Pavlovian fear conditioning, in which an initially neutral conditional stimulus (CS), like a tone or context, is paired with an aversive unconditional stimulus (UCS), like a footshock. Although it is clear that gene expression in both the amygdala and hippocampus is required for the formation of long-term context fear memory, it is less clear how gene expression is coordinated by the cell to produce the robust and persistent memory characteristic of fear learning. Epigenetic mechanisms (changes in gene expression that occur through alterations in chromatin structure) may produce lasting changes in cellular function that give rise to enduring memory for fear conditioning. One major epigenetic mechanism important for memory is histone acetylation, in which acetyl groups are added or removed from histone tails by histone acetyltransferases (HATs) or deacetylases (HDACs), respectively. Increasing histone acetylation by blocking HDAC activity generally enhances both gene expression and long-term memory. HDAC3, the most highly expressed Class I HDAC in the brain, appears to be

particularly important for long-term memory formation. Blocking HDAC3 produces persistent object location memory following subthreshold training. Here, we tested whether hippocampal HDAC3 also negatively regulates fear memory formation. First, we demonstrated that cFos expression rapidly and robustly increases in both the dorsal and ventral hippocampus after fear conditioning, confirming that context fear learning induces new gene expression throughout the hippocampus. Next, we identified subthreshold conditioning parameters that are normally insufficient for long-term context fear memory formation. Finally, we tested whether HDAC3 inhibition could transform this subthreshold context fear into lasting long-term memory by virally overexpressing a dominant negative form of HDAC3 in the dorsal hippocampus. Consistent with our hypothesis, blocking HDAC3 in the hippocampus transformed subthreshold conditioning into long-term memory for context fear. This is consistent with the idea that HDAC3 negatively regulates memory formation for aversive events. We are currently working to understand how HDAC3 regulates gene expression dynamics, which appears to be key to the formation of robust and persistent memories following HDAC3 inhibition.

Title: Subdomain 2 of the neuron-specific chromatin remodeling subunit BAF53b is required for synaptic plasticity and memory

Authors: *A. VOGEL-CIERNIA[1], D. P. MATHEOS[1], E. KRAMAR[2], B. TRIEU[2], C. COX[2], C. MAGNAN[3], M. ZELLER[3], A. TRAN[1], A. LOPEZ[1], K. SAKATA[1], S. AZZAWI[1], R. DANG[1], R. BARRETT[4], P. BALDI[3], G. LYNCH[2], M. WOOD[1];
[1]Neurobio. & Behavior, [2]Anat. & Neurobio., [3]Computer Sci., Univ. of California, Irvine, Irvine, CA; [4]Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Gene expression is considered a key step for long-term memory processes. Transcription does not occur on naked DNA, but rather in the context of chromatin, the protein complex that condenses and organizes genomic DNA. The repeating unit of chromatin is called a nucleosome, and nucleosome positioning along the DNA can be altered by nucleosome remodeling complexes to regulate gene expression. Recent human exome sequencing studies have implicated polymorphic Brg1-Associated Factor (BAF) complexes (mammalian SWI/SNF chromatin remodeling complexes) in several intellectual disabilities and cognitive disorders, including autism. However, it is unclear how mutations in BAF complexes result in impaired cognitive function. Post-mitotic neurons express a neuron-specific assembly, nBAF, characterized by the neuron-specific subunit BAF53b. Mice harboring mutations of BAF53b show severe defects in long-term memory and long-lasting forms of synaptic plasticity (Vogel-Ciernia, et al., 2013), but the neuron-specific function of BAF53b is unknown. BAF53b shares 93% similarity with its non-neuronal homologue BAF53a, which is expressed in all non-neuronal cells. The most divergent region between BAF53b and BAF53a is within subdomain 2. Subdomain 2 of BAF53b has previously been shown to be critical for dendritic arborization during neuronal development (Wu, et al., 2007), hinting at a unique role for subdomain 2 in neuronal function. To examine the role of subdomain 2 of BAF53b in long-term memory formation, we generated transgenic animals that over-express a dominant negative BAF53b with a deletion of subdomain 2 (BAF53bΔSB2). BAF53bΔSB2 animals show long-term memory impairments, but normal short-term memory. Targeting BAF53b subdomain 2 also impairs maintenance of long-term potentiation and activity-dependent gene expression. These findings indicate that BAF53b, and specifically subdomain 2, confers a unique function to the nBAF complex for regulating neuronal gene expression required for long-term memory formation.

Title: Bi-directional pharmacogenetic manipulation of the CA1 using DREADDs leads to modulation in object location memory, but not object recognition memory

Authors: *A. J. LOPEZ, A. O. WHITE, A. VOGEL-CIERNIA, M. A. WOOD;
Dept. of Neurobio & Behavior; Ctr. for the Neurobio. of Learning & Memory, Univ. of California, Irvine, Irvine, CA

Abstract: Pharmacogenetics can lead to a dramatic change in how neural circuits are studied and understood. Particularly, Designer Receptors Exclusively Activated by Designer Drug (DREADDs) are a novel tool with the potential to bi-directionally drive cellular, circuit, and, ultimately, behavioral changes. These receptors have no endogenous ligand and can only be activated with exposure to clozapine-n-oxide (CNO), which is otherwise an inert ligand. To examine how this technique can be used to manipulate the activity of specific cell populations, we used this pharmacogenetic system to test memory formation in a hippocampus-dependent task. Here, we use DREADD technology to show the explicit role of the CA1 hippocampal subfield in object location memory (OLM), but not object recognition memory (ORM) formation. Excitatory DREADD (HM3D), inhibitory DREADD (HM4D), or GFP control were expressed virally in the CA1 subfield of the hippocampus. The lab has previously shown that for both OLM and ORM tasks, a 3 minute training session is a subthreshold event for long-term memory (LTM) formation, while a 10 minute training session is sufficient for LTM formation. For activation experiments, mice were given a 3 minute training session in the OLM and ORM tasks paired with systemic CNO administration (I.P., 3 mg/kg, 0.25% DMSO, 0.9% saline). For inactivation experiments, mice were given a 10 minute training session in the OLM and ORM tasks paired with systemic CNO administration. Mice were tested for LTM 24 hours following each respective training event. Compared to control animals, HM3D mice showed dramatic increase in LTM formation in the OLM task, but not ORM task. In contrast, HM4D mice showed LTM impairments in the OLM task, but showed no such impairments in LTM formation for the ORM task. Using c-Fos as a marker for neuronal activation, RT-qPCR revealed an increase in expression in CA1 of HM3D mice, while showing a decrease in activity of HM4D mice following CNO injections. Together, these experiments show a novel way of modulating LTM

formation in behaving animals while further demonstrating hippocampal dependence in OLM but not ORM task LTM formation. Moreover, this provides evidence for DREADDs being a robust and reliable means of modulating circuit function to manipulate behavior.

Title: Molecular mechanisms of spatial working memory and reference memory in the hippocampus: A western blot analysis

Authors: ***N. FRAIZE**[1,2], M. HAMIEH[2], M. JOSEF[2], M. TOURET[2], P. SALIN[2], G. MALLERET[2];
[1]Nicolas Fraize, Lyon, France; [2]Ctr. de Recherche en Neurosciences de Lyon, Lyon, France

Abstract: Working Memory (WM) and Reference Memory (RM) are two processes aimed to store information. WM is a specific form of short-term memory that refers to the ability to retain information within a single trial. This information can then be stored into long-term/reference memory. RM refers to the long-term storage of information that remains constant over time, that is gradually acquired over many training sessions and is widely believed to be dependent on long term potentiation (LTP) of the synaptic efficacy. However, not all information that comes from working memory needs to be transferred into long-term memory. Insignificant data is better to be erased in order not to overload the brain with irrelevant things. It has been demonstrated that WM is very sensitive to proactive interference (PI) which is a phenomenon whereby information learned in the past interferes with the learning of more recently presented material. Consequently, forgetting this old information would be necessary to perform everyday tasks requiring WM abilities. Work from our team suggest that long term depression (LTD) of synaptic efficacy may serve to weaken previous memory traces, thus preventing them to interfere with new ones. In order to assess post-synaptic changes in receptors trafficking and signaling involved in LTP or LTD, we performed a selective WB analysis in the different areas of the

hippocampus in control and test rats submitted to 10 days of training in a RM or WM task with or without interference. Our results show that, in the dentate gyrus (DG), the WM task with high level of interference induces a selective increase in the phosphorylation of the CamKinaseII (CamKII) as compared to controls and rats tested in RM or WM task with low interference. This increase was not observed in CA1 and CA3 area of the hippocampus. CamKII is a key protein involved in long-term synaptic plasticity and is activated by a synaptic increase in calcium concentration. Thus, our results suggest that long-term synaptic plasticity occurs selectively in the DG during the WM task with high interference, and that, in this task that requires a high level of cognitive flexibility, the memory trace must be quickly formed as well as quickly erased.

Title: Spatial learning capabilities and mitochondrial function in creatine-supplemented mice

Authors: W. M. SNOW[1,4], C. CADONIC[2,4], S. K. ROY CHOWDHURY[4], E. THOMSON[4], S. ALASHMALI[3], E. PLATT[4], M. SUH[3], P. FERNYHOUGH[1,4], *B. C. ALBENSI[1,2,4]; [1]Pharmacol. & Therapeut., [2]Biomed. Engin., [3]Human Nutritional Sci., Univ. of Manitoba, Winnipeg, MB, Canada; [4]Div. of Neurodegenerative Disorders, St. Boniface Hosp. Res., Winnipeg, MB, Canada

Abstract: Objective: Dietary supplementation with creatine, a neuroprotective organic acid, has been shown to improve memory in humans and animals. Whether creatine enhances the acquisition and retention of spatial memory in the Morris water maze (MWM), a well-characterized rodent memory assay, is unknown. Further, the physiological mechanisms for the memory enhancements reported thus far are unclear. The transcription factor nuclear factor

kappa B (NF-κB) has been implicated in creatine-induced enhancements in cultured neurons. CREB signaling is implicated in creatine-enhanced spatial memory assayed using the Barnes maze in mice. We have shown a role for NF-κB in maintaining synaptic plasticity, memory, and neuronal energy homeostasis. Thus, this study sought to investigate: 1) the effects of creatine supplementation on hippocampal-dependent spatial memory in the MWM; 2) the effects of creatine on neuronal mitochondrial function *in vitro;* 3) CREB and NF-κB levels in the hippocampi of creatine-fed mice; and 4) the NF-κB complex as a possible target of creatine-induced memory enhancements and mitochondrial function. **Methods:** C57BL/6 male mice (age 7 mos) were fed either a creatine-supplemented (3% w.w.) or control diet for 8-9 wks. During wk 8, mice underwent MWM training to assess spatial learning and memory. In a subset of animals, mitochondrial function was assessed (i.e., oxygen consumption rates (OCR); XF24 Analyzer, Seahorse Biosciences)) following MWM training. Cortical neurons from embryonic mice were cultured. Mitochondrial bioenergetics were measured in creatine-treated (1 mM) vs. untreated neurons alone and in the presence of sulfasalazine, an NF-κB blocker. Western blot experiments were used to determine hippocampal protein levels of CREB and NF-κB with and without creatine. **Results:** *In vivo*, creatine dietary supplementation significantly enhanced spatial learning in the MWM ($p<0.05$) relative to control-fed mice. *In vitro*, creatine increased OCR in cultured cortical neurons vs. untreated neurons ($p<0.05$). Blockade of NF-κB with sulfasalazine, however, resulted in diminished mitochondrial OCR ($p<0.05$). Western blot experiments to determine NF-κB and CREB levels are ongoing. **Conclusions:** These data establish creatine-induced enhancements in learning and neuronal cellular bioenergetics in mice and suggest the involvement of NF-κB as a key regulator of energy homeostasis. Such research has important implications for the treatment of disorders affecting memory, including Alzheimer's disease. Title: Reelin supplementation rescues synaptic plasticity and cognitive deficits in a mouse model for Angelman syndrome

Authors: *W. HETHORN, S. L. BLANKENSHIP, E. J. WEEBER;
Univ. of South Florida, Tampa, FL

Abstract: The reelin pathway has implications in synaptic plasticity, through the modulation of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor insertion and ion conductance through N-methyl-D-aspartate (NMDA) receptors, and in hippocampal learning and memory. Past research has demonstrated that through a single application of reelin, long-term potentiation (LTP) can be enhanced, dendritic spine density augmented, and associative and spatial learning and memory improved. Angelman Syndrome (AS) is a neurological disorder that presents with an overall change in synaptic function, including decreased LTP, reduced dendritic spine density, and deficits in learning and memory, making it an attractive model to examine reelin's ability to recover synaptic function and cognitive deficits. In this study, we investigated the effects of reelin on synaptic plasticity and cognitive function in a mouse model for AS, demonstrating that a single *in vivo* injection of reelin can enhance LTP, increase dendritic spine density, and rescue learning and memory associated with hippocampal dependent behavior. Furthermore, we detected alterations to the reelin profile in AS, both in mouse and human tissue, alluding to reelin as a possible therapeutic in the AS community.

Title: Role of neurobeachin in fear memory reconsolidation

Authors: *B. LEE, T. CHO, E. BANG, A. PAYDAR, S. LEE, W.-S. YANG, H.-S. SHIN;
Cognition and Sociability, Inst. For Basic Sci., Seoul, Korea, Republic of

Abstract: Memory consolidation is a process that stabilizes a memory trace into long term memory after the initial learning. This consolidated memory becomes vulnerable after memory retrieval and either reinforced or weakened through reconsolidation. Many reports have

suggested that de novo protein synthesis is required for both consolidation and reconsolidation. However, the underlying mechanisms of the newly synthesized proteins in memory reconsolidation were not fully understood. Here, we show that neurobeachin (Nbea), a regulator of synaptic protein trafficking, plays a critical role in fear memory reconsolidation. First, in proteomic analysis Nbea was identified to be increased in mouse hippocampus after contextual fear memory retrieval. We studied the temporal expression of Nbea after fear conditioning and retrieval. Interestingly, Nbea was gradually increased after fear conditioning but was rapidly and transiently increased after fear memory retrieval suggesting different roles of Nbea during consolidation and reconsolidation. Next, we utilized shRNA knockdown (KD) system to understand the role of Nbea in the hippocampus during consolidation and reconsolidation. Nbea KD mice showed no significant differences for fear memory acquisition and consolidation from control group. However, Nbea KD mice clearly showed enhanced fear memory reconsolidation suggesting a specific role of Nbea during reconsolidation. Due to the enhanced fear memory with inhibition of Nbea expression in hippocampus, we suggest neurobeachin as a negative regulator for maintenance or stabilization of context-dependent fear memory during reconsolidation.

Title: Space radiation improves pattern separation in older mice without influencing gross hippocampal function

Authors: ***M. J. LUCERO**[1], R. L. REDFIELD[1], N. ITO[1], G. PALCHIK[2], D. R. RICHARDSON[1], R. P. REYNOLDS[1], S. MUKHERJEE[1], H.-Y. SHIH[2], P. D. RIVERA[1], S. G.

BIRNBAUM[1], B. P. C. CHEN[2], A. J. EISCH[1];
[1]Dept. of Psychiatry, [2]Dept. of Radiation Oncology, UT Southwestern Med. Ctr., Dallas, TX

Abstract: High atomic weight and energy (HZE) particles are a major component of space radiation, and chronic low doses may be detrimental to astronauts during deep space missions by decreasing adult hippocampal neurogenesis (Rivera et al., 2013) and impairing cognitive ability (Raber et al., 2011). This raises concerns that HZE radiation may diminish hippocampal function (e.g. by decreasing memory or mood control) and thus compromise mission success. Furthermore, it is unknown how HZE radiation alters subtle aspects of hippocampal function such as pattern separation, the ability to distinguish unique patterns or contexts sharing overlapping features, in "astronaut-age" equivalent mice. To fill these knowledge gaps, we exposed C57BL/6J mice (9-week old [Young Adult] or ~6-month-old [Mature] mice) to HZE particles (^{28}Si, 275 MeV/n, 72.1 KeV/μm LET or ^{56}Fe, 600 MeV/n, 174.1 KeV/μm LET) and examined general behavior (e.g. locomotion) and 2 hippocampal-dependent functions, contextual fear conditioning (CFC) and pattern separation (contextual discrimination fear conditioning, CDFC) 2 to 6 months post-irradiation. For the ^{28}Si HZE particle radiation experiment, Young Adult and Mature mice received a single exposure of 20 cGy, a single exposure of 100 cGy, or 0 cGy (Sham). For the ^{56}Fe HZE particle experiment, mice received a single exposure of 20 cGy (Non-fractionated), a protracted dose of 20 cGy (Fractionated, 6.7 cGy x 3 days, 48h intervals), or 0 cGy (Sham). After ^{28}Si or ^{56}Fe irradiation, Young Adult mice showed normal general behavior, but diminished CFC and dose-dependent effects on CDFC. In contrast, Mature mice displayed normal locomotor activity and normal CFC. Interestingly, Mature irradiated mice that received ^{28}Si or ^{56}Fe showed improved CDFC compared to Sham. The improvement in CDFC in Mature mice was unexpectedly neurogenesis-independent, as doublecortin-immunoreactive immature neurons were lower than Sham in irradiated Young Adult and Mature mice. Thus, ^{28}Si and ^{56}Fe HZE particle radiation enhance pattern separation in mice of astronaut-equivalent age, but decrease hippocampal function in younger mice. We are currently exploring changes in local hippocampal neural circuitry as an explanation for the age-related improvement in pattern separation after HZE radiation exposure.

Title: Sparse encoding of a memory of a meal in the dorsal hippocampus as revealed with Arc expression

Authors: *M. B. PARENT[1], Y. O. HENDERSON[1], A. VAZDARJANOVA[2];
[1]Neurosci. Inst., Georgia State Univ., ATLANTA, GA; [2]Charlie Norwood VA Med. Ctr., Augusta, GA

Abstract: Our overarching hypothesis is that hippocampal neurons form a memory of a meal and inhibit meal onset during the period following a meal. In support of this, we discovered that inactivation of dorsal hippocampal neurons after a sucrose meal decreases the interval between two meals and increases total intake. Moreover, sucrose consumption is associated with small, but significant increases in the expression of the plasticity-related immediate early gene *Arc* (activity-regulated cytoskeleton-associated protein) in the dorsal hippocampus. It is possible that sucrose consumption produced low levels of *Arc* activation in dorsal hippocampal neurons because the rats had been given repeated exposure to the sucrose solution. That is, we hypothesize that extensive familiarity with the sucrose solution decreased the mnemonic demands associated with that meal, resulting in sparse encoding of the memory of the meal as revealed by Arc expression. To test this hypothesis, experimental rats were trained daily to consume a 32% sucrose solution at the same time and location and latency to contact the sipper tube during training was used to manipulate the degree of familiarity with the sucrose solution. The "more familiarized" group was trained until their latencies were less than 30-sec for 2 consecutive days and the "less familiarized" group was trained using a 60-sec criterion. The day after the criterion was reached, the experimental rats were given the sucrose solution for 7 min, euthanized immediately, and their brains were harvested. Caged control rats were handled and transported in a similar manner during training and on the experimental day, but were never given the sucrose solution. *Arc* mRNA expression in dorsal hippocampal neurons was measured using fluorescence *in situ* hybridization. Our preliminary findings based on a small sample size suggest that familiarity with the sucrose solution decreases sucrose-associated *Arc* activation in dorsal hippocampal neurons. Specifically, the less-familiarized group had more *Arc* activation than the more familiarized group, and the more familiarized group had more *Arc* activation than the caged controls. Additionally, when both groups were combined, the percentage of *Arc* expression in the dorsal hippocampus decreased as the number of training days increased. These findings suggest that an eating episode induces synaptic plasticity in dorsal hippocampal

neurons, which is consistent with our overarching hypothesis that dorsal hippocampal neurons form a memory of a meal. Moreover, our findings suggest that familiarity with the meal produces sparse encoding of the memory of that meal.

Title: Post-retrieval hippocampal infusions of HDACi enhance spatial memory reconsolidation

Authors: *I. BALDERAS, G. CHAVEZ-MARCHETTA, A. AGOITIA-POLO, C. M. GOMEZ, A. DIAZ-GONZALEZ, F. BERMUDEZ-RATTONI;
IFC-UNAM, Mexico city, Mexico

Abstract: It has been proposed that a short retrieval induces impairments in reconsolidation or enhancement of extinction. Reconsolidation refers to the destabilization/re-stabilization process upon memory reactivation. We tested the effect of a short retrieval on spatial memory reconsolidation in the Morris water maze. We found that infusions of an inhibitor of HDAC in the hippocampus immediately after a short retrieval enhanced memory, when tested 24 h and 7 days after. Moreover, CNQX infusion in the hippocampus blocked retrieval; however, CNQX did not impede memory enhancement by infusions of HDACi. We observed that infusions of HDACi in the hippocampus enhanced reconsolidation in the absence of retrieval. The results indicate that short retrieval not necessarily produce memory impairments in a reconsolidation protocol in a declarative memory model. Moreover, the HDACi induces a reliable spatial memory reconsolidation enhancement.

Title: PDE11A4, a phosphodiesterase enriched in the ventral hippocampus, is required for consolidation of social memories and normal social approach behaviors

Authors: *M. P. KELLY, S. HEGDE;
Pharmacology, Physiol. & Neurosci., Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: Social deficits are key features of several neuropsychiatric disorders, such as autism, schizophrenia, and PTSD, yet no medicines are available to remedy these symptoms. Despite the fact that appropriate social behaviors are vital to thriving in one's environment, little is understood of the molecular mechanisms that control social behaviors or how social experiences modify these signaling pathways. Here, we show that Phosphodiesterase 11A (PDE11A), an enzyme that is restricted to the hippocampus and that breaks down cAMP and cGMP, may be a fundamental molecular mechanism of social behavior. First, we tested male and female PDE11A knockout (KO) and sex-matched wild-type (WT) littermates for social vs non-social odor recognition (SOR vs nSOR) using odor-saturated wooden beads as stimuli. Male and female PDE11A KO mice exhibited intact short-term memory (STM, 1 hour after training) for SOR but absolutely no long-term memory (LTM, 24 hours after training). This LTM deficit was reversed when PDE11A4 (the PDE11A isoform expressed in brain) was delivered back to the hippocampus of KO mice. Although PDE11A KO mice showed no LTM for SOR, they exhibited robust LTM for nSOR. Next, we determined if PDE11A KO mice would form memories for non-social odors if they learned about them via social interactions instead of odor-

saturated wooden beads. To test this, we used the social transmission of food preference (STFP) assay. Similar to results obtained in SOR, PDE11A KO mice demonstrated intact STM for STFP but no LTM. These results suggest that PDE11A4 is specifically required for the consolidation of social memories. Next, we tested PDE11A WT and KO mice in a social approach/social avoidance assay. When given the choice of exploring a cagemate versus a novel PDE11A WT mouse, neither male nor female PDE11A KO mice differed relative to WTs with regard to their approach behavior. When given the choice between a cagemate and a C57BL/6J, however, both male and female PDE11A KO mice approach the C57BL/6J mouse significantly less than do PDE11A WT mice. Since PDE11A appears to be required for intact social behaviors, we next asked if social experience might feed back to regulate PDE11A4 . We found that 1 month of social isolation, vs. group housing, changed the compartmentalization of PDE11A4 protein within both the dorsal and ventral hippocampus. This isolation-induced shift in the compartmentalization of PDE11A4 was mimicked by phosphorylation of serine 162 (see Pathak et al., SFN 2014). Together, our findings suggest that PDE11A4, a highly druggable target, regulates social behavior and is a key mechanism by which social experience modifies the brain.

Title: Memory traces and their underlying mechanisms during the infantile amnesia period

Authors: *A. TRAVAGLIA, R. BISAZ, C. M. ALBERINI;
New York Univ., New York, NY

Abstract: Clinical and basic research over the past century has demonstrated that the developing brain is extraordinarily sensitive to environmental influences and that early life aversive

experiences profoundly affect the neural systems critically involved in cognition and emotions, resulting in lifelong consequences on brain and behavior. On the other hand, there is very little recollection in adulthood of memories occurred during the early period of life, a phenomenon known as infantile amnesia. We have used a negatively reinforced one-trial operant conditioning paradigm (inhibitory avoidance, IA) in rats to investigate the expression, temporal dynamics and mechanisms of memory formation and retention in infant rats. In agreement with previous literature, we found that rats trained at postnatal day (PN) 17, which corresponds to early childhood in humans, acquired and expressed the memory immediately after training. This memory was then very rapidly forgotten, and no long-term memory was detected, in line with the theory of infantile amnesia. We will refer to this as infantile memory trace. However, a reminder experience (combination of context and footshock), which per se does not evoke any IA response, given at later times (up to at least one month after training) produced a significant IA memory, which was very long lasting and specific to the training context. Infantile amnesia was not found in rats trained at PN24, which showed a very strong and long lasting IA memory similar to that of adult rats. We asked whether the hippocampus is involved in establishing the infantile memory trace. Inactivation of the hippocampus with muscimol at the time of training prevented memory reinstatement, suggesting the functional involvement of the hippocampus in the acquisition of the memory. As expected, muscimol at the time of training of PN24 rats blocked long-term memory formation suggesting that at this age, like in adulthood, the hippocampus is required to form IA memory. Quantitative western blot analyses of activity, plasticity and memory markers in the dorsal hippocampus indicated that training at PN17 leads to the activation of the immediate early genes Egr-1 and Arc, as well the BDNF/TrkB pathway. We conclude that the hippocampus is critically engaged in the formation of memories during the period of infantile amnesia, and that, despite the memories are not expressed, traces of the experience must be stored long term and later can be reactivated by reminders.

Title: Insulin-like growth factor 2 prevents memory decay associated with normal aging

Authors: *S. A. JOHNSON, C. M. ALBERINI;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Memory loss is a common problem in aging that manifests as rapid forgetting of newly learned information. This suggests that memory consolidation, the process that occurs after learning and leads to stable memory retention, is likely compromised by aging. Targeting consolidation mechanisms may therefore prove to be an effective strategy for preventing or reversing age-related memory deficits. Work from our laboratory has shown that memory consolidation in young adult rats requires the induction of insulin-like growth factor 2 (IGF-II) expression in the dorsal hippocampus. Furthermore, administration of recombinant IGF-II during the early stages of consolidation enhances memory and prevents forgetting (Chen et al 2011; Stern et al 2014). Here we sought to determine whether dysregulation of hippocampal IGF-II expression contributes to age-related changes in memory formation and persistence, and whether targeting consolidation with exogenous IGF-II can prevent age-related memory loss. Young adult (4 months) and aged (26 months) male Fischer 344 x Brown Norway (FBN) F1 hybrid rats were injected with IGF-II or vehicle in the dorsal hippocampus immediately after inhibitory avoidance (IA) training. When tested 14 or 28 days after training, aged rats injected with vehicle showed memory impairment relative to young adult rats. IGF-II injections significantly prevented this memory loss. Quantitative western blot analyses revealed that expression of IGF-II in hippocampal synaptic fractions is reduced in aged relative to young adult rats, supporting the hypothesis that a decrease in hippocampal IGF-II function contributes to age-related cognitive impairment. Further, in aged rats, IA training did not lead to induction of plasticity mechanisms such as Arc in the dorsal hippocampus; however, a significant rescue of training-induced Arc expression was observed in aged rats injected with IGF-II. Our results indicate that administering IGF-II within the initial consolidation period can effectively prevent memory deficits in aged rats, potentially by targeting Arc-dependent mechanisms.

Title: β-adrenergic receptors and memory consolidation: the role of astrocytic mechanisms

Authors: *V. GAO[1,2], A. SUZUKI[3], S. LENGACHER[4], P. J. MAGISTRETTI[4], C. M. ALBERINI[1];
[1]New York Univ., New York, NY; [2]Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]Univ. of Toyama, Toyama, Japan; [4]École polytechnique fédérale de Lausanne, Lausanne, Switzerland

Abstract: Emotionally charged events generate strong memories. Norepinephrine (NE) modulates the strength of emotional memories by binding to β-adrenergic receptors on target cells. Antagonists of β-adrenergic receptors such as propranolol are known to block memory consolidation. β-adrenergic receptors are expressed on astrocytes in addition to neurons. In fact, stimulation of astrocytic β-adrenergic receptors *in vitro* promotes glycogenolysis, a process that occurs in astrocytes but not in neurons in the adult brain. Using inhibitory avoidance (IA) training in rats, we previously reported that learning requires glycogenolysis, which results in release of lactate from astrocytes and its transport into neurons. This lactate-mediated astrocytic-neuronal coupling is required for long-term memory formation, long-term potentiation, and underlying molecular mechanisms required to mediate memory consolidation. Here we tested the hypothesis that β-adrenergic receptors in the hippocampus mediate memory formation via astrocytic-neuronal lactate coupling. We found that the hippocampal increase in lactate after IA training is completely blocked by intra-hippocampal administration of propranolol. Infusion of propranolol into the hippocampus before training blocks long-term, but not short-term memory, and this memory impairment is rescued by co-administration of L-lactate. Induction of long-term plasticity markers including Arc, phosphorylated CREB, CCAAT-enhancer-binding protein β (C/EBPβ), phosphorylated Ca2+/calmodulin-dependent protein kinase II (CaMKII), and phosphorylated cofilin after training are also blocked by propranolol and rescued by co-administration of L-lactate, as measured by quantitative Western blot analysis. The effect of propranolol on memory does not appear to be mediated by β1-adrenergic receptors, as intrahippocampal injections of β1 blocker betaxolol had no effect on memory. We conclude that β-adrenergic receptors mediate memory consolidation by critically recruiting astrocytic mechanisms.

Title: A critical role for the hippocampus-prelimbic/infralimbic cortex-amygdala circuit in retrieval-mediated memory strengthening

Authors: *X. YE[1], C. INDA[2], N. HUMALA[1], C. M. ALBERINI[1];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Mem. Sloan-Ketterring Cancer Ctr., New York, NY

Abstract: Memory impairment is often observed in aging as well as many cognitive disorders. It is an important yet challenging goal for mental health research to develop effective treatments for memory disorders. Several current strategies for memory improvement target the initial learning and consolidation period, which is temporally limited and requires de novo gene expression. It was once thought that following its consolidation memory is stable. However, many studies showed that a consolidated memory can become labile again if reactivated, such as by retrieval, and requires again gene expression to be re-stabilized. This process, referred to as reconsolidation, offers another opportunity for changing memory strength. Using the inhibitory avoidance task in rats, we have reported that three brief and spaced reactivations of a recent memory (3R) significantly enhance memory strength via reconsolidation processes (Inda et al., 2011). In the current study, we sought to determine the neural circuitry and molecular mechanisms underlying the retrieval-dependent memory strengthening. Using endogenous immediate early gene expression as tracers of brain activation, we found that memory reactivation induces Arc expression in dorsal hippocampus (dHC), basolateral amygdale (BLA), prelimbic/infralimbic cortex (PrL/IL) and anterior cingulate cortex (ACC). Blocking reactivation-induced Arc induction in different brain regions produces distinct effects on memory strength: (1) in the dHC, PrL or IL, it completely prevents memory enhancement evoked by 3R without affecting the memory strength induced by training; (2) in the BLA it causes memory loss indicating a role in reconsolidation; (3) in the ACC, it has no effect. We examined the molecular mechanisms in the dHC and PrL/IL accompanying retrieval-mediated

memory enhancement. We found that 3R significantly and selectively increases the phosphorylation levels of the transcription factor cAMP response element binding protein (CREB) and of the actin-binding protein cofilin in the dHC and PrL/IL. 3R also lead to significant expression changes in the PrL/IL region of several synaptic proteins, including AMPA receptors and the cell adhesion molecule neuroligins, Finally, blocking reactivation-induced Arc expression in dHC not only prevents molecular changes induced by 3R in dHC, but also in the PrL/IL, suggesting that dHC crosstalk to PrL/IL to promote memory enhancement. Taken together, these findings suggest a critical role for dHC-PrL/IL-BLA circuit in retrieval-dependent memory strengthening, and pave the way for developing and understanding retrieval-based strategy for memory improvement.

Abstract: The intracellular protein Disabled-1 (Dab1) acts downstream of the Reelin signaling pathway to promote dendritic outgrowth and neuronal migration in the developing brain. In the adult brain the Reelin signaling pathway is important in synaptic plasticity, dendritic arborization, and learning and memory. Using novel Dab1 knockout mice in excitatory (eKO; Camk2 promoter) and inhibitory (iKO; GAD2 promotor) cells, we examined the role of Dab1 in adult synaptic plasticity and learning and memory. We found that Dab1 eKO mice had deficits in hippocampal synaptic function, dendritic spines size, and associative and spatial learning. Dab1 iKO mice had significant increases in the levels of several excitatory synaptic proteins, while the

levels of other excitatory and inhibitory synaptic proteins were normal. Glutamatergic synapse alterations were supported by CA1 field recordings which revealed increases in both the presynaptic activation as well as postsynaptic excitatory neurotransmission in the Dab1 iKO mice. However, the iKO mice had impairments in theta-burst stimulated long term potentiation. Collectively, these data demonstrate an important new method role for examining Reelin-Dab1 signaling in the adult brain, and underscore the importance of this pathway in learning and memory.

Title: The role of protein synthesis and protein degradation in the amygdala during fear extinction

Authors: ***E. K. ROTONDO**, N. C. FERRARA, F. J. HELMSTETTER;
Psychology, Univ. of Wisconsin- Milwaukee, Milwaukee, WI

Abstract: The amygdala is important for fear memory consolidation, reconsolidation, and extinction. Evidence indicates that both protein degradation and synthesis in the amygdala are critical processes during the consolidation and reconsolidation of cued and contextual fear memories. It has been suggested that protein degradation by the ubiquitin-proteasome system (UPS) may mediate reorganization of the post-synaptic density as well as remove transcriptional repressors to promote *de novo* protein synthesis (Jarome et al., 2011). While the administration of protein synthesis inhibitors in the amygdala prior to extinction training impairs later retention of extinction learning, post-training protein synthesis inhibition does not appear to impair extinction memory consolidation. (Duvarci, ben Mamou, & Nader, 2006; Lin et al., 2003). Similarly, infusion of protein degradation inhibitors in the amygdala prior to extinction training impairs the consolidation of extinction learning but it remains unknown if blocking protein degradation in the post-extinction period impairs consolidation (Mao et al., 2006). To test

whether protein synthesis and degradation in the amygdala are critical for time-dependent consolidation after extinction training, animals were trained using auditory fear conditioning. The next day, fear was extinguished with 40 CS presentations. Bilateral amygdala infusions of the protein synthesis inhibitor anisomycin (ANI), the proteasome inhibitor clasto-Lactacystin β-lactone (βlac), or vehicle were given immediately after the extinction session. At a retention test 24 hours later, rats infused with ANI, βlac, and vehicle all showed similarly low freezing, indicating that the extinction memory had successfully consolidated regardless of drug infusion. These results suggest that, following extinction training, neither protein synthesis nor degradation in the amygdala is necessary for the consolidation of extinction. However, given evidence that pre-training protein synthesis or degradation inhibition in the amygdala impairs extinction retention, the critical factor in determining the effect of protein synthesis inhibition on extinction learning may be when this inhibition occurs relative to CS exposure. Current work is focused on understanding the sequence of cellular events in the amygdala that influence the induction of extinction-related plasticity and control post-training consolidation of memory for extinction.

Title: Activity dependent proteolysis in the amygdala modulates protein synthesis in the amygdala and dorsal hippocampus during consolidation of fear conditioning

Authors: *D. S. REIS, M. SEHGAL, F. J. HELMSTETTER;
Univ. of Wisconsin - Milwaukee, Milwaukee, WI

Abstract: The requirement for protein synthesis in the consolidation of fear memories in the amygdala is well documented. Post-training infusions of the translation inhibitor anisomycin into the amygdala impair the formation of both auditory and contextual fear memory. Recent work from our lab has shown that protein degradation mediated by the ubiquitin-proteasome system (UPS) is also critically involved in the consolidation of auditory fear memories in the amygdala.

Some evidence suggests that UPS-mediated protein degradation may drive the requirement for de novo protein synthesis during the consolidation period. However, the specific relationship between synthesis and degradation remains unclear. Here, animals were trained with auditory fear conditioning and given immediate post-training intra-amygdala infusions of vehicle, the protein synthesis inhibitor anisomycin, or the proteasome inhibitor clasto-lactacystin-β-lactone. Using a modified version of the surface sensing of translation (SUnSET) assay, we measured the level of protein synthesis in the amygdala and dorsal hippocampus of each rat at 60 min after fear conditioning. Our results indicate that inhibition of UPS-mediated protein degradation in the amygdala significantly reduces the amount of protein synthesis. In addition, we found that inhibition of protein synthesis or UPS-mediated protein degradation in the amygdala immediately after fear conditioning dramatically reduces the amount of global protein synthesis in the dorsal hippocampus as compared to the vehicle infused group. In fact, these manipulations seem to reduce protein synthesis in the dorsal hippocampus back to basal levels, as seen in the untrained vehicle group. Together these data suggest that the activity of the ubiquitin-proteasome system in the amygdala may have regulatory influence on the rate of mRNA translation in both the amygdala and dorsal hippocampus following auditory fear conditioning. These results provide *in vivo* evidence of an interaction between UPS-mediated protein degradation and de novo protein synthesis in memory and support the idea that UPS-mediated protein degradation may be a primary regulatory mechanisms critical to the initial formation and consolidation of auditory fear memory. Finally, the finding that inhibition of protein synthesis or degradation in the amygdala impairs global protein synthesis in the dorsal hippocampus lends further support to the idea that the amygdala is a primary site of synaptic plasticity during fear conditioning and may regulate specific mechanisms of memory consolidation, like protein synthesis, in other supporting neural structures.

Title: ERK-mTOR interactions in the lateral, basolateral, and central amygdala during fear memory consolidation

Authors: *N. FERRARA[1], M. R. GILMARTIN[1,2], D. S. REIS[1], J. L. LEE[1], F. J. HELMSTETTER[1];
[1]Psychology, Univ. of Wisconsin--Milwaukee, Milwaukee, WI; [2]Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: The amygdala receives projections from the thalamus and hippocampus and is generally considered a critical locus of neural plasticity following fear conditioning. The different subnuclei within the amygdala interact through intrinsic connections and have different roles during the consolidation and expression of aversive learning. The details about how the lateral, basolateral, and central nuclei interact during long term memory (LTM) formation are not well understood. ERK and mTOR are two major signaling pathways that regulate synaptic plasticity supporting memory consolidation in the amygdala. mTOR complex 1 regulates downstream translational machinery, and the phosphorylation of ERK regulates transcriptional and translational processes. There is some evidence supporting an interaction between ERK- and mTOR-mediated translation during activity dependent synaptic plasticity (e.g.,Tsokas et al., 2007). The current study focused on amygdala-subnuclei specific interactions between ERK and mTOR during LTM consolidation after fear conditioning. Consistent with our prior work, results suggest that bilateral microinfusion of pharmacological inhibitors of ERK (U0126) or mTOR (rapmycin) phosphorylation into the lateral amygdala, leaving the central nucleus of the amygdala unaffected, is sufficient to prevent memory formation when assessed 24-hours after training. Conversely, blocking ERK phosphorylation within the central nucleus of the amygdala did not impact fear memory. Immunohistochemistry results revealed that mTOR inhibition reduced phosphorylated ERK in the lateral amygdala, phosphorylated p70s6k in the lateral and basolateral amygdala, and increased phospho-ERK immunopositive cells in the central amygdala. Additionally, inhibition of ERK resulted in a significant reduction of both phosphorylated p70s6k in the basolateral and ERK in the lateral amygdala. This effect suggests a bi-directional interaction between the ERK and mTOR pathways that is dependent on the specific population of cells within the amygdala.

Title: Hippocampal protein degradation is required for context memory formation

Authors: *P. K. CULLEN, N. C. FERRARA, B. CALLIF, F. J. HELMSTETTER;
Psychology, Univ. of Wisconsin, Milwaukee, Milwaukee, WI

Abstract: Simple exposure to a novel context results in the formation of a memory for that environment. Animals that have formed this memory do not show the deficits in context fear conditioning typically seen with immediate shock presentations, a phenomenon known as the context-preexposure facilitation effect (CPFE). Forming a representation of a context following chamber exposure requires de novo protein synthesis in the CA1 region of the dorsal hippocampus (dHPC) (Barrientos, et al., 2002; Huff, et al., 2006). However, it remains unclear whether hippocampal activity-dependent protein degradation, which has been shown to underlie the consolidation and retrieval of context-shock associations (Jarome, et.al, 2014; Lee, et al., 2008), is required for the formation of context memory in the absence of shock. We predicted that the synaptic plasticity required here would also require ubiquitin-proteasome system (UPS) mediated protein degradation. In Experiment 1, rats were placed into an observation chamber and allowed to explore for 5 min and then returned to their home cage. Animals were sacrificed 30 min, 60 min, 90 min or 2 hrs following this exposure. We quantified activity of the 20S proteasome by measuring three types of proteolytic activity (chymotrypsin-, trypsin-, and peptidylglutamyl-like) in synaptosomal fractions from the dHPC and ventral hippocampus (vHPC). We found that exposure to the context resulted in different changes in proteasome activity between the dHPC and vHPC. In Experiment 2, we verified the functional role of hippocampal protein degradation by blocking UPS activity in the period after context exposure. Animals received a 5-minute exposure to the context followed by an immediate intra-dHPC infusion of the UPS inhibitor clasto-lactacystin β-lactone (βLac) (32ng/μl), anisomycin (ANI) (125 μg/ μl), or vehicle. Twenty-four hours later, rats were returned to the context and received 5 immediate shocks (1-sec, 1mA; 1-sec ITI). Context conditioning was assessed 24-hours after shock delivery in the training context. Animals that received either ANI or βLac after initial exposure exhibited impaired context conditioning compared to vehicle controls. These data suggest that both protein synthesis and protein degradation are required for the formation of a context representation in the absence of the UCS. Taken together, these data suggest that the formation of a context memory requires UPS-mediated protein degradation within the hippocampus and that the dHPC and vHPC undergo biochemically distinct degradation processes.

Title: Stathmin-dependent changes in microtubule stability are critical for memory formation

Authors: *G. P. SHUMYATSKY[1], S. UCHIDA[1], G. MARTEL[1], A. PAVLOWSKY[2], S. TAKIZAWA[1], C. HEVI[1], Y. WATANABE[3], E. KANDEL[4], J. ALARCON[2];

Abstract: Changes in microtubule stability, ubiquitous cytoskeletal structures, regulate many biological processes, but their role in memory remains unclear. Here we show that learning causes biphasic changes in the microtubule-associated network in the hippocampus. In the early phase, dephosphorylation regulating microtubule-destabilizing activity of stathmin, stathmin-tubulin binding and microtubule instability are increased, whereas in the late phase these processes are reversed leading to an increase in microtubule/KIF5-mediated localization of the GluA2 subunit of AMPA receptors at the synaptic sites. A microtubule stabilizer paclitaxel decreases or increases memory when applied at the early or late phases, respectively. Stathmin mutations disrupt changes in microtubule stability, GluA2 localization, synaptic plasticity and memory. Aged wild-type mice show impairments in stathmin levels, changes in microtubule stability, and GluA2 localization. Blocking GluA2 endocytosis rescues memory deficits in

stathmin mutant and aged wild-type mice. These findings demonstrate the role for microtubules in memory in young adult and aged individuals.

Title: A new mechanism of translational control of hippocampal mGluR-dependent long-term depression and object-place learning

Authors: *G. VIANA DI PRISCO[1], W. HUANG[1], S. BUFFINGTON[1], C.-C. HSU[1], P. BONNEN[1], A. PLACZEK[1], C. SIDRAUSKI[2], K. KRNJEVIC[3], R. J. KAUFMAN[4], P. WALTER[2], M. COSTA-MATTIOLI[1];

Abstract: At hippocampal synapses, activation of group-I metabotropic glutamate receptors (mGluRs) induces long-term depression (LTD), which requires new protein synthesis. However,

the underlying mechanism remains elusive. Here we describe the translational program that underlies mGluR-LTD and identify the translation factor eIF2α as its master effector. Genetically reducing eIF2α phosphorylation, or specifically blocking the translation controlled by eIF2α phosphorylation, prevents mGluR-LTD and the reduction of surface AMPA receptors (sAMPARs). Conversely, direct phosphorylation of eIF2α, bypassing mGluR activation, triggers a sustained LTD and removal of sAMPARs. Combining polysome-profiling and RNA-sequencing, we identify the mRNAs translationally up-regulated during mGluR-LTD. Translation of one of these mRNAs mediates the LTD induced by eIF2α phosphorylation. Remarkably, mice with deficient p-eIF2α-mediated translation are impaired in object-place learning, a behavioral task that induces hippocampal mGluR-LTD *in vivo*. Our findings identify a novel model of mGluR-LTD, which promises to be of value in the treatment of mGluR-LTD-linked cognitive disorders.

Title: Inhibiting histone deacetylation overrides the erasure of long-term memory caused by inhibition of PKM in *Aplysia*

Authors: *D. CAI[1], K. PEARCE[1], S. CHEN[1], J. PARK[1], D. L. GLANZMAN[1,2,3,4]; [1]Integrative Biol. and Physiol., Univ. California LA, LOS ANGELES, CA; [2]Neurobio., David Geffen Sch. of Med. at UCLA, Los Angeles, CA; [3]Brain Res. Inst., [4]Integrative Ctr. for Learning and Memory, David Geffen Sch. of Med. at UCLA, Los angeles, CA

Abstract: A major outstanding question in neuroscience is how memories persist in the brain over years to decades. Studies in mammals have shown that inhibiting PKMζ, the constitutively

active catalytic fragment of the atypical PKC isoform PKCζ, appears to erase consolidated memories. Previously, we reported that inhibition of PKM Apl III, the *Aplysia* homolog of PKMζ, appears to erase the memory for long-term sensitization (LTS) in *Aplysia*, as well as long-term facilitation (LTF), the specific form of synaptic plasticity that underlies LTS (Cai et al., 2011). Moreover, we found that inhibition of PKM Apl III reverses the synaptic growth associated with long-term memory (LTM) (Chen et al., unpublished). Recently, however, we discovered that LTM is not actually eliminated following inhibition of PKM Apl III by the PKC inhibitor chelerythrine, as indicated by our ability to fully restore LTM by retraining with a sensitization regimen that is insufficient to induce LTS in naïve animals (Pearce et al., 2014). This result is surprising, because, according to standard electrophysiological and morphological criteria, the memory should be fully erased after the chelerythrine treatment. How can LTM persist despite chelerythrine's reversal of synaptic facilitation and sensitization-related synaptic growth? Possibly, LTM is maintained in *Aplysia* by epigenetic changes. To test this idea, we examined whether inhibition of histone deacetylases (HDACs) with trichostatin A (TSA) can override chelerythyrine's disruption of LTM. There were five experimental groups: a Control-Veh group (untrained plus injection of vehicle), a Trained-Veh group (sensitization trained plus injection of vehicle), a Trained-TSA group (sensitization trained plus injection of TSA), a Trained-Chel group (sensitization trained plus injection of chelerythrine), and a Trained-Chel-TSA group (sensitization trained plus injection of TSA prior to injection of chelerythrine). The sensitization training consisted of five bouts of electrical shocks, spaced 20 min apart, delivered to the tail via implanted electrodes. The drug/vehicle solution was injected into an animal's hemocoel after the 24 hr posttest. Animals in all four trained groups exhibited significant sensitization at 24 hr after training. As previously reported, the Trained-Chel animals did not exhibit LTS at 48 hr, while the Trained-Veh animals did. By contrast, the Trained-Chel-TSA group did exhibit significant sensitization at 48 hr. These results indicate that the TSA treatment overrode chelerythrine's reversal of LTM, and suggest that histone acetylation plays a critical role in the maintenance of long-term memory in *Aplysia*.

Title: Reinstatement of long-term memory after its apparent erasure by inhibition of PKM or blockade of reconsolidation in *Aplysia*

Authors: K. PEARCE[1], D. CAI[1], S. CHEN[1], R. CHOE[1], R. SINGH[2], M. KIMBROUGH[1], K. SARMIENTO[1], X. ZHAO[1], T. DEHGHANI[1], *D. L. GLANZMAN[3,4,5];

Abstract: Reactivation of consolidated long-term memory (LTM) in *Aplysia*, as in mammals, is thought to trigger its reconsolidation, during which it is, apparently, vulnerable to disruption by protein synthesis inhibition (Cai et al., 2012; Lee et al., 2012). Moreover, inhibition of PKM Apl III, a homolog of PKMζ, appears to erase LTM in *Aplysia* (Cai et al., 2011). But do these two disruptive manipulations actually eliminate LTM or do they merely suppress its expression? To address this question, we asked whether the memory for long-term sensitization (LTS) can be reinstated following its disruption by PKM inhibition. There were two groups. The first received 5 bouts of tail shocks (full sensitization training), followed by an injection of chelerythrine at 24 hr, and 3 bouts of shocks (truncated sensitization training), which does not induce LTS in naïve animals, at 48 hr (5XTrained-Chel-3XTrained group). Animals in the second (control) group were given a vehicle injection at 24 hr and the truncated training at 48 hr. Animals in the 5XTrained-Chel-3XTrained group exhibited significant sensitization at 24 hr, but not at 48 hr, compared to the control group. However, at 72 hr LTM was reinstated in the 5XTrained-Chel-3XTrained group. Next we tested whether LTM can be reinstated after reconsolidation blockade. There were four groups: (i) a control group that received an injection of the vehicle solution at 48 hr and truncated sensitization training (3 bouts of tail shocks) at 72 hr (Control-Veh-3XTrained group); (ii) a group that initially received full sensitization training (5 bouts of tail shocks) followed by an injection of anisomycin at 48 hr (Trained-Aniso group); (iii) a group that was initially given full sensitization training, and the reminder stimulus followed by anisomycin injection at 48 hr (5XTrained-Reminder-Aniso group); and (iv) a group that was initially given full sensitization training, followed by the reminder stimulus and anisomycin injection at 48 hr, and, finally, truncated training at 72 hr (5XTrained-Reminder-Aniso-3XTrained group). There was significant sensitization at 48 hr in all three groups that received the initial training compared with the Control-Veh-3XTrained group. The Trained-Aniso group also exhibited sensitization at 72 hr and 96 hr. Sensitization was absent in the Trained-Reminder-Aniso group during the 72 and 96 hr posttests. But, although absent at 72 hr, sensitization reappeared at 96 hr

in the 5XTrained-Reminder-Aniso-3XTrained group. Taken together with our previous work, these data indicate that LTM can be fully restored despite elimination of the synaptic expression of LTM, and argue against the idea that memories can be erased.

Title: A subpopulation of cortical fast spiking parvalbumin interneurons surrounded by perineuronal net (PNN) expresses various metallopeptidases including Adamts8, Adamts15 and Neprilysin. Their possible importance in plasticity and long-term memory

Authors: *J. P. ROSSIER[1], A. URBAN[2], A. SAVOYE[2], A. BERNARD[3], M. HAWRYLYCZ[3], E. LEIN[3];
[1]Hop. Sainte Anne, Optogenetics and Brain Imaging, Paris, France; [2]Hop. Sainte Anne, CPN INSERM U894, Paris, France; [3]Allen Inst. for Brain Res., Seattle, WA

Abstract: The *in situ* hybridization (ISH) Allen Mouse Brain Atlas was mined for proteases genes expressed in the somatosensory cerebral cortex. Among the 480 genes coding for protease/peptidases in the mouse genome, 4 were found enriched in cortical interneurons: *reln* coding for reelin; *Adamts8* and *Adamts15* belonging to the class of metzincin proteases involved in reshaping the perineuronal net (PNN) and *Mme* encoding for Neprilysin, the enzyme degrading amyloid beta peptides accumulating in Alzheimer's plaques. The pattern of expression of these proteases in interneurons defines a new class of interneurons. In this report, single cell RT multiplex PCR (scRT-mPCR) after patch-clamp was performed for the simultaneous expression of 27 genes including these 4 peptidases,10 commonly accepted interneurons markers, 12 additional genes from the Allen database that are expressed in cortical interneurons

and 1 marker for excitatory neurons. Clustering of these genes by K-means algorithm displays five distinct clusters. The SOM cluster expresses *Sst* coding for somatostatin. Two clusters are co-expressing *Kit,* a tyrosine kinase and *Sema3c,* a semaphorin guiding growth cone molecule with VIP (KS-VIP) or without VIP (KS-neurogliaform). Two clusters of fast spiking (FS) interneurons expressing the calcium-binding protein *Pvalb* were identified, one co-expressing *Pvalb* with *Sst* (PV-SOM) and another co-expressing *Pvalb* with three metallopeptidases *Adamts8, Adamts15* and *Mme* (PV-MP). PV-MP interneurons are surrounded by a PNN whose role in plasticity is established. The three MPs identified in PV-MP cluster are secreted and may reshape the PNN highlighting the importance of FS interneurons in plasticity and long-term memory.

Title: Direct examination of how supramammillary activity alters neurotransmission in hippocampal area CA2/CA3a

Authors: V. ROBERT[1,2], V. CHEVALEYRE[3], *R. A. PISKOROWSKI[4];
[1]Ecole Normal Superior, Cachan, France; [2]Cnrs umr8118, [3]CNRS UMR 8118, [4]Univ. Paris Descartes, Paris, France

Abstract: The experiments presented in this poster rely on a combination of recently developed methods to examine and better understand how the supramammillary nucleus (SuM), a hypothalamic region that is known to be active during reward and emotional-laden behaviors, alters hippocampal activity. The SuM sends axonal projections to area CA2/CA3a and the dentate gyrus of the hippocampus. It is well established that the SuM plays a significant role in

controlling the hippocampal theta rhythm, a phenomenon critical for memory formation. While the SuM-hippocampal projection has been investigated *in vivo* and at an anatomical level, several large and important questions remain. Using stereotaxic injection of viral vectors in combination with transgenic mouse lines in order to express light-activated channels in a precise location- and cell-specific way, we have been able to selectively stimulate SuM fibers in the hippocampus, allowing for the direct examination of synaptic transmission. Whole-cell recordings of principal cells and interneurons have been performed in acute hippocampal slices in order to elucidate the precise cellular targets of SuM fibers, and to determine which neurotransmitters or neuropeptides are released. We have found strong evidence of direct glutamatergic transmission onto principal cells in area CA2/CA3a, as well as release of the neuropeptide substance P (SP). Our experiments reveal that SP appears to be acting on gabaergic transmission in this area. Thus, we are currently investigating which class of interneuron in modulated by SP and the resulting effect on CA2 transmission.

Abstract: The Hippocampal Formation (HF) is the brain system that supports declarative memory in human and nonhuman primates. The HF is made up of dentate gyrus (DG), Cornu

Ammonis fields CA3, CA2 and CA1, subiculum (S), presubiculum (PrS), parasubiculum (PaS) and entorhinal cortex (EC). The unidirectional circuit that links all these structures through several synaptic steps ultimately, end up in stable memories, very likely, in the cerebral cortex. This consolidation process takes place once the brainstem activity is cancelled (Logothetis et al., 2012). The HF receives cortical input from polymodal association areas, as well as subcortical brain centers, which are monoaminergic brainstem nuclei. The main centers with direct access to the HF, are dopamine containing cell groups such as the ventral tegmental area (VTA) and the substantia nigra (SN) and adjacent mesencephalic reticular formation, serotonergic (centralis superior and dorsal raphe nuclei), and noradrenergic (Locus coeruleus) as retrograde tracing studies demonstrated. The paths and termination of those brainstem projections to the different HF fields are unknown. In the course of an ongoing study aiming at the study of brainstem projections to the HF, we describe the resulting labeling after deposits into the SN and the in different parts of the VTA. 1) Direct nigro-hipocampal fibers are scarce, but present in all components of the HF in particular rostrally, while VTA are somewhat denser. 2) Both VTA and SN fibers were observed in non-cellular strata of the HF. 3) Both SN and VTA present fibers that change course and adopt a direction in a transversal plane to the main axis of the hippocampus, in stratum radiatum and lacunosum-moleculare, usually orthogonal to the direction of the dendrites. 4) The SN, was observed giving off fibers to the polymorphic cell layer of the DG, which crossed the granule cell layer, into innermost portion of the molecular layer of the DG. Our results are in agreement with retrograde studies in which scarce retrograde labeled neurons were found, and suggest that direct and presumably through modulation of the excitability of the dendritic field of neurons in the HF, they possibly produce an effect on the HF function in memory, as it has been shown already in the monkey (Logothetis et al., 2012). Title: Re-emergence of cholinergic/nestin cells in the medial septum/diagonal band after exercise

Authors: *J. M. HALL, L. M. SAVAGE, C. D. ALVARADO;
Binghamton Univ., Binghamton, NY

Abstract: It is well known that exercise leads to increases in a variety of neurotrophin and growth factors within the hippocampus and other brain regions that subsequently lead to cognitive improvements. Our laboratory has shown that exercise recovers spatial memory performance in an animal model (pyrithiamine-induced thiamine deficiency [PTD]) of the amnestic disorder Korsakoff syndrome. Our recent data indicate that exercise enhances behaviorally-evoked acetylcholine (ACh) efflux in the hippocampus of both healthy and PTD-treated rats. We hypothesize that exercise mediates the hippocampal cholinergic response by eliciting remodeling of cholinergic neurons within the medial septum/ diagonal band (MS/DB). Interestingly, a subpopulation of nestin+ cholinergic neurons have been discovered within in the basal forebrain and these neurons retain greater plasticity compared to nestin- cholinergic neurons. We hypothesized that exercise mediates the hippocampal cholinergic response by eliciting differential effects on nestin- and nestin+ cholinergic neurons. It was found that exercise increased the soma size of cholinergic neurons, but increases the number immunopositive nestin+ neurons in the MS/DB. Understanding the molecular mechanisms of activating these nestin+ cholinergic neurons could lead to pharmacological therapies in neurological disorders afflicted by cholinergic dysfunction.

Abstract: Many studies investigating memory function in humans use functional magnetic resonance imaging (fMRI). Recent translational studies have shown that the adaptation of human memory tasks to rodents is especially helpful to study memory processes by extrapolating results obtained in animals to humans, while potentially applying invasive methods. However, set-ups that allow for fMRI studies in awake animals are very rare to date. Here, we developed a new fMRI compatible setup designed to study perception and memory performances based on the recognition of odors. This setup includes an olfactometer that can release an unusually high number of odors (40 versus 3-4 published), an new animal holder that includes a head fixation system, a steady, but comfortable attachment solution of the coil to the rats head, and a respiration mask that allows for the rat to sample different odors while being head fixed. Furthermore, a safe, but effective, body restraining technique was developed to reduce stress on the head fixation, hence motion artefacts. The setup was first tested by imaging the olfactory bulb during the delivery of odors in sedated rats and is currently used to test odor memory performance within the frame of human to rat translational projects.

Title: Organization and neuroanatomy of the Cetartiodactyl hippocampus: an examination of 18 species

Authors: *N. PATZKE[1,2], K. Æ. KARLSSON[3], A. N. ALAGAILI[4], O. B. MOHAMMED[4], N. C. BENNETT[5], P. R. MANGER[2];
[1]Inst. de Ciências Biomédicas, Univ. Federal Do Rio De Janeiro, Rio De Janeiro, Brazil; [2]Sch. of Anatom. Sci., Univ. of the Witwatersrand, Johannesburg, South Africa; [3]Biomed. Engin., Reykjavik Univ., Reykjavik, Iceland; [4]Dept. of Zoology,, King Saud Univ., Riyadh, Saudi Arabia; [5]Dept. of Zoology and Entomology, Univ. of Pretoria, Pretoria, South Africa

Abstract: Cetaceans (whales, dolphins and porpoises) and Artiodactyls (even-toed ungulates) belong in the same mammalian order the Cetartiodactyla. While cetacean brains are generally larger than other mammals, cetaceans have absolutely and relatively small hippocampi in comparison to other mammals. The cetacean hippocampus exhibits a disorganized architecture and displays no evidence of adult hippocampal neurogenesis, which is present in all mammals analysed to date. A chemoarchitectonic description of the cetartiodactyl hippocampus is absent from the literature. Here we provide the first detailed chemoarchitectonic description of the hippocampus in 18 Cetartiodactyla species, 2 cetaceans: the northern minke whale (Balaenoptera acutorostrata) and the harbour porpoise (Phocoena phocoena) and 16 artiodactyls: Scimitar-horned oryx, (Oryx dammah), Arabian oryx (Oryx leucoryx), Black wildebeest (Connochaetes gnou), Blue wildebeest (Connochaetes taurinus), Blesbok (Damaliscus pygargus phillipsi), Arabian Ibex (Capra ibex), Springbok (Antidorcas marsupialis), Sand gazelle (Gazella subgutturosa), African buffalo (Syncerus caffer), Eland (Taurotragus derbianus), Kudu (Tragelaphus strepsiceros), Nyala (Tragelaphus angasii), Hippopotamus (Hippopotamus amphibious), Pig (Sus scrofa), Camel (Camelus dromedaries), using immunohistochemical staining for the calcium binding proteins parvalbumin, calbindin and calretinin and histological staining for Nissl. We reiterate that the cetacean hippocampus is small and architecturally disorganized, the most prominent difference being the loosely packed granular layer of the dentate gyrus. In all artiodactyls analysed the molecular layer could be clearly separated into an outer and inner layer, a feature not obvious in the cetaceans. In the cetaceans the stratum radiatum and stratum lacunosum moleculare of the hippocampus could not be clearly separated chemoarchitectonically as it was the case in artiodactyls. In most artiodactyls the parahippocampus was clearly delineated from the neighbouring areas by a strong immunoreactivity to calbindin and/or calretinin, but this was not present in cetaceans. Taken together the small size, undefined architecture and the lack of adult neurogenesis in the hippocampus of cetaceans, question the current assumptions regarding cognitive abilities associated with hippocampal function in the cetaceans.

Title: Anatomical Biomarkers of Learning in a murine model

Authors: S. KULASON, D. TWARD, K. NG, Y. ZHANG, J. ZHANG, J. W. KRAKAUER, *J. T. RATNANATHER, R. O'BRIEN, M. MILLER;
Johns Hopkins Univ., BALTIMORE, MD

Abstract: Motor training is thought to lead to structural changes in regions of the brain involved in motor control. While murine models are more convenient for studying brain development and its cellular and molecular underpinnings compared to human models, detecting small structural changes of the mouse brain is challenging. We hypothesized that combining high resolution MRI data with a sophisticated surface-based analysis tool would detect statistically significant structural changes. The mice were subjected to a 28-day motor training regimen of a skilled prehension task involving the right paw. Images were taken before and after training with *in vivo* longitudinal T2-weighted images acquired on a 9.4T MRI scanner with spatial resolution of 0.125 mm x 0.125 mm x 0.2mm. In order to segment the brain, the images were skull-stripped, rigidly aligned, and then mapped to an atlas using single-channel Large Deformation Diffeomorphic Metric Mapping (LDDMM). The 46 previously hand-segmented structures of the murine atlas were mapped onto each subject. Each region's bounding surface was calculated through a process of tessellation, smoothing, and downsampling. For each structure, surface driven transformations (LDDMM surface mapping) were calculated between the atlas and each subject to analyze changes in shape. We tested for differences between control and experimental populations using a global (volume of each structure), and local (log-Jacobian, or local volume change, at each surface vertex) measure of structural changes. Statistical significance was analyzed without making assumptions about the data's distribution by using permutation testing, which corrects for multiple comparisons by controlling the familywise error rate at $p<0.05$. The results show significant volume change in the left and right neocortex, as well as significant volume change and local expansion in left inferior and superior colliculus, left thalamus, and right piriform cortex. These regions may underlie brain changes important in motor learning. Our results suggest that subtle morphometric changes can be detected quantitatively in a murine

model to identify individual regions that are influenced by motor training. This indicates a role for MRI and quantitative surface-based analysis in studying brain plasticity.

Title: Tracking value in an uncertain environment: Contrasting functional roles of primate mediodorsal thalamus and perirhinal cortex during learning

Authors: ***A. S. MITCHELL**[1], S. CHAKRABORTY[2], M. J. BUCKLEY[1], M. E. WALTON[1]; [1]Oxford Univ., Oxford, United Kingdom; [2]Bioengineering, Imperial Col., London, United Kingdom

Abstract: Recent evidence from monkey models of amnesia supports a more critical role for the magnocellular mediodorsal thalamus (MDmc) in new learning than in retention of previously acquired information (Mitchell & Gaffan, 2008). However, there are several ways in which animals can learn about object-reward relationships in complex environments and exactly how MDmc lesions affect these processes remains unclear. Primate MDmc has strong reciprocal connections with the orbitofrontal cortex (OFC), which has been shown to be necessary to enable appropriate, flexible value assignment and value-based choices. Primate MDmc and OFC also receive inputs from anterior temporal lobe structures such as perirhinal cortex (PRh). The current study compared functional roles of MDmc and PRh when flexibly assigning values to stimuli. Macaque monkeys were preoperatively trained on a decision making task using three objects per session that required the animals to learn and track probabilistic object-reward associations. In some task conditions, the value probabilities linked to each object would change dynamically during the session whereas in others the probabilities were fixed throughout. After receiving bilateral neurotoxic injections into MDmc, animals were able to learn to choose the highest value

option and to track fluctuations in its value, just like the unoperated control monkeys. However, MDmc lesion animals were impaired at updating their behaviour following reversals in the identity of the best option. By contrast, PRh lesioned animals exhibited a small but significant decrease in learning object-reward values, both before and after reversals. Regression analyses suggest that MDmc animals exhibited a selective reduction in the influence of recent choices on current learning and decision-making, whereas PRh lesions reduced the influence of the most recently selected object-reward combination. These results provide new evidence about specific functional roles of MDmc and PRh in one aspect of associative learning, where the object-reward associations are changing within session.

Title: Differences in network activation patterns may underlie learning enhancement with spaced training

Authors: *C. A. KARSTEN[1], C. D. COX[1], K. WANG[1], G. LYNCH[1,2], C. M. GALL[1,3]; [1]Anat. and Neurobio., [2]Psychiatry and Human Behavior, [3]Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: First described by Ebbinghaus in the 1800s, and routinely demonstrated in different experimental animals and humans, training that is spaced across multiple trials is more effective than a single massed training session for memory encoding. Nevertheless, the mechanisms underlying the potency of spaced training remain unknown. Recent studies in our lab showed that spaced training in mice improves encoding of object location memory. The present studies, using immunolabeling of the immediate early gene product Fos to identify recently activated neurons, tested the hypothesis that spaced training engages different network patterns than a single (massed) learning episode. Cohorts of mice were trained in the object location memory task using either a single session or three spaced sessions with total training times being equal between paradigms. Animals were sacrificed 60-90 minutes after the final, or single, training episode, and spaced series of tissue sections through the forebrain were processed for immunofluorescence localization of Fos. In-house software was designed to align images - montages of full coronal cross sections - to the Allen Mouse Brain Reference Atlas and then automatically count highly active cells within specific fields. Correlation matrices were used to approximate network coherence. Mice that received effective spaced training exhibited robust patterns of correlated forebrain activity that were significantly different from patterns in the massed training group. As notable examples, the massed training group had greater coherence between hippocampal subfields whereas the spaced animals had a statistically greater correlation between orbital frontal cortex and hippocampus. Forebrain-wide descriptions of neuronal activation, as presented here, suggest a new interpretation of why distributed practice is so effective in encoding new information. The relationship of this hypothesis to psychological theories for the spaced trials effect will be discussed.

Title: Differential contribution of the medial and lateral entorhinal cortices, the perirhinal and postrhinal cortices and the hippocampal subfields to familiarity

Authors: *A. MALET-KARAS[1], N. NAKAMURA[1], T. KITSUKAWA[2], M. SAUVAGE[1]; [1]Ruhr Univ. Bochum, Bochum, Germany; [2]Osaka university, osaka, Japan

Abstract: Recognition memory is known to rely on two distinct processes recollection and familiarity. It is well-accepted that the hippocampus supports recollection. However, the specific neural basis for familiarity remains elusive. Indeed, a major controversy in recognition memory is whether only the parahippocampal region supports familiarity or whether the hippocampus also does in addition to recollection. This discrepancy emerged principally because of the lack of tools with spatial resolution high enough to dissociate activity occurring in adjacent regions in humans (for example the hippocampus and the parahippocampal region). Also, a growing number studies have reported a functional segregation within the parahippocampal region itself, e.g. between the lateral and medial entorhinal cortices and the perirhinal cortex and postrhinal cortices. Yet, the specific contribution of those areas to familiarity remains unclear. Moreover, the medial entorhinal cortex was recently found to selectively contribute to recollection and not familiarity, suggesting that not all parahippocampal areas would support familiarity. Here, we tested this hypothesis by combining a rat behavioral memory paradigm shown to yield familiarity-only judgments and high resolution molecular imaging to map the activity of the different MTL areas (the lateral and medial entorhinal cortices, the perirhinal cortex and postrhinal cortices, CA1 and CA3) during the retrieval of odor memory. The neuronal activation is assessed by the detection by fluorescent in-situ hybridization of the immediate-early gene Arc which is tightly linked to plasticity processes. Preliminary results indicate a functional segregation of the MTL areas in terms of their contribution to the familiarity process.

Title: Topographical and functional innervation of non-canonical back-projection from the subiculum to hippocampal CA1

Authors: *Y. SUN, T. IKRAR, A. J. LÓPEZ, X. XU;
Anat. & Neurobio., Univ. of California, Irvine, Irvine, CA

Abstract: While the hippocampal formation largely has a feedforward, unidirectional circuit organization, we recently established the existence of an under-described pathway, the direct backward projection from the subiculum (Sub) to CA1, using monosynaptic rabies tracing (Sun et al., 2014 Cell Reports). In the present study, topographical and functional relationships of the projection from Sub to CA1 are addressed through multiple new and effective approaches. We first examined if Sub-> CA1 connections follow any topographical rules and whether its connectivity strength varies with proximal and distal CA1. Subicular cells retrogradely labeled from rabies tracing targeting excitatory pyramidal neurons in proximal versus distal CA1 *in vivo* were examined, and we found that distal CA1 receives stronger subicular connections than proximal CA1 as determined by the measurement of the relative abundance of connected populations. The ratios of labeled pre-synaptic subicular neurons relative to the number of starter neurons in CA1 increased from 0.12 to 1.15 with targeting locations shifting from proximal to distal CA1. In addition, we used fast voltage sensitive dye imaging to detect CA1 excitatory ensemble responses to subicular photostimulation via glutamate uncaging in slice preparations. The imaging experiments revealed an exponential decay relationship between CA1 activation strength and the subicular photostimulation distance from Sub/CA1 border with the stronger Sub-evoked responses in the more distal region of CA1. To characterize subicular innervation of single CA1 neurons, we performed microiontophoretic injection of anterograde AAV expressing channelrhodopsin-2 (ChR2) fused with YFP in Sub and conducted subcelluar ChR2-assisted circuit mapping (sCRACM). The YFP-expressing subicular axons were distributed across CA1 laminae with prominent labeling in stratum oriens (SO), lacunosum moleculare (SLM) and radiatum (SR). Whole-cell recordings from CA1 excitatory neurons in slice preparations were combined with focal photoactivation of subicular axons in CA1. The sCRACM approach mapped the spatial distribution of subicular inputs to the recorded CA1 neurons; both excitatory and inhibitory inputs were robustly detected around their perisomatic regions as well as in SO and SR. Together these data provide new and important information on the non-canonical Sub-> CA1 circuit connections, and this work has laid a foundation for further functional studies of this pathway.

Title: Topographical organization of multisynaptic inputs to the hippocampus: Dual transsynaptic tracing with rabies virus vector in the rat

Authors: *S. OHARA[1], S. SATO[1], K.-I. TSUTSUI[1], M. P. WITTER[2], T. IIJIMA[1];
[1]Tohoku Univ. Grad Sch. Life Sci., Sendai, Japan; [2]Kavli Inst. for Sys Neurosci and Cen for Neural Comp, NTNU, Trondheim, Norway

Abstract: Behavioral, anatomical, and gene expression studies have shown functional dissociations between the dorsal and ventral hippocampus with regard to their involvement in spatial cognition, emotion, and stress. In this study we examined the difference of multisynaptic inputs to the dorsal and ventral hippocampus in the rat by using dual transsynaptic tracing which employs two recombinant rabies viruses expressing different fluorescent proteins. This method allows us to distinctly label two neural circuits and visualize the divergent projection of these two circuits from a single neuron by the co-expression of the two fluorescent proteins (double labeling). In a previous study, we injected two rabies virus vectors into the dorsal and ventral dentate gyrus (DG) respectively (Ohara et al., PLoS One 8(11), 2013). We reported topographically arranged monosynaptic inputs from entorhinal cortex layer II, medial septum, diagonal band, and supramammillary nucleus. Disynaptic inputs from the piriform and medial prefrontal cortices, endopiriform nucleus, claustrum, cortical amygdala, medial raphe nucleus, medial habenular nucleus, interpeduncular nucleus, and lateral septum were also topographically organized. Here we report the results of injecting the two virus vectors into the dorsal and ventral pole of the DG and CA1 regions. In addition to the regions labeled following DG-injection, a two day survival resulted in labeled neurons in entorhinal cortex layer III, cortical amygdala, and the thalamic nucleus reuniens. After five days survival, labeled neurons were additionally present in the anterior cingulate cortex and presubiculum. In all areas we observed two differently situated populations of labeled neurons, showing almost no double labeled cells. These results indicate that the cortical and subcortical inputs to the dorsal and ventral CA1, like those to DG, are conveyed through parallel disynaptic pathways. This second-order input difference in the dorsal and ventral hippocampus is likely to contribute to the functional differentiation of the hippocampus along the dorsoventral axis.

Title: Anatomical pathways for auditory memory II: Information from rostral superior temporal gyrus to dorsolateral temporal pole and medial temporal cortex

Authors: *M. MUNOZ[1], R. INSAUSTI[1], A. MOHEDANO-MORIANO[1], M. MISHKIN[2], R. C. SAUNDERS[2];
[1]Univ. of Castilla-La Mancha Sch. of Med., Albacete, Spain; [2]Lab. of Neuropsychology, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Monkeys' auditory recognition memory differs from recognition memory in other sensory systems, in that they unable to store auditory stimuli in long-term memory. Monkeys learn the rule for tactile and visual delayed matching-to-sample within a few sessions, and then show one-trial recognition memory lasting 10-20 minutes. By contrast, monkeys require hundreds of sessions to master the rule for auditory recognition and then show retention lasting no longer than 30-40 seconds. Moreover, unlike the severe effects of rhinal lesions on visual memory, such lesions have no effect on the monkeys' auditory memory performance. In vision, long-term recognition memory relies on anatomical connections from the visual association area TE with areas 35 and 36 of the perirhinal cortex (PRC). We wondered whether a similar anatomical route for auditory processing existed or was the lack of auditory recognition memory a result of the lack of such a pathway. We hypothesized that an auditory pathway for recognition memory would originate in the higher order processing areas of the rostral superior temporal gyrus (rSTG) and then connect via the lateral temporal pole to access the rhinal cortex of the medial temporal lobe. To test this, we placed retrograde (3% FB and 2% DY) and anterograde (10% BDA 10,000 MW) tracer injections in rSTG and dorsolateral area of the temporal pole. Results showed, that area 38DL of the lateral temporal pole receives dense projections from auditory association areas Ts1, TAa, TPO, of the rSTG and from the rostral parabelt and to a lesser extent from areas Ts2-4 and PGa. In addition, area 38DL projects densely to area 35 of PRC, area 28, and to areas TH/TF of the parahippocampal cortex, while the projection avoids most of area 36r/c of the PRC. The results suggest that auditory information can access the

perirhinal cortex of the medial temporal lobe but taken together with the previous evidence this is not sufficient to support recognition memory.

Title: The nucleus reuniens and perirhinal cortex are critical to memory for sequences of events

Authors: *C. R. QUIRK[1,2], T. A. ALLEN[1,2], N. J. FORTIN[1,2];
[1]Ctr. for the Neurobio. of Learning and Memory, Univ. of California Irvine, Irvine, CA;
[2]Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Memory for sequences of events is fundamental to episodic memory. However, the neurobiology of this form of sequence memory is poorly understood. Using a cross-species sequence memory task we developed (Allen et al., 2014), our previous work in rodents has shown that neurons in the hippocampus (HC) and prefrontal cortex (PFC) code for sequences of events. Additionally, we have shown that infusions of fluorescent muscimol (FCM), a $GABA_A$ agonist, into the HC or PFC impaired sequence memory. Further, HC-PFC disconnection inactivations also impaired performance on the task, suggesting that interactions between the HC and PFC are critical to sequence memory. Similarly, our ongoing work using BOLD fMRI imaging in humans indicates that the HC and PFC regions are strongly engaged during task performance. Collectively, these findings suggest that the HC and PFC are part of a system that underlies the memory for sequences of events. However, little is known about the functional roles of distinct pathways that connect the HC and PFC. To begin to address this issue, we temporarily inactivated the nucleus reuniens or perirhinal cortex using FCM while rats performed the sequence task. The nucleus reuniens is reciprocally connected with the HC and PFC forming a *thalamic route* of communication. The perirhinal cortex is also reciprocally connected with the HC and the PFC forming part of the *cortical route* of communication. In the sequence task, rats are presented with a sequence of four odors through an odor port. On most

trials, odors are presented in the correct sequence (InSeq; ABCD). On probe trials, an odor is presented out of sequence (OutSeq; e.g., ABDD). Rats are required to hold in the odor port for ≥1sec for InSeq odors and withdraw from the port in <1sec for OutSeq odors. Sequence memory is demonstrated when rats correctly discriminate between InSeq and OutSeq odors. We report that inactivations of the nucleus reuniens or perirhinal cortex impaired sequence memory, indicating that both structures are critical to memory for sequences of events. Overall, these findings support the hypothesis that the HC and PFC communicate through both the thalamic and cortical routes in support of sequence memory. Further, these data motivate further examination of the roles of the thalamic and cortical pathways in memory for sequences of events.

Title: Island cells control temporal association memory

Authors: ***T. KITAMURA**[1], M. PIGNATELLI[1], J. SUH[1], K. KOHARA[1], A. YOSHIKI[2], K. ABE[2], S. TONEGAWA[1];
[1]MIT, Cambridge, MA; [2]RIKEN BioResource Ctr., Ibaraki, Japan

Abstract: Episodic memory requires associations of temporally discontiguous events. In the entorhinal-hippocampal network, temporal associations are driven by a direct pathway from layer III of the medial entorhinal cortex (MECIII) to the hippocampal CA1 region. However, the identification of neural circuits that regulate this association has remained unknown. In layer II of entorhinal cortex (ECII) we report clusters of excitatory neurons called Island Cells, which appear in a curvilinear matrix of bulb-like structures, directly project to CA1 and activate interneurons that target the distal dendrites of CA1 pyramidal neurons. Island Cells suppress the excitatory MECIII input through the feedforward inhibition to control the strength and duration of temporal association in trace fear memory. Together, the two EC inputs comprise a control circuit for temporal association memory.

Title: Nucleus incertus and hippocampal prefrontal cortical pathway - a stress responsive circuit in rats

Authors: *G. S. DAWE, Y. WU, W. TAN, J. KUMAR, U. FAROOQ, N. RAHADI, R. RAJKUMAR;
Natl. Univ. Singapore, Singapore, Singapore

Abstract: The nucleus incertus (NI) is the major brainstem source of the relaxinergic projection system in the mammalian brain. Recent reports suggest that the NI projects to the hippocampus and prefrontal cortex, structures that play a key role in cognition. The NI expresses corticotropin-releasing factor type 1 (CRF1) receptors and responds to water restraint stress with increased c-Fos expression. Previous studies from our lab showed that the NI projects to medial prefrontal cortex and that infusion of CRF into nucleus incertus suppresses medial prefrontal cortical activity and hippocampo-medial prefrontal cortical (HP-mPFC) long-term potentiation (LTP). The current study investigated the role of the NI in stress and synaptic plasticity in the HP-mPFC pathway in male Sprague-Dawley rats. Effects of various types of stress - repetitive (10-10 min in 24 ºC) and prolonged swim (30 min in 24 ºC) stress, and exposure to an elevated platform (30 min) - on c-Fos and relaxin-3 expression in the NI were examined using immunofluorescence and western blotting techniques, respectively. Serum corticosterone levels were measured to confirm stress induction. Further, we explored the effects of these stressors on LTP in the HP-mPFC pathway. The results showed that the NI responds to the stressors as indicated by increased c-Fos and relaxin-3 expression. LTP in the HP-mPFC pathway was significantly suppressed by 30-min swim and elevation stress. Finally, infusion of antalarmin, a CRF1 receptor antagonist, into the NI before or after elevation stress, partially but significantly

reversed the suppression of LTP in the HP-mPFC pathway. These results indicate that the NI responds to stress and could contribute to stress-induced impairment of cognitive processes involving the hippocampus and prefrontal cortex.

Title: Catecholamine release from the locus coeruleus to the dorsal hippocampus mediates the selective attention underlying spatial learning and memory

Authors: *K. A. KEMPADOO, E. R. KANDEL;
Columbia Univ., New York, NY

Abstract: Catecholamine signaling in the hippocampus mediates aspects of attention and arousal, however the precise roles of dopamine and norepinephrine in driving the selective attention that underlies spatial learning and memory are largely underexplored. We attempt to probe these questions by utilizing optogenetics to selectively stimulate dopamine release from the ventral tegmental area (VTA) to the hippocampus (HPC). Surprisingly, our immunohistochemistry results suggest that the locus coeruleus (LC), not the VTA, may provide the main source of dopamine to the HPC. We have therefore functionally assayed the role of LC catecholamine release in the HPC during learning and memory tasks. Photostimulation of the LC-to-hippocampal catecholamine pathway enhances performance in a spatial recognition task and attenuates performance in a novel object recognition task. These findings suggest dichotomous hippocampal function as a direct result of catecholamine release and therefore provide a framework for further exploring catecholamine anatomy and function in the HPC.

Title: A high-fat diet impairs hippocampal-dependent learning but spares hippocampal-independent learning

Authors: *E. M. STOUFFER, E. E. WARNINGER, P. N. MICHENER;
Bloomsburg Univ. of PA, Bloomsburg, PA

Abstract: Two experiments were conducted to examine the effects of consumption of a high-fat diet on a hippocampal-dependent and hippocampal-independent latent learning task (Experiment 1) and classical conditioning task (Experiment 2; in progress). In both experiments, 5-month old male Sprague-Dawley rats were first given free access to a high-fat diet (45% of calories from fat; Research Diets D12492) or a low-fat diet (10% of calories from fat; Research Diets D12450J) for 8 weeks prior to training. Experiment 1 involved the use of two versions of the Latent Cue Preference (LCP) task, in which water-replete rats sampled water (a neutral stimulus) in 1 compartment of a 3-compartment LCP box on 1 day, and then had no water in a second compartment of the LCP box the following day (1 training trial), for a total of 4 training trials over 8 days. In the hippocampal-dependent version of this task, there were several multi-modal (visual, tactile, olfactory) cues in each of the 3 compartments, while the hippocampal-independent version used a single (visual) cue in each of the 3 compartments. Rats were then water-deprived prior to a compartment preference test, during which they were allowed to move freely among the compartments with the water removed. Latent learning was demonstrated during the preference test if rats spent more time in the compartment that previously contained the water. Experiment 2 was similar to Experiment 1, but involved the use of two versions of a Conditioned Cue Preference task. Training and testing was identical to the LCP task, except that rats were water-deprived during both training and testing, making the water an unconditioned stimulus. Just as in Experiment 1, the 3-compartment box either had several multi-modal cues (hippocampal-dependent version) or a single cue (hippocampal-independent version) in each of the compartments. The results of Experiment 1 showed that the rats that consumed the high-fat diet prior to training showed impaired latent learning in the multi-cue LCP task compared to rats

that consumed the low-fat diet. However, rats that consumed either diet showed intact latent learning in the single-cue LCP task. These results indicate that consumption of the high-fat diet impaired hippocampal-dependent latent learning but did not impair hippocampal-independent latent learning. We are predicting the same pattern of results for Experiment 2. The hippocampal-dependent learning impairment induced by consumption of a high-fat diet was most likely due to increased oxidative stress, decreased antioxidant activity, decreased levels of brain-derived neurotrophic factor, and/or disrupted glutamate transmission in the hippocampus.

Title: Impaired hippocampal place cell stability and local field potential characteristics in a mouse model of Fragile X mental retardation

Authors: *T. ARBAB[1], C. A. BOSMAN[1], R. WILLEMSEN[2], F. P. BATTAGLIA[3], C. M. A. PENNARTZ[1];

Abstract: Hippocampal pyramidal cells fire strongly when the animal is at a specific location of the environment: the cell's place field. Proper spatial learning and memory consolidation have been associated with temporal stability of place fields, as well as certain characteristics of local field potentials (LFPs) and sharp-wave ripple events (SWRs) during subsequent sleep. Fragile X syndrome (FXS) is an inherited mental retardation, caused by a mutation that silences the X-chromosomal Fragile X Mental Retardation 1 gene (Fmr1). This leads to disturbed synaptic structure and function, which affects hippocampal synaptic plasticity. We have investigated in Fmr1-KO mice (Mientjes et al., 2006, Neurobiol Dis 21, 549-555) how the compromised synaptic function affects hippocampal network and single cell activity *in vivo* in a spatial exploration paradigm. These animals show impaired spatial and reversal learning deficits; however, little is known about how the mutation affects the functioning of hippocampal networks during cognitive processing *in vivo*. Multitetrode recordings were done in animals

freely exploring an open field arena surrounded by visual cues to evaluate the organization of hippocampal neural coding. We observed no differences between Fmr1-KO (n=6) and control (n=6) animals with regards to behavior and basic neurophysiological properties. We find that temporal stability of place fields, LFP power amplitude dynamics at different frequency bands, and properties of SWRs associated with proper spatial memory consolidation, are altered in Fmr1-KO animals. Together, these results suggest impaired mechanisms of spatial information processing and memory formation, linking the FXS genotype and its cognitive phenotype *in vivo*.

Title: NMDA antagonist MK-801 leaves latent inhibition intact in rats

Authors: A. S. ADAMS[1], *J. A. WILLNER[2], A. G. ADAMS[1];
[1]Psychology, [2]Radford Univ., RADFORD, VA

Abstract: Prior exposure to a stimulus retards later conditioning of that stimulus, an outcome known as “latent inhibition”. Although the hippocampus has long been thought to be critical for latent inhibition, studies employing neurotoxin lesions suggest that an intact hippocampus is not needed for the effect. The present study investigated this question by examining whether MK-801, a non-competitive NMDA antagonist that impairs hippocampal synaptic plasticity, would affect latent inhibition for a pre-exposed stimulus. Young adult male Long-Evans rats (N=24) were reduced to 90% of their free-feeding weights and assigned to groups that differed in pre-session drug treatment (subcutaneous injection of 0.05 or 0.1 mg/kg MK-801, or isotonic saline 20 min before all daily sessions). Rats were initially trained to retrieve food pellets from a feeder in a cylindrical chamber. They then received 4 sessions of non-reinforced exposure to either a 2 Hz clicker or a white noise in the chamber, each session consisting of 20 presentations of the 10-sec stimulus. Finally, the rats received 4 conditioning sessions during which the exposed and non-exposed auditory cues were individually presented and paired with delivery of two food pellets (15 trials with each stimulus per session). Videos recorded just before (PreCS) and during

each conditioning trial (CS) were scored every 2 sec by one of the authors for occurrence of five different behaviors (Magazine, Headjerk, Rear, Perambulate, Other), with excellent inter-rater reliability on 10 randomly selected sessions scored by another author (r = .96). The relative frequency of Magazine and Headjerk behaviors significantly increased from PreCS to CS periods over days, whereas the relative frequency of other behaviors decreased. Analysis of daily averages for Magazine and Headjerk behaviors during CS periods demonstrated a significant effect of stimulus exposure, with rats conditioning more rapidly to the novel auditory stimulus than they did to the pre-exposed auditory stimulus, thus demonstrating latent inhibition. There was no overall effect of drug treatment, however, nor were there any interactions between drug treatment and stimulus exposure (no impairment or enhancement of latent inhibition). These results suggest that NMDA receptors are not critical for the basic latent inhibition effect. Whether NMDA receptors play a role in other aspects of latent inhibition tied to hippocampal function (e.g., context dependence) remains to be determined.

Title: LLTP stimulation causes long term depression in conditional neuronal Deaf1 knockout mouse hippocampus

Authors: ***A. GHOSH**[1], S. RAJAMANICKAM[1], P. JENSIK[1], M. COLLARD[1], G. ROSE[2]; [1]Physiol., [2]Physiology, Anatomy, CIR-CNS, Southern Illinois Univ. Carbondale, Carbondale, IL

Abstract: Mutations within the DNA binding domain of the DEAF1 gene in humans result in severe intellectual disabilities. Conditional neuronal knockout of Deaf1 in mice result in anxiety like behavior and impaired contextual memory (Am. J. Human Genetics., 2014). This led us to analyze hippocampal plasticity in the knockouts. Briefly, hippocampal slices from male C57Bl/6J mice with floxed Deaf1 allele and positive for Nes-cre (Deaf1fl/fl;Nes-cre) or NKOs and controls (lacking Nes-cre), median age 14 months were used. The animals were anesthetized using isoflurane, after which the brain was quickly extracted and placed in artificial

cerebrospinal fluid (aCSF, composition in mM: 124 NaCl, 3 KCl, 2.5 CaCl2, 1.3 MgSO4, 1.4 NaH2PO4, 26 NaHCO3, 10 dextrose) bubbled with 95% O2 / 5% CO2, pH ~7.3, 0°C. 400 µm-thick coronal slices containing the middle one-third of the hippocampus were cut into 0°C aCSF using a Vibratome. The slices were trimmed to isolate the hippocampus and overlying neocortex and then transferred to an interface-style recording chamber and maintained at 32.5 °C. The slices were perfused with 95% O2/5% CO2-bubbled aCSF (2.5 mL/min flow rate) and humidified 95% O2/5% CO2 gas flowed continuously over their exposed surfaces. Slices were equilibrated for at least 2 hours before recordings began. Schaffer/commissural afferents to CA1 were stimulated using a concentric bipolar stimulating electrode (25µm center diameter, 0.033 Hz base rate). Negative field EPSP slopes were recorded from stratum radiatum using 3-5 MΩ glass recording electrodes filled with aCSF. Baseline responses were set at approximately half-maximal amplitude. Protocols for plasticity studies were: ELTP - a single burst of 15 pulses @ 100 Hz; LLTP - 4 trains of 100 pulses @ 100 Hz with a 5 minute inter-train interval. Baseline responses and ELTP (~120% of baseline 30 minutes after stimulation) were not different between Control and NKO mice. However, LLTP stimulation produced divergent effects in the two groups. In Control mice, fEPSP slopes were enhanced in 70% of recordings (average increase to 190% of baseline, measured 30 and 180 minutes after stimulation). In NKO mice the predominant response was a lasting depression of fEPSP slope, observed in 60% and 90% of cases at 30 and 180 minutes, respectively. Average slopes were reduced to 50% and 30% of baseline at the two time points. Further work is being done to try to explain this paradoxical finding of induction of LTD following LLTP stimulation.

Title: Delay dependent effect of Nucleus Reuiens/Rhomboid inactivation on working memory performance

Authors: *D. M. LAYFIELD, M. PATEL, H. L. HALLOCK, A. GRIFFIN;
Univ. of Delaware, Newark, DE

Abstract: Electrophysiological evidence has shown that the hippocampus (HPC) and prefrontal cortex (PFC) functionally synchronize during working memory tasks in rodents, indicating that the two brain structures form a neural circuit that is important for working memory performance (Jones and Wilson 2005, Gordon 2011). Recent evidence suggests a time-dependent functional relationship between HPC and PFC, with functional inactivation studies suggesting that HPC and PFC act together during tasks that require working memory over long delays, and operate in parallel over short delays (Churchwell & Kesner 2011). The nucleus reuniens and rhomboid nucleus (RE/Rh) of the thalamus are anatomically connected to both the HPC and PFC and are thus well positioned to gate the flow of information between them (Vertes, 2006). RE/Rh have been shown to be necessary for the performance of spatial working memory tasks (Hembrook & Mair 2011); however, the extent to which RE/Rh are necessary for the transfer of information between HPC and PFC over both long and short delays remains unclear. If inactivation of RE/Rh produces delay length-specific impairments that parallel those following hippocampal-prefrontal disconnection in working memory tasks, then RE/Rh inactivation should cause a delay-dependent impairment on working memory task performance. To test this prediction, we inactivated RE/Rh using the GABAA agonist muscimol while rats performed one of 3 different tasks: Delayed alternation with a 30-second inter-trial delay period (DA30), delayed alternation with a 5-second inter-trial delay period (DA5), or continuous alternation with no inter-trial delay period (CA). All 3 tasks require rats to alternate between a left and a right goal arm to obtain a reward, relying on their previous choice of direction to determine the location of the next reward, with the difference being the duration over which the rat must remember trial-specific information. We found that RE/Rh inactivation produced a deficit in both DA30 and DA5 groups, but no deficits in the CA group. These results are consistent with previous hippocampal-prefrontal disconnection studies and suggest that the dependence on RE/Rh for working memory tasks increases as the delay period for the tasks increases, providing evidence for a time-dependent component of RE/Rh activity in working memory.

Title: Rodents with lesions of the medial prefrontal cortex path integrate normally despite working memory deficits

Authors: *M. SAPIURKA[1,4], A. OCAMPO[4,1], L. R. SQUIRE[4,1,2,3], R. E. CLARK[4,1];
[1]Psychiatry, [2]Neurosciences, [3]Psychology, UCSD, San Diego, CA; [4]VAMCSD, San Diego, CA

Abstract: Path integration refers to the ability to use self-motion cues to keep track of a reference location. Earlier studies showed that the hippocampus is critical for path integration in the rodent, even for very short, simple paths that are traversed in 3 seconds. In contrast, humans with damage that includes the hippocampus performed normally on path integration tasks when the paths were simple, presumably by relying on their intact working memory (Kim, Sapiurka et. al. 2013). We explored the possibility that rats with hippocampal damage fail at path integration because the information needed for path integration exceeds the capacity of working memory in the rat and that intact rats must therefore rely on long-term memory to path integrate. We lesioned the medial prefrontal cortex (mPFC) in rats, a structure thought to be important for working memory. Following recovery, we first tested the rats on the forced-choice alternation task. In this task, animals must remember whether they turned left or right in a T-maze on the previous trial in order to enter the alternate arm and receive a food reward. An intertrial interval of 5 seconds was used. Performance was measured as the percentage of correctly alternated trials. We then tested rats on path integration. Rats were placed on a circular table (2m diameter) with eight holes around the perimeter that had removable screens to provide access to a refuge box below the table. On each trial, one box was opened and the rat placed inside. Different holes were used for each trial. In complete darkness the rat left the box and explored the environment until it located a piece of food that had been placed in the interior of the table. The rat then spontaneously returned to the start box in order to consume the food. The time, distance, and number of turns needed to find the food was recorded as well as the accuracy of the return path. Rats with mPFC lesions were impaired on the delayed alternation task but not on path integration. We suggest that in rats path integration requires long-term memory because in the rat the complexity of the spatial information exceeds the capacity of working memory.

Title: Frustration-based anxiety and magnitude of reward-based pattern separation

Authors: *R. P. KESNER;
Univ. Utah, SALT LAKE CTY, UT

Abstract: In a previous study Salinas et al., 1996) ran rats in a runway task for food reward and focused on recovery time associated with reduced reward in order to measure frustration-based anxiety. Based on previous findings that ventral dentate gyrus (vDG) lesions disrupt anxiety, seven rats with colchicine lesions of the vDG and ten vehicle control rats were trained to run down a runway for 20 food pellets. After reaching running speed asymptote, the two groups of rats received on five consecutive trials 1, 9, or 17 food pellets and at the same time running speed was measured. The order of pellet presentations was counterbalanced. Usually 2-3 days for the vehicle controls were required to re-reach asymptote. The results for the vehicle control rats indicated a linear decrease in running speed as a function of an increase in reward magnitude change. In contrast, vDG lesioned rats maintained the same running speed independent of a change in reward magnitude. The results suggest that the vDG support a frustration-based anxiety effect and a possible frustration-based anxiety pattern separation effect.

Title: Externalilty in obesity: A hippocampal-dependent phenomenon

Authors: C. H. SAMPLE[1], J. MAK[1], P. MACIVER[1], *L. E. JARRARD[2], T. L. DAVIDSON[1]; [1]Psychology, American Univ., Washington, DC; [2]Washington & Lee Univ., Lexington, VA

Abstract: Hypersensitivity to external food-related cues and hyposensitivity to interoceptive satiety signals has been suggested to play an important role in the development and maintenance of obesity. Previous research showed that consuming a diet high in saturated fat and carbohydrate (i.e., Western diet (WD)) promotes excessive body weight gain and impairs performance on hippocampal-dependent learning and memory problems. Other research showed that hippocampal lesions impaired rats' ability to use interoceptive cues arising from different levels of food deprivation as discriminative signals relative to exteroceptive (e.g., auditory and visual) cues. The current research assessed whether stimulus control of appetitive behavior by food deprivation cues would be reduced relative to control by external stimuli following maintenance of rats on the WD. In Experiment 1, rats were first trained to solve a food deprivation intensity discrimination problem using only interoceptive cues arising from 0- and 24- hr food deprivation as discriminative stimuli for the delivery of sucrose pellets. The rats were then assigned to two groups matched on terminal discrimination performance; one group was maintained for 6 weeks on ad libitum WD and the other on standard lab chow ad libitum. All rats were then tested with their original discriminative deprivation cue contingencies. Following testing, rats were then trained with both external cues and deprivation stimuli as compound discriminative cues. The results showed that discrimination performance based on interoceptive food deprivation cues was impaired only for WD-fed rats. WD-fed rats' performance remained intact when external cues could be used to solve the discrimination. Experiment 2 investigated the effects of exposure to WD prior to the beginning of discrimination training with deprivation and external cues as compound discriminative stimuli. Furthermore, following 20 days on WD or chow, rats were categorized as diet-induced obese (DIO) or diet-resistant (DR). All rats were then tested with and without external cues. WD-fed rats (DIO and DR) were impaired in discriminating based on their food deprivation cues, but maintained significant discrimination when external cues were also present. CHOW rats maintained discrimination throughout the experiment. These results suggest that WD consumption diminished rats' ability to use energy state cues relative to food cues in discriminative control. A WD-induced impairment in the ability to use deprivation cues to control appetitive behavior could underlie excess intake and obesity. This effect may represent a hippocampal-dependent mechanism for externality.

Title: Role of FosB/JunD transcription factors in male pathological aggressive behavior in mice

Authors: *H. ALEYASIN[1,2], S. A. GOLDEN[2], M. E. FLANIGAN[2], M. L. PFAU[2], G. E. HODES[2], M. HESHMATI[2], S. J. RUSSO[2];

Abstract: Male aggression is an innate social behavior that helps individuals to defend their territory against competitors, as well as increase the probability of successful mating and reproduction with females. Indeed, adaptive aggressive behavior is conserved across most mammalian species. However, the use of extreme violence during aggression is considered pathological and can have devastating consequences on society. In the past couple of years a number of studies implicate reward circuitry as an important modulator of aggressive behavior. However, little is known about the molecular mechanisms modulating the initiation and motivation for aggressive behavior. Our study provides experimental evidence that supports the role of Fos/Jun transcription factors in nucleus accumbens, a key brain reward region, in regulating pathological aggression. Considering the role of these transcription factors in other reward-related behaviors, such as drug addiction, sexual pleasure and alcohol drinking, our data help to understand molecular basis for maladaptive motivational aspects of aggressive behavior in mice.

Title: *In vivo* MRI studies of structural changes in mouse brain following forced treadmill training

Authors: *B. D. ADDISON[1], A. C. EVANS[2], B. J. BEDELL[2];
[1]McGill Univ., Verdun, QC, Canada; [2]McGill Univ., Montreal, QC, Canada

Abstract: Introduction Environmental enrichment and exercise are known to promote brain plasticity. The cellular underpinnings associated with plasticity-related changes of brain structure, however, remain poorly understood. Previous studies have demonstrated volumetric changes in particular regions of the rodent brain by histological methods. However, a comprehensive assessment of structural alterations following exercise has not been performed. As such, the objective of this study was to perform an exploratory analysis of changes in regional cortical thickness and neuroanatomical volumes from longitudinal, *in vivo*, mouse brain magnetic resonance imaging (MRI) data following a short-term exercise regimen. Methods Three month-old, male, CD1 mice were randomly assigned to two groups. The exercise group (n =15 mice) was exposed to six weeks of forced treadmill (FT) exercise. The baseline treadmill speed was 24 cm/s, which was increased by 1cm/s per week. The control group (n = 12 mice) did not undergo treadmill exposure (NX) during this six week interval. Anatomical MRI scans were acquired at baseline and following completion of the six week exercise regimen. Scanning was performed on a 7T Bruker Pharmascan MR system. The MRI data was processed using a fully-automated image processing pipeline to generate regional cortical thickness (5 regions) and neuroanatomical volumetric (7 regions) measures. Group differences were analyzed by two-tailed t-tests with Bonferroni correction for multiple comparisons. Results Analysis of volume measurements taken from baseline and post-exercise scans revealed that six weeks of FT exercise resulted in a significantly greater increase in hippocampal volume (13.74%) compared to NX controls (4.13%) ($p < 0.001$). The amygdala showed an increase in volume in the FT group (6.21%) compared to a slight decrease in the NX controls (-1.39%) ($p < 0.01$). No significant differences in cortical thickness changes were identified. Conclusions We observed a statistically significant increase in the volumes of the mouse hippocampus and amygdala following six weeks of FT exercise. Interestingly, none of the cortical regions, including motor cortex, demonstrated significant differences between FT and NX groups. Correlative quantitative immunohistochemistry (qIHC) studies are currently underway to elucidate the cellular changes (*e.g.* increased synaptic density, astroglial activation) underlying the MRI-defined increases in regional brain volumes.

Title: Retrograde ventral hippocampal lesions after visual discrimination training impair context-specific conditioned inhibition

Authors: *R. J. BALOG[1], D. BENIS[2], N. S. HONG[2], J. TROW[2], S. H. DEIBEL[2], R. J. MCDONALD[2];
[1]Univ. of Lethbridge, Canadian Ctr. For Beha, Lethbridge, AB, Canada; [2]Canadian Ctr. for Behavioural Neuroscience, Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: It is well documented that during simple discrimination learning an excitatory association is accrued to the reinforced cue and an inhibitory association is acquired to the non-reinforced cue. We have utilized a visual discrimination task developed for the 8-arm radial maze and shown that excitatory instrumental conditioning was dependent on the dorso-lateral striatum and was not context specific. The inhibitory association acquired to the non-reinforced cue was mediated by the ventral hippocampus and was context-specific. The latter finding suggested that the ventral hippocampus had to be intact for rats to acquire this kind of context-specific conditioning. However, it was unclear what would happen if the lesion was induced in the retrograde direction. Our hypothesis was that the ventral hippocampus is both the storage site and key retrieval portal for these types of inhibitory associations and so we predicted that ventral hippocampal lesions induced after visual discrimination training should impair the expression of context-specific inhibitory associations as well. In the present study we trained a group of normal rats to asymptotic levels of performance on the visual discrimination task and then half of the animals were given neurotoxic lesions of the ventral hippocampus. After recovery, all groups were given reversal learning in the same context as original training. Rats with ventral hippocampal lesions reach asymptote on the reversal phase of training faster than normal rats. We have previously shown that normal rats needed extensive amounts of training in the original training context compared to rats reversed in a different context. This effect, combined with

other evidence, suggested that the non-reinforced cue during original training became a conditioned inhibitory and that it was context-specific. Combined with other work, these results suggest that the ventral hippocampus is required for the acquisition and expression of context-specific conditioned inhibition.

Title: Behavioral phenotypes differ depending on background mouse strain

Authors: *A. STAVNEZER;
Col. of Wooster, WOOSTER, OH

Abstract: This research follows in the footsteps of Wimer, Wimer, Crawley, Belknap, Wahlsten and others that have published data indicating differences between inbred strains of mice on both behavioral and histological variables. As researchers continue to create genetically manipulated rodent models of disease and disorders, and to assess the impact of endocrine disrupting chemicals (EDC) and toxins in our environment, it is increasingly important to know the abilities of your underlying background strain. EDC are known to reverse sex differences, but that means there has to be a sex difference in the strain you are treating to begin with, for example. We have tested hundreds of animals from a variety of strains on a basic battery of open field activity, simple water maze escape, Morris water maze and complex pattern discrimination. Data indicate that the strains do not have similar performance across the board. The background strain for a transgenic model of Alzheimer's Disease outperform even the standard C57BL/6 workhorse - this has serious implications for the impact of the AD genes. If you have a "bright" strain, there is perhaps less of a chance that the genetic manipulation will impair performance. In addition, the sex differences across the strains are not similar, despite blanket statements in the literature that males and females differ on some tasks. Data on several strains will be presented along with discussion of having a strong foundation of knowledge on background strain and behavioral testing ability.

Title: Adult behavioral consequences of prenatal nanomaterial exposure

Authors: *E. B. ENGLER-CHIURAZZI[1,2], J. J. STALNAKER[1,2], X. REN[1,2], H. HU[1,2], S. N. SARKAR[1,2], S. JUN[1,2], D. D. QUINTANA[1,2], P. A. STAPLETON[1], T. R. NURKIEWICZ[1], C. M[1], J. YI[1], J. W. SIMPKINS[1,2];
[1]Physiol. and Pharmacol., [2]Ctr. for Basic and Translational Stroke Res., West Virginia Univ., Morgantown, WV

Abstract: Engineered nanomaterials (ENM), such as titanium dioxide (TiO_2), are commonly used and have tremendous clinical and commercial potential. However, systemic and central toxicities during the critical period for early nervous system development are unclear. Prenatal ENM exposure (maternal TiO_2 inhalation) alters the uterine microvascular environment and influences birth outcomes (Stapleton et al., 2013). Further, prenatal TiO_2 via maternal injection accumulates in cranial nerves (Takeda et al., 2009), is associated with alterations in genes related to cell death, mitochondrial function, oxidative stress, and apoptosis, and increases dopamine in the prefrontal cortex and striatum of 3-6 week old offspring (Shimizu et al., 2009; Takahashi et al., 2010). Only one study has evaluated the effects of prenatal TiO_2 inhalation exposure on adult cognitive outcomes, finding that exposure was associated with decreased center time in the open field (a measure of increased anxiety) and altered pre-pulse inhibition (Hougaard et al., 2010). The objective of this study was to determine if prenatal ENM exposure (via maternal TiO_2

inhalation during gestation) affects adult brain and behavior. Pregnant rats were exposed to aerosolized TiO_2: 11.3 +/-0.039 mg/m^3 for 5 hours/day for eight days. The final maternal deposition was 85 +/-3 µg. At five months, cognitive behavior was assessed in male pups with a battery of cognitive tests selected to tap into several unique mnemonic functions, including the anxiety-like behavior (open field, elevated plus maze), spatial navigation memory (Morris water maze, radial arm water maze), locomotor coordination (rotarod), and depressive-like behavior (forced swim test). While we observed no impact of exposure to prenatal TiO_2 via maternal inhalation on measures of anxiety-like behavior, locomotor coordination, nor depressive-like behavior, we did observe a spatial navigation memory impairment on the water radial arm maze. Specifically, animals that experienced prenatal TiO_2 exposure had higher working memory correct errors relative to unexposed control rats. This behavioral change could be accounted for by the dysregulation of synaptic plasticity-related proteins and proteins mediating inflammation. We therefore assessed the potential dysregulation of these proteins by measuring the expression of microRNA in serum. Preliminary data indicate that microRNA associated with the inflammatory response are altered in TiO_2-exposed animals. These findings are consistent with the notion that prenatal ENM exposure imparts alterations in cognitive behaviors that ultimately manifest in adulthood.

Title: The lateral entorhinal cortex exhibits a highly selective code that integrates physical and relational aspects of sensory stimuli

Authors: *M. PILKIW[1], N. INSEL[2], Y. CUI[3], S. SARKAR[2], M. MORRISSEY[2], K. TAKEHARA-NISHIUCHI[2];

Abstract: The relevance of environmental correlations is often not immediately obvious, and it is therefore advantageous for the brain to build associative maps that are rich in incidental details. The lateral entorhinal cortex (LEC) may be a key hub for these maps. Lesions of the LEC disrupt behavioral expression of associations that predict upcoming reinforcers (Morrissey et al., 2012; Tanninen et al., 2013), as well as those associations that do not (Wilson et al., 2013). Here we examine how single neurons and neuron populations in the LEC encode both conditioned and non-conditioned associations and compare these patterns with those observed in the primary auditory cortex (AUC). Each recording session contained three conditioning epochs of 70 trials. In the first 20 trials, stimuli were presented alone. In the following 50 trials, a trace-eyeblink paradigm was used, in which a conditioned stimulus (CS) was paired with electrical stimulation of the eyelid (the unconditioned stimulus, or US) separated by a 500 ms trace interval. Between epochs, rats moved between two visually and spatially distinct conditioning chambers, and in the final epoch the CS was switched from an auditory to a visual stimulus. We found that about one half of the recorded LEC neurons changed firing rates upon CS presentation, and a large majority of these signaled a conjunction of trial type, conditioning chamber, and modality of the CS. In contrast, no neurons recorded from the AUC were selective for the conjunction of all three dimensions: most fired at the onset of the auditory CS and a small, partially overlapping set discriminated between environmental contexts. These patterns were also apparent at the neuron population level: in the LEC, the population state vectors during CS presentation were relatively uncorrelated between epochs and trial types, while in the AUC, state vectors were highly correlated for trials in which the auditory CS was used. These results suggest that the LEC forms a highly conjunctive code that integrates the relational and physical features of environmental stimuli, including information that is not necessarily predictive of upcoming reinforcers.

Title: Cholinergic, but not NMDA, receptors in the lateral entorhinal cortex mediate acquisition in trace eyeblink conditioning

Authors: *K. TAKEHARA-NISHIUCHI, X. YU, T. GIRITHARAN, L. TRAN, R. BAKIR, M. D. MORRISSEY, S. N. TANNINEN;
Dept. of Psychology, Univ. Toronto, Toronto, ON, Canada

Abstract: Anatomical and electrophysiological studies collectively suggest that the entorhinal cortex consists of several sub-regions, each of which is involved in the processing of different types of information. Consistent with this idea, we previously reported that the dorsolateral portion of entorhinal cortex (DLE), but not the caudomedial portion, is necessary for the expression of memory association between two temporally discontiguous stimuli in trace eyeblink conditioning (Morrissey et al., 2012; Tanninen et al., 2013). The present study examined whether memory acquisition depends on the DLE and what types of local neurotransmitter mechanisms are involved in acquisition and expression. Male Long-Evans rats received trace eyeblink conditioning, in which an auditory conditioned stimulus (CS) was paired with a mildly aversive electric shock to the eyelid (US), following a microinfusion of neuro-reactive substances into the DLE. Reversible inactivation of the DLE with GABAA receptor agonist, muscimol, significantly impaired memory acquisition when the interval between the CS and US was 500 msec, but not when the interval was shortened to 250 msec. Furthermore, blockade of local muscarinic acetylcholine receptors (mACh) with scopolamine retarded the acquisition of CS-US association with a 500-msec interval whereas blockade of local NMDA receptors with APV had no effect. In contrast, memory expression was not impaired by either type of receptor blockers. These results suggest that the DLE is necessary for memory acquisition only when the length of temporal gap between the paired stimuli is sufficiently long, and that acquisition depends on the integrity of local cholinergic, but not NMDA, receptors.

Title: The overexpression of mutated tau in the entorhinal cortex: Its effects on local neurons, cortical theta oscillations, and memory

Authors: *S. E. TANNINEN[1], M. D. MORRISSEY[1], R. L. KLEIN[2], K. TAKEHARA-NISHIUCHI[1];
[1]Psychology, Univ. of Toronto, Toronto, ON, Canada; [2]Louisiana State Univ. Hlth. Shreveport, Shreveport, LA

Abstract: The accumulation of hyper-phosphorylated tau protein in the entorhinal cortex is one of the first abnormalities observed in Alzheimer's disease (AD). The entorhinal cortex is reciprocally connected with many cortical regions critical for memory formation and expression. Entorhinal tau pathology would therefore disrupt the transfer of information within the cortical memory network, resulting in abnormal neural activity which may lead to memory impairments in AD. To test this hypothesis, we expressed, through transduction with a viral vector, an excess of human tau with the P301L mutation (Tau rats) or green fluorescent protein as a control (GFP rats), specifically in the entorhinal cortex of adult rats. We then tested the rats' ability to acquire an associative memory in trace eyeblink conditioning while monitoring local field potentials in the hippocampus, a major efferent target of the entorhinal cortex. One month after transduction, approximately 20% of entorhinal neurons were filled with hyper-phosphorylated tau and the area adjacent to the injection sites showed signs of astrogliosis and neurofibrillary tangles. When tested in trace eyeblink conditioning, the Tau rats formed the association between a tone and eyelid stimulation in a comparable manner to the GFP rats; however, the hippocampus of the Tau rats had relatively smaller amplitude of theta oscillations during conditioning in comparison to GFP rats. Thus, minor entorhinal tau pathology alters hippocampal neuronal activity even before memory impairments become apparent.

Title: Role of the vasopressin 1b receptor in rodent aggressive behavior and synaptic plasticity in hippocampal area CA2

Authors: *S. YOUNG[1], J. H. PAGANI[1], M. ZHAO[2], Z. CUI[1], S. K. WILLIAMS AVRAM[1], D. A. CARUANA[2,3], S. M. DUDEK[2];

Abstract: The vasopressin 1b receptor (Avpr1b) is critical for social memory and social aggression in rodents, yet little is known about its specific roles in these behaviors. Some clues to Avpr1b function can be gained from its profile of expression in the brain, which is limited to the pyramidal neurons of the CA2 region (and immediately adjacent CA3 region) of the hippocampus, and from experiments showing that inactivation of the gene or antagonism of the receptor leads to a reduction in social aggression. Here we show that partial replacement of the Avpr1b through lentiviral delivery into the dorsal CA2 region restored the probability of socially motivated attack behavior in total Avpr1b knockout mice, without altering anxiety-like behaviors. To further explore the role of the Avpr1b in this hippocampal region, we examined the effects of Avpr1b agonists on pyramidal neurons in mouse and rat hippocampal slices. We found that selective Avpr1b agonists induced significant potentiation of excitatory synaptic responses in CA2, but not in CA1 or in slices from Avpr1b knockout mice. In a way that is mechanistically very similar to synaptic potentiation induced by oxytocin, Avpr1b agonist-induced potentiation of CA2 synapses relies on NMDA receptor activation, calcium and calcium/calmodulin-dependent protein kinase II activity, but not on cAMP-dependent protein kinase activity or presynaptic mechanisms. Our data indicate that the hippocampal CA2 is important for attacking in response to a male intruder and that the Avpr1b, through its role in regulating CA2 synaptic plasticity, is a necessary mediator. Title: Episodic-like memory is rapidly compromised by a high-fat diet in C57Bl/6 mice and is associated with markers of hippocampal neuronal damage identified by proteomics

Authors: *F. H. MCLEAN[1], R. F. LANGSTON[2], F. M. CAMPBELL[1], A. LORENZO-ARRIBAS[3], L. M. WILLIAMS[1];
[1]RINH, Univ. of Aberdeen, Aberdeen, United Kingdom; [2]Div. of Neurosci., Univ. of Dundee, Dundee, United Kingdom; [3]Biomath. and Statistics Scotland, Univ. of Aberdeen, Aberdeen, United Kingdom

Abstract: Obesity and type 2 diabetes are associated with increased risk of dementia and Alzheimer's disease (Luchsinger et al 2009 J Alzheimer's Dis 16:693-704). A high-fat diet (HFD) is known to cause memory loss in rodents; however, complex, episodic-like memory has not been tested in response to HFD. Episodic memory is the recollection of events using a "what-where-which" experience and is lost early in Alzheimer's disease (Eacott et al 2004 J Neurosci 24:1948-1953, Easton et al 2012 J Learn and Mem 19:146-150, Swainson 2001 Dem and Ger Cog Dis 12:265-280). To identify a link between a HFD and episodic memory loss, 12 week old, male, C57Bl/6 mice, were fed either a HFD (60% energy from fat) or a LFD diet (10% energy from fat) *ad libitum* and tested daily for 2 weeks with an object-place-context (OPC) recognition memory task. This task challenges episodic-like hippocampal dependent memory, with rats bearing hippocampal lesions showing OPC deficits (Langston et al 2010 Hippo 20:1139-1153), as well as the 3xTgAD mouse model of Alzheimer's disease being impaired in this task (Davis et al 2013 J Alzheimer's Dis 33:681-698). We also used additional behavioural tests alongside the OPC task; a novel object recognition task (NOR), an object-place task (OP) and an object-context task (OC). The NOR task uses the perirhinal cortex, and the OP and OC tasks have recently been hypothesised to activate the lateral entorhinal cortex and postrhinal cortex (Eacott et al 2004 J Neurosci 24:1948-1953, Wilson et al 2013 Hippo 23:352-366). We used the OP and OC tasks as they test components of the OPC task which do not depend on the hippocampus.

Animals were killed by exsanguination, under terminal anaesthesia, after 3 days, 1 week or 2 weeks on diet. Brains were rapidly removed and frozen over dry ice until the hippocampus was dissected for proteomic analysis. A separate group of mice underwent intraperitoneal glucose tolerance tests (IPGTTs) as a non-recovery procedure. We found that episodic-like memory is compromised after only 1 week of a HFD together with OP and OC, however, the ability to carry out the NOR was preserved. IPGTT showed that glucose tolerance was compromised after 3 days on HFD. These results indicate that functions of the lateral entorhinal and postrhinal cortex and hippocampus are compromised rapidly by HFD. Proteomic analysis of the hippocampus revealed changes in a number of proteins associated with neuronal damage after only 3 days on HFD. These data link HFD to the rapid induction of glucose intolerance, indices of hippocampal damage and memory deficit and have implications for the link between diet, obesity and cognitive decline.

Title: Antagonizing dorsal hippocampal dopamine D1-type receptors with SCH23390 affects social learning and social interactions but not food intake in male and female mice

Authors: *R. MATTA, A. N. TIESSEN, M. M. KIVLENIEKS, A. M. MEERSSEMAN, Y. O. ADJEI-AFRIYIE, E. CHOLERIS;
Dept. of Psychology and Neurosci. Program, Univ. of Guelph, Guelph, ON, Canada

Abstract: The neurotransmitter dopamine (DA) is involved in many motivationally relevant behaviors, such as drug/alcohol addiction, as well as social learning and feeding behavior. With systemic studies, our lab has previously implicated DA D1-type receptors in the social transmission of food preferences (STFP) (Choleris et al., 2011). However, where DA D1-type receptors are acting in the brain to influence social learning remains unknown. The ventral tegmental area has direct dopaminergic neuronal projections to many limbic structures, such as

the amygdala, nucleus accumbens, and the hippocampus. The latter is important for learning and memory, as well as social learning in the STFP. In the present study, we microinfused the DA D1-type antagonist SCH23390 (at 1, 2, 4 and 6 μg/μL) directly into the Cornu Ammonis 1 (CA1) region of the dorsal hippocampus of adult male and female CD-1 mice. Infusions were 15min before a 30 minute social interaction where mice had the opportunity to acquire a food preference from a recently fed same-sex conspecific. We found that females infused with 4 and 6 μg/μL and males infused with 1, 4 and 6 μg/μL of SCH23390 failed to acquire the socially learned food preference. In addition, the total amount of food consumed was not influenced by D1-type inhibition. Video analysis of the social interactions also revealed that the social learning impairment could not be explained by a reduced exposure to the food odor found on the breath of the demonstrator conspecific, since oronasal investigation was not influenced by SCH23390 treatment. Further analysis revealed that together with blocking social learning, SCH23390 also reduced agonistic related behaviors in males, and social investigatory related behaviors in females. A follow-up olfactory discrimination task also showed that mice infused with the highest dose of SCH23390, at 6 μg/μL, that blocked the STFP, could distinguish between the two food types used in the social learning test. Thus, DA D1-type receptors in the CA1 may be mediating social learning, specifically and not via other behavioral or sensory effects. This study highlights the potential importance that hippocampal dopamine plays in the 'social brain'.

Title: Neurostructural analysis of the hippocampal dentate gyrus neurons in the intraventricularly streptozotocin-injected rats

Authors: *A. S. SHINGO[1], S. KITO[2], T. MURASE[1];
[1]Okinaka Mem. Inst. For Med. Res., Minato-Ku, Tokyo, Japan; [2]Chigasaki Tokushu-kai Clin., Chigasaki, Japan

Abstract: Resent epidemiological studies have associated type 2 diabetes mellitus with an increased risk of developing Alzheimer's disease (AD). Previously, we examined the effects of

intracerebral administration of streptozotocin (STZ) on cognitive performance in rats. The STZ-treated rats, one of the AD models showed significant declines in all the parameters of the MWM task compared to control rats. Immunohistochemical analysis using hippocampal formations revealed decreases in pCREB, Akt, somatostatin, insulin receptor, and insulin-degrading enzyme immunoreactivities and a meaningful increase in amyloid beta immunoreactivity that was especially marked in the crest of the dentate gyrus. An intraventricular injection of a long acting insulin analogue improved these STZ-induced behavioural and immunohistochemical changes In this study, morphological analysis of the granule cell layer neurons of the dentate gyrus using COX-Golgi stain and spine density counting was done since Alzheimer disease is a disease of synaptic failure in the hippocampus. After the intracerebral STZ injection, there was the decrease of the ratio to which the granule cell layer fills the space that was recovered by intracerebral insulin administration, In addition, the STZ-3V-treated rats showed diminished spine densities in all the 3 types of spines. It is concluded that in the STZ-3V-rats, there are injuries in the primary recipients of excitatory input into the granule cell layer through the perforant pathway.

Title: Damage to the retrosplenial cortex impairs context discrimination

Authors: J. S. ADELMAN, *S. ROBINSON;
Oberlin Col., Oberlin, OH

Abstract: The retrosplenial cortex (RSP) provides visuospatial sensory information to the hippocampal memory system in rodents and primates. Consistent with a role for RSP in hippocampal-dependent learning and memory, RSP lesions produce deficits in contextual fear learning and sensory preconditioning in rats. Together, these findings support the view that RSP may be involved in the formation and recollection of associations between diverse sensory stimuli which contribute to contextual representations. The present study combined electrolytic lesions of RSP and a context discrimination paradigm to further assess the contribution of RSP to context-based learning. During the first training phase of the procedure one auditory stimulus was presented in Context A whereas a second auditory stimulus was presented in Context B. In

the second training phase, one auditory stimulus was paired with footshock in Context C whereas the second auditory stimulus was presented in Context C, but was not paired with footshock. During the context test phase, rats were exposed to Context A and B and freezing levels were evaluated. During a fourth and final phase, freezing behavior in response to the auditory stimuli was evaluated while rats were in Context C. Control rats exhibited more freezing behavior in the context where they heard the auditory cue that was paired with footshock compared to the context where they heard the unpaired cue, indicating that stimulus-stimulus associations had been formed during the first phase of training. In contrast, RSP-lesioned rats failed to show context discrimination, but maintained the ability to discriminate between the individual auditory stimuli. These data support the notion that RSP is involved in forming associations between neutral stimuli even in the absence of reinforcement.

Title: Real-time decoding of hippocampal replay events

Authors: ***D. F. LIU**[1], X. DENG[3], M. KARLSSON[2], U. EDEN[4], L. FRANK[2];
[1]UC Berkeley - UCSF Grad. Program in Bioengineering, [2]Dept. of Physiol., UCSF, San Francisco, CA; [3]Program in Statistics, [4]Dept. of Mathematics and Statistics, Boston Univ., Boston, MA

Abstract: The hippocampus plays an essential role in learning and memory-guided decision making. Previous results have established the importance of hippocampal activity during sharp-wave ripple (SWR) events. Disruption of SWRs during sleep can impair performance the next day, suggesting a role in consolidation. Similarly, disruptions of SWRs during awake behavior causes specific learning and memory deficits associated with trials when animals need to link multiple experiences across time. During SWRs, sequences of place cells are "replayed", recapitulating sequences seen during past experience. While the presence of replay during SWRs is well established, the role of the specific information content of these sequences for learning and decision making processes remains unknown. We have therefore developed a real-time decoding system that makes it possible to identify the content of SWRs with low latency and then interrupt them before they would naturally terminate, degrading the related information available in downstream regions. For this system we optimized the speed of algorithms for cluster-less spike encoding and decoding (Kloosterman et al., 2013). The software architecture utilizes high performance computing techniques, such as parallel computing across networked clusters implemented through the Message Passing Interface (MPI) Protocol. MPI allows the scalable distribution of calculations to encode and decode across many recording channels. A simulation framework was developed to evaluate the system on raw data collected from animals learning a hippocampal-dependent W-track alternation task. Using data collected from 6 tetrodes implanted in an animal, we are able to estimate the content being replayed with an average lag of ~15ms (~10ms mode). These results show we are capable of detecting and disrupting SWRs that encode information related to a specific experience, with short enough latency to disrupt the processing of that information in downstream areas. This technology will allow for investigations of the causal role SWR memory replay in learning, memory, and decision making processes. Title: Neurons in the primate nucleus basalis signal error during associative learning

Authors: *C. MARTINEZ-RUBIO[1], O. J. AHMED[1], D. SIERRA-MERCADO[1,2], E. N. ESKANDAR[1];
[1]Massachusetts Gen. Hosp., Boston, MA; [2]Anat. & Neurobio., Univ. Puerto Rico Sch. of Med., San Juan, Puerto Rico

Abstract: Reward and motivation have an important role in learning. The Nucleus Basalis of Meynert (NBM) is a group of neurons found in the substantia innominata of the basal forebrain that provides cholinergic innervation to the neurons of the cerebral cortex. These cortical cholinergic innervations have been implicated in behavioral and cognitive functions, such as learning and motivation. However, the neurophysiological mechanisms by which the NBM is involved in learning and motivational control is unclear. To address this issue, we recorded neural activity in the NMB using single-unit recordings in behaving non-human primates (NHPs) during an associative learning task. During this task, the animal was required to learn, by trial and error, to associate a visual image with a specific direction of eye movement. Our results show that the firing rate of 34% of neurons in NBM differentiate between incorrect and correct choices. Together, these results provide physiological support for the idea that the NBM is necessary for associative learning.

Title: Amygdalar NMDAr and AMPAr activity on aversive memory retrieval: neurochemical modulation in the insular cortex

Authors: *D. OSORIO-GÓMEZ[1], K. R. GUZMAN-RAMOS[2], A. LUYEN DIAZ[1], F. BERMUDEZ-RATTONI[1];
[1]Inst. de Fisiologia Celular, UNAM, Mexico City, Mexico; [2]Univ. Autonoma Metropolitana, Mexico city, Mexico

Abstract: Memory retrieval involves the quick reactivation of neural circuits that were modified during learning. It is widely known that AMPA and beta-adrenergic receptors activity modulates aversive memories retrieval, whereas the activation of NMDA receptors takes part in the memory consolidation process. There is plenty of evidence that the insular cortex (IC) and the amygdala (Amy) have a key role in the acquisition, consolidation and retrieval of conditioned taste aversion (CTA), a learning paradigm where animals associate a novel taste (CS) with gastric malaise, decreasing CS intake in further presentations. Previously, we have demonstrated an interaction between Amy and IC which contributes to memory consolidation and retention of CTA, but it is still unknown whether this interaction participates in CTA retrieval. In this study, we measured through *in vivo* microdialysis, extracellular levels of Glu and norepinephrine (Ne) in the IC during CTA retrieval. Male Wistar rats were implanted with a guide cannula aimed to the IC, changes in extracellular level of Glu and Ne were monitored at CTA retrieval using a capillary electrophoresis method based on micellar electrokinetic chromatography. During CTA retrieval, significant increments in Glu and Ne within the IC were related to the exposure to CS. To evaluate the role of Ne and Glu in CTA retrieval, bilaterally infusions of saline solution, AP5 (10ug/uL), CNQX (1ug/uL) or Propranolol (5ug/uL) in the IC were given. Inactivation of AMPA receptors or beta-adrenergic receptors in the IC impaired memory retrieval, neither saline solution nor AP5 affected memory recall. Many studies have demonstrated that retrieval process in the amygdala is mediated by the activation of AMPA receptors, but not NMDA. Our data have shown that the IC also uses the same mechanisms for retrieval. However, the Amy-IC interaction seems to be very important for taste aversive information recovery, so we inactivated AMPA or NMDA receptors in the Amy before retrieval and measured extracellular levels of Glu and Ne within IC during presentation of the CS; our data showed that inactivation of amygdalar NMDA receptors impairs only Glu release but does not disrupt memory recall. Interestingly, infusion of AMPA receptors antagonist in the Amy inhibits memory retrieval, as well as Glu and Ne release disruption within IC. These results suggest that impairment in aversive memory retrieval with AMPA receptors inactivation within the amygdala is through inhibition of norepinephrine release in the insular cortex.

Title: Neuronal oscillations in the rat hippocampus during object-in-location recognition memory

Authors: *J. B. TRIMPER[1], C. R. GALLOWAY[1], M. G. FARINA[2], N. A. HERNANDEZ[3], J. R. MANNS[1];
[1]Psychology, [2]Emory Univ., Atlanta, GA; [3]Georgia State Univ., Atlanta, GA

Abstract: Neuronal oscillations in the hippocampus have been found previously to correlate with recognition memory performance in rats and monkeys. For example, in a study of rat novel object recognition memory (Trimper et al., 2014; Hippocampus, 24, 341-353), increased coherence between oscillations in hippocampal subregions CA3 and CA1 in the low gamma range (30-55 Hz) during novel object exploration correlated with subsequent memory for those objects. It was unclear whether the increase in CA3-CA1 low gamma coherence for a well-remembered object in that study reflected memory for the object's identity, for the object's location, or for an association between the object and its location. In the present study, we adapted the novel object recognition memory task used in that previous study to distinguish between objects that were subsequently remembered poorly (poor memory), objects for which the object identity but not location was remembered (object-only), and objects for which both the object identity and location were remembered (object-in-location). Local field potentials were recorded in the pyramidal layer of regions CA3 and CA1 in rats. Levels of CA3-CA1 low gamma coherence during novel object exploration were similar for object-only and object-in-location memory conditions. These results suggest that this particular correlate of recognition memory might not distinguish between different types of recognition memory judgments (e.g., object-only vs. object-in-location) and may instead reflect memory strength more generally.

Title: Brain structural changes through long-term learning of tool use supported by sustained motivation for tool use in adult non-human primates

Authors: *A. IRIKI[1], Y. YAMAZAKI[3,1], K. HIKISHIMA[4,5], M. SAIKI[1], M. INADA[1], E. SASAKI[4,5], R. LEMON[6], C. PRICE[7], H. OKANO[4,2];

London, London, United Kingdom

Abstract: Acquisition of new behavior requires formation and activation of new brain networks, which are supported and maintained by active interaction between organisms and environments for long periods of time. We developed a step-by-step protocol to train common marmosets to use a rake-shaped tool to retrieve food: almost one year of training was needed to acquire this new skill. Then we explored volumetric changes in the brain structure of the trained marmosets as they learnt this new technology. Structural MRI scans were performed before, during, and after tool-use training. Long term training of tool-use behavior induced volumetric changes in several brain structures which clearly differed from those of short term training. The volume of nucleus accumbens (Acb) increased in the later phases of the training, and was significantly positively correlated with performance indices, but not with the number of reinforcers earned. So this change could reflect increased motivation for tool use as marmosets learned to use the rake effectively. We found other brain regions with increased volume including visual areas (V2-V3), superior temporal areas, and the anterior trunk of the corpus callosum. The latter has never previously been reported to increase through motor skill training. White matter changes also occurred in the middle and inferior cerebellar peduncles which could reflect the sustained capacity for tool use long after training was completed. These unique areas reflected the behavioral and motivational changes during long-term training, both for acquisition and maintenance of a newly developed skill.

Title: Coordinated awake reactivation of behaviorally related hippocampal-prefrontal ensembles

Authors: *S. P. JADHAV, G. ROTHSCHILD, D. K. ROUMIS, I. GROSSRUBATSCHER, L. M. FRANK;
Dept. of Physiology, Sandler Neurosci. Ctr., Univ. of California San Francisco (UCSF), San Francisco, CA

Abstract: Interactions between the hippocampus and medial prefrontal cortex (PFC) play a critical role in learning and memory-guided decision making, but the nature of these interactions remains unclear. We have previously shown that awake sharp wave ripple (SWR) events, during which hippocampal memory replay occurs, are critical for spatial memory. Here we show that there is coordinated and content-specific reactivation of hippocampal-prefrontal ensembles during awake SWRs. We simultaneously recorded activity of hippocampal (CA1) and prefrontal (prelimbic and infralimbic) cells in adult male Long Evans rats over multiple days of spatial learning. Distinct hippocampal patterns of activity, SWRs (150-250 Hz) and theta periods (6-12 Hz), were detected using local field potential and speed criteria during behavior. We found that a substantial fraction of PFC cells (36%) showed significant firing rate modulation during awake SWRs. Changes in rates included both excitation and inhibition. This SWR modulation was related to previously reported theta phase locking in PFC: the majority of SWR modulated cells were significantly phase-locked to hippocampal theta (74%), and SWR modulated cells showed significantly stronger theta modulation than non-SWR modulated cells. We also found coordinated reactivation of CA1-PFC neurons during awake SWRs, recapitulating activity seen during behavior. The SWR-triggered activity of 14% of CA1-PFC cell pairs was significantly

correlated, such that activity of one cell predicted the activity of the other cell. Across the population, the covariance of CA1-PFC cell pairs during theta periods was significantly correlated with their SWR correlations. Importantly, spatial coding properties were also preserved during awake SWR reactivation. CA1-PFC cell pairs that encoded similar locations were reactivated together, and their SWR correlations were significantly higher than pairs that encoded distinct spatial locations. Highly specific functional networks comprised of CA1-PFC ensembles underlie this structured reactivation, as revealed by generalized linear models (GLM) that significantly predicted PFC activity during SWRs from ensemble CA1 activity during both SWRs and theta periods. Our results establish awake SWRs as a prominent network activity pattern mediating hippocampal-PFC interactions during behavior. Further, our findings of coherent reactivation of behaviorally relevant information across CA1-PFC networks during awake SWRs suggests that this coordinated reactivation is well suited to support learning and memory-guided behavior.

Title: Inhibition of de novo synthesis of plasmalogens in the mice hippocampus results in the memory loss associated with the reduction of BDNF

Authors: *T. KATAFUCHI[1], S. M. HOSSAIN[2], S. Y. M. AHMED[2], K. MIAKE[3];

Abstract: The special ether phospholipids Plasmalogens (Pls) are characterized by the presence of a vinyl ether linkage at the *sn-1* position of the glycerol moiety. The ethanolamine plasmalogens (EthPls) was found to be highly comprised in the hippocampus but its role was mostly elusive. A reduction of brain Pls in advanced Alzheimer's disease (AD) patients

suggested a possibility that Pls might be associated with the memory dysfunction. Our present study was aimed to see the memory performance of the adult mice after down-regulating the Pls synthesis enzymes, GNPAT (glyceronephosphate O-acyltransferase) and AGPS (alkylglyceronephosphate synthase) in the hippocampus. To knock down the Pls synthesis enzyme genes in the hippocampus, we have designed short hairpin RNAs (shRNAs) against mouse genes *GNPAT* and *AGPS*. Two individual lentiviral shRNAs for each gene was confirmed for their knockdown efficiencies both *in vitro* (in cells) and *in vivo* (in the hippocampus tissue). For the behavioral study, we injected the lentiviruses at the dose of ($5X10^5$ transduction unit) in the hippocampus directly by stereotaxic instrument. For the memory performance, Morris water navigation task was carried out using the control and Pls knock-down mice and showed a significant reduction in the memory from first week to the 5^{th} weeks of the injection. This prolong reduction of the memory in those mice was associated with the reduction in the expression of brain derived neurotrophic factor (BDNF) and its target genes Synapsin-1 and Synaptotagmin-1. Furthermore, knock down of Pls in the neuronal cells Neuro-2A also confirmed a reduction of BDNF, Synapsin-1 and Synaptotagmin-1 expression suggesting that Pls can maintain the expression of these memory-related genes in the neurons. Our present findings suggest for the first time that the endogenous Pls in the hippocampus are very important for memory and do so via regulating the expression of memory-related genes.

Title: Mangosteen fruit hull extract improves memory and affects brain acetylcholinesterase activities in normal aged rats

Authors: *R. SRISAWAT[1], W. TONGJAROENBUANGAM[2], N. NONTAMART[1];
[1]Sch. of Physiology, Inst. of Sci., Suranaree Univ. of Technol., Amphur Muang, Thailand;
[2]Preclinical Div., Fac. of Medicine, Mahasarakham Univ., Mahasarakham Province, Thailand

Abstract: Natural polyphenols have been reported to possess a wide variety of biological activities, including enhancement of neuroprotective, learning and memory, and acetylcholinesterase (AChE) inhibitory activities. They can be found in large quantities in the fruit hull of mangosteen. Thus, the effects of mangosteen fruit hull extract (GME) on learning and memory, and brain AChE activity were investigated in normal aging. Ten months old male Wistar rats received vehicle (10% tween80, 1 ml/kg), vitamin E (40 mg/ml/kg), GME (500 or 1000 mg/ml/kg) orally once daily for 30 days. Spatial memory and learning of rats were tested by Morris water maze test. The protocol consisted of 21 training trials (3 times per day for 7 days on day 24-30) and probe trial on day 30. Immediately after last trial, rats were decapitated and brains were removed. Cerebral cortex, hippocampus, and basal forebrain were dissected out and homogenated. AChE activity of homogenized brains was determined by colorimetric method. The Morris water maze test study showed that time to find platform on day 7 of training trial was significantly decreased from day 1 in all groups. Time spent in target quandrant was significantly increased in vitamin E-treated group and 500 mg/ml/kg GME-treated group, but not 1000 mg/ml/kg GME-treated group, when compared to vehicle treated group ($P<0.05$). All doses of GME and vitamin E tended to increase, but not significant difference, in number of entries into the target quadrant when compared to vehicle treated group. The AChE activity study showed that GME at 1000 mg/ml/kg, but not 500 mg/ml/kg and vitamin E, significantly increased AChE activity in hippocampus when compared to vehicle treated group ($P<0.05$). All doses of GME and vitamin E did not showed significant difference in AChE activity in both basal forebrain and cerebral cortex when compared to vehicle treated group ($P<0.05$). This study provides the first evidence of memory and learning enhancing effects and anti-acetylcholinesterase action of GME on selected brain areas in aging. GME may be useful for the prevention of the development or progression of cognitive impairment caused by natural aging, however, the underlying mechanisms are still not fully understood.

Title: Novel exploration of positional or directional spatial cues induces Arc mRNA expression in distinct hippocampal subfields

Authors: *D. MANAHAN-VAUGHAN[1], V. ALIANE[2];
[1]Ruhr Univ. Bochum, Med. Faculty,, Bochum, Germany; [2]Neurophysiol., Ruhr Univ. Bochum, Bochum, Germany

Abstract: The hippocampus is crucially involved in declarative or explicit forms of learning and memory. Spatial memory is presumably encoded by means of changes in hippocampal synaptic efficiency and neuronal networks. However, the specific roles of the CA1, CA3 and dentate gyrus subregions are still unclear. In the hippocampus, learning about navigationally relevant information facilitates log-term depression (LTD) in the dentate gyrus, whereas learning about discrete environmental content facilitates LTD in the CA1 region (Kemp & Manahan/Vaughan, 2007, Trends Neurosci. 30:111-118). We examined the impact of these kinds of spatial learning on hippocampal neuronal activity. We observed increased Arc mRNA in the CA1 region after exploration of discrete spatial features and in the dentate gyrus after exploration of large spatially-distinct landmarks. These observations are in line with the parallel map theory of spatial representations (Jacobs & Schenk, 2003, Psychol Rev. 110:285-315) and support that these hippocampal subfields may contribute different components of a spatial representation.

Title: Protein malnutrition and caloric restriction during the lactation period affects NPY distribution in the rat hippocampus

Authors: *P. L. GUEDES DA SILVA, A. C. B. BARBOSA, M. L. M. ROCHA, P. C. BARRADAS, F. TENORIO;
Farmacologia e Psicobiologia, UERJ, Rio De Janeiro, Brazil

Abstract: Perinatal malnutrition can lead to permanent impairments in brain morphology, physiology and neurochemistry. The hippocampus is a very vulnerable structure that is selectively affected by alterations on food intake during the developmental period. Several molecules are involved in hippocampal development, maintenance and cognitive phenomena, such as neuropeptide Y (NPY). NPY is highly expressed in this structure and studies have shown its participation in neurogenesis, learning and memory. In this work we evaluated the effects of protein malnutrition and caloric restriction during the first 10 days of lactation on NPY expression in offspring hippocampus. This study was approved by our University Ethics Committee (CEA/055/2009). We used rats from 5 to 20 postnatal (P) days of age whose dams were either fed a 0% protein diet (MG) or a normoprotein diet (CG) from P1 to P10 (n=3 per group/age). To reproduce the same amount of calories ingested by the MG we used a pairfed group (PFG). Animals were anesthetized and perfused with 0.9% saline solution, 4% paraformaldehyde (PF) and PF plus 10% sucrose. Sections were immunostained using anti-NPY antibody, revealed with a secondary antibody conjugated with Alexa 488 and observed at a fluorescence microscope. At P5, NPY positive (NPY+) cell bodies were small and the processes were well stained in the three groups. The number of NPY+ cells reduces during development in CG whereas this reduction was not so conspicuous in MG and PFG. At P5, MG and PFG presented less stained cell bodies in the dentate gyrus (DG) than CG ($p<0.01$ and $p<0.05$). At P10, NPY+ cells were bigger and fusiform in DG and their number was decreased in PFG when compared to CG ($p<0.05$). In CA1 of MG and PFG it is observed that most of cell bodies are concentrated in the outer layer, in a different pattern than CG. In CA3, there was a decrease in the number of NPY+ cells that are placed in all layers of that region in the MG ($p<0.01$) and PFG ($p<0.001$). P20 animals showed rounded cell bodies, differing from the younger ages. At this age there was no difference concerning NPY+ cell number between groups in any region. Our results showed that both proteic and caloric restriction during lactation affects NPY distribution in the hippocampus. Furthermore the differences observed in the pattern of NPY+ cells distribution in CA1 may suggests a delay in cell migration during development.

Title: Memory-enhancing intra-amygdalar clenbuterol enhances intrinsic excitability of CA1 pyramidal neurons during consolidation

Authors: E. S. LOVITZ, M. CHAVEZ, D. PROCH, *L. T. THOMPSON;
Behavioral & Brain Sci., Univ. of Texas At Dallas, RICHARDSON, TX

Abstract: Emotional arousal enhances memory formation, creating strong lasting memories. Stress from fear activates the amygdala, and in turn modulates memory consolidation via the hippocampus. Packard et al. (1994) reported bilateral amphetamine infusion into the amygdala after a hippocampal-dependent task enhanced memory compared to controls. Beta-adrenergic modulation of basolateral amygdala (BLA) directly alters consolidation: norepinephrine (NE) released in the BLA during training on an inhibitory avoidance (IA) task correlates with memory retention. Post-trial beta-adrenergic agonist clenbuterol infusion into BLA dose-dependently enhances, while propranolol, a beta-antagonist, impairs IA memory. During consolidation, hippocampal pyramidal cells exhibit reduced post-burst after-hyperpolarizations (AHPs). AHP plasticity enhances memory, with drugs reducing AHPs improving acquisition and consolidation in several different tasks. After acquisition of new spatial or trace eyeblink learning, CA1 pyramidal neurons exhibit reduced AHP amplitude and duration *in vitro* up to 72 hr later. AHP plasticity is also seen during consolidation of IA, up to 24 hr post-trial in CA1 and CA3, and 1 hr post-trial in BLA pyramidal cells. AHPs are generated by medium (mAHP) and slow (sAHP) currents, and both are reduced during consolidation. AHP plasticity also affects accommodation, another measure of intrinsic excitability. In the current study, rats received a single paired IA training trial then were immediately infused with clenbuterol into the BLA. Effects on both a behavioral measure of memory and on intrinsic excitability in the CA1 region of hippocampus were assessed 24 hr later. A dose-response curve for clenbuterol (bilaterally infused) was first determined, enhancing memory retention 24 hr later. Using the most effective dose (15 ng), we then compared AHP and accommodation measures from CA1 neurons in clenbuterol-infused hemispheres to those in contralateral vehicle-infused hemispheres in slices prepared 24 hr post-

trial, as well as to neurons from clenbuterol- and vehicle-infused untrained controls 24 hr post-infusion. Reductions in AHP amplitudes occurred in CA1 neurons from trained clenbuterol-infused hemispheres compared to untrained vehicle-infused hemisphere neurons, consistent with other findings linking amygdala activation to memory consolidation mediated by the hippocampus.

Title: Modulation of cellular properties by environmental enrichment that may underlie learning enhancement and seizure prevention

Authors: *M. J. VALERO-ARACAMA[1], M. M. SAUVAGE[2], M. YOSHIDA[1];
[1]Fac. of Psychology, [2]Fac. of Med., Ruhr Univ. Bochum, Bochum, Germany

Abstract: Animals housed in enriched environments (EE) show an improved learning and memory (L&M) performance and a reduced propensity to suffer from epileptic seizures. While an increased cellular excitability in the hippocampus is suggested to be a possible cellular underpinning of enhanced L&M, the literature in this area is controversial. In addition, it remains unclear how an EE can diminish the probabilities for the animals to develop epileptic seizures, which would require a decreased excitability. In order to better understand these issues, we conducted *in vitro* patch clamp recordings in hippocampal CA1 pyramidal cells from mice housed either in an enriched or control environment. We observed that an EE increased the cellular excitability of these cells after a short (< 40 days) but not after a long (> 40 days) period of enrichment. In addition, this increased excitability was mainly limited to the dorsal CA1 region. We also report that the increased excitability was supported by the modulation of the input resistance and spike threshold. Furthermore, the slow after hyperpolarization potential (sAHP), a property that is the focus of some anticonvulsant therapies, was larger in the cells from animals housed in the EE. In conclusion, controversial results among studies regarding cellular excitability may stem from the housing duration- and anatomical region-dependent effects of an

EE. Moreover, enhanced L&M performance and seizure prevention, which may require increased and decreased excitability, may be enabled by the combination of increased cellular excitability and increased sAHP.

Title: Cardiac change-based fear index and its application for measuring fear memory consolidation

Authors: ***F. ZHAO**[1,2], J. LIU[1], W. WEI[1,2], J. Z. TSIEN[1];
[1]BBDI, Georgia Regents Univ., Augusta, GA; [2]Banna Biomed. Res. Inst., Xi-Shuang-Ban-Na Prefecture, China

Abstract: Changes of heart rate (HR) and heart rate variability (HRV) have been identified as highly useful indicators for assessing emotion status. Yet cardiac changes upon the presentation of conditioned cues or unconditioned stimuli have not been systematically studied in mice. Here, we examined changes in heartbeat interval dynamics as physiological readout for assessing fearful reactions as mice were subjected to sudden air puff, free-fall drop inside a small elevator, and a laboratory-version earthquake. Cardiac changes were analyzed in details by measuring three distinct phases: namely, the rapid rising phase in HR, the maximum plateau phase during which HRV is greatly decreased, and the recovery phase during which HR gradually recovers to baseline values. We developed the fear resistance index based on specific cardiac response features. We demonstrated that the fear resistance index remained largely consistent across distinct fearful events in a given animal, thereby enabling us to compare and rank individual mouse's fear responsiveness among the group. We also investigated changes in HR and HRV in both short-term and long-term contextual and cued fear conditioning. We found that the HRV

reduced significantly in fear conditioning. Moreover, the time duration of the highly rhythmic phase of HRV were sensitive enough to reflect the transition from short-term to long-term fear memories and detect the fear extinction effect during the repeated tone recall. Therefore, these results suggest that the fear resistance index described here can represent a useful parameter for measuring personality traits or individual differences in stress-susceptibility in both wild-type mice and post-traumatic stress disorder (PTSD) models. In addition, HRV is a valuable physiological indicator for sensitively measuring the consolidation and expression of fear memories in mice.

Title: Consumption of high-energy diets induces cognitive impairment, neuroinflammation, and neurovascular damage

Authors: ***S. L. HARGRAVE**[1,4], T. L. DAVIDSON[4], W. ZHENG[2], K. P. KINZIG[3]; [2]Hlth. Sci., [3]Psychological Sci., [1]Purdue Univ., West Lafayette, IN; [4]Psychology, American Univ., Washington, DC

Abstract: Obesity and exposure to high-energy diets increase the risk for developing dementia, and short-term hyperglycemia has been shown to transiently impair memory and information processing in humans. Amnesia due to hippocampal damage has also been demonstrated to alter food intake patterns, in some cases leading to obesity. We have previously demonstrated that diet-induced obese (DIO) rats fed a high-energy (HE) diet are impaired at hippocampal-dependent tasks following 10d and 90d (but not 40d) diet access. At 90d, these rats had increased hippocampal blood-brain barrier (BBB) permeability. The present study characterized the progression of the molecular and functional chnages following HE diet exposure, and correlated these changes with cognitive ability. Compared to chow-fed rats, HE-fed animals were impaired at hippocampal-dependent spatial tasks at 10d and 90d (but not 40d), and relied on a hippocampal-independent response strategy to solve the task. Further, these animals showed

increased hippocampal and hypothalamic cytokine mRNA, decreased hippocampal and hypothalamic BDNF mRNA, and reduced hippocampal CD31 at 90d. BBB permeability to the hippocampus, dorsal striatum, hypothalamus, and hindbrain was increased following 90d access to diets. Cognitive deficits significantly correlated with increased ventral hippocampal BBB permeability. These data suggest that maintenance on HE diets can damage structures associated with both ingestive behavior and cognition. This, in turn, has the potential to increase responding to food cues. An improved understanding of the molecular and cellular processes involved in HFD-induced inflammation and neurovascular damage could yield options for the treatment or prevention of obesity and cognitive dementia

Title: The relationship between pupil diameter and neuronal activity in multiple brain areas

Authors: *S. JOSHI[1], Y. LI[1], R. M. KALWANI[2], J. I. GOLD[1];
[1]Dept. of Neurosci., Univ. of Pennsylvania, Philadelphia, PA; [2]Sch. of Med., Temple Univ., Philadelphia, PA

Abstract: The locus coeruleus (LC) is the primary source of norepinephrine (NE) in the central nervous system. The LC-NE system plays important roles in normal brain functions including arousal and sensory-motor processing. It has also been implicated in clinical disorders including attention-deficit/hyperactivity disorder (ADHD), anxiety, and schizophrenia. However, attaining a deeper understanding of this system's contributions to normal and abnormal brain function is hindered by the LC's small size and location deep in the brainstem, which make it difficult to record from or image using existing methods. It would be useful to obtain an alternative measure that reliably reflects LC activity. It has been suggested that one such measure is non-luminance-

mediated changes in pupil diameter (PD), which can be obtained relatively easily using video-based technologies. Accordingly, we have obtained the first quantitative assessment of the relationship between LC single-unit activity and PD. Our results are consistent with the hypothesis that common brain circuits affect both LC neuronal activity and PD and provide a basis for interpreting PD changes in terms of LC activity. However, LC provides NE innervation to nearly the entire brain. Thus, to accurately interpret changes in PD, it is critical to evaluate the relation between neural activity and PD in multiple brain areas. We compared the relationship between PD and neural activity in LC, superior colliculus (SC), inferior colliculus (IC), the middle temporal area (MT) of extrastriate visual cortex and the anterior cingulate cortex (ACC) of awake macaques. The monkeys performed a fixation task that allowed for reliable measurement of PD over several seconds. We found correlations between PD and neural activity in all brain areas tested over a range of timescales, including reliable spike-triggered changes in PD when averaged across spontaneously occurring spikes. For LC, SC, and IC measurements, we also used two methods to assess how PD was related to evoked changes in neuronal activity. First, we applied electrical microstimulation to the three brain regions, which in each case elicited reliable changes in PD. Second, we played a loud sound while the monkeys maintained fixation, which served as an arousing stimulus (beep trials). The beeps consistently caused phasic changes in PD, which were accompanied by phasic neural responses in LC and IC but not SC. Together, these results imply that LC-mediated arousal, assessed via changes in PD, can serve to coordinate neural activity throughout the brain.

Abstract: Learning a skill requires many repetitions of that skill, and the pattern of engagement across dorsal striatal regions changes over the course of training (Thorn and Graybeil 2014). Rats learning to navigate a T-maze for food reward initially use a *place* strategy attributed to greater dorsomedial engagement, and later switch to using a *response* strategy attributed to greater dorsolateral engagement (Packard and McGaugh 1996). Here we investigate how the transition between early- and late-training is reflected in medium spiny neurons (MSNs) in dorsomedial and dorsolateral striatal subregions. Specifically, we test whether changes in neurons' synaptic plasticity, intrinsic excitability, and morphology correspond to learning, and evaluate the distribution of these changes across striatal subregions and hemispheres relative to the practiced turn. Bidirectional plasticity was measured in field recordings and induced using either 20 Hz or theta burst stimulation. Intrinsic excitability was tested using whole cell current clamp recordings from medium spiny neurons. These same cells were biocytin-filled and reconstructed to analyze morphology. For early-trained rats, which demonstrate a mixture of *place* and *response* strategy use, dorsomedial MSN excitability is enhanced, but plasticity is reduced. Specifically, in the hemisphere contralateral to the turn, LTP is reduced, while in the hemisphere ipsilateral to the turn, LTD is reduced. There was no change in either cell excitability or plasticity in the dorsolateral striatum. For late-trained rats, which overwhelmingly demonstrate a *response* strategy, MSN excitability and LTP are restored to control levels. However, LTD is reduced dorsolaterally ipsilateral to the learned turn, and dorsomedially contralateral to the learned turn. In addition, our morphology analysis demonstrates adult dendritic remodeling across learning stages which, while recently demonstrated in mice (Cazorla et al, 2012), has not previously been linked to striatal learning. Our findings suggest that the encoding of novel information in the striatal network is facilitated by elevated intrinsic excitability in dorsomedial MSNs, and reduced proximal dendritic complexity. In our ongoing work, we are using channelrhodopsin to investigate the role of action potentials in striatal plasticity in either MSN cell class.

Title: An active hippocampal network not driven by ripples

Authors: *K. KAY, M. SOSA, J. E. CHUNG, M. P. KARLSSON, I. GROSSRUBATSCHER, L. M. FRANK;
UCSF, San Francisco, CA

Abstract: The hippocampus has a central role in memory, yet we still do not know how hippocampal neural activity underlies the cognitive functions of the hippocampus. One promising lead is the hippocampal network pattern known as the sharp-wave ripple (SWR, or "ripple"), a rhythmic event (150-250 Hz) that occurs during stationary periods and during slow-wave sleep in the behaving animal. Recent findings indicate that SWRs are necessary for hippocampal function at the behavioral level, thereby qualifying a link between SWRs and higher-level hippocampal functions. At the circuit level, the SWR reflects highly synchronous hippocampal spiking, and appears to dominate the hippocampal network with strong excitation for its duration (10-100 ms). However it is not clear whether unit activation during SWRs is universal in the hippocampal network. We thereby sought to evaluate SWR spiking activity at the unit-by-unit level, using local field potential (LFP) and spike data collected from rats implanted with multitetrode arrays and performing a hippocampus-dependent memory task. SWRs in multiple running environments and from sleep sessions were detected and analyzed. Surprisingly, we have found a subpopulation of principal units in the hippocampus that are not driven by SWRs, and in some cases even consistently reduce baseline spiking during SWRs. These units are moreover highly active during behavioral epochs in which the animal is awake and engaged in the memory task. During these awake periods, SWR-driven hippocampal units are known to fire in spatial receptive fields known as place fields. We observe that non-SWR driven hippocampal units show proportionally less traditional place activity, instead often firing more when the animal is behaviorally stationary. These basic findings (1) advance our understanding of SWRs, (2) indicate that the hippocampal circuit stages an informational stream distinguishable from that associated with SWRs, (3) suggest that non-SWR activity during periods of immobility may be of special importance for hippocampal function.

Title: Grid cells reflect the locus of attention, even in the absence of movement

Authors: N. WILMING[1,2], P. KÖNIG[1,4], *E. A. BUFFALO[2,3];
[1]Inst. of Cognitive Sci., Univ. of Osnabrück, Osnabrück, Germany; [2]Physiol. and Biophysics, [3]Washington Natl. Primate Res. Ctr., Univ. of Washington, Seattle, WA; [4]Neurophysiol. and Pathophysiology, Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: The grid cell network allows for the precise decoding of the position of freely moving animals and is therefore implicated in spatial navigation. Recent work (Killian et al. 2012) has demonstrated that overt attention in the form of eye-movements is sufficient to activate the grid cell network in macaque monkeys. This suggests that grid cells may be able to support other cognitive functions besides spatial navigation. It has recently been suggested that firing patterns among grid cells may support both navigation and memory and that the neuronal algorithms underlying navigation in real and mental space are fundamentally the same (Buzsaki and Moser, 2013). A critical prerequisite for this idea is that the grid cell network can function even in the absence of physical movement through space. We examined this possibility by training a macaque monkey to covertly attend to a moving dot in the periphery while maintaining central fixation on a computer monitor. On each trial, the monkey's task was to monitor the dot and release a bar when the dot changed color after a variable amount of time (700-2200ms). Over the course of the experimental session, the dot covered the entire screen with several passes through each area of the screen. We recorded the spiking activity of 100 units in the entorhinal cortex of one macaque monkey and computed the gridness of 2D firing rate maps obtained by plotting spike trains as a function of dot position. In preliminary results, we identified entorhinal neurons that showed a significant grid-like activation with 60º rotational symmetry between the firing fields (bootstrapping procedure, $p<0.05$). Neurons were also identified that fired when the location of attention was near the borders of the screen. These findings support the hypothesis that covert attention is sufficient to activate the grid cell network, and that the primate entorhinal cortex can reflect space even in the absence of any physical movement.

Title: Contribution of the different hippocampal synapses to classical eyeblink conditioning in mice and rabbits

Authors: *J. DELGADO-GARCIA[1], R. SÁNCHEZ-CAMPUSANO[2], A. CARRETERO-GUILLÉN[2], A. GRUART[2];
[1]Pablo Olavide Univ., Seville, Spain; [2]Univ. Pablo de Olavide, Sevilla, Spain

Abstract: Although it is generally assumed that the hippocampus is involved in associative learning tasks, the specific contribution of the different synapses present in its intrinsic circuit or comprising its input and output pathways is still poorly defined. We have addressed this important question by recording the activity-dependent changes in synaptic strength of nine hippocampal synapses (corresponding to the intrinsic hippocampal circuitry and to its main inputs and outputs) during the acquisition of a trace conditioning of eyelid responses in alert behaving mice. The evolution of the timed changes in synaptic strength of the synapses included in the study allowed us to determine their functional organization, which did not coincide with their sequential distribution according to anatomical criteria and connectivity. Results confirmed that the acquisition of a classical eyeblink conditioning is a multisynaptic process in which the contribution of each synaptic contact is different in strength, and takes place at different moments across the learning process. In a subsequent experiment, we studied the contribution of both context (environmental details) and cues (conditioned and unconditioned stimuli: CS, US) to those activity-dependent changes in synaptic strength. We recorded in rabbits the monosynaptic field excitatory post-synaptic potentials (fEPSPs) evoked at six different hippocampal synapses during the acquisition and extinction of a classical eyeblink conditioning using trace and delay paradigms, as well as during pseudoconditioning and in the absence of CS and US presentations (context). Context and pseudoconditioning training evoked early, lasting changes in synaptic strength in perforant pathway synapses in dentate gyrus (PP-DG), and hippocampal CA3 (PP-CA3) and CA1 (PP-CA1) areas. Pseudoconditioning also evoked early, non-lasting changes in strength within the intrinsic hippocampal circuit (CA3-CA1 and CA3-

cCA1 synapses). In contrast, during both trace and delay training sessions, synaptic changes in strength were mostly noticed within the intrinsic hippocampal circuit (DG-CA3, CA3-CA1; CA3-cCA1). In conclusion, the precise and timed activation of the multiple synaptic contacts in the hippocampal circuit during classical conditioning of eyelid responses evokes a specific, dynamic map of functional synaptic states in that circuit. In addition, the response of hippocampal synapses to afferent impulses seems to be modulated by both context and cues during pavlovian associative learning in behaving rabbits.

Title: Memory ontogeny in the juvenile rat

Authors: *S. A. LYON, R. F. LANGSTON;
Div. of Neurosci., Univ. of Dundee, Dundee, United Kingdom

Abstract: Episodic memory is the recollection of unique autobiographical events, including rich detail of times, places and associated contextual information and in neurodegenerative diseases, such as Alzheimer's disease, episodic memory is greatly impaired (1). The ability to recall episodic memories is thought to develop later in childhood than other types of memory such as novelty recognition (2), however this ontogeny in animals is so far unconfirmed due to a lack of suitable behavioural tests (3). We wish to model the emergence of episodic memory for 2 reasons: firstly it will be invaluable for creating age appropriate animal models of developmental disorders (4) and secondly we wish to use memory ontogeny as a novel tool to investigate the neurobiological basis of episodic memory. We used a battery of spontaneous novelty detection tasks to assess the ontogeny of different types of memory in juvenile rats from P25 to adulthood. The episodic memory test was adapted from Eacott and Norman (5) and used alongside other control tests of recognition and associative memory adapted from Langston and Wood (6). These tasks included Novel Object Recognition, Object Context, Object Place and Object Place

Context tasks. The test battery was compressed into a 4-day protocol so as to enable acute testing of rats during restricted developmental time windows. Adult rats performed significantly above chance on all the memory tasks using this novel behavioural protocol but juvenile rats, display a differential emergence of memory types. References 1. Title: Polymer probes allow long lasting, high-density recordings in awake, freely behaving animals

Authors: *J. E.-C. CHUNG[1], D. F. LIU[2], I. GROSSRUBATSCHER[3], V. M. TOLOSA[4], K. G. SHAH[4], A. C. TOOKER[4], S. H. FELIX[4], S. S. PANNU[4], L. M. FRANK[3];

Abstract: The brain is a massively interconnected network of specialized circuits. All brain functions depend on millisecond timescale interactions across these brain networks, and there is a pressing need to develop technologies that make it possible to measure these interactions. We have therefore developed flexible multielectrode polymer probes that have the potential to yield

long-lasting recordings from single neurons across many sites in a distributed circuit. We used a novel implantation approach wherein arrays are bound to removable silicon stiffeners using polyethylene glycol, a water-soluble adhesive, allowing for insertion into the brain during implantation. Following a 10-30 minute period, the adhesive dissolves and the stiffener can be removed, leaving the probe in place. We used this method to implant a first set of high-density probes into rat pre-limbic and infra-limbic cortices. We were able to obtain high quality single units (maximum amplitude ~ 250 uV) for approximately 40 days. We are currently experimenting with changes to probe and stiffener geometry, and implantation procedures. These changes, alongside ongoing development of data-acquisition hardware and software, will further optimize recording quality, electrode stability, as well as the quantity of implanted probes and recording channels. These polymer probes provide an integral part of the path towards awake, freely behaving, high-density, chronic recording across distributed neural circuits.

Title: Dopaminergic modulation of lateral amygdala neuronal activity: Differential influences of D1 and D2 receptor activation on thalamic and cortical afferent inputs

Authors: *C.-H. CHANG, A. A. GRACE;
Dept. of Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: In Pavlovian auditory fear conditioning, the lateral nucleus of the amygdala (LA) integrates an acoustic conditioned stimulus (CS) with an aversive unconditioned stimulus (US). The CS reaches the LA via a direct input from auditory thalamus (medial geniculate nucleus, MGN), as well as the auditory association cortex (Te3). The thalamic input is generally believed to provide a basic version of the CS, while the cortical input provides a more processed representation of the stimulus. Dopamine (DA) is released in the LA during numerous

conditions, such as under heightened arousal of the presentation of an affective CS. However, how DA modulates the excitability of LA neurons in response to thalamic and cortical afferent inputs is poorly understood. In the current study, the effects of D1 or D2 receptor activation on LA afferent-driven neuronal firing were examined using *in vivo* extracellular single-unit recordings with local micro-iontophoretic drug application in anesthetized rats. Electrical stimulating electrodes were placed in either the MGN or Te3 (0.5 Hz, 0.25 ms pulse duration, 1 mA) in search of responsive neurons in the LA. The stimulation current was then adjusted to evoke ~50% response (baseline, 20-30 spikes in 50 trials), followed by iontophoresis of either the D1 agonist, SKF38393 (20mM in 100mM NaCl), or the D2 agonist, quinpirole (10mM in 10mM NaCl), in successively increasing doses (5, 10, 20, and 40nA). Putative LA projection neurons were categorized into "excitatory" or "inhibitory" to D1 or D2 agonists if changes in evoked responses (per 50 trials) were 1) unitary in direction, and 2) greater than 15% change relative to baseline in any of the doses applied. A total of 87 neurons were recorded from 40 rats. We found that the majority of the neurons recorded (77 out of 87) exhibited either excitatory or inhibitory response to activation of D1 or D2 receptors in both the thalamic and cortical pathways. In general, it requires significantly higher current to evoke ~50% baseline response to the cortical input compared to the thalamic input. Activation of the D1 receptor showed no difference in modulation of the inhibitory or excitatory response between the thalamic or cortical pathways. On the other hand, activation of the D2 receptor has a stronger inhibitory modulation in the cortical pathway, but a stronger excitatory modulation in the thalamic pathway. Our results suggested that there is a shift in balance favoring the thalamic pathway in response to DA acting via the D2 receptor.

Title: Hippocampal-cortical dynamics underlying distributed memory representations

Authors: *G. ROTHSCHILD, L. Y. TIAN, I. GROSSRUBATSCHER, L. M. FRANK;
Ctr. for Integrative Neurosci., UCSF, San Francisco, CA

Abstract: Animals and humans form associations between different sensory experiences, and these memories guide future behavior. However, the systems-level neural mechanisms underlying formation of learned associations is largely unknown. Building upon the strong natural sensitivity of rodents, we studied the formation of place-sound association in rats. We examined the interplay of activity patterns across three structures: the hippocampus, which is critical for location encoding and memory formation, the auditory cortex (AC), which is a central cortical region involved in auditory processing and sound-related learning, and the prefrontal cortex (PFC), which is involved in task-relevant processing, decision making and memory processes. To do so we carried out multi-tetrode recordings of multiple single units in CA1, AC and PFC of rats learning a place-sound association task. Rats learned to associate a specific sound with a specific location on a track, and reached 80-90% performance in 6-7 days of training and recording. We found that responses of AC neurons to the target sound were behaviorally modulated, highlighting the importance of accounting for behavioral state when assessing response profiles in AC. In addition, while responses to the target sound in AC modestly increased immediately after training, the population representation did not change markedly across the week of learning. These findings suggest that AC itself is not the repository of learned sound-place associations. We therefore asked if learning could be manifested in information flow between the hippocampal CA1, AC and PFC. We focused on activity during hippocampal sharp wave ripples (SWRs), which has been identified as a key candidate mechanism of information transfer between hippocampus and cortex. During SWRs, replay of behavioral firing patterns occur, and coordination with cortical regions involved in memory processes is enhanced. Moreover, blocking SWRs during sleep or behavior impedes learning. Surprisingly, we found that spiking of many AC neurons was strongly modulated during hippocampal SWRs. For a subset of neurons, spiking activity during SWRs in sleep, when no sounds were presented, resembled responses to the target sound on the track, suggesting an offline “sound replay” mechanism. We also found that many CA1-AC pairs were significantly correlated specifically during SWRs, indicating that SWR events coordinate specific CA1 place cells and AC neurons. In addition, some neuronal pairs across PFC and AC showed enhanced correlations during SWRs. These results indicate that SWR-related activity could be a systems-level mechanism of associative memory formation.

Title: Endogenous levels of Lipoxin A4, a cannabinoid allosteric enhancer, impact learning and memory in mice

Authors: *L. M. LEO[1,2], C. A. CANETTI[3], O. B. AMARAL[3], F. A. BOZZA[1,2], F. A. PAMPLONA[2];
[1]Inst. Oswaldo Cruz, FIOCRUZ, Rio De Janeiro, Brazil; [2]D'Or Inst. for Res. and Education, IDOR, Rio de Janeiro, Brazil; [3]Univ. Federal do Rio de Janeiro, UFRJ, Rio de Janeiro, Brazil

Abstract: Lipoxin A4 (LXA4) is an anti-inflammatory molecule produced by 5-Lipoxygenase (5-LO), which also yields inflammatory leukotrienes, at the expense of arachidonic acid. In the brain, LXA4 augments anandamide signaling through its action as an allosteric enhancer on CB1 cannabinoid receptors. In light of this finding, we have recently demonstrated a role for LXA4 in mouse anxiety-like behavior (Leo et al., PLOS ONE 2014). Henceforth, we seek to identify other physiological functions regulated by the endocannabinoid system that may be skewed by LXA4 availability, such as learning and memory. Memory was assessed by the step-down inhibitory avoidance test. In this task, 5-LO knockout mice, that have reduced LXA4 levels, presented reduced step-down latency in the test session, suggesting memory impairment. In addition, these mice also presented reduced expression of CB1 receptors in the hippocampus, but not in cortex, as observed by Western Blot analysis. This finding suggests that the observed memory impairment is secondary to a down-regulated CB1-related endocannabinoid signaling in the hippocampus, as has been shown by other studies with rodents that described impaired memory in response to local infusion of a CB1 antagonist into the hippocampus. Aged Swiss mice (12 months) were also evaluated. The endogenous plasma levels of LXA4 and cysteinyl leukotrienes (cysLTs) were assessed by ELISA. Aged mice exhibited reduced LXA4 and increased levels of cysLTs, consequently presenting a lower ratio of LXA4/cysLTs. Accordingly, these mice also performed poorly in the step-down inhibitory avoidance task, compared to 3-month-old mice. These results point to an inflammatory imbalance in the brain of aged mice, with increased production of leukotrienes in detriment of LXA4. The reduction of the latter may dampen endocannabinoid signaling, contributing to the cognitive deficit observed. Our results indicate

that LXA4 may contribute to memory modulation, possibly via a CB1-related endocannabinoid mechanism.

Title: Transmitters involved in the action of neuromedin S on passive avoidance learning in rats

Authors: *G. TELEGDY, SR;
Pathophysiology, Univ. of Szeged,Department of Pathophysiology, Szeged, Hungary

Abstract: The effects of different neurotransmitters was studied in the action of neuromedin S (NMS) in the memory consolidation of passive avoidance behavior by pretreating rats with receptor blockers in doses which alone did not change the test. The involvement of cholinergic, dopaminergic, adrenergic, serotonergic, opiate and GABA-ergic receptors and nitric oxide was tested. The animals were pretreated with the non selective muscarinic acetylcholine receptor antagonist, atropine, the non selective α-adrenergic receptor antagonist phenoxybenzamine**,** the β-adrenergic receptor antagonist propranolol, the D2, D3, D4 dopamine receptor antagonist haloperidol , the non selective 5-HT2 serotonergic receptor antagonist cyproheptadine, the nonselective opioid receptor antagonist naloxone,. the γ-aminobutyric acid subunit A (GABA-A) receptor antagonist bicuculline, or the nitric oxide synthase inhibitor nitro-L-arginine. Atropine, haloperidol, phenoxybenzamine, propranolol, cyproheptadine, naloxone and nitro-L-arginine prevented the effects of NMS on passive avoidance learning. Bicuculline did not change the effects of NMS. The results demonstrate that , muscarinic acetylcholine, α- and β- adrenergic, dopaminergic , 5-HT2 serotonergic and opioid receptors and nitric oxide are involved as mediators. in the action of NMS on the consolidation of passive avoidance learning. 1 2

Title: Grid cells require experience with local boundaries during development

Authors: *I. U. KRUGE, T. WAAGA, T. WERNLE, E. I. MOSER, M.-B. MOSER;
NTNU, Kavli Inst. For Systems Neurosci., Trondheim, Norway

Abstract: Grid cells in the medial entorhinal cortex (MEC) represent a metric for space. In rodents, receptive fields of individual grid cells tessellate environments with regularly repeating firing fields of hexagonal spacing. Developmental studies have shown that adult-like grid cells appear during the fourth postnatal week, beginning approximately one week after pups open their eyes and actively explore their surroundings for the first time. During this developmental window it is not known whether the grid cell network relies on experience with salient spatial features in order to form an optimal connectivity, or whether the emergence of grid patterns is established by purely maturational processes. To explore this question we tested whether development of grid cells is biased by the spatial environment in which rats are raised. Rats were born and raised in a spherical environment (70-100 cm diameter) made from frosted 8 mm acrylic material, and so were deprived from experience with sharp boundaries and distal visual cues. As controls, we raised rats in frosted cubes (50 x 50 cm) with sharp vertical edges but equally limited distal visual cues. A third group was raised in enriched cages with no limitations in spatial experience. In the sphere and cube conditions all animals were handled and trained in darkness to prevent visual access to spatial features external to their home cage. Adult rats were implanted with tetrodes aimed for MEC, and putative grid cells were localized during recording in the home cage in complete darkness. When stable theta-modulated cells appeared in the MEC recordings, the rats were introduced to a lighted room and a novel square environment. Single unit activity was subsequently recorded during free foraging in normally lighted sessions over three to seven days. Grid cells with repeating firing fields were immediately present in the

spatially enriched control group. In the sphere-raised rats, a reliably regular hexagonal pattern could not be detected, although grid-like patterns started to emerge by the end of one week of recording in the new environment. In the cube-raised group, grid cells with symmetric hexagonal features developed after some days of exposure. Further experiments will determine whether the observed differences between animals raised under deprived or normal conditions persist with further training. Our results suggest that the repetitive firing of grid cells is genetically hardwired from birth, but that the animal needs experience with stable vertical reference boundaries during development in order to express perfectly hexagonal grids at adult age.

Title: A neural circuit for goal-directed spatial coding

Authors: *H. T. ITO, S.-J. ZHANG, M. P. WITTER, E. I. MOSER, M.-B. MOSER; CNC, NTNU, TRONDHEIM, Norway

Abstract: Spatial navigation to a desired location requires information about the combinatorial relationship between an animal's choices of action and subsequent spatial positions. A number of studies indicate that this relationship is represented in the activity of hippocampal CA1 neurons, which fire not only at the animal´s current spatial position but also dependent on the trajectory taken to reach a subsequent goal location. Although such trajectory-dependent activity is likely

to be a result of associations between spatial position and behavior, how the hippocampus acquires information about intended actions is still poorly understood. Here we report a neural circuit, composed of the medial prefrontal cortex (mPFC) and the midline thalamic nucleus reuniens (Re), that is required for trajectory representation in the CA1 field of the hippocampus. In a continuous alternation task on a figure-8 maze, trajectory-dependent firing was observed in both CA1 and Re cells, but significantly less in CA3 cells, which do not receive Re inputs. Trajectory-dependent firing of CA1 cells was significantly reduced by lesions or optogenetic silencing of Re cells, indicating a causal link between Re input and trajectory representation in the hippocampus. Trajectory-dependent firing was also observed in neurons in mPFC, which has reciprocal anatomical connections with Re, suggesting that mPFC shares the information with Re. The trajectory information represented in this prefrontal-to-hippocampal circuit was sufficient to predict a correct choice of trajectory, which was disrupted on error trials. Furthermore, lesions of Re led to a disruption of prospective trajectory representation in CA1, supporting the idea that Re provides information about animal's future behavior. Taken together, the results point to a functional circuit composed of mPFC, Re and CA1 that is required for the hippocampus to represent the animal's future choice of action together with spatial position.

Title: Grid cells in non-planar environments

Authors: *H. YAMAHACHI, M.-B. MOSER, E. I. MOSER;
Kavli Inst. for Systems Neuroscience, CNC, NTNU, Trondheim, Norway

Abstract: Information about how an animal represents a complex environment in the brain is vital to understand navigation in the real world. The discovery of the grid cells in the entorhinal cortex supports the idea of an internal metric representation of space. So far, most of the experiments have been done in arenas with horizontal surfaces, and little is known about how grid cells are modulated in undulating environments. Are grid cells bound to the traversed surface? Is the map continuous or is it fragmented? In the present work, we have recorded grid cells in rats that forage in a rectangular arena (1 m x 2 m) that can be morphed from a planar to a non-planar configuration. To enable this transformation, the arena was made of three sections: both ends were flat, while the central section could be moved vertically. When the central section moved down, a rugged rubber floor created a concave curvature on the surface of the arena (Fig.). We found that firing fields of grid cells remained unaffected by the extra travelled space (7.5 to 25 cm equivalent to a curvature of maximum depth of 13 to 26 cm). Instead, their firing field positions matched exactly the ones on the planar configuration. The correspondence between planar and curved environments was present even on the first exposure to the curvature. The firing fields maintained their regularly spaced positions even where they intersected with the edges of the curvature indicating that the whole environment was represented as a single continuous map. Taken together, these data indicate that grid cells in the entorhinal cortex of the rat disregard the z-plane in undulating terrains, and instead anchor their firing fields to a horizontal x-y plane that covers the entire environment. Title: Speed cells in the medial entorhinal cortex

Authors: *E. KROPFF CAUSA[1,2], J. E. CARMICHAEL[3,2], E. I. MOSER[2], M.-B. MOSER[2]; [1]Leloir Inst. - IIBBA - CONICET, Buenos Aires, Argentina; [2]Kavli Inst. For Systems Neurosci. and Ctr. For Neural Computation, NTNU, Trondheim, Norway; [3]Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Grid cells in the medial entorhinal cortex (MEC) have spatial maps characterized by periodicity (Hafting et al, 2005). Their spatial code applies to several places within an environment as well as across environments (Fyhn et al, 2007), which suggests they could be the basis of a path-integration representation of space (McNaughton et al, 2006). A path integrator would receive a speed signal as an input and integrate it along a short window of time to obtain the displacement of the animal, using this result to update the spatial maps. Although weak correlations with theta frequency (Jeewajee et al, 2008) or grid cell firing (Sargolini et al, 2006; Wills et al, 2012) have been reported, the local availability and nature of a speed signal in MEC is still unclear. We recorded neural activity in the MEC and hippocampus of rats in a 1mx1m open field and in the Flintstone car, a task designed to control their speed. The car, which was ran by a computer along a 4m track, had no floor, constraining rats to run by their own means at an experimenter-determined speed in order to keep up and reach the end of the track, where a food reward was delivered. We report that running speed is coded in the firing rate of a large population of MEC cells, representing around 10% of the overall cell count in all layers. The firing of these speed cells is characterized by a positive-linear relationship with running speed and low spatial and head-directional information content. While other entorhinal populations (grid, head direction and border cells) present large overlaps with each other, their overlap with the population of speed cells is in all cases significantly lower than expected by chance. In agreement with the functional segregation of speed cells, when experimentally disentangling speed and position we were unable to find any modulation by speed in the grid cell population, and found only a weak modulation in hippocampal place cells. Finally, MEC speed cells exhibited prospective coding, anticipating the rats' movements around 60ms on average, although in some selected examples the anticipation reached 200-300ms. In turn, grid cells recorded in the same experiments behaved as if guided by a prospective rather than a regular path integrator, as evidenced by the anticipation of their firing position when acceleration was positive as opposed to negative, an effect that was absent in simultaneously recorded hippocampal place cells. This shift in firing position was stronger in a) layer II and b) the last portion of the theta cycle, not associated in grid cells with phase precession proper. Put together, our results point to the coordinated involvement of MEC grid cells and speed cells in path integration.

Title: Grid cell orientation is constrained by environmental geometry

Authors: T. STENSOLA, H. STENSOLA, *M. HAGGLUND, M.-B. MOSER, E. I. MOSER; Kavli Institute, CNC, Trondheim, Norway

Abstract: Grid cells express spatially selective firing fields which tile the environment. Earlier work has shown that grid cells form separate modules in which certain parameters are shared, such as orientation, size and ellipticity of the grid pattern. The absolute orientation of the grid axes has been assumed to be randomly distributed. Here we show that there is a striking similarity in the way grid orientation distributes in relation to the geometry of the recording environment, not only across different modules within an animal, but also across different animals in the same environment. Grid cells were recorded in two different square boxes in separate rooms. In one of the rooms, grid orientations were unimodally distributed around 7.5 degrees relative to one of the walls. In the other room, orientations took on a bimodal distribution with 7.5 degree offsets from either of the two orthogonal walls. Grid orientations near 0 or 15-degrees were almost completely absent. We next addressed possible mechanisms for the 7.5 degree orientation preference. We hypothesized that orientations were determined by the degree of asymmetry between the grid pattern and the geometry of the box. 7.5 degrees lies between the two symmetrical grid arrangements of 0 degrees (symmetry with one wall) and 15 degrees (symmetry with the diagonal) and could provide the most unambiguous representation with reference to the box geometry. To test this possibility we simulated 300 grid cell maps with uniformly distributed phases and coherent orientation. We then varied the orientation and

analyzed how well the activity between two orthogonal walls of the box correlated. The results show that 7.5 degrees is indeed the optimal solution for decorrelating border segments, and that 0 and 15 degrees are the least optimal solutions. There was a strong similarity between the correlation values in the simulated data and orientation preferences in the real data. To further investigate the importance of interactions between walls and grid orientations, we recorded grid cells from animals running in either an equilateral triangle, where offsets should be similar along all walls for a perfect hexagonal grid, or in a truncated cylinder, which had only a single straight reference wall. In both of these enclosures, the grid took on a zero degree angle in several of the experiments. These results corroborates that grid orientation is constrained by environment geometry, and suggest that grid orientation is determined by a process that optimizes disambiguation of geometrically ambiguous environments. We hypothesize that this is a result of competitive interactions imposed by the boundaries of the environment.

Title: Interhemispheric connections between left and right medial entorhinal cortices

Authors: ***K. ZHENG**, Ø. W. SIMONSEN, M. P. WITTER;
Neurosci. Dept, Kavli Inst/Cnc, NTNU, Trondheim, Norway

Abstract: The rodent medial entorhinal cortex (MEC) contains a variety of spatially modulated neurons, including grid cells, head direction cells, border cells and speed cells. Grid cells are mostly prominent in layer II, as are stellate cells, suggesting that the stellate cell is a candidate for grid cells. We have previously reported that stellate cells are locally interconnected through fast spiking interneurons. It is well known that the left and right MEC are strongly connected and that these reciprocal connections show a strict topological organization. We studied this interhemispheric connection between the left and right MEC. We used anterograde and retrograde tracing and established that the main origin of the commissural projection is from neurons in layer III, although a low number of layer II cells contribute as well. The commissural fibers terminate in layers I/II. With the use of confocal microscopy, we observed that stellate

cells and interneurons within layer II are among the innervated targets. Using an optogenetic approach, we specifically activated axon terminals of the commissural fibers and recorded the postsynaptic responses by way of whole cell patch recordings in horizontal slices Our data corroborate the confocal findings showing that commissural fibers make excitatory synaptic contacts with stellate cells as well as interneurons in layer II of MEC. This circuit may allow the left and right grid networks to generate a unified spatial representation.

Title: Grid cells interact with local boundaries

Authors: M. HÄGGLUND, T. STENSOLA, H. STENSOLA, M.-B. MOSER, *E. I. MOSER; Kavli Inst. Systems Neurosci, Trondheim, Norway

Abstract: Entorhinal grid cells produce a stereotyped and highly coherent triangular firing pattern when recorded in small open environments. We recently discovered that the orientation of the grid pattern is not randomly distributed, but is constrained by the geometry of the local environment. Recordings of grid cells in differently sized square boxes from 7 animals showed that grid orientation distributes with an average offset of 7.5 degrees from either wall of the box, an offset that is optimal for disambiguating geometrically similar locations within the box. The reliable offset of grid orientation suggests that grid fields anchor to environmental boundaries in

a stereotypical fashion. It is not clear, however, whether this anchoring process is global (expressed throughout the environment) or local (with different anchoring solutions at different locations). To address this question, we first recorded grid cells in large square environments, where local variations may become more visible. Grid patterns were not always coherent across the environment. Often the grid pattern would take on distinct orientations at different locations of the environment, with each local grid orientation being offset 7.5 degrees to the closest wall. When the grid anchored to two orthogonal walls, with one orientation in one part of the box and another in the rest of the environment, the grid often showed inconsistencies in hexagonality and coherence in the middle, where the two patterns merged. To further examine the effect of wall interactions on grid anchoring, we next recorded grid cells in a large triangular environment. Here the grid became highly elliptic, and took on complex forms, likely reflecting different anchoring solutions along different walls of the triangle. Orientation along one grid axis was often non-coherent, and would shift gradually across the environment. Because total area was smaller in the triangle compared to the square, despite equally long walls, reduced overall hexagonality in the pattern likely reflected a less graded merging of the locally anchored pattern fragments. Taken together, these results imply that grid cells anchor to walls locally and stitch together in open areas. The development and stabilization of grid maps in large individual environments may thus be an experience-dependent process.

Title: Graph analysis of the rat (para)hippocampal connectome

Authors: *N. M. VAN STRIEN[1,2,3], F. Z. M. BINICEWICZ[2], W. J. WADMAN[2], M. P. WITTER[1], M. P. VAN DEN HEUVEL[3], N. L. M. CAPPAERT[2];

Abstract: The hippocampal formation (HF) and the parahippocampal region (PHR) contribute to encoding, consolidation and retrieval of declarative memories. Knowledge of the neuroanatomical connections of the HF and PHR will underpin our efforts to understand the network function. Connectomes are therefore indispensable, since they transparently summarize and categorize the brain's anatomical connections. From the tract tracing literature we have constructed a connectome of the 11 subregions of the rat HF and PHR (van Strien et al., 2009; Sugar et al., 2011; www.temporal-lobe.com). These subregions were further split in a three dimensional manner along the rostrocaudal, dorsoventral and laminar axis to provide unprecedented detailed information about the origin and termination of each included connection. This HF-PHR connectome is currently the most fine-grained representation of a mammalian cortical network. We have now applied graph analysis to our HF-PHR connectome in order to systematically disclose the inherent characteristics of the structural network. To obtain biologically meaningful values, we collapsed the data over each three-dimensional axis creating sub-connectomes. The network regarding the laminar dimension has a density of 19%, a path length of 2.1 and a correlation coefficient of 0.4. We tested the latter values against a set of random null models, concluding that the laminar network is regularly organized. Within this laminar network, thirteen rich club nodes were discovered, mainly situated in the PHR. Six of these rich club nodes were connector hub nodes, all six of them were positioned in the medial and lateral entorhinal cortex. This suggests that the entorhinal cortex is crucially important for information transfer in the HF-PHR network. Several modules were detected that showed a close relationship between the perirhinal and postrhinal cortex as well as between the lateral and medial entorhinal cortex. These findings are incompatible with the two stream memory model (Eichenbaum & Lipton, 2008), in which the spatial and non-spatial perceptual information streams towards the hippocampus are carried by separate routes: the postrhinal - medial entorhinal cortex 'spatial' stream versus the perirhinal - lateral entorhinal cortex 'non-spatial' stream. In our analysis, the interconnectivity between the streams is prevailing, which is supported by recent physiological evidence (van Cauter et al,2013; Deshmuk & Knierim, 2011; Hunsaker et al, 2013; Tsao et al, 2013). Although our connectome is incomplete due to lack of anatomical data in the current literature, our graph analysis nevertheless suggests that the two-stream model is not tenable.

Abstract: The lateral entorhinal cortex (LEC) is likely one of the main gateways by which sensory information reaches the hippocampus. However, it is currently unknown how the LEC represents basic sensory stimuli, and it is unclear how this representation is modified or utilized during behavior. To address these questions, we recorded activity in LEC neurons expressing the genetically encoded calcium indicator GCaMP6f while presenting a wide range of odor stimuli (including diverse single odorants, mixtures, and different concentrations). We observed sparse activation to all odor stimuli, with only a few percent of cells responding to any given odor. To test if sparse sensory representation is a general feature of LEC, we then imaged while presenting a wide range of auditory stimuli including pure tones, ultrasonic vocalizations, and birdcalls. Preliminary results indicate that representation of auditory stimuli in LEC is similarly sparse as for odor stimuli. In order to examine whether and how the sparse representation of basic odors is used during behavior, we have developed a virtual T-maze task which mice, guided by odor cues, learn consistently. We are currently imaging activity in LEC while mice perform this task to examine whether the sparse representation of odor cues changes with learning, as well as whether and how goal-oriented behavior affects representations of sensory cues. Through a better understanding of sensory processing within LEC, we may gain insight into what roles LEC plays in its interactions with the hippocampus as well as higher-order regions.

Title: Grid representation for merged space

Authors: *T. WERNLE[1], E. I. MOSER[2], M.-B. MOSER[2];
[1]Kavli Institute/CNC The Fac. of Medicine, NTNU, Trondheim, Norway; [2]Kavli Inst. / CNC The Fac. of Medicine, NTNU, Trondheim, Norway

Abstract: Grid cells are part of the brain's metric for space. Their firing locations define a periodic triangular array overlaid on the entire space available to a moving animal (Hafting et al. 2005). In natural environments, space is likely represented as a mosaic of discrete grid maps that stitch together at salient landmarks such as the turning points of a maze (Derdikman et al. 2009). However, it is not clear how a global coherent map is established from discrete fragments. To address this question, we recorded from grid cells in separated and merged spatial compartments. We first trained rats in a large square environment (2 x 2 m) which was separated into two similar rectangular compartments by a central wall sharing common distal cues. Once two distinct grid maps were generated for each rectangle, we removed the wall, allowing the animal to walk instantaneously from one compartment into the other. The two distinct grid maps did not always change into a merge of the two original maps. Instead, a single global coherent map was often established from one of the two pre-existing representations, depending on the starting position of the rat. The calibration of this global map was experience-dependent and required successive visits to the different parts of the environment. Furthermore, we found that grid cells within one module operated coherently in order to establish one global map and that distinct grid modules represented merged space independently. Ongoing work is testing whether the response to merged environments is general across animals and if not, which factors determine whether a merged map is formed or not.

Title: Modular organization of gamma oscillations in medial entorhinal cortex

Authors: *K. M. IGARASHI, H. STENSOLA, T. STENSOLA, M.-B. MOSER, E. I. MOSER; Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway

Abstract: Grid cells in the medial entorhinal cortex (MEC) provide the animal with a metric of the environment via regularly-spaced spatial firing patterns. We recently showed that grid cells are organized into discrete modules with different grid spacing (Stensola et al., 2012). Grid cells of different modules can respond independently to environmental change, whereas cells in the same module respond coherently. However, underlying mechanisms for the coherent spatial firing within modules are not clear. One possibility is that gamma oscillations promote communication between cells in the same module, and that different modules operate at different frequency bands. To test this hypothesis, we characterized gamma oscillations in local field potentials recorded from tetrodes with layer III cells belonging preferentially to a single module. Wavelet analysis was performed to characterize cross-frequency coupling of gamma oscillations against theta oscillations. The analysis showed that there are three distinct gamma bands: slow gamma (25-55 Hz), fast gamma (55-100 Hz) and very fast gamma (>100 Hz). The existence of the three gamma bands is similar to the frequency organization observed in the hippocampus (Colgin et al., 2009; Belluscio et al., 2012). We used the slow and fast gamma bands for further analyses. Preliminary analysis suggests that tetrodes predominated by cells from modules with short grid wavelengths (short spacing) exhibit fast gamma, whereas tetrodes predominated by larger-scaled modules show both slow and fast gamma oscillations. Tetrodes with large-scale modules had slow gamma oscillations that were more strongly phase-locked to theta oscillations than gamma oscillations on tetrodes with small-scale modules. Phase-locking analysis of spikes from grid cells further showed that spikes in large-scale modules are more strongly phase-locked to slow gamma oscillations than those in small-scale modules. No difference between large-scale and small-scale modules was observed for fast gamma oscillations in cross-frequency coupling and spike phase-locking. These results support the idea that modules with short spacing use only fast gamma whereas modules with larger spacing use both fast and slow gamma oscillations, and point to gamma oscillations as a mechanism for independent representation across grid modules in MEC.

Title: 2-photon imaging of the medial entorhinal cortex in mice performing a virtual reality navigation task

Authors: *F. DONATO[1], A. TSAO[1,2], M.-B. MOSER[1], E. I. MOSER[1], T. BONHOEFFER[2]; [1]Kavli Inst. For Systems Neurosci., Trondheim, Norway; [2]Max Planck Inst. of Neurobio., Martinsried, Germany

Abstract: Navigation is thought to rely on path integration-dependent maps of the spatial environment, expressed in different forms in the hippocampus and the medial entorhinal cortex. The formation of such depends on a broad ensemble of interconnected neurons whose firing is tuned to spatial features, including place cells in the hippocampus and grid cells and border cells in the medial entorhinal cortex. Grid cells are thought to provide the metric of the spatial representation. Despite extensive characterization of the physiological properties of these cells, their organization in the entorhinal microcircuit remains elusive. In particular, conventional electrophysiological recordings have not been able to determine (i) how grid cells and other entorhinal cell types are organized in anatomical space, (ii) whether grid cells have specific molecular or morphological profiles, or (iii) how grid cells with different grid phases (firing locations) show topographical organization of any kind at a detailed level. Here, we developed a preparation that allows us to perform chronic 2-photon calcium imaging in the superficial layers of the medial entorhinal cortex of head-restrained animals navigating in a virtual reality environment. High-resolution images were obtained by imaging through a glass microprism directly placed behind the medial entorhinal cortex, therefore allowing standard calcium imaging of the deep structure while maintaining the integrity of all cortical structures surrounding MEC. Cells close to the prism face could be imaged repeatedly and reliably across several days, and their firing properties could be related to specific aspects of the navigation task. The preparation allows us to study the fine-scale anatomical distribution of spatially modulated cells as well as their molecular identity and lateral connectivity, in order to directly observe the local anatomical

organization of spatial cell types, thereby hopefully further elucidating the functional network underlying grid cells as well as other functional cell types in the medial entorhinal cortex.

Title: Towards a functional identification of stellate cells in medial entorhinal cortex layer II

Authors: *D. C. ROWLAND, E. R. SKYTØEN, C. G. KENTROS, M.-B. MOSER, E. I. MOSER;
NTNU, Trondheim, Norway

Abstract: Layer II of the medial entorhinal cortex (MECII) contains two principal cell types: pyramidal cells and stellate cells. Accumulating evidence suggests that these two cell types have distinct physiological properties and projection patterns, with the reelin-expressing stellate cells providing the main excitatory input to the dentate gyrus and CA3 region of the hippocampus. At least a subset of the pyramidal cells differ from stellate cells in that they express calbindin but not reelin, receive strong cholinergic input, and do not project directly to principal cells in the hippocampus. This calbindin-expressing pyramidal cell population forms tight clusters intermingled among stellate cells. Together, these observations hint at a fundamental difference between stellate cells and pyramidal cells but the functional identity of the two cell classes needs to be worked out. Here we investigate a transgenic mouse line (Yasuda and Mayford, 2006; Rowland et al., 2013) where the transgene is expressed almost exclusively in MECII. In the first part of the study, we sought to determine the morphological identity of the transgene-expressing

cell population. Two lines of evidence suggested that the transgenic neurons are stellate cells. First, GFP was expressed widely but with distinct circular gaps, suggesting that the transgenic neurons are outside of calbindin-expressing clusters Second, viral labelling of the transgenic cells showed that the cells have a stellate morphology and that they project to the dentate gyrus and CA3 region of the hippocampus. Molecular characterization of the cells using antibodies for calbindin and reelin is ongoing. In the second part of the study, we sought to identify the functional properties of the cells *in vivo* by expressing the optogentic silencer archaerhodopsin in the same cells and using short pulses of light to identify the transgene-expressing cells. Light-responsive cells included grid cells and border cells, but not head direction cells or interneurons. Taken together, these data suggest that the population of hippocampal-projecting stellate cells most likely includes both grid cells and border cells.

Title: Head direction cells before the time of eye opening in rat pups

Authors: *T. L. BJERKNES[1], R. F. LANGSTON[2], I. U. KRUGE[1], E. I. MOSER[1], M.-B. MOSER[1];
[1]Kavli Inst. for Systems Neuroscience, NTNU, Trondheim, Norway; [2]Div. of Neuroscience, Med. Res. Inst., Univ. of Dundee, Dundee, United Kingdom

Abstract: The brain's map of space consists of several functionally specific neurons, including place cells in the hippocampus and grid cells, border cells and head direction cells in medial entorhinal cortex (MEC), pre- and parasubiculum. Head direction cells are cells that fire selectively when animals hold their head in a certain direction in the horizontal plane. The preferred firing direction of these cells can be manipulated by visual changes to the environment, for instance, the preferred direction can rotate together with visual landmarks. Head direction cells can also maintain a sharp directional representation during locomotion in the dark, but their preferred direction may drift significantly over time. In the present study we investigated the developmental origin of the head direction signal. Previous work has shown that head direction cells in rats exhibit stable directional firing from the day of eye opening at P15, well before the emergence of stable positional signals. We asked whether this directional representation is present ahead of eye opening, in the absence of visual cues. We implanted rat pups from the age of P10. Directionally modulated cells were detected in pre- and parasubiculum already at P12. Directional modulation was unstable, however, especially between trials. The stability of the head direction cells increased significantly as the rat pups opened their eyes. Head direction signals were able to rotate with visual landmarks within the first two days after eye opening. These data indicate that visual input may not be necessary for formation of directional signals in rat pups but that anchoring to visual landmarks is important for stabilizing head direction cells.

Title: Reduced rate remapping in hippocampal subregion CA2

Authors: ***L. LU**, K. M. IGARASHI, M. P. WITTER, M.-B. MOSER, E. I. MOSER;
Kavli Inst. For Systems Neurosci. and Ctr. For Neural Computation, NTNU, Trondheim, Norway

Abstract: Hippocampal place-cell populations use a dual coding scheme to represent the external environment. While the animal's coordinates in space are expressed by the collective firing locations of the place cells, differential experience in the environment is often accompanied by differences in the distribution of activity among subsets of place cells with fixed firing locations. Complete transitions of firing patterns are defined as global remapping whereas transitions between rate patterns only are referred to as rate remapping. Both global remapping and rate remapping have been observed in place cells of dentate gyrus, CA3 and CA1; however, the remapping properties of CA2 place cells remain unknown. To explore the behaviour of CA2 place cells during remapping, we recorded activity of pyramidal neurons from CA2 and CA1 / CA3 simultaneously, while rats were exposed to different experiences which regularly induce global remapping and rate remapping in the hippocampus. As expected, CA2 pyramidal neurons were place cells but the spatial tuning of CA2 place cells was weaker compared to place cells in CA1 and CA3, as indicated by significantly lower spatial information content, spatial coherence and spatial stability. During random foraging in similar boxes in two different rooms, place cells recorded from all three subregions showed clear global remapping, indicated by a dramatic decrease of spatial cross correlation between different rooms. However, when the wall color of the box was reversed between trials in the same room, place cells in both CA1 and CA3 showed rate remapping, expressed by changes in rate distribution in the presence of high spatial corrrelation. The firing of the CA2 place cells, in contrast, remained almost identical across trials. Taken together, these data suggested that CA2 place cells are less sensitive to contextual input. The findings shed light on our understanding of the functional role of the CA2 subregion of the hippocampus.

Title: Retrosplenial cortex and Hippocampus share modulation of firing activity by allocentric space and the Hippocampal theta rhythm

Authors: *A. ALEXANDER, B. LA, S. A. COHANTZ, M. NGUYEN, D. A. NITZ;
UCSD, San Diego, CA

Abstract: Retrosplenial cortex (RSC) neurons map position in both egocentric and external frames of reference. Egocentric mapping takes the form of neurons whose activity reflects movement to the left or right of the longitudinal axis of the rat (i.e., 'left-turn' and 'right-turn' neurons). One external frame of reference mapped by RSC neurons is the space of known routes through the environment, also known as 'route' space. Such mapping takes two main forms: 1) neurons exhibit different turn-related activity rates depending on the position of turns in a route and, 2) neurons exhibit complex but reliable changes in activity across route traversals. Critically, both forms of spatial mapping are modulated by a second external frame of reference, the 'allocentric' space, defined by the boundaries of the environment. The result is consistent with RSC anatomy, as it receives direct inputs from hippocampal (HPC) sub-region CA1 and the subiculum. RSC may influence HPC through an excitatory projection to the entorhinal cortex, the main input to the HPC. Notably, RSC inactivation disrupts navigation in the allocentric frame of reference and the reliability of place-specific firing of HPC neurons. At this time, little is known as to the forms by which RSC and HPC interact to generate spatial cognition and episodic memory processes. We examined the spatial and temporal dynamics of HPC and RSC neurons recorded while the animal performed a simple track running paradigm with the track in two different room (allocentric frame) locations on any given recording day. Correlations between positional firing rate vectors for different track locations in the room were low for both RSC and HPC neurons, indicating modulation by the allocentric spatial frame. However, some RSC neurons had similar patterns across track positions, an effect not observed for the HPC population. Mapping of position in allocentric space also took the form of 'head direction' cells whose firing followed specific orientations of the animal's head relative to the environment. Another sub-population of RSC neurons exhibited activation patterns analogous to HPC place fields. Despite the impact of allocentric position on the firing activity of RSC neurons, there was no evidence that RSC neurons exhibit 'phase precession', a phenomena wherein HPC place cell firing is organized relative to theta-frequency local field potentials. Nevertheless, a subset of RSC neurons had activation that was phase-locked to theta rhythms recorded in the HPC. The results suggest that RSC and HPC can interact in the distribution of their firing rates in both the spatial and temporal domains.

Title: Positional mapping of route space in the medial precentral cortex and superior colliculus

Authors: *J. M. OLSON, D. A. NITZ;
Dept. of Cognitive Sci., UCSD, San Diego, CA

Abstract: Neurons of the rat posterior parietal cortex (PPC) map position in both egocentric and external frames of reference. Subpopulations of PPC neurons map egocentric space by firing with relatively high regularity when movements to the left or the right are made. PPC neurons also map the external frame of reference of a well-learned route, defined by inflection points in behavior (e.g., starts, stops, turns) and the straight-run spaces that separate them. Such 'route-based', spatially-specific firing is observed irrespective of the route position in a larger environment (Nitz, Neuron, 2006). Mapping in the route-based frame of reference takes the form of: 1) neurons with left or right turn related activity that is, in turn, modulated strongly by the position of the turn in a route; and 2) neurons whose rate vectors across route space are complex, but reliable across trials. PPC efferents reach many targets, but particularly dense innervation reaches a limited number of target structures (Nitz, 2009, Neurobiology of Learning and Memory). In the present study, we address the spatial firing correlates of two such structures, the medial precentral cortex (MPC, a prefrontal cortex sub-region often referred to as M2) and the superior colliculus (SC). Published data indicate that SC neurons are sensitive to direction of movement and have correlates to locomotor behaviors (Cooper, Miya, and Mizumori, Hippocampus, 1998). Prior work (Nitz et al., Society for Neuroscience Abstracts, 2013) indicates that many MPC neurons exhibit activity tightly correlated to track positions associated with left turns, right turns, or simple forward locomotion. Additional MPC neurons exhibit 'planning' activity wherein firing rates along straight-run track sections is highly predictive of whether the animal will, at a later time and place, turn left or right. Planning activity in MPC is not limited to only one or two positions in the environment, but occurs anywhere a straight-run segment leads to a left/right-turn intersection. At issue in the present work is whether MPC neurons and/or SC neurons exhibit route-based mapping (an external frame of reference) that goes beyond activity correlates to locomotor behaviors. Sensitivity to route position has been observed in a sub-population of MPC neurons and can be readily observed, at the population level, in covariance matrices revealing that track positions associated with like turns (left versus right) yield similar,

but not indiscriminable ensemble rate vectors. The results support a model in which spatial information is gradually transformed from external to egocentric frames of references for the purpose of fluid, efficient navigation.

Title: Tracking vertical movements and vertical space in the posterior parietal cortex

Authors: *L. E. SHELLEY, A. S. ALEXANDER, B. LA, D. A. NITZ;
UCSD, La Jolla, CA

Abstract: Neurons of both the hippocampus and posterior parietal cortex map the position of an animal in external frames of reference. Hippocampal neurons primarily map position within the space of the observable environment. In a complementary fashion, posterior parietal cortex neurons map position within the space of known routes irrespective of the position of those routes in the observable environment. In both cases, spatially-specific firing has been examined almost exclusively with respect to the horizontal dimensions. However, recently published experiments suggested that the form by which vertical space is mapped by hippocampal place cells and entorhinal cortex grid cells is fundamentally different and of lower resolution than that of horizontal space (Hayman, et al., Nature Neuroscience, 2012). Maps of route position given by the activity of some posterior parietal cortex neurons appear to derive initially from the tendency of a subset of these neurons to have activity correlates to specific locomotor behaviors such as left or right turns or simple forward locomotion. A mapping of route position is then achieved when robust and reliable modulation in the firing activity during performance of the preferred locomotor behavior occurs as a function of the location of that behavior along a full route. For other posterior parietal cortex neurons, firing patterns across route space are more complex, yet reliable from trial to trial and not related in any obvious way to specific locomotor behaviors. In the present work, we addressed the possibility that posterior parietal cortex neurons could effectively map position in the vertical dimension, which, in principle, could derive from a

tendency for a subset of its neurons to have activity correlates to locomotor behaviors that yield movement in the vertical dimension. As in previous work, posterior parietal cortex neurons recorded in rats exhibited spatially-specific activity during traversal of defined routes along tracks. Track positions combining movement in the vertical dimension with locomotion in the horizontal dimensions were associated with specific activity peaks in a sub-population of posterior parietal cortex neurons. The results suggest that posterior parietal cortex is capable of: 1) mapping specific vertical movement behaviors; and 2) generating a map of route space containing position information in the vertical dimension. Further analyses will examine the extent to which spatially-specific firing for posterior parietal cortex neurons is isotropic for the horizontal and vertical dimensions or whether, like hippocampal mapping, the representation of vertical space takes a lower-resolution form.

Title: No movement-related oscillations in the entorhinal-hippocampal system of behaving bats despite low-frequency cellular resonance

Authors: T. ELIAV[1], M. GEVA-SAGIV[1,2], M. YARTSEV[1], A. FINKELSTEIN[1], A. RUBIN[1], L. LAS[1], *N. ULANOVSKY[1];

Abstract: The hippocampal formation of rodents and bats contains several types of spatial neurons - including place cells and grid cells - which share very similar functional properties between bats and rodents. However, while spatial neurons in rodents exhibit continuous theta-rhythmic firing, bat neurons were found to exhibit very little theta rhythmicity in their spike trains. This finding created a major controversy over the role of the mammalian theta-rhythm - for example, its proposed role in generating the grid formation, as posited by 'oscillatory interference models'. Recent in-vitro experiments reported possible intrinsic membrane resonance in bat entorhinal neurons at low frequencies, indicating that the oscillatory interference model might perhaps work in bats - but at a lower, sub-theta frequency band. To test this hypothesis, we recorded several new in-vivo datasets - including extensive new data from

3D place cells in flying bats, as well as from bat hippocampal interneurons; the latter is particularly important because hippocampal interneurons in rodents exhibit very strong theta-rhythmicity, and their high firing-rate allows robust identification of oscillations, if they exist. To analyze possible rhythmicity in these new and existing datasets, we used two types of analyses: (i) spectral analysis, based on the power spectrum of the spike-train autocorrelation; and (ii) time-domain fit analysis, based on fitting an exponentially-decaying sinewave to the autocorrelation. Both types of analyses showed that grid cells, place cells and interneurons in bat entorhinal cortex and hippocampus do not exhibit in-vivo movement related oscillations in their spike trains - neither at the theta-band nor at lower frequencies - neither during 2D crawling nor in 3D flight. These findings suggest that oscillation-based models cannot account for the generation of place-fields and grid-fields across mammals - neither at theta nor at lower frequencies.

Title: Switching sensory modalities elicits remapping and sharpening of 3-D spatial codes in the hippocampus of flying bats

Authors: ***M. GEVA-SAGIV**[1,2], L. LAS[1], N. ULANOVSKY[1];
[1]Neurobio., Weizmann Inst. of Sci., Rehovot, Israel; [2]Edmond and Lily Safra Ctr. for Brain Res., Hebrew Univ., Jerusalem, Israel

Abstract: How do inputs from different sensory systems affect hippocampal spatial representations? We set out to dissociate the effects of using two long-range sensory systems - vision versus echolocation - on hippocampal neural-activity, in an animal model that allows clean dissociation between sensory modalities: the Egyptian fruit bat. We trained bats to fly back and forth along a "linear flight track" using vision without sonar - in a lit environment, or using sonar without vision - in the dark, while controlling for olfaction. We conducted in-flight tetrode recordings from hippocampal areas CA1 and Subiculum, and found that 3-D place-cells are selective to flight direction in this paradigm. Many cells exhibited “remapping” when switching

between vision and echolocation (which reverted when switching back to vision) - suggesting different cognitive maps for different sensory modalities. Surprisingly, this remapping phenomenon was observed both in pyramidal cells and in interneurons. This is the first demonstration of hippocampal remapping in a non-rodent species. Finally, we predicted that we will find more compact (sharper) hippocampal place-fields under vision versus echolocation - because visual resolution is known to be better than sonar-based sensory resolution in this species. Our preliminary results are indeed consistent with this prediction, which provides support for sensory-based models of place-field formation in the mammalian hippocampus (e.g., BVC model, View model).

Title: Neural-network model of 3D head-direction tuning in bats

Authors: ***A. RUBIN**, N. ULANOVSKY, M. TSODYKS;
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Electrophysiological studies in Egyptian fruit bats demonstrate 3D head-direction neurons of several types: pure azimuth cells, pure elevation cells, and conjunctive cells (which are tuned to a specific combination of head azimuth and elevation). Moreover, the tuning of these cells is consistent with a toroidal representation of head-direction. Here, we set out to investigate the theoretical conditions for the co-existence of these 3 classes of cells in a neural-network model. We found that this system can be modeled using the classical ring attractor and its extension to a toroidal attractor. This model supports mixed populations of neurons tuned to two cyclical variables - in our case, head azimuth and elevation. We show that the coexistence of conjunctive and two types of pure representations is achieved over a broad parameter regime, and even in cases of unbalanced population sizes, as has been observed in the experiments. However, for certain areas of phase-space this coexistence collapses, and one population takes over - which illuminates the theoretical constraints on the co-existence of pure-variable and mixed-variable coding populations. The model can be generalized for additional brain regions that encode multiple cyclical variables, such as primary visual cortex - where neurons encode

visual orientation and spatial phase representation; or medial entorhinal cortex - where some "conjunctive grid cells" encode the spatial phase of the grid and the animal's head azimuth.

Title: 3-D grid cells in flying bats

Authors: G. GINOSAR, A. FINKELSTEIN, *L. LAS, N. ULANOVSKY;
Dept. of Neurobio., Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Spatial orientation and navigation are crucial for all animals. 'Grid cells' are neurons found in the mammalian medial entorhinal cortex and nearby regions. These cells discharge when the animal passes through the vertices of a two-dimensional (2D) hexagonal grid spanning the 2D movement surface. However, although many animals navigate daily through 3D space - including squirrels, bats, dolphins, and monkeys - no studies to date have attempted to characterize the 3D volumetric firing of grid cells, in any species. To address this, we used Egyptian fruit bats to investigate whether 3D grid cells exist, and to elucidate their 3D spatial code. We have previously found 2D grid cells in bats crawling on a 2D surface, as well as volumetric 3D place cells in freely-flying bats. Here, bats were trained to fly in a large flight room (~6 x 5 x 3 m) in search of randomly-positioned food, while we wirelessly recorded single-neuron activity in several brain regions where 2D grid cells are known to exist. Preliminary results indicate the existence of grid-like structures in recorded 3D firing-rate maps, consisting of repetitive blobby firing-fields. We are now analyzing whether these 3D firing-fields are arranged in a mathematically-optimal packing arrangement, as predicted by computational models of 3D grid cells.

Abstract: Head-direction cells are neurons that become active whenever the animal's head points to a specific direction (azimuth) in the horizontal plane, and were suggested to be crucial for the mammalian navigation system. Although the survival of the animal may depend on successful orientation in three-dimensional (3D) space, it is unclear how 3D head-direction is represented in the brain. Here we recorded from neurons in dorsal presubiculum of Egyptian fruit bats, and found head-direction cells tuned to azimuth, pitch or roll. Many of these cells were conjunctively tuned to multiple combinations of Euler angles. This 3D tuning was found in 3 different sets of experiments: (i) in bats crawling on an arena floor, (ii) in bats crawling on a vertical ring that allowed 360° pitch maneuvering, and (iii) in flying bats. Head-direction cells were organized according to a functional-anatomical gradient along the transverse axis of the presubiculum. When bats were held upside-down, most neurons remained directionally-tuned; surprisingly, however, their azimuth-tuning was shifted by 180° relative to the upright position - suggesting that 3D head-direction is represented on a toroidal manifold, rather than in standard spherical coordinates. The toroidal model was also supported by new preliminary findings from bats crawling on a vertical ring, in which we found that individual pitch cells were narrowly-tuned to a specific circular pitch angle within the available 360° of pitch. Taken together, these results demonstrate, for the first time, a 3D head-direction mechanism in mammals, which could support navigation in 3D space.

Abstract: Hippocampal activity during spatial exploration is characterized by two distinct coding patterns: A rate code and a temporal code. The rate code refers to spatially localized firing of spikes called place fields. The temporal code refers to systematic change in local field potential (LFP) theta-phase of spikes as a function of the position of the rat within a place field, termed phase precession. Many theories and experiments suggest that the rate and temporal codes are closely linked but this has been difficult to directly test experimentally. In addition, another aspect of hippocampal activity pattern has received little attention, namely neurons fire at an elevated rate for prolonged periods (1), about 1-2 seconds, as a subject traverses the place field. To understand the link between the rate code, temporal code and sustained activity, we measured hippocampal activity while rats foraged for randomly scattered rewards in a two dimensional environment either in the real world (RW) or virtual reality (VR). We found a large reduction in spatial selectivity in VR compared to RW (see Acharya et al., SfN abstract 2014). Despite the absence of spatial selectivity, hippocampal activity was not entirely random. Specifically, instead of sporadic spikes, pyramidal neurons invariably generated approximately two-second long spike sequences. We call these hippocampal motifs. A majority of spikes were contained within motifs in both worlds, however in VR the motifs were distributed randomly over space unlike their spatially localized counterparts in RW. Motif characteristics were comparable in RW and VR including motif duration and variability at a population level. Concatenation of all motifs generated by a neuron, irrespective of their spatial location, yielded motif fields which had similar properties in RW and VR. Spikes within motifs not only showed identical theta modulation, but also comparable phase precession in both worlds. These results suggest that during spatial exploration in normal rats, sustained activation and phase precession can occur without spatial selectivity. We hypothesize that internal, network mechanisms generate

phase-precessing motifs which require coherent multisensory input for spatial localization. 1. Hahn, T. T. G., McFarland, J. M., Berberich, S., Sakmann, B. & Mehta, M. R. Title: Mechanisms of persistent activity and persistent inactivity *in vivo*

Authors: ***S. BERBERICH**[1], J. M. MCFARLAND[2], T. T. G. HAHN[1], M. R. MEHTA[3,4,5,6,7]; [1]Computat. Neurosci., Central Inst. of Mental Hlth., Mannheim, Germany; [2]Dept. of Biol. and Program in Neurosci. and Cognitive Sci., University of Maryland, MD; [3]W. M. Keck Ctr. for Neurophysics, University of California, CA; [4]Dept. of Physics and Astronomy, Los Angeles, CA; [5]Brain Res. Inst., Los Angeles, CA; [6]Integrative Ctr. for Learning and Memory, Los Angeles, CA; [7]Dept. of Neurology, Dept. of Neurobio., Los Angeles, CA

Abstract: Persistent activity is thought to be crucial for learning and memory. Hence, it has been studied extensively *in vitro*1. However, few studies have investigated the mechanisms of persistent activity *in vivo*, where the network dynamics could be quite different from that *in vitro*. Further, while persistent activity has been studied *in vitro* extensively, persistent inactivity has received little attention. This is important since in a complex neural circuit, both activity and inactivity play an equally important role in governing the circuit dynamics. Recently, we showed that membrane potential of neurons in layer 3 of medial entorhinal cortex (MECL3) *in vivo* exhibit spontaneous persistent activity during Up-Down state oscillations (UDS) under anesthesia and during drug-free slow wave sleep2. This persistent activity was locked to neocortical UDS, but persisted over several cortical UDS cycles. Here we show that the MECL3

neurons engage in another form of selective decoupling from the neocortical UDS, where they remain in a persistently inactive state, skipping several neocortical Up states. As with persistent activity, these persistent inactivity occurred significantly more often in MECL3 neurons than in similar neurons in the lateral entorhinal cortex neurons in layer 3 (LECL3), and neither form of persistence was observed in recordings from neocortical neurons from several areas. The probability of MECL3 neurons generating persistent activity and inactivity was not random, and was closely related to the instantaneous properties of the afferent cortical network state. Our results demonstrate that MECL3 neurons perform a state-dependent, nonlinear transformation on afferent cortical inputs to generate both persistent activity and inactivity. Finally, as with the persistent activity, MECL3 persistent inactivity exerted a strong influence on spiking activity of the downstream hippocampal CA1 neurons to which they project. Thus, persistent activity and inactivity *in vivo* provide a mechanism for MECL3 neurons to selectively and bidirectionally control the influence of neocortical activity on hippocampal neurons. The results reveal the strong cortico-entorhinal-hippocampal interaction during slow wave sleep oscillations and reveal the contribution of nonlinear mechanisms within the medial entorhinal cortex in shaping these interactions, which could play a significant role in learning and memory and memory consolidation. Title: Variability of hippocampal place fields on one dimensional tracks in real world and virtual reality

Authors: K. SAFARYAN[1], P. RAVASSARD[1], A. KEES[1], *M. R. MEHTA[1,2,3];
[1]Departments of: Physics & Astronomy, Neurology, Neurobio., Univ. of California at Los

Angeles (UCLA), Los Angeles, CA; [2]Keck center for Neurophysics, [3]Integrative Ctr. for Learning & Memory, UCLA, Los Angeles, CA

Abstract: The activity of hippocampal place cells provides a cognitive map of space. The mechanisms governing this map formation remain to be understood. It is thought that place cells are strongly influenced by the distal visual cues. However, several other variables too influence place cells' activity including internal cues such as theta rhythm, sensory cues such as olfactory and somatosensory cues; and by behavioral variables, including running speed and vestibular cues. Hence, to understand the contribution of sensory inputs in governing place cells while minimizing the behavioral variability over many trials, we measured the extracellular activity of more than 300 putative pyramidal cells from CA1 of five rats trained to run reliably on a narrow linear track in the real world (RW). Consistent with previous data, most neurons showed focused place fields, i.e. sustained level of activity in restricted region of space. All neurons did not show similar levels of spatial selectivity and there was a wide range with some neurons showing robust and focused place fields and others showing poor spatial selectivity. Could this reduced spatial selectivity arise because of the changes in non-specific sensory cues across different trials in a session in the RW maze, or are there other mechanisms governing this variable spatial tuning? To address this question we used a virtual reality system mimicking the RW experiment by reproducing similar room and track dimensions and visual cues. Thus, unlike the RW, in VR only the distal visual cues provided spatial information and other nonspecific cues did not have a systematic relationship with the distal visual cues. Remarkably, we not only found a large variation in spatial information among place cells, but also a large reduction in spatial information in VR compared with RW. The results suggest that mechanisms other than purely sensory, such as intrinsic network properties, are responsible for the variability of place cells' spatial coding.

Title: Impaired spatial selectivity in two-dimensional virtual reality

Authors: *L. ACHARYA[1,2,3,4], Z. M.AGHAJAN[1,2,3,5], J. CUSHMAN[6], C. VUONG[1,2,3,5], J. MOORE[1,2,3,7], M. MEHTA[1,2,3,5,8];

Abstract: Principal neurons in the CA1 region of the hippocampus fire in a spatially selective fashion in the real world (RW) to form an allocentric map of the environment. This is hypothesized to be primarily governed by Distal Visual Cues (DVC), but the contributions of other modalities have not been ruled out. To test this hypothesis it is necessary to eliminate cues other than DVC, which cannot be achieved in the real world. However a virtual reality (VR) environment allows us to make all other cues, apart from DVC, spatially non-informative. Virtual reality has been recently used to study spatial selectivity where clear spatially tuned activity has been reported[1,2]. However, all of these studies have used one-dimensional tracks or trajectories, and so do not constitute a cognitive map based on DVC alone since spatial selectivity on such paths could also arise due to other stimuli, such as self-motion cues or specific features of the DVC which have high correlation with spatial location. So, we studied the activity of principal neurons in hippocampal CA1 while rats foraged for randomly scattered rewards in a two dimensional VR environment where only DVC are spatially informative and other cues do not have a fixed relation with them, allowing us to unequivocally determine the contribution of DVC alone to the hippocampal cognitive map. We measured hippocampal activity during a random foraging task from three (four) male Long Evans rats in RW (VR). The two worlds had identical dimensions and DVC. While visual and somatosensory cues indicated the platform edge in RW, in VR any movement beyond the edge of the platform caused no change in the visual scene. Rats, therefore, quickly learned to avoid the edge of the platform based entirely on visual cues in VR[3]. We recorded the activity of more than 500 putative pyramidal neurons from dorsal CA1 in RW and VR. Consistent with prior studies, in RW firing of neurons was highly localized in space. However, in VR there was a large, (> 70%) reduction in all measures of spatial selectivity, including spatial information content and spatial stability of firing rate maps, with the latter being near chance level in VR. These results show that the distal visual cues alone are insufficient to generate a robust hippocampal cognitive map of space.

Title: Behavioral modulation of neocortical dendritic spikes in freely behaving rats

Authors: *J. J. MOORE[1,2,3,4], M. R. MEHTA[1,2,3,5,6];
[1]W. M. Keck Ctr. For Neurophysics, [2]Integrative Ctr. for Learning and Memory, [3]Brain Res. Inst., [4]Neurosci. Interdepartmental Program, [5]Dept. of Physics and Astronomy, [6]Dept. of Neurology, Dept. of Neurobio., UCLA, Los Angeles, CA

Abstract: The vast majority of information about neural activity in awake, behaving animals comes from extracellular measurements of somatic spikes. However, the soma represents a small fraction of the total volume of a neuron, and neurons fire somatic spikes rarely. To understand neural dynamics, it is necessary to record sub- and supra-threshold memberane potentials not just in the soma but also in the dendrites, where the majority of excitatory synapses are made. While sharp electrodes and whole cell patch clamp can record somatic membrane potential *in vivo*, these recordings are limited in time due to injury caused to the neurons, are restricted to the soma or proximal dendrites, and must be performed in head-fixed animals. *In vitro* studies show that dendrites can support back-propagation of somatic spikes and, under certain conditions, can generate dendritic action potentials (DAP) independent of somatic spiking. It is unclear if dendritic spikes occur *in vivo* and, if they do, what their underlying mechanisms are and how they are modulated by behavior. To determine the DAP mechanisms and receptive fields it is necessary to measure dendritic membrane potential over long periods of time during unrestrained behavior. We have developed a novel technique using modified tetrodes that can achieve high amplitude dendritic recordings over long periods of time, up to several days. Using this method we have recently reported the measurement of DAP in unanesthetized rats during slow-wave sleep (SWS) and have also examined the influence of the subthreshold potential on DAP firing, also during SWS. Combining video tracking with our dendritic recordings, we have now investigated the activity of dendrites in Posterior Parietal Cortex, an area shown to encode movement in an egocentric reference frame, during free behavior. DAPs, which fire at very high

rates during SWS, also fired at high rates during locomotion. We investigated the modulation of DAP rate by several behavioral variables such as running speed, acceleration, and turning maneuvers. These variables all significantly modulated DAP firing rate. These results constitute the first measurements of dendritic spikes during drug-free, natural behavior over prolonged periods. They show that DAP do occur during natural behavior and that dendrites in Posterior Parietal Cortex have behaviorally relevant receptive fields that could shape cortical network dynamics, synaptic plasticity and learning.

Title: Head direction cell activity in the dorsal striatum and medial precentral cortex requires intact anterodorsal thalamic nuclei

Authors: ***M. L. MEHLMAN**, S. S. WINTER, J. S. TAUBE;
Dartmouth Col., Hanover, NH

Abstract: Animals must maintain a sense of direction to effectively navigate within their environment. At the neural level, direction is represented by the activity of head direction (HD) cells. These neurons fire as a function of the animal's allocentric directional heading, operating much like a compass. While most rodent HD cells are located within the limbic system structures that form the HD circuit, small numbers are found elsewhere in the brain, including the dorsal striatum (DS) and medial precentral cortex (PrCM). Is the HD signal in these regions derived from limbic HD circuit output or is it generated independently? To examine this issue we recorded single unit activity in the DS and PrCM of freely moving rats and compared HD cell activity observed in control animals to that observed in animals with neurotoxic lesions of the anterodorsal thalamic nuclei (ADN), a manipulation known to disrupt the HD circuit. Large ADN lesions (> 85%) completely abolished the HD signal in both the DS and PrCM. Animals

with smaller lesions exhibited degraded HD cell activity in the DS; these HD cells fired over a significantly wider directional range compared to HD cells from control animals. No HD signal was identified in the PrCM of any lesioned animal. Interestingly, units modulated by the animal's angular head velocity (AHV) were found in the DS and PrCM; unlike HD cells, the activity of these units was unaffected by ADN lesions. We conclude that the HD signal is first generated by the limbic HD circuit and then projected to the DS and PrCM, possibly via the retrosplenial cortex. The AHV signal we observed in the DS and PrCM must either arise from a separate pathway, possibly a subcortical pathway involving the habenula, or be generated internally.

Title: Anterior thalamus inactivation disrupts grid cell firing in the entorhinal cortex

Authors: *S. S. WINTER[1], B. J. CLARK[2], J. S. TAUBE[1];
[1]Psychology and Brain Sci., Dartmouth Col., Hanover, NH; [2]Univ. of New Mexico, Albuquerque, NM

Abstract: Maintaining spatial orientation is a complex process that requires the coordination of multiple brain regions. Regions involved in spatial orientation contain cells with unique patterns of spatial tuning. Head direction (HD) cells discharge as a function of the animal's heading orientation within their environment, similar to that of a compass. Theta rhythm is modulated by running speed in a freely moving rat, functioning like a speedometer. Grid cells in the medial entorhinal cortex (MEC) discharge in a repeating hexagonal grid throughout the environment. The functional role of grid cells is still unknown but they are hypothesized to play an essential role in path integration. Computational models posit that grid cell firing patterns are generated from directional information and velocity information integrated over time, and suggest an integration of HD cells and theta rhythm as a possible mechanism. Inactivation of theta rhythmicity disrupts grid cell firing characteristics; however, the role of the HD cell circuit in

grid cell generation has yet to be tested. The current study inactivated the anterior thalamus (AT), a key structure in the HD circuit that projects to regions containing grid cells, and assessed the effect upon MEC grid cells in the rat. We isolated grid cells during a baseline session in a 1.2 m square chamber. Then lidocaine, at various concentrations, was infused into the AT and an inactivation recording session was immediately conducted. Finally, we recorded a recovery session 1.5 hours following the infusion of lidocaine. During inactivation grid cell firing patterns were disrupted and the length of disruption was dependent upon the concentration of lidocaine. Inactivation had no effect on theta rhythmicity in MEC. These results provide evidence that grid cell function is dependent upon inputs from the HD cell circuit, indicating that HD cells are providing the heading information necessary for generating hexagonal grid-like firing patterns. Given that lesions to the HD circuit disrupt the ability of an animal to navigate by means of path integration; this suggests that grid cells, which are dependent upon HD cells, may play a role in path integration as well.

Title: Do orbitofrontal cortex neurons encode relative value during free gaze?

Authors: *V. B. MCGINTY[1], A. RANGEL[2,3], W. T. NEWSOME[1,4];
[1]Neurobio., Stanford Univ., Stanford, CA; [2]Humanities and Social Sci., [3]Computat. and Neural Systems, Caltech, Pasadena, CA; [4]Howard Hughes Med. Inst., Stanford, CA

Abstract: Does the brain encode object value on an absolute scale? Or does the value representation for a given object depend on the value of other objects nearby? In a recent human

imaging study, when subjects were shown two objects, BOLD signals in the frontal lobe were positively related to the value of the object that was the target of the subjects' gaze, and negatively related to the value of the non-fixated target (Lim et al. (2011), J Neurosci 31:13214) - suggesting a gaze-dependent, relative value code. Consistent with this, we showed that for singly presented objects, some OFC neurons expressed a value code that was strongest when the subjects fixed their gaze on the object, and weakest when they looked away (McGinty et al. (2013), SfN Abstracts Prog. No. 858.20). However, an outstanding question is how OFC neurons represent value when two objects are shown - whether their firing reflects the value of the fixated object alone, or reflects the fixated target value relative to the non-fixated as in Lim et al. Here, we address this question using Pavlovian-conditioned visual cues during free gaze. Using Pavlovian conditioning, we trained macaque monkeys to associate three visual targets with juice rewards of 0, 1 and ~3 drops. After these single-target associations were learned, we issued trials in which two randomly chosen targets were shown simultaneously, followed by random delivery (i.e. not influenced by the monkeys' behavior) of a reward associated with one of the two targets. In these trials the monkeys' gaze was unrestricted, and they usually fixated each target at least once per trial. We measured OFC neuron firing during on-target fixations, and asked whether it was driven by the fixated target value alone, or by the relative value (fixated minus non-fixated), while also controlling for other task variables. This analysis had two parts. In the first, we considered a large set of potential task-relevant variables, and used lasso regression to identify which variables most frequently explained fixation-evoked firing. In the second, we built focused linear models using only the variables identified by the lasso procedure. According to the first analysis, both relative value and fixated value alone were strongly represented in the OFC population, and according to the second analysis, fewer neurons encoded relative value compared to fixated value alone. Thus, relative value was represented in OFC, but was not the dominant gaze-based value signal. One major difference between our study and Lim et al. was the use of a Pavlovian task, rather than a choice task. Therefore, we are currently investigating value coding in OFC, and other frontal and limbic areas, during decision-making.

Title: Local administration of FAUC 213 in the thalamic reticular nucleus of rat reduces anxiety

Authors: *M. GARCIA-RAMIREZ[1], G. AVILA[1], E. CHUC-MEZA[1], J. ACEVES[2]; [1]fisiologia, ENCB-IPN, DF, Mexico, Mexico; [2]CINVESTAV ZACATENCO, Mexico, city, Mexico

Abstract: Has been reported that bilateral loss of the dopaminergic innervation of the thalamic reticular nucleus (TRn) has anxiolytic effects (Picazo et al, 2008) whereas local administration of methamphetamine in the same nucleus produced anxiety which is reverted by haloperidol, which is D2 and D4 antagonist receptor. The TRn presented D4 dopamine receptor, so the aim of this work was show if FAUC 213 (a selective D4 antagonist receptor) could produce anxiolysis. Rats were implanted with cannulas in the TRn and infused with FAUC 213 at doses of 5 nM, anxiety was tested by the shock burying electrode test (SBT), elevated-plus maze (EPM) and motor activity in automated activity counters. Motor activity was measured after the end of EPM or SBT. In rats administered with FAUC 213 consistently produced anxiolysis viewed as increased in time in open arms, whereas infusion of Vh not reduced anxiety , motor activity was not affected. The results confirm that dopamine D4 receptor in the TRn reduces anxiety

Title: The Neural Genesis of a Joke

Authors: O. AMIR, *I. BIEDERMAN;
Psychology/Neuroscience, USC, Los Angeles, CA

Abstract: The nature of the cognitive processes employed in humor creation has proven highly resistant to introspection. It has even been suggested that the spontaneous and unpredictable fashion in which funny ideas present themselves renders functional imaging studies of humor creation impossible (Martin, 2006). An fMRI study of 14 improv-comedians from the Groundlings troupe and the Setlist Show, who make their living coming up with funny ideas on cue and under pressure, perhaps could serve as a challenge to such pessimism. They viewed drawings of people interacting in various situations and were instructed, in one condition (HUM), to think of a humorous line for a character and, in the control condition (MUN), to think of something mundane and non-humorous. The comedians rated the funniness of their ideas after each trial. Participants showed greater activation in the HUM condition bilaterally in temporal association regions (particularly in the temporal poles, superior temporal gyrus and in the temporo-occipital junction), as well as bilaterally in the ventral striatum, a region involved in reward. Conceiving funny ideas thus involves activation in semantic association regions where remote associations are linked in a meaningful way, and greater activation in those regions results, on average, in funnier ideas. These temporal association regions are particularly dense in μ-opioid receptors and there is converging evidence that activation in such high order association areas is in itself pleasurable (Biederman & Vessel, 2006; Yue et al., 2007) and that in the case of humor appreciation a surprising burst of activity in those regions may lead to the feeling of mirth (Amir et al., 2013). We found that while approximately the same regions of neural activation are involved in humor creation vs. humor appreciation (Amir et al., 2013), the order of activation is reversed: during humor appreciation temporal association regions are activated first (where remote associations are linked meaningfully reflecting the cognitive process of "getting the joke"), followed by activation in reward regions. Conversely, during humor generation, activation in reward regions precede the activation in temporal association regions, likely reflecting an expectation of the reward of conceiving a funny idea, but likely also helping to configure/modulate the temporal association regions to facilitate humor generation. This conjecture is supported by our observation of a dose response function that within the HUM trials, higher ratings were associated with stronger early activation in the reward regions as well as the subsequent activation in temporal association regions.

Title: Serotonergic innervation of the basal, central, medial, and cortical nuclei of the amygdala

Authors: *S. B. LINLEY[1], W. B. HOOVER, III[1,2], R. P. VERTES[1];
[1]Florida Atlantic Univ., Boca Raton, FL; [2]Max Planck Florida Inst. for Neurosci., Jupiter, FL

Abstract: The neural substrates underlying affective behavior have been well studied. Both serotonin (5-HT), chemically, and the amygdala, anatomically, are two key elements underlying emotion. We analyzed the distribution of 5-HT fibers within the basal, central, medial and cortical nuclei of the amygdala using an antisera for 5-HT and for the serotonin transporter (SERT) in 5 male and 5 female rats. We observed 5-HT labeled fibers throughout the amygdala but differentially distributed across nuclei. Labeling was most pronounced in the basal nuclei of the amygdala. Of these, the basolateral nucleus (BLA) showed the strongest labeling, with an increase in density across the rostrocaudal plane, so that the posterior division (BLAp) showed the most intense labeling of the entire amygdala. Very dense fiber labeling was also present in the lateral nucleus of amygdala (LA), with the heaviest concentration of fibers in the dorsolateral division of LA. By contrast, 5-HT labeling in the central nucleus was modest. While most divisions of the central nucleus (CEA) received moderate amounts of serotonergic fibers, the lateral division (CEAl) was lightly labeled and the caudal aspect of CEAl sparsely labeled. There was a similar gradual reduction in fiber density proceeding rostrocaudally in the medial nucleus of amygdala (MEA). The anterior divisions displayed moderately dense 5-HT labeling, with only a light plexus of fibers covering the posterior division. The cortical nuclei of amygdala received strong 5-HT input. Both the anterior cortical nucleus and nucleus of the olfactory tract exhibited dense labeling homogenously distributed across laminar fields. Whereas the posterior lateral division of the cortical nucleus showed a similar pattern of labeling, 5-HT fibers were more densely concentrated in layer 1 than 2/3 in the posterior medial division. In summary, all regions of the amygdala receive significant 5-HT input, but differentially distributed across subnuclei. This further indicates that serotonin exerts pronounced actions on the amygdala thus impacting anxiety, fear, stress, and other related behaviors.

Title: Lesions of the ventral midline thalamus impair reversal learning using an odor texture discrimination task in the rat

Authors: *R. P. VERTES[1], M. M. GALLO[1], R. J. ELLIS[2], P. PINEDO[2], B. N. CLARK[2], S. B. LINLEY[1];
[1]FAU/Ctr Complex Systems, BOCA RATON, FL; [2]Dept. of Psychology, Florida Atlantic Univ., Boca Raton, FL

Abstract: The reuniens (RE) and rhomboid nuclei (RH) of the ventral midline thalamus are positioned as a critical relay between the medial prefrontal cortex (mPFC) and the hippocampus (HF). As such, it has been suggested RE/RH play an important role in cognition and mnemonic behaviors (Vertes et al., 2014). Recent studies have not found a strong link between RE and hippocampal dependent memory, but have demonstrated a tie between behaviors dependent on both the mPFC and HF (Cassel et al., 2013). Presently, we examined the effect of electrolytic lesions of the ventral midline thalamus on attention and executive functioning using an odor texture intradimensional/extradimensional (IED) test in rats. This test measures several cognitive behaviors sensitive to prefrontal functioning including attentional set, attentional set shifting, and behavioral flexibility. Rats were tested on seven stages of olfactory and texture discriminations: a simple discrimination, compound discrimination (CD), an intradimensional shift (ID) (introduction of two novel odor pairs), an extradimensional shift (ED) (two novel odor/texture pairs where the digging medium is now attended to) and CD, ID, and ED reversal learning stages. Test measures included trials to stage completion, incorrect choices (aborted trials and errors), and latencies. We found that destruction of the RE/RH produced impairments in behavioral flexibility. Lesioned rats needed more trials to complete the CD reversal than sham controls. Behavioral inflexibility is known to be associated with orbitomedial prefrontal (PFC) functioning and is found in a number of PFC disorders such as schizophrenia and obsessive compulsive disorder. Ventral midline connections with the PFC may, in part, mediate behavioral flexibility.

Title: Anatomical investigation of projections from the noradrenergic nucleus locus coeruleus to the mediodorsal thalamic nucleus in the rat

Authors: *E. W. PROUTY[1], B. DUFFY[1], D. J. CHANDLER[2], B. D. WATERHOUSE[1]; [1]Drexel Univ. Col. of Med., Philadelphia, PA; [2]Dept. of Psychiatry, Univ. of Pennsylvania, Philadelphia, PA

Abstract: The locus coeruleus (LC) provides norepinephrine to the entire central nervous system, including medial prefrontal cortex (mPFC) and mediodorsal thalamic nucleus (MD). The mPFC is involved in higher order executive functions and has dense reciprocal connections with the MD which, in turn, makes connections with other cortical and subcortical structures. A significant portion of the information conveyed to and from the mPFC is via the MD, making it a critical site of relay and integration in limbic and cognitive networks. The noradrenergic projections from the LC to the mPFC and MD maintain appropriate modulation of the diverse circuitry within those regions. Dysfunctions of the PFC and MD are implicated in several neuropsychiatric disorders including ADHD, schizophrenia and post-traumatic stress disorder (PTSD). The goal of this study is to examine the tendency for individual LC neurons to send axon collaterals to both PFC and MD. Prior studies from this laboratory have shown that functionally related structures along the same sensory pathway receive input from common pools of LC neurons. Because PFC and MD thalamus are likewise anatomically distinct yet functionally related, we predict that individual LC neurons project to both regions. Fluorescent retrograde tracers were injected unilaterally into the mPFC and MD of adult male Sprague-Dawley rats. Coronal sections through the injections sites (80μm) and brainstem including LC (40μm) were made using a sliding microtome. The injection sites were verified and the pattern of fluorescently labeled cells in LC was analyzed. It has been previously established that projections from LC to neocortical terminal fields are almost entirely ipsilateral while projections to thalamic nuclei are bilateral, but with an ipsilateral predominance. In both cases projections to these targets arise from cells scattered throughout the rostral - caudal extent of LC. Preliminary

results agree with those findings and additionally indicate that MD and mPFC receive projections from segregated populations of LC neurons. While this latter finding differs from our prediction, it raises the intriguing possibility of differential activation of target-specific LC neurons and asynchronous release of NE within cortical and sub-cortical terminal fields of the MD-PFC network. To explore that possibility, future work will examine if MD vs mPFC-projection neurons in LC show differences in their molecular and physiological properties.

Abstract: Vegetative and minimally conscious states (VS/MCS) are devastating conditions which involve severe deficits in brain arousal, occurring as a result of vascular, traumatic or metabolic insults. Improved function in VS/MCS patients following application of drugs

affecting the basal ganglia or electrical stimulation of the centromedian thalamus (CM) suggests the possibility for rational treatments. In particular, paradoxical excitation caused by the hypnotic, Zolpidem, in VS/MCS patients may be due to increased inhibition of GABAergic basal ganglia inputs to CM (Schiff, 2010). Thus, development of novel, rational treatments for VS/MCS requires a better understanding of GABAergic inputs to CM and the effects of CM on cortical activity. Accordingly, here we investigate this circuit in mice. Application of the retrograde tracer, Fluorogold (0.5-1 %), into CM in wild-type mice (n=4) confirmed that CM receives major inputs from regions containing GABAergic neurons, including a basal ganglia output nucleus, the substantia nigra pars reticulata (SNr), as well as from the thalamic reticular nucleus (TRN). Immunohistochemical staining for the calcium binding protein, parvalbumin (PV), revealed that ~40 % of the inputs from TRN and SNr were PV-positive. Whole-cell patch-clamp recordings from CM neurons showed that the GABAB receptor agonist, baclofen, reduced the frequency of spontaneous inhibitory synaptic currents to 57 % of control (n=4, p=0.05). Optogenetic stimulation of CM in isoflurane anesthetized mice expressing channelrhodopsin2 constitutively in the thalamus (Thy1-ChR2-EYFP mice) revealed increases in cortical power which were particularly pronounced in frontal regions and at gamma band frequencies (40, 50 Hz). Thus, as in humans, the CM receives GABAergic inputs from the basal ganglia as well as from TRN and increased activity of CM enhances frontal cortical activity typical of conscious states. Inhibition of GABAergic inputs to CM by the anti-spastic agent, baclofen, suggests a possible mechanism which may help explain occasional cases of improved function in patients receiving intrathecal administration of this compound.

Title: Cognitive and neural processing of facial size and valence in comorbid depression and obesity

Authors: *T. Y. PAN[1], A. C. DEMARCO[1], R. ATCHLEY[1], L. E. MARTIN[2], C. R. SAVAGE[3]; [1]Dept. of Psychology, Univ. of Kansas, Lawrence, KS; [2]Hoglund Brain Imaging Ctr., [3]Ctr. for Hlth. Behavior Neurosci., Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Prior research suggests that obesity is a risk factor for developing depression, but not all obese individuals develop depression. It is, therefore, important to understand common factors underlying comorbid obesity and depression that may serve as markers for depression risk. To date, there has been no exploration of neural processing differences or similarities in comorbid depression and obesity. This study investigated whether attention bias differences, measured using the P300 (P3) ERP component, exist between currently obese and depressed (Dep/O, n=16, mean Age=27.13, mean BMI=37.44), currently obese and never depressed (ND/O, n=13, mean Age=19.77, mean BMI=36.01), and healthy weight and never depressed (ND/HW, n=16, mean Age=21.69, mean BMI=21.58) females when participants viewed target face pictures of varying valence (happy, sad) and weight status (healthy weight, overweight). A 3 x 2 x 2 mixed model analysis of variance (ANOVA) was implemented for P3 amplitude: 3 Group (Dep/O, ND/O, ND/HW) by 2 Stimuli Valence (happy, sad) by 2 Stimuli Weight Status (healthy weight, overweight). This analysis was run within "early" P3 (248-352 ms post stimulus onset) and "late" P3 (356-460 ms post stimulus onset) windows and with the mean difference wave averaged across a single channel (channel 62 on high-density, 128-channel Electrical Geodesic Sensor Net) with the least noise within the region corresponding to the P3 component. We found a main effect of weight in the early window [$F(1, 42)=6.23$, $p=0.01$], such that all groups responded with greater P3 amplitude to stimuli of overweight status. We also found a main effect of valence in the late window [$F(1, 42)=7.50$, $p=0.007$], such that all groups responded with greater P3 amplitude to stimuli of negative valence. In the early window, we found a two-way interaction that approached significance of group by stimuli valence, where ND/HW individuals responded with greater P3 amplitude to positive stimuli, while both ND/O and Dep/O group allocated more attention to negative stimuli [$F(2, 42)=2.54$, $p=0.08$]. The main effects of greater P3 amplitude for overweight faces and negative valence likely reflect the impact of current cultural expectations of weight and size due to decreased exposure to overweight individuals in the media and the impact of the "negativity bias", the phenomenon of heightened sensitivity to negatively valence information. The present study also provides preliminary support that neural processing of faces may be different in obese individuals versus healthy weight, non-depressed individuals and may be an important area of research in larger studies.

Title: Thalamic encoding of dynamic audiovisual signals in the actively foraging mouse

Authors: *R. S. WILLIAMSON[1,3], K. E. HANCOCK[2,4], B. E. SHINN-CUNNINGHAM[3], D. B. POLLEY[2,4];
[1]Eaton Peabody Labs., [2]Massachusetts Eye and Ear Infirmary, Boston, MA; [3]Boston Univ., Boston, MA; [4]Harvard Med. Sch., Boston, MA

Abstract: Purposeful behavior requires the dynamic integration of many sensory cues, each with a corresponding neural representation. Such representations are subject to significant modulatory effects related to the behavioral state of the animal. These include both global changes such as arousal or motivation as well as "top-down" modulation that reflects task-specific cognitive processes. Both types of modulation have been widely documented in sensory cortex, but whether such effects could be inherited from earlier stages in the sensory hierarchy is poorly understood. To address this question, we developed an audiovisual foraging task that allowed us to characterize how activity in sensory regions of the thalamus is modulated during natural search behaviors. In this task, mice attend to dynamic shifts in the interval separating pairs of visual flashes or acoustic chirps to locate the position of a randomly placed invisible target on a circular track. One modality served as the target, where successful identification triggered a water reward, while the other was a distractor that did not predict reward. This allowed us to measure how behavioral search strategies and thalamic audiovisual encoding were modulated in real time as mice accumulated sensory evidence relating to the position of a hidden target location. In addition, we were able to separate global modulation related to factors such as locomotion and motivation from "top-down" effects related to dynamic changes in the representation of task-relevant and distractor cues. Mice typically learned this task within 30 daily training sessions (~1800 trials), with additional time yielding a modest increase in both performance accuracy and decrease in trial completion time. Well-trained mice exhibited search strategies conducive to solving the task; they spent more time moving towards the target location than away from it, and also modulated their running speed whilst in the vicinity of the target

location. Chronic extracellular recording of thalamic units was achieved through implanted 32-channel silicon probes positioned to simultaneously record from the lateral and medical geniculate nuclei (LGN and MGB, respectively). Preliminary results confirm that locomotion is not associated with shifts in thalamic audiovisual encoding in a manner that has been identified in the primary visual and auditory cortex. Our ongoing analysis is focused on top-down modulation of thalamic sensory representations that accompany modality-specific changes in behavioral search strategy.

Title: A developmental examination of face emotion labeling

Authors: *A. H. OAKES[1], J. L. WIGGINS[1], N. E. ADLEMAN[2], P. KIM[3], M. A. BROTMAN[1], E. LEIBENLUFT[1];
[1]NIH, Bethesda, MD; [2]The Catholic Univ. of America, Washington, DC; [3]Univ. of Denver, Denver, CO

Abstract: Background: Emotional facial expressions provide information that is critical in guiding social interaction and functioning. Examining face emotion labeling in typically developing children and adults is important for understanding the trajectory of socioemotional development. The use of varying expression intensities in this study allows us to examine the subtleties of normative emotion processing. Related work has focused on infancy and early childhood, whereas this work explores late childhood and adolescence. **Method:** 21 healthy children (age 9-17, M=14.94, SD=2.43; 9F) and 21 healthy adults (age 19-47; M=29.8, SD=7.66; 11F) completed a face-emotion labeling task while participating in an fMRI study. Participants viewed images of angry, fearful, happy, and neutral expressions. Varying emotion intensities were created by morphing the 100% expression with the neutral images. Participants identified the emotion (angry, fearful, happy) for each face. A repeated-measures ANOVA on percent

correct was conducted with Emotion and Intensity as within-subjects factors and Age as a between-subjects factor to examine the Emotion (angry, fearful, happy) x Intensity (50, 75, 100) x Age (Children vs. Adults) interaction. Bonferroni-corrected post-hoc analyses were performed. **Results:** The Emotion x Intensity x Age interaction [$F(4,37) = .66$, $p = .62$] was not significant. However, the Emotion x Intensity interaction was significant [$F(4,37) = 15.69$, $p < .001$]. Post-hoc tests indicate that fewer correct answers were given on 50 intensity faces in each of the Emotions than in 75 and 100 intensity faces. 75 and 100 intensity faces did not differ from each other in any of the Emotion conditions. At 50 intensity, angry and fearful were indistinguishable from each other in terms of percent correct; at both 75 and 100 fearful and happy were indistinguishable. There were no significant Age effects. Parallel results were observed for reaction time. **Conclusions:** This study demonstrated that children and adults do not differ in ability to label facial emotions. Children and adults are equally accurate at identifying angry, fearful, and happy faces at high intensity (75, 100), and are equally inaccurate at interpreting less intense facial emotions (50). Results suggest when above a certain intensity threshold, both children and adults are able to correctly identify the emotion, regardless of age. When processing less intense emotional stimuli (50), happiness is recognized with the greatest accuracy. Future work should examine the developmental neural correlates of these behavioral findings.

Title: Erotic visual stimulation increases cortical eeg correlations in young men during performance of the tower of hanoi task

Authors: ***C. AMEZCUA**, M. RUIZ-DÍAZ, M. HERNÁNDEZ-GONZÁLEZ, M. GUEVARA, A. SANZ-MARTIN;
Univ. De Guadalajara, Guadalajara, Mexico

Abstract: Emotional stimuli elicit changes in the electroencephalographic activity (EEG) of several brain structures, including the prefrontal cortex (PFC). In humans, this cortical area has been associated primarily with cognitive processes and motivational processes, such as sexual

behavior. It has been reported that sexual activation generated by observing erotic visual stimuli is related to high activation of the PFC. On the other hand, the main role that the PFC plays in conjunction with the parietal and temporal cortices in the executive functions -i.e., working memory, planning, organizing, goal-setting, and decision-making, among others- is also well known. In clinical medicine and research, these cognitive processes have typically been evaluated through tasks like the Tower of Hanoi. Given that the degree of EEG correlation changes in relation to the observation of erotic stimuli and during performance of cognitive tasks, the aim of this work was to determine whether the cortical correlation patterns during performance of the Tower of Hanoi in young men is affected by previous observation of videos with sexual or aggressive content. Sixty-nine healthy heterosexual men were assigned to 3 groups. The Neutral Group was shown a video of a subject walking, taken from the movie The Long Shadow (Zsigmond); the Erotic Group watched scenes of explicit sexual interaction from The Catwoman (Leslie); and the Aggressive Group watched scenes showing aggression from Hostel (Roth). EEGs from the left and right prefrontal, temporal and parietal zones were recorded under the following conditions: at rest; during visual stimulation; and while executing the Towers of Hanoi task. A sexual arousal scale was applied to all subjects at the end of each session. Only after observation of the erotic video did subjects report a moderate state of sexual arousal, associated with an increased degree of interprefrontal and intertemporal coupling of the slow bands (delta and theta) during performance of the Tower of Hanoi. This higher synchronization in the slow bands between the prefrontal and parietal cortices could be associated with specific cognitive strategies, or with functional adaptations while the subjects were experiencing sexual arousal. The results of this study may contribute to a better understanding of the cerebral functionality that underlies the cognitive effects of emotional stimulation, particularly of an erotic nature.

Title: Modulation of structures putatively involved in anxiety, memory, pain and aversion - the ventral hippocampus, raphe nuclei, periaqueductal gray area and lateral habenula - by the nucleus incertus

Authors: *U. FAROOQ, R. RAJKUMAR, G. S. DAWE;
Dept. of Pharmacol., Natl. Univ. of Singapore, Singapore, Singapore

Abstract: The nucleus incertus (NI), located in the brainstem, consists principally of gamma-aminobutyric acid releasing (GABAergic) projection neurons which exhibit remarkable similarity to the projections of monoamine releasing nuclei (the serotonergic raphe nuclei and the noradrenergic locus coeruleus). Furthermore, its projections release a plethora of other co-neurotransmitters: it is the main source of the neuropeptide relaxin-3 in the brain; while a small population of NI neurons is glutamate releasing (glutamatergic) in nature. Recent studies implicate this nucleus in modulation of hippocampal oscillations, anxiety and stress-mediated impairment of cognition (Ma et al., 2009; Ryan et al., 2011; Farooq et al., 2013). Based on these and other findings, it has been proposed that this nucleus might play a role in anxiety, depressive, volitional and mnemonic disorders. However, electrophysiological evidence for the effects of modulation of this heterogeneous nucleus on structures putatively involved in these functions is lacking. We studied the effects of electrical stimulation of the NI on single neuronal firing characteristics in brain regions implicated in these behaviors which receive dense afferent projections from the NI. A total of 197 single-units were isolated from the ventral hippocampus, raphe nuclei, lateral habenula and periaqueductal grey area in anaesthetized male Sprague-Dawley rats using glass microelectrodes. Various stimulation protocols at the NI revealed that the nucleus incertus significantly inhibited the majority of neurons in these structures during stimulation. The degree of inhibition varied from complete inhibition to mild reduction. A small population of neurons in all structures (except the ventral hippocampus) showed excitation during stimulation. Post-stimulation, a large proportion of neurons exhibited a significant 'rebound' increase in firing while some neurons exhibited complete inhibition for up to seconds (a subset of neurons in the ventral hippocampus and raphe nuclei). These findings indicate that the NI significantly modulates processing of neural information in structures putatively involved in anxiety, memory, pain and aversion. Furthermore, our findings corroborate and extend earlier studies which demonstrated that the projections of the NI exhibit heterogeneity (glutamatergic or GABAergic - targeting the soma or dendrite).

Title: Alpha asymmetry study in undergraduate health sciences students with hazardous alcohol consumption, but not alcohol dependence, in southeastern Mexico

Authors: *L. NUÑEZ-JARAMILLO[1], P. VEGA-PERERA[1], J. V. REYES-LÓPEZ[2], L. RAMÍREZ-LUGO[3], W. V. HERRERA-MORALES[1], E. SANTIAGO-RODRÍGUEZ[4];

UNAM, México, D.F., Mexico; [4]Neuroclin: Diagnóstico, Tratamiento e Investigación Neurológica, S.C, Querétaro, Mexico

Abstract: Frontal alpha asymmetry has been proposed to reflect frontal cortical activation in an inverse relationship, a higher alpha activity reflecting lower cortical activity. In this regard, a higher frontal left activity (lower alpha) has been related with an approach behavior, while a higher right frontal activity has been related with an inhibition behavior, with an imbalance in this asymmetry being associated with a dysregulation in motivation and emotion. A higher right frontal activity has been associated with a tendency to experience depression and anxiety and has been also reported in alcohol dependent subjects, while a higher frontal left activity has been related with impulsiveness and aggression. However, inconsistent results have also been reported. Hazardous alcohol consumption is defined as a pattern of alcohol consumption that increases the risk of harmful consequences for the user or others. Since it has been found a relation between impulsiveness and hazardous alcohol consumption, it is probable that subjects with hazardous alcohol consumption present higher alpha activity in the right frontal cortex, indicating a higher left frontal activity. The incidence of hazardous alcohol consumption has been reported to be high among medicine students. We performed an alpha asymmetry study in undergraduate health sciences students (Medicine, Nursery and Pharmacy; age 18-22) who rated negative for ADHD, and suicide risk tests, while in the AUDIT test rated positive for hazardous alcohol consumption, but negative for alcohol dependence, in order to avoid the possible influence of dependence on alpha asymmetry. Interestingly, we found no difference in alpha asymmetry between controls and the hazardous alcohol consumption groups. As mentioned, while there are many reports showing a relationship between alpha asymmetry and motivation/inhibition dysregulation, inconsistent results have also been found. In different reports an influence of ethnicity has been found in qEEG studies addressing alcoholism. We suggest that results can be attributed to particular EEG features in the population under study, outlining the importance of establishing the particular characteristics of qEEG in this study population for further studies.

Title: Functional connectivity between subthalamic nucleus and orbito-frontal cortex during vocal emotion decoding

Authors: ***J. PÉRON**[1,2], S. FRÜHHOLZ[1,2], D. GRANDJEAN[1,2];
[1]Fac. of Psychology, Geneva, Switzerland; [2]Swiss Ctr. for Affective Sci., Geneva, Switzerland

Abstract: Background: Subthalamic nucleus (STN) deep brain stimulation (DBS), a neurosurgical treatment for Parkinson's disease (PD) and obsessive-compulsive disorder (OCD), has recently advanced our understanding of the apparently major role played by this structure in human emotion processing. However, the potential presence of several confounds related to the use of pathological models raises the question of how far they affect the relevance of observations regarding the physiological function of the STN itself, underscoring the crucial importance of obtaining evidences from neurologically healthy participants. Aim: In this study, we sought to probe the functional connectivity between the STN and other brain regions related to vocal emotional processing from participants without CNS disorders. Methods: To this end, we re-analyzed previous high-resolution fMRI data in N=17 healthy participants performing a vocal emotions (i.e., emotional prosody) task and using functional connectivity measures (psycho-physiological interactions, PPI) and taking the STN as seed region of these analyses. Based on Péron and colleagues (Neuroscience and Biobehavioural Reviews, 2013), we hypothesized that the STN is functionally connected to the structures known for their involvement in emotional prosody decoding, notably the OFC, and the auditory cortices as well as the amygdala and the other basal ganglia such as the caudate nucleus. Results: As expected, we showed that the STN is functionally connected to the structures known for their involvement in emotional prosody decoding, notably the OFC, the IFG and the auditory cortices as well as the other basal ganglia (pallidum) and the amygdala. More specifically we observed that the left STN showed functional connectivity to the contralateral right orbito-frontal gyrus, the right

inferior-frontal gyrus and the right temporal sulcus as well as the ipsilateral pallidum and amygdaloïd nuclei during emotional prosody processing. Conclusion: The present results confirm, in healthy participants, the major role played by the STN in human emotion and its functional connectivity with the brain network involved in vocal emotions.

Title: Differences in quantitative EEG activity between normative database from Cuban population and age and gender matched health sciences undergraduate students in southeastern Mexico

Authors: ***P. VEGA**[1], L. NÚÑEZ-JARAMILLO[1], J. V. REYES-LÓPEZ[2], L. RAMÍREZ-LUGO[3], W. V. HERRERA-MORALES[1], E. SANTIAGO-RODRÍGUEZ[4];
[1]Univ. of Quintana Roo, Chetumal, Mexico; [2]Inst. Nacional de Psiquiatría, México, D.F., Mexico; [3]Inst. de Fisiología Celular. UNAM, México, D.F., Mexico; [4]Neuroclin: Diagnóstico, Tratamiento e Investigación Neurológica, S.C., Querétaro, Mexico

Abstract: Quantitative electroencephalography (qEEG) allows a deep and precise analysis of brain electrical activity in both patients and healthy subjects. It is important to establish basal levels of qEEG activity in order to determine possible anomalies in patients under different conditions such as cognitive or behavioral disorders. In this regard, there has been extensive work on the development of normative qEEG databases. However, even though many qEEG studies have differences have been reported in qEEG activity of different study groups under the same experimental conditions. In the present work we performed qEEG analysis to undergraduate health sciences students (Medicine, Nursery and Pharmacy). Inclusion criteria included age 18 to 22, and negative results in ADHD, AUDIT, depression and suicide risk tests. We compared, through Z transformation, the results obtained in absolute power (AP), relative power (RP) and mean frequency (MF) for delta, theta, alpha and beta frequency bands with those obtained in Cuban population. We found a statistically significant increase in AP in the delta band in FP1, F7, F8, T3, T4 and T5, and a decrease in AP for this frequency band in F3, F4, C3, C4, P3, P4, FZ, CZ and PZ. In theta band we found an increase in AP in F7, F8, T3, T4, T5 y T6,

and a decrease in F3, F4, C3, C4, P3, P4, FZ, CZ y PZ. In alpha AP we found an increase in FP1, FP2, F7, F8, T3, T4, T5 y T6 and a decrease in C3, CZ y C4, while for beta AP we found an increase in FP1, F7, F8, T3, T4, T5, T6 y O1; and a decrease in FZ, C3, C4, CZ, P3 y PZ. For RP, in the theta frequency band we found a decrease in RP in FP1, F7, F8, T3, T4 and CZ; for alpha we found an increase in RP in CZ, while for beta we found an increase in RP in F7 and F8. For MF, we found a reduction in delta MF in FP1, F7, F8, T3, T4, C3, C4, CZ, P3, P4, PZ y T6; for alpha we found an increase in MF in F7, F8 y PZ; and for beta MF an increase in F7, T3, T5, O1 and a decrease in PZ was found. Altogether, these results outline the importance of determining the basal qEEG activity in the particular study population in order to reliably study changes in qEEG activity under different conditions.

Title: Using information theory to quantify behavioral phenotypes in free-ranging rhesus macaques

Authors: *J.-F. GARIEPY[1,2,3], J. SUNDARARAJAN[3,2], S. MADLON-KAY[2], E. DU[2,1], D. L. XIE[2,1], L. J. N. BRENT[2,1], M. L. PLATT[1,2,3];
[1]Ctr. for Cognitive Neurosci., [2]Duke Inst. for Brain Sci., [3]Dept. of Neurobio., Duke Univ., Durham, NC

Abstract: Neuropsychiatric disorders often present complex sets of behavioral impairments that most strongly manifest in dynamic, naturally-occurring social contexts like school or the workplace. Such conditions are thought to result from the interactions of genes and environment. In principle, better understanding of the causes of these disorders could be achieved by improving how researchers process information about behaviors occurring in dynamic social

contexts. Here we propose a novel approach using information theory to examine the causal influences on behaviors observed in a large, free-ranging population of rhesus macaques on Cayo Santiago Island. Our initial study focused on 266,720 behavioral events collected over 2 years from iterated focal animal samples in which individual monkeys were observed for 10 minutes and all behaviors from a 55-categories ethogram were recorded. An average of 13.3 hours of observation per adult monkey in the group (114 animals) was analyzed. Information theory allows us to find statistical links between pairs of variables without prior hypotheses about the form of the relation between these variables. Observations were grouped in 1-minute bins and mutual information was computed between behaviors at time 0 and behaviors in preceding bins up to 5 minutes. Among the multiple relations found, mounting behavior was observed significantly more often following a submissive display (bootstrap test on mutual information; significant for all time windows 1 to 5 minutes before the mount event). Conversely, fear grimacing strongly co-occurred with aggression, but it was not predictive of aggression in the following minutes (bootstrap test on mutual information). We also examined the probability of occurrence of specific behaviors in various social contexts (e.g., the presence of dominants, subordinates, females, or males). For instance, mounting was more commonly performed by dominant monkeys toward subordinates than by subordinates toward dominants. For females, subordinates were more likely to actively approach a dominant individual than dominants were to approach a subordinate. Females were also more likely to emit affiliative vocalizations (short grunts, girneys and lipsmacks) in the presence of males than in the presence of females. Despite these general tendencies, most behaviors were highly variable across individuals and thus potentially associated with genetic variation. To test this idea, the behavioral models we have developed will be compared to genetic data based on >300 single nucleotide polymorphisms (SNPs) in neuromodulatory and regulatory pathways linked to neuropsychiatric disorders.

Title: Differences in facial affect processing between deaf signers and normal hearing non-signers

Authors: A. V. GONZALEZ, C. C. MORALES, J. I. RAMIREZ, S. SARKISSIANS, J. P. ABARA, *S. KANG;
psychology, California State Univ., Northridge, CA

Abstract: Previous research has explored holistic processing of face recognition using Event-Related Potentials (ERPs), but little research has focused on the differences in emotion recognition between normal hearing and deaf individuals. Deaf individuals who use American Sign Language rely heavily on facial information to read emotions and to detect linguistic cues for communication. Due to this unique behavioral practice among deaf signers, it has been speculated that deaf signers might process facial information somewhat differently compared to normal hearing non-signers (Mitchell, Letourneau, & Maslin, 2013). The main purpose of this study was to investigate the difference in facial information processing by focusing on N250 using full and half faces of emotions. N250 is a component of the ERP that peaks at approximately 250 milliseconds after the stimulus has been presented. Past literature has shown that N250 is related to facial affect processing and face specific structure processing. The main hypothesis of this study was that when participants are asked to identify emotions on full faces, deaf signers would show higher amplitude of N250 than hearing non-signers, indicating that they recruit more neural resources to process facial information. The group difference in the amplitude of N250 was expected to decrease in the half face condition. In this study, the ERPs were recorded while the participants reported the emotion they perceived on the full and half faces (either top or bottom half of the face) presented on a computer screen. Six basic emotions (happy, fear, anger, disgust, surprise, sad) taken from the NimStim Face Stimulus Set (Tottenham et al., 2002) were used. The total of 11 electrodes was placed on using the 10-20 international system. The preliminary results based on 10 college students (5 congenital deaf signers and 5 hearing non-signers) from this on-going study seemed to be encouraging. In the full face condition, the mean amplitude of N250 of the deaf group was much larger (M = -5.66, SD = 4.36) than the mean of the normal hearing group (M = -2.82, SD = 2.86), although the group differences were not statistically significant, F (1, 8) = 1.47, $p > .05$. The N250 amplitude of the deaf group (M = -3.36, SD = 3.48) in the half face condition was also higher than that of the normal hearing group (M = -1.49, SD = 1.46), while the group mean difference in the amplitude decreased. The patterns of these results were consistent with the main hypotheses, implying that deaf signers' information processing for facial affect is based more on feature-based processing than holistic processing.

Title: Damage to the macaque anterior cingulate cortex impedes decision-making and eliminates social preference

Authors: *E. BLISS-MOREAU, G. MOADAB, D. AMARAL;
Psychiatry and Behavioral Sci., Univ. California, Davis, DAVIS, CA

Abstract: The anterior cingulate cortex (ACC) has been broadly implicated in cognitive, social, and emotional processing. In humans, ACC activity has been observed during diverse tasks ranging from the experience of detecting behavioral errors to social interactions in virtual environments to the experience of pain and discrete emotions like disgust. Despite the robust human literature, the extent to which normal ACC function is required to execute these functions is not clear. The present experiment evaluated both decision-making and preference for social information in a cohort of male rhesus macaque monkeys that received either neurotoxic lesions to the ACC (N=6) or sham operations (N=7) four years prior to testing. Testing occurred over five test days in a sound attenuated chamber using an infrared eye tracker. Subjects indicated their responses to specific stimuli by fixating on a given stimulus for a defined duration. Each test day included a maximum of 40 trials or was ended after approximately two hours. Experimental stimuli were dynamic video stimuli that either featured conspecifics engaged in species typical behaviors (i.e., “social” stimuli) or footage from nature documentaries (i.e., “nonsocial” stimuli). Each trial began when the animals fixated on a stimulus (a #) presented in the center of the computer screen. They were then presented with two visual stimuli (i.e., “choice” stimuli)-a blue square or a yellow square. For half of the subjects, fixating on the blue square activated a social video and fixating on the yellow square activated a nonsocial video. For the other subjects, the contingency was reversed. Over the five test days, control animals completed significantly more trials than the ACC-lesioned animals. Overall, control animals also

had fewer fixations on choice stimuli, and in particular nonsocial choice stimuli, indicating more efficient decision-making. Control animals selected a higher ratio of social videos, relative to nonsocial videos, than did ACC-lesioned animals. Control animals also demonstrated a preference for social information insofar as they selected social videos more frequently than chance. In contrast, animals with ACC damage did not select either social or nonsocial videos more frequently than chance, indicating no preference for social information. Implications for the ACC's role in cognitive control and social processing will be discussed.

Title: Adolescent development of interoceptive pathways mediating response focused emotion regulation

Authors: *D. LI, N. L. ZUCKER, P. A. KRAGEL, V. E. COVINGTON, K. S. LABAR; Duke Univ., Durham, NC

Abstract: Adolescence is a critical period for the neural development of emotion regulation capacities, which play a key role in managing social interactions. The neural basis of emotion regulation in adolescence is relatively unknown, and the few existing studies have focused on antecedent-based strategies, such as the use of cognitive reappraisal in reinterpreting the meaning of affective stimuli in ways that alter their emotional impact. A less well-studied method of emotion regulation involves response-focused strategies such as those that alter interoceptive processes associated with emotion induction. To this end, we used functional magnetic resonance imaging (fMRI) to study developmental brain mechanisms of interoceptive regulation in healthy adolescent females. Across trials, participants were presented with virtual roller coaster movie clips (interoceptive induction phase) followed by a regulation phase, during which they were instructed to regulate their interoceptive response to the roller coaster induction either by visually monitoring their online electrogastrogram activity through a virtual thermometer (biofeedback condition), or by deep breathing exercises without visual feedback from the interoceptive

response (no-biofeedback condition). Interoceptive induction was associated with increased bradygastria that attenuated during the regulation phase and was accompanied by a compensatory increase in tachygastria. Bilateral ventrolateral prefrontal cortex and left temporoparietal junction were both activated during interoceptive regulation. The left insula showed increased activation in the no-biofeedback compared to biofeedback regulation trials, suggesting that the participants relied more on interoceptive input when external feedback was unavailable through other senses. By contrast, visually-guided biofeedback elicited more activation in the visual cortex than the no-biofeedback condition. Linear increases in age were associated with greater fMRI activation in the bilateral anterior insula during regulation but smaller structural volume, suggesting developmental pruning mechanisms that target interoceptive capacities. Across ages, the increase in tachygastria during regulation was associated with increased fMRI signal in the bilateral insula. These results suggest an increasingly important role of the insula in interoceptive regulation during adolescent development.

Title: Effects of emotional words on inhibitory control in adolescents

Authors: *J. RAMOS-LOYO, E. S. MARTÍNEZ-VELÁZQUEZ, L. M. SÁNCHEZ-LOYO, A. A. GONZALEZ-GARRIDO;
Inst. de Neurociencias, Univ. de Guadalajara, Guadalajara, Mexico

Abstract: Impulsive behavior related to inhibitory control difficulties is present during adolescence, particularly when emotional stimuli are involved. The aim of the present study was to explore the differences in the effects of emotional words on the attentional control in adolescents and adults, through event related oscillations (EROs) and event related potentials (ERPs). Method: 30 male subjects, 15 adolescents and 15 adults performed 3 Stroop tasks

involving neutral, compliments or insulting words. The subjects had to press a key that corresponded to the color of the word. N2 amplitude and amplitude enhancement factor for EROs were evaluated. There were no differences between groups in behavioral measures. Adults showed lower reaction times with compliments than insults. N2 amplitude was higher in adults than adolescents in tasks involving neutral and compliment words. Adults also showed higher amplitudes than adolescents in theta for compliment words in Cz and Pz; for slow alpha in neutral words in Fz and; in fast alpha in neutral in Cz and Pz. Only the adults showed differences between conditions. Slow alpha showed lower amplitude in neutral vs compliments in Fz and; fast alpha lower in neutral vs insults. Present results suggest that even though there were no differences between adolescents and adults with respect to their behavioral measures, there were differences in the underlying brain electrical activity, that may suggest an incomplete brain maturation.

Title: Dynamic pupillary response to tonic and phasic patterns of Locus Coeruleus activity

Authors: *Y. LIU, E. LI, Q. WANG;
Biomed. Engin., Columbia Univ., New York, NY

Abstract: Changes in pupil size have been widely used as a measure of mental activity and changes in mental states for more than half a century. However, the underlying neurophysiological mechanism still remains poorly understood. Recent findings suggest that the locus coeruleus (LC) plays a complex role in many cognitive tasks, and it has been postulated that two distinct modes of neural activity in the LC differently modulate pupil dilation. Phasic activation of the LC would result in transient change in pupil size, whereas tonic activation of the LC would modulate average pupil size. Nevertheless, this hypothesis has not been tested yet. Here, using high-speed videography, we simultaneously measured pupillary responses of both eyes to patterned microstimulation in the LC. The location of the stimulating electrodes has been confirmed by characteristic response to tail/paw pinch of single LC neurons that were recorded

prior to the microstimulation and post-experiment histological analysis. Preliminary results demonstrate that patterned microstimulation in the LC evoked synchronous changes in pupil size for both ipsilateral and contralateral eyes, whereas changes in ipsilateral pupil size are bigger than contralateral pupils. Tonic stimulation with different frequencies (i.e. 0.5, 1, 2 and 5 Hz) evoked small changes in average pupil size and the changes increased with the stimulation frequency. In contrast, phasic stimulation elicited significantly larger and longer-lasting pupil dilation. Background tonic stimulation modulates the amplitude of pupil dilation in response to the phasic stimulation. Taken together, our results provided for the first time direct experimental evidence that different LC activity patterns have distinct effects on changes in pupil size.

Title: Emotional contexts exert a differential effect on the inhibition of a prepotent response in men and women that refer high and low behavioral regulation

Authors: *L. Á. LLAMAS, SR, J. RAMOS-LOYO, A. GONZÁLEZ-GARRIDO, J. HERNÁNDEZ-VILLALOBOS;
Inst. De Neurociencias, Guadalajara, Mexico

Abstract: The purpose of the present study was to explore sex differences in the effects of emotional contexts in response inhibition in adolescents, comparing those who refer a high behavioral regulation capacity (HRC) in social environments and those who refer a low capacity (LRC). Sixty adolescents were divided in 4 groups (n=15 each): women and men with HRC and LRC (BRIEF-A). Subjects performed 4 Go-NoGo response inhibition tasks under 4 context conditions: stimuli without context, context with neutral emotional content; pleasant and unpleasant. Subjects had to press a key when an arrow located in the middle of the screen, coincided both in direction and color with a bar presented in the left or right edges (Go) and to withhold the response when it did not match (NoGo). Women had higher number of correct inhibitions than men. LRC men showed lower number of correct inhibitions than HRC and women of both groups, in particular in emotional contexts. Women showed longer N2 latency than men. N2 amplitude was higher in LRC than HRC, both in men and women. Unpleasant

context generated higher N2 amplitude and longer P3 latency. Los hombres de BRC tienen mayores dificultades en la inhibición de sus respuestas que los de ARC y este efecto es mayor ante contextos emocionales. Results suggest that women had better inhibitory control than men, although they took more processing time. Adolescents that reported having lower abilities in their behavioral control within everyday activities, demonstrated more difficulties in response inhibition at emotional contexts than those who report higher abilities. These difficulties were related to higher N2 amplitude, which may indicate that they require recruiting more attentional and inhibitory resources in order to achieve task performance, particularly under emotional contexts. Emotional contexts attract attention making more difficult to inhibit a prepotent response than non-emotional ones, which is evidenced both in behavioral and electrophysiological measures.

Title: Brainstem stimulation increases functional connectivity of basal forebrain-paralimbic network in isoflurane-anesthetized rats

Authors: ***S. PILLAY**[1], X. LIU[1], P. BARACSKAY[2], A. G. HUDETZ[1];
[1]Anesthesiol., Med. Col. of Wisconsin, Milwaukee, WI; [2]Inst. of Biology, Lab. of Proteomics, Eötvös Loránd Univ., Budapest, Hungary

Abstract: Brain states and cognitive-behavioral functions are precisely controlled by subcortical neuromodulatory networks. Manipulating key components of the ascending arousal system (AAS) via deep brain stimulation may help facilitate global arousal in anesthetized animals. Here we test the hypothesis that electrical stimulation of the oral part of the pontine reticular nucleus (PnO) under light isoflurane anesthesia associated with loss of consciousness leads to cortical

arousal and specific changes in blood-oxygenation-level dependent (BOLD) functional connectivity (FC) of the brain. BOLD signals were acquired simultaneously with frontal epidural EEG before and after PnO stimulation. Whole-brain FC was mapped using correlation analysis with seeds in major centers of the AAS. PnO stimulation produced cortical desynchronization, a decrease in δ-and θ-band power, and an increase in approximate entropy. Significant increases in FC after PnO stimulation occurred between the left nucleus Basalis of Meynert (NBM) as seed and numerous regions of the paralimbic network. Smaller increases in FC were present between the central medial n. of thalamus and retrosplenium seeds and the left caudate putamen and NBM. The results suggest that, during light anesthesia, PnO stimulation preferentially modulates basal forebrain-paralimbic networks. We speculate that this may be a reflection of disconnected awareness.

Title: Deletion of phospholipase C beta1 in thalamic reticular nucleus lead to spontaneous absence seizures in mice

Authors: *B. CHANG[1,3], K. KIM[4], S. LEE[4], K.-S. KIM[2], E. CHEONG[3], H.-S. SHIN[4];
[1]Ctr. for Neural Seience, [2]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [3]Yonsei university, Seoul, Korea, Republic of; [4]institute for basic science, daejeon, Korea, Republic of

Abstract: The thalamocortical networks have long been considered to be important in control of consciousness. Absence seizures are caused by abnormal synchronized oscillations in the thalamocortical circuit, resulting in widespread spike-and-wave discharges (SWDs) in the electroencephalogram(EEG) in parallel with an impairment of consciousness. Many reports have demonstrated that thalamic reticular nucleus (TRN) and thalamocortical (TC) neurons are critical for the generation of thalamocortical oscillations during SWDs. Phospholipase C β1 (PLCβ1) knockout (KO) mice show spontaneous complex type seizures, including convulsive and absence. This spontaneous SWDs are attenuated by application of anti-absence seizure drug, ethosuximide (ETX) known as a T-type Ca2+ channel blocker. PLCβ1 is expressed only in the TRN region in the thalamus, we explored the possibility that PLCβ1 in the TRN may be critical

for the induction of spontaneous SWDs. To that end, we utilized PLCβ1 shRNA knockdown (KD) system to inhibit PLCβ1 expression in the TRN. The result showed that PLCβ1 KD mice also developed only spontaneous SWDs but no other types of seizure; indicating that the deletion of PLCβ1 in TRN leads to the absence seizure. We used γ-butyrolactone (GBL), known to induce absence seizure primarily by acting on GABAB receptors, in PLCβ1 KO mice to see further increase of SWDs. Interestingly, the number of SWDs and duration were not significantly altered by GBL injection. In contrast THIP (4,5,6,7-tetrahydroisoxazolo(5,4-c)pyridin-3-ol) a GABAa agonist which is known to induce absence seizure significantly increased the number of SWDs and duration. We conclude that PLCβ1 in the TRN plays key roles in the induction of absence seizures both in spontaneous and in drug induced seizure. Our study could provide not only understanding the thalamocortical pathway in induction of SWDs but also guide the development of therapeutic tools for absence epilepsy.

Title: A genome-wide association study of neonatal brain volumes

Authors: K. XIA[1], S. JHA[1], F. ZOU[2], H. ZHU[2], P. SULLIVAN[1], M. STYNER[1], J. H. GILMORE[1], *R. C. KNICKMEYER[1];

Abstract: Brain development in the prenatal and perinatal period is critically important for later cognitive function and mental health. Genetic factors likely play a key role in determining individual variation in early brain development, but are understudied in human populations due to practical and technical challenges. The aim of this study is to use genome-wide genotyping technology combined with statistical genetics methods to facilitate the discovery of common and rare genetic variants associated with individual variation in brain structure during early postnatal development. Buccal samples from neonates were genotyped using Affymetrix Axiom Genome-Wide LAT and Exome arrays for common variants and rare variants respectively. 594 subjects (278 singletons and 316 twins/siblings) were obtained after various quality control metrics, followed by SNP imputation using reference panel of 1000 Genome Project. Structural magnetic resonance imaging (MRI) scans of neonates were acquired with a Siemens TIM Trio or Allegra 3T scanner. An automatic, atlas-moderated expectation maximization segmentation tool was used to classify brain tissue as gray matter (GM), white matter (WM), or cerebral spinal fluid (CSF). In addition to total tissue volumes, we also investigated intracranial volume (ICV) and cortical GM and WM. To account for correlation structure between twins and siblings, linear mixed effect model was used to test a total of 9.5 million genotyped and imputed SNPs against each MRI variable. An intergenic hotspot in 15q13.3 between KLF13 and OTUD7A was significantly associated with ICV (rs8030297; p=2.98 x 10-8), total WM (rs6493639, p=4.24 x 10-8), and marginally associated with GM (rs8030297; p=5.25 x 10-7 and cortical WM (rs6493639, p=1.17 x 10-7). Deletion within 15q13.3 has been associated with a range of neurodevelopmental phenotypes including developmental delay, mental retardation and seizures. KLF13 is highly expressed during murine neural development. CNVs close to KLF13 can result in microcephaly, macrocephaly, intellectual disability (ID), and psychosis. A number of marginally significant hotspots were also identified for all phenotypes. Our results suggest that common genetic variants are associated with brain volumes in neonates and they are located in/near biologically plausible genes.

Title: Whole proteome analysis of peripheral nerve injury via Mass Spectrometry

Authors: *A. S. YEKKIRALA, H. CHEN, K. HEMPEL, J. A. STEEN, C. J. WOOLF; Harvard Med. School/children's Hosp. Boston, Boston, MA

Abstract: It is an intriguing fact that peripheral nerves can regenerate well after injury while injury to the CNS is often debilitating, as CNS neurons do not exhibit such regenerative capacity. To identify novel proteins involved in peripheral nerve regeneration we, for the first time, utilized the Q-exactive MS/MS proteomics platform. Initial analysis of whole DRG lysates yielded a proteome of ~5000 proteins. TMT-labeling performed to identify protein differential expression in DRGs after a 5-day sciatic nerve crush injury (SNI) yielded 129 novel proteins that have not been implicated in regeneration. However, we were unable to identify many transcription factors (TFs), as they are not abundantly expressed. Efforts to improve proteome coverage helped identify >9000 proteins with numerous TFs and surface receptors and these methods are currently being used for a new multiplex experiment utilizing whole DRGs and sciatic nerve fragments 5 days after SNI. The results provide the first insights into whole proteome networks regulating the regenerative process in the PNS.

Title: Single-cell transcriptomic analysis identifies molecularly distinct subclasses of excitatory and inhibitory neurons in mouse visual cortex

Authors: *V. MENON, B. TASIC, T.-N. NGUYEN, C. LEE, T. KIM, N. SHAPOVALOVA, B. LEVI, J. GOLDY, D. BERTAGNOLLI, S. PARRY, K. SMITH, S. M. SUNKIN, M. HAWRYLYCZ, H. ZENG;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: The mammalian nervous system comprises numerous neuronal populations, some of which can be distinguished based on various properties or molecular signatures. As part of the Mouse Cell Types program at the Allen Institute for Brain Science, we have characterized and categorized neurons in the mouse visual system using single-cell transcriptomic profiling methods. Having developed procedures to reliably isolate individual neurons labeled by specific transgenic Cre lines, we used single-cell RNA-sequencing methods to obtain transcriptional readouts of hundreds of individual excitatory and inhibitory cells from multiple cortical layers. Unsupervised clustering of the data reveals that excitatory neurons from the same cortical layer tend to have similar expression profiles, whereas interneurons cluster by known marker types. However, this analysis also identifies subtypes of excitatory neurons within a single layer, as well as among interneurons expressing the same canonical marker. Based on these data-driven clusters, we extract a set of well-known and lesser-studied genes to generate combinatorial codes of transcription factors, cell adhesion molecules, and ion channels to distinguish each of these neuron types. Finally, we also examine differential exon usage within single cells belonging to the same and different types to address the extent to which alternative splicing helps refine neuronal taxonomy.

Title: Brainpix - Rodent brain region-specific RNA bank

Authors: A. ZAVALA, Z. MA, *L. C. KUDO, S. KARSTEN;
NeuroInDx, Inc., Signal Hill, CA

Abstract: RNA isolation from specific subanatomical regions is a challenging task requiring high cost laser assisted microdissection instrument or flow sorting instruments. This complicates carrying out numerous pilot studies when information for a specific regional gene regulation has to be obtained in order to generate or support a hypothesis. To facilitate access for the scientific community to brain region specific RNA, we constructed a BrainPix bank of RNA isolated from rodent brain subanatomical regions. A recently developed low-cost cell and tissue acquisition system, KuiqpicK v.1.0, was used to acquire region specific samples from fresh frozen rat and mouse brain tissues. Representative collection of rat CA1, CA2 and CA3 regions of hippocampus are shown below. Total RNA was isolated from KuiqpicK dissected brain tissues using time proven protocols to yield highly pure, intact RNA. Every RNA sample underwent through rigorous quality controls that included analysis using Agilent 2100 Bioanalyzer. Currently RNA isolated from over twenty brain subanatomical areas is provided in RNase-free storage solution at convenient concentrations from 10 to 100 ng/µl, depending on the initial size of the dissected region (www.neuroindx.com/brainpix/). Purified RNA is DNase treated and ready to use in any downstream applications. It is ideal for pilot gene expression studies including microarray based analysis and high throughput sequencing.

Abstract: Nitric oxide (NO) mediates a substantial part of its physiologic functions via S-nitrosylation, however the cellular substrates for NO-mediated S-nitrosylation are largely unknown. Here we describe the S-nitrosoproteome using a high-density protein microarray chip containing 16,368 unique human proteins. We identified 834 potentially S-nitrosylated human proteins. Using a unique and highly specific labeling and affinity capture of S-nitrosylated proteins, 138 cysteine residues on 131 peptides in 95 proteins were determined, defining critical

sites of NO's actions. Of these cysteine residues 113 are novel sites of S-nitrosylation. A consensus sequence motif from these 834 proteins for S-nitrosylation was identified, suggesting that the residues flanking the S-nitrosylated cysteine are likely to be the critical determinant of whether the cysteine is S-nitrosylated. We identify eight ubiquitin E3 ligases, RNF10, RNF11, RNF41, RNF141, RNF181, RNF208, WWP2, and UBE3A, whose activities are modulated by S-nitrosylation, providing a unique regulatory mechanism of the ubiquitin proteasome system. These results define a new and extensive set of proteins that are susceptible to NO regulation via S-nitrosylation. Similar approaches could be used to identify other post-translational modification proteomes.

Title: A fast and simple preparation method for whole-genome bisulfite sequencing library preparation from ultra-low dna input

Authors: X. SUN[1], K. GIANG[1], T. CHUNG[1], *L. CUI[2], X.-Y. JIA[1];
[1]Zymo Res. Corp, Irvine, CA; [2]Zymo Res. Corp., Irvine, CA

Abstract: The distribution of 5-methylcytosine (5-mC) in DNA within the eukaryotic genome is known to greatly affect gene regulation and is currently a major topic of research. Studies on DNA methylation have been aided by advancements in bisulfite conversion and next-gen sequencing technologies which, when coupled, provide single-base resolution of 5-mC in the whole genome. Many whole-genome bisulfite sequencing (WGBS) library preparation protocols designed to analyze 5-mC distribution in the whole genome employ bisulfite to convert unmethylated cytosine bases to uracil after the library preparation. While these protocols produce reliable results, degradation of DNA is inherent to bisulfite conversion. As such, a large proportion of the adapterized library is fragmented and can no longer be amplified, which requires these protocols to call for large amounts of starting input DNA that is often times impossible to obtain. By rearranging the order of library preparation and bisulfite conversion, we developed a streamlined protocol that reveals whole-genome methylation patterns at single-base

resolution. The work-flow leads with the degradation inherent to bisulfite conversion to randomly fragment the DNA prior to the library preparation, which allows the protocol to accommodate for pico-gram quantities of starting input, making it ideal for analysis in precious and limited samples. Comparisons of sequencing data from this WGBS library preparation method with the established Reduced Representation Bisulfite Sequencing (RRBS) method using human DNA showed a correlation coefficient of 0.95 for CpG sites with more than 10X coverage. With slight modifications, this protocol is versatile in its ability to prepare libraries for ChIP-seq and RNA-seq.

Title: D-amino acid-containing peptides in the mammalian nervous system

Authors: *H.-C. TAI, I. LIVNAT, E. T. JANSSON, S. S. RUBAKHIN, J. V. SWEEDLER; Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Neuropeptides undergo a variety of post-translational modifications (PTMs) that are often critical for their cell-to-cell signaling properties. Peptide isomerization is a PTM in which an L-amino acid in the peptide chain is enzymatically converted into a D-amino acid, leading to important changes in the three-dimensional structure and bioactivity of the resulting D-amino acid-containing peptide (DAACP). Due to the lack of a molecular mass shift upon isomerization, this PTM is difficult to characterize in current mass spectrometry based peptidomics [1]. To address this challenge, we have developed a multi-stage method for the discovery of DAACPs in complex biological samples. Our method begins with screening for potential DAACPs based on resistance to degradation by aminopeptidase M (APM), an enzyme that selectively cleaves off L-amino acids but stops at a D-amino acid in the peptide. A common feature of DAACPs found in vertebrates is that L-to-D isomerization occurs at the second residue from the N-terminus,

making them poor substrates for an aminopeptidase. Therefore, we use APM to assay mixtures of endogenous neuropeptides, and peptides that degrade slowly on exposure to APM become candidate DAACPs. When a resistant peptide is found, we use liquid chromatography to purify greater quantities of the peptide and acid-hydrolyze it. The resulting amino acids are derivatized with Marfey's reagent (1-fluoro-2,4-dinitrophenyl-5-L-alanine amide) to enhance chiral separation, and then analyzed with a triple quadrupole mass spectrometer to determine the presence of specific D-amino acids. While initial experiments have used the well-defined *Aplysia* central nervous system (CNS), we are adapting these approaches to neuropeptides extracted from the CNS of the rat. We have already discovered several candidate DAACPs in preliminary screening of the rat pituitary. Several peptides have been found that are resistant to APM degradation. As one example, endogenously isolated little SAAS (amino acid sequence SLASAASAPLAETSTPLRL), is resistant to APM degradation while a synthetic all-L-amino acid version of little SAAS was easily degraded, suggesting a structural difference between the two. We are currently confirming the presence of this modification in little SAAS and several other mammalian peptides. 1. Bai et al., Analysis of endogenous D-amino acid-containing peptides in Metazoa, Bioanal Rev (2009) 1:7-24.

Title: Discovery of D-amino acid containing peptides in rodent islets of Langerhans

Authors: E. T. JANSSON, I. LIVNAT, H.-C. TAI, E. V. ROMANOVA, S. S. RUBAKHIN, *J. V. SWEEDLER;
Dept Chem., Univ. Illinois, Urbana, IL

Abstract: As the number of new drug approvals by the FDA has steadily declined since the mid-1990s, one may need to turn to more exotic and understudied peptide modifications in the search of novel drug candidates. The epimerization of a single amino acid in an endogenous peptide may occur as a post-translational modification (PTM) through *in vivo* enzymatic activity, recently shown in the mouse heart. However, the specific enzyme identity and its resulting endogenous rodent D-amino acid containing peptides (DAACPs) remain to date unknown. Quite a few biologics have been developed to treat various diseases based on peptides such as insulin, oxytocin, and C-peptides. Changing the three-dimensional structure of a peptide often changes its interaction with a receptor, and may hence affect its bioactivity and degradability. Given the presence of enzymatic activity and information on this modification in an increasing number of animals, the question we address here is whether there are endogenous mammalian DAACP hormones. Here, we are developing methods for performing studies of DAACP content in the peptidergic islets of Langerhans isolated from rat pancreas. While PTMs that do not induce any mass nor charge changes are inherently challenging to study with mass spectrometry (MS), they often impose changes in other physicochemical properties of the peptide which may be utilized for detection and characterization with MS. In liquid chromatography separations, DAACPs and their all-L-form counterparts can be separated due to their different interactions with the stationary phase. Also, DAACPs are more slowly digested than all-L-peptides by Aminopeptidase M, a digestive enzyme which can be utilized to highlight DAACPs from a complex biological sample. Further, in tandem MS, the intensity of the fragments of L- and D-form peptides upon collision induced dissociation can be different. Using a combination of these analytical state-of-the-art techniques, we investigated the presence of putative DAACPs in rat islets of Langerhans. Peptide extractions with a synthetic DAACP (NdWFa) added as an internal standard, were subjected to digestion with Aminopeptidase M, and the following MS-analysis uncovered peptides which remain intact - analogously as the DAACP-standard - while other peptides were readily degraded. Our results indicate that DAACPs are present in the islets of Langerhans. We also confirmed that the major cell-to-cell signaling molecules, e.g. the insulin C-peptide, synthesized by islets in healthy animals do not possess D-amino acids. Further development of our methodology will allow us to identify the exact site of epimerization in the peptide backbone.

Title: Genetics of hippocampal gene expression in Diversity Outbred mice

Authors: *E. J. CHESLER[1], N. RAGHUPATHY[1], R. F. ROBLEDO[1], D. M. GATTI[1], S. C. MUNGER[1], C. PHILLIPS[2], J. NDUKUM[1], T. WILCOX[1], J. GRABER[1], M. HIBBS[1], G. A. CHURCHILL[1], M. LANGSTON[2];
[1]The Jackson Lab., Bar Harbor, ME; [2]The Univ. of Tennessee, Knoxville, TN

Abstract: Genetic analysis of gene expression in laboratory mice has enabled the discovery of regulatory variation and covariation among transcripts and behavioral traits. Early studies typically relied on microarray analysis in two-progenitor populations for the detection of quantitative trait loci (QTL) and genetic correlation. Recent advances in genetic mapping populations and RNA quantitation have improved the utility, information content, precision and power of these studies tremendously. RNA sequencing now enables genetic analysis of more precisely characterized isoforms, allelic variants, and imprinted loci. The Diversity Outbred (DO) mouse population, derived from an intercross of the five common and three wild-derived inbred mouse founders strains of the Collaborative Cross (CC) has over 45 million segregating SNPs, high recombinational precision and high behavioral diversity. We sequenced the transcriptome from the hippocampus of >290 DO mice of both sexes. A genome-wide expression QTL analysis using 17,539 genes against 7700 SNP genotype markers revealed 10,341 significant associations at 1% FDR threshold (11,863 significant eQTLs at 5% FDR threshold). Among the significant associations, over 85% of the associations are within 2MB of the transcription start site of the gene. The remaining 15% of the significant associations are away from the start site, and 4.2% are on different chromosomes. Allelic effects of each of the eight founder haplotypes are estimated for every transcript, and through the integration of publicly available inbred strain sequence data, several of these allelic effects are attributable to specific polymorphic variants. Combinatorial, genome wide gene co-expression analysis of genes co-expressed at $|r| > .7$ reveals ~100 precise, functionally coherent co-expression networks. For example, a network consisting only of seven co-expressed genes in the AP-1 transcriptional network was extracted in an unsupervised analysis. Genetic analysis of expression correlation to behavior and convergent functional genomic analyses in the GeneWeaver system enable interpretation of the functional role of co-expression values in the context of other functional genomic experimental results. The availability of these data will enable the interpretation and refinement of new and existing QTL analyses of brain and behavior.

Title: Gene network strategy to elucidate the complexity of brain trauma and related neurological disorders

Authors: *Z. YING[1], Q. MENG[1], R. AGRAWAL[1], X. YANG[1], F. GOMEZ-PINILLA[2]; [1]Dept of Integrative Biol. and Physiol., [2]Dept of Neurosurgery, and Integrative Biol. and Physiology,, UCLA, LOS ANGELES, CA

Abstract: Traumatic brain injury (TBI) affects a large variety of cellular and molecular processes ultimately compromising brain function and cognitive abilities. The complexity of the pathology of TBI that involves multiple components seems to pose crucial challenges for development of effective cures. Indeed, current pharmacological approaches focusing on single events have yielded poor results on the prevention of the short- or long-term consequences of TBI. The lack of a comprehensive mechanistic understanding of the complexity of TBI pathology likely explains the poor outcomes of the current therapeutic approaches. We carried out a systems biology study to address these challenges by using state-of-the art methodologies that can capture the tremendous genomic variability inherent to TBI. The unique aspect of our approach is to determine the effects of TBI on the interaction of genes within a genome-wide scale to grasp the whole dimension of the TBI pathology. We used next generation sequencing and integrative genomics analyses to determine how TBI affects networks of genes that could characterize main events in the TBI pathology. We report that moderate fluid percussion injury (FPI) engages the action of master genes such as Anxa2 and Ogn to coordinate the function of hundreds of genes in the network. Increasing evidence indicates that TBI poses risks for neurological disorders such as Alzheimer's disease, and psychiatric disorders. We report that gene network reorganization in our rodent model of TBI overlaps with existing human libraries of gene-wide association studies (GWAS) for brain disorders such as Alzheimer's disease, bipolar disorder, autism, etc. These results reveal mechanistic information how TBI impacts specific gene networks which may confer vulnerability to neuropsychiatric disorders. Our ongoing studies suggest that the broad spectrum of action of dietary docosahexaenoic acid

(DHA) is instrumental to counteract TBI pathology by restoring gene network reorganization. These studies may set basis for development of network-based medicine, a new line of therapeutic strategy, to improve TBI outcome and prevent TBI-associated brain disorders.

Title: Application of translational profiling method for the molecular characterization of post-ischemic inflammatory response

Authors: ***H. BOUTEJ**, L.-C. BÉLAND, M. LALANCETTE-HÉBERT, J. KRIZ; CRIUSMQ, Le Ctr. De Recherche De L'Institut Univ., Québec, QC, Canada

Abstract: Microglial cells are the resident macrophage-like cells of the brain and act as the first line defense in the central nervous system. Activation of this primary immune effector can be observed in almost all CNS pathologies, including stroke. Brain damage following transient or permanent ischemia results from a series of pathophysiological events that evolve in time and space. They include acute necrosis in the centre of infarction, followed by peri-infarct (the penumbra) depolarizations, glutamate-mediated excitotoxicity and oxidative stress. Although there is evidence that inflammation in ischemic injury is orchestrated by microglia, their dual role (neurotoxicity/neuroprotection) still remains ambiguous. To gain a better understanding of the molecular mechanisms involved in the post-ischemic inflammatory response, we used a translational profiling approach. This elegant method, developed in recent years, first elucidate the biological properties of distinct neuronal populations (Doyle et al., 2008; Heiman et al., 2008). Basically, the translating ribosome affinity purification (TRAP) allows the opportunity to capture gene expression after genetic alteration, disease or pharmacological perturbations. For this purpose, we generated a BV2 cell-line that stably expresses a double epitope-tagged form of the large subunit ribosomal protein L10a: Flag-EGFP-RPL10a. Cells were treated with lipopolysaccharide (LPS) (1ug/ml) or with glutamate (100μM). Cells lysates were

immunoprecipitated with anti-Flag resin. Bound proteins were eluted with EDTA-elution buffer and tryptic fragments of ribosomes-associated proteins were sequenced by mass spectrometry. Scaffold was used to validate MS/MS based peptide and proteins identifications. The TRAP analysis resulted in detection of several proteins that belong to different functional categories: cytoskeletal proteins, metabolic enzymes, chaperones, kinases, proteases and proteins involved in signalling and in proteins degradation. Interestingly, we found that some of these proteins are enriched in LPS or glutamate treated cells compared to untreated cells. This differential proteomic analysis enabled us to characterize gene expression pattern, *in vitro*. Furthermore, we have established a transgenic mouse that expresses the large subunit ribosomal protein L10a: Flag-EGFP-RPL10a under the control of the CD11B promoter. The resulting mouse line will help us to draw up an, *in vivo*, translational profile. Finally, these observations may contribute to decipher the molecular mechanisms involved in microglial cells activation and inflammatory response *in vitro* and *in vivo*.

Abstract: The gene expression programs necessary for development, learning, and memory in neurons are coordinated by genomic enhancers. The locations of these enhancers within the mouse and human genomes are now known, thanks to the ENCODE Project and related studies. However, the specific nucleotides within enhancer sequences that are necessary for gene regulation remain to be identified. It therefore remains difficult to predict the effects of human genetic variation on enhancer activity, neural development, and neural function. We analyzed the sequences of neural enhancers and identified enriched transcription factor binding site sequences,

8 to 15 nucleotides long, likely to be important for neural enhancer function. Then, we tested our computational predictions of important sequences using a Massively Parallel Reporter Assay (MPRA) that we adapted to primary neurons. In MPRA experiments, we infect cortical neurons with a library consisting of thousands of synthetically produced enhancers that control the expression of unique barcodes. We have identified hundreds of enhancers that are activated by neural activity, as well as many predicted transcription factor binding sites required for their function.

Title: Transcriptome tomography: Mapping genes onto 3D brain structures

Authors: *Y. OKAMURA-OHO[1,2], K. SHIMOKAWA[3], S. NAKAMURA[1], Y. TSUJIMURA[1], M. NISHIMURA[1], S. TAKEMOTO[1], M. MORITA[1], T. IJIRI[1], T. TAWARA[1], H. YOKOTA[1]; [1]RIKEN Ctr. For Advanced Photonics, Wako-Shi, Saitama, Japan; [2]Brain Res. Network (BReNt), Zushi-shi, Japan; [3]Tohoku Med. Megabank Organization, Tohoku Univ., Sendai-shi, Japan

Abstract: Expression-anatomy association is crucial for understanding molecular functions of, in particular, novel coding and non-coding genes. We have invented a framework for comprehensive gene expression density mapping on the whole three dimensional (3D)

anatomical context, Transcriptome Tomography (PLoS One 2012; 7, e45373, Video http://www.youtube.com/watch?v=Td4rGRQIZuY&list=UUIGmhpdcVev1Wc0YK7FHIig). Expression densities measured with high-throughput methods are usable for their mapping onto the 3D brain structure detected with other modalities such as MRI. Also they are usable directly for gene-by-gene correlation analysis of co-expression. This framework comprehensively assesses co-expression patterns that are latent within expression maps. Expression maps and co-expression search results in the mouse brain can be browsed in our website, ViBrism-DB (http://vibrism.neuroinf.jp/). In this presentation we would focus on previously uncharacterized mouse-specific genes that were co-expressed with gene groups encoding transcription factors and related molecules. The genes were expressed in areas associated with specific brain functions and the previously uncharacterized non-coding genes were located in a co-expression network position linking the groups. This linkage suggests characteristics of the non-coding genes that may coordinate multiple gene groups and create mouse-specific neural designs. A part of this work was supported by members in RIKEN Neuroinformatics Japan Center and conducted within the WHS and DAI Task Forces of the INCF Program on Digital Brain Atlasing.

Title: Compartmentalization and collaboration in neuroblastoma tyrosine kinase signaling networks

Authors: *M. L. GRIMES[1], J. PALACIOS-MORENO[2], A. GUO[3], M. STOKES[3], M. J. COMB[3], E. KUEHN[4];
[1]Div. of Biol. Sci., [2]Neurosci. Grad. Program, Univ. of Montana, MISSOULA, MT; [3]Cell Signaling Technology, Inc., Danvers, MA; [4]Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Phosphorylation of proteins on tyrosine residues, and the recognition of these modifications by specific binding domains, play central roles in creating a highly dynamic network of interacting proteins that reads and responds to signals from growth factors in the cellular microenvironment. Mutations that cause aberrant activation of receptor tyrosine kinases cause tumors, for example point mutations in anaplastic lymphoma kinase (ALK) are a major contributor to familial neuroblastoma. We found that more than half of all the receptor tyrosine kinases in the human genome were activated in a large scale study that examined phosphorylated proteins in neuroblastoma cell lines and cell fractions including endosomes and detergent-resistant membranes. To understand tyrosine kinase signaling mechanisms, new computational and bioinformatics approaches were developed. Neuroblastoma phosphoproteomic data analyzed using pattern recognition algorithms revealed clusters of interacting phosphorylated proteins that are likely to represent functional signaling pathways. Statistical patterns of phosphorylation in the same samples, combined with protein interaction data, suggest that receptor tyrosine kinases are functionally compartmentalized into distinct collaborative groups. Signaling components were also compartmentalized within cells. The SRC-family kinases, FYN and LYN, responded differently to different RTKs, and, together with the scaffold protein, PAG1, were phosphorylated and localized in endosomes and lipid rafts differently under conditions where different receptor tyrosine kinases are activated. These results suggest that dynamic activation and intracellular localization of SFKs provide a mechanism to distinguish signaling responses to different receptors that govern cell differentiation and cancer, and that tyrosine kinase signaling plays a major role in developmental pathways that govern the behavior of neural crest, which gives rise to neuroblastoma.

Title: Genetic analysis of RNF213 c.14576G>A variant in various phenotypes of intracranial major artery stenosis/occlusion

Authors: *S. MIYAWAKI[1], H. IMAI[1], M. SHIMIZU[2], S. YAGI[2], H. ONO[1], A. MUKASA[1], H. NAKATOMI[1], T. SHIMIZU[2], N. SAITO[1];
[1]Neurosurg., Fac. of Medicine, The Univ. of Tokyo, Bunkyo-Ku / Tokyo, Japan; [2]Kanto Neurosurgical Hosp., Kumagaya / Saitama, Japan

Abstract: (Background and Purpose) The c.14576G>A variant in ring finger protein 213 (RNF213) was recently identified as a susceptibility gene variant for moyamoya disease (MMD). We assumed that the c.14576G>A variant could be the cause of a wide spectrum of phenotypes of intracranial major artery stenosis/occlusion (ICASO) including MMD, and so some cases of ICASO originally considered to originate from atherosclerosis might be associated with the c.14576G>A variant in RNF213. In this study, the occurrence of c.14576G>A variant was evaluated in patients with ICASO without signs of MMD (non-MMD ICASO), as well as in patients with MMD and other cerebrovascular diseases as controls. (Methods) Study participants were recruited from The University of Tokyo Hospital and Kanto Neurosurgical Hospital. The occurrence rate of c.14576G>A variant was investigated in 519 patients, 64 with definite MMD, 14 with unilateral MMD, 125 with non MMD-ICASO, 55 with extracranial carotid atherosclerosis, 105 with cerebral aneurysm, 21 with intracerebral hemorrhage, and 135 control subjects. (Results) RNF213 c.14576G>A variant was found in 82.8% (53/64) of the definite MMD group, and 57.1% (8/14) of the unilateral MMD group. Moreover, the variant was found in 23.2% (29/125) of the non-MMD ICASO group. RNF213 c.14576G>A variant had significant associations with definite MMD ($P<0.0001$; odds ratio, 320.4; 95% confidence interval, 68.6-1494.4), unilateral MMD ($P<0.0001$; odds ratio, 88.6; 95% confidence interval, 15.3-511.3), and also with non-MMD ICASO ($P<0.0001$; odds ratio, 20.0; 95% confidence interval, 4.68-86.2). There was no significant association with extracranial carotid atherosclerosis, cerebral aneurysm, or intracerebral hemorrhage. (Conclusions) A particular subset of patients with various phenotypes of ICASO has a common genetic variant, RNF213 c.14576G>A, indicating that RNF213 c.14576G>A variant is a high-risk allele for ICASO (Miyawaki et al Stroke 2012, Miyawaki et al Stroke 2013).

Title: Using Single-cell RNA-seq to classify retinal cell types

Authors: ***Y.-R. PENG**[1,2], Q. MU[1,2], X. ZHANG[1,3], A. K. SHALEK[3,4,5], B. HAAS[5,6], H. PARK[1,3,4], A. REGEV[5,6], J. R. SANES[1,2];

Abstract: The mouse retina contains ~100 types of cells that process visual information gathered by photoreceptors and send it to the brain via retinal ganglion cell (RGC) axons. Understanding how visual information is processed requires classifying cells so that they can be identified, marked and manipulated. However, classification is currently incomplete and markers are unavailable for many types that have been distinguished morphologically. Single-cell RNAseq (scRNAseq) has the potential to circumvent these limitations by providing transcriptome data without a priori identification of the cell type. However, retinal cells are small, so establishing an unbiased amplification method is critical. Here, we asked whether newly developed scRNAseq methods could be used for this purpose. As an initial step, we compared two very different classes of retinal cells, photoreceptors and RGCs. We then compared two different types of RGCs: alpha-cells and on-off directional selective RGCs (ooDSGCs). Finally, we compared two very closely related subtypes: ooDSGCs that respond to ventral or nasal motion (DRD4-RGCs, Huberman et al., Neuron, 2009; HB9-RGCs, Trenholm et al., Neuron, 2011). In each case, we used fluorescence-activated cell sorting (FACS) to isolate individual cells from transgenic lines in which specific cell types express a fluorescent protein (Kay et al., Nature, 2012). We then amplified transcripts using either the Multiple Annealing and Looping-Based Amplification

Cycles (MALBAC) or SMART-Seq2 method and performed scRNAseq on multiple cells of each type. In cone photoreceptors, we detected expression of cone-specific genes (opn1sw, opn1mw, arr3), but not genes from other retinal cells types, such as rhodopsin (rods), Vsx (bipolar cells), GFAP (glial cells), or Thy1 (RGCs). Conversely, only RGC-specific genes were detected in RGCs. Using principal component analysis and gene-expression distance analysis, we could easily separate cones from RGCs and alpha-RGCs from ooDSGCs. Strikingly, these methods even separated HB9-RGCs from DRD4-RGCs, indicating the ability to distinguish very similar subtypes. Ongoing studies are aimed at identifying new subtypes in mixed populations, and assessing the degree of heterogeneity within nominally homogeneous subtypes.

Title: Down-regulation as the dominant hippocampal gene expression profile with voluntary resistance wheel running by DNA microarray analysis

Authors: *M. LEE[1,2], R. RAKWAL[3], J. SHIBATO[1], K. INOUE[1], H. SOYA[1];
[1]Exercise Biochem., Univ. of Tsukuba, Tsukuba-Si, Ibaraki-Ken, Japan; [2]Res. Fellow of the Japan Society for Promotion of Sci., Tokyo, Japan; [3]Organization for Educational Initiatives, University of Tsukuba, Japan

Abstract: BACKGROUND: Physical exercise has beneficial effects on our brawn and brain, not only with regard to muscular adaptations, but also with respect to brain function enhancing neuronal plasticity and cognitive enhancement. We have recently demonstrated that voluntary resistance wheel running (RWR) exercise can increase neurogenesis and spatial memory associated with hippocampal brain-derived neurotrophic factor (BDNF) signaling. Despite these

new evidence, underlying molecular mechanisms for RWR-induced improvement of hippocampal function remained to be clarified. Here we have utilized the high-throughput DNA microarray approach to gain deep insight into molecular mechanisms underlying. These changes could be novel targets of RWR-induced hippocampal plasticity. METHODS: 10-week-old adult male Wistar rats were assigned randomly to sedentary control (Sed), wheel running with no resistance (WR), and resistance wheel running to 30% of body weight (RWR) groups for 4 weeks. Whole genome (4x44K) high-density oligonucleotide microarrays were used to monitor the expression level of gene transcripts in the hippocampus of rats voluntary running for 4 weeks in comparison with sedentary animals. RESULTS: Our results showed that a significant decrease in average running distances was observed although average work levels increased immensely by 12-fold in the RWR compared to the WR group, resulting in muscular adaptation for the fast-twitch plantaris muscle without any negative stress effects. Additionally, transcriptome data on the hippocampi revealed that 128 (sedentary x WR) and 169 (sedentary x RWR) genes were up-regulated (> 1.5-fold change) as compared with 97 (sedentary x WR) and 468 (sedentary x RWR) down-regulated genes (< 0.75-fold change). Functional categorization using pathway- or specific disease states-focused gene classifications and Ingenuity Pathway Analysis (IPA) revealed expression pattern changes in the major categories of disease and disorders, molecular functions, and physiological system development and function. Among the RWR specifically regulated genes, we found highly down-regulated SYCP3, PRL, PDK4 genes, inflammatory cytokines (IL1B, IL10, IL2RA, and TNF) and chemokines (CXCL1, CXCL9, CXCL10, CCL2, CCL13, and CCR4), which might help to counteract neuronal dysfunction and vulnerability. CONCLUSION: Our findings indicate that this is a first study presenting not only new information on the voluntary RWR influenced transcriptome in the rat hippocampus, but also these gene candidates are suggested to play a critical role in hippocampal plasticity.

Title: Examining the serine/threonine kinome in complex mental illness

Authors: *J. L. MCGUIRE[1], S. MARWAHA[2], A. A. FUNK[1], E. A. CAREY[1], J. H. HAMMOND[3], V. HAROUTUNIAN[4], H. R. EGHBALNIA[2], R. E. MCCULLUMSMITH[1]; [1]Psychiatry, [2]Mol. and Cell. Physiol., Univ. of Cincinnati, Cincinnati, OH; [3]Psychiatry and Behavioral Neurobio., Univ. of Alabama, Birmingham, Birmingham, AL; [4]Psychiatry, Mount Sinai Sch. of Med., New York, NY

Abstract: A kinome represents the full complement of protein kinase activity in a cell or tissue. High throughput peptide array screening was recently developed to identify altered kinase activity in tumor cells. These have been instrumental in the identification of new drug targets and therapies for multiple cancer types. Here we applied kinome array technology to investigate patterns of serine/threonine kinase activity in schizophrenia. We used complimentary approaches to more fully elucidate putative abnormalities in signaling cascades in schizophrenia. First, we analyzed peptides differentially phosphorylated between schizophrenia and control groups based on fold-change. We anticipated that small changes in kinase activity within related networks could profoundly effect cellular functioning without the gross abnormalities seen in cancer. 19 substrates were differentially phosphorylated +/- 1.15-fold. We used Ingenuity pathway analysis (IPA) to further analyze the dataset (dataset 1). IPA determines the probability (with associated p-values) that identified peptides act within particular known pathways. Functions and pathways with p-values less than .05 and containing > 5 peptides were considered most relevant. Second, we analyzed the kinome array using an algorithm calculating significance based on consistency rather than magnitude of signal changes. From this analysis we took the 10 substrates with the lowest p-values (dataset 2). These substrates partially overlapped with dataset 1. Dataset 2 was also analyzed using IPA. Finally, principal component analysis (PCA) was used to attempt to extract patterns in kinase activity differentiating schizophrenia and control subjects. PCA identified 10 components explaining 90% of the variance in the dataset. Only 1 component, containing a single substrate, differentiated schizophrenia from control. Separate IPA analyses of datasets 1 and 2 identified leukocyte development and differentiation, cytoskeletal remodeling, molecular transport, ion homeostasis, and Ca2+ mobilization as probable functions and pathways. Additionally, direct and indirect targets of protein kinase B (AKT) and the ERK and JNK mitogen-activated protein kinase pathways were overrepresented in both datasets. Total ERK1/2 and JNK1/2 protein was increased in schizophrenia however AKT protein was equivalent to the control samples. These analyses implicate relatively small changes across multiple components in key interrelated signaling cascades in schizophrenia and demonstrate the utility of this technology in investigating new avenues for drug development and targeted therapies in complex mental illness.

Abstract: Various types of neurons have been classified in accordance to morphology, biochemical and electrophysiological features. Recently, pinpointing of genes enriched in a given brain area as well as discovery of selective marker proteins for subtypes of neurons may allow for development of noble animal models in which certain animal behavior would be controlled and the underlying neural circuits could be elucidated in the system level. Hence, gene expression profiles provide an informative modality to define cellular diversity in the brain. Despite functional importance and practical applicability, genome-wide histological data sets have not be systematically produced and analyzed to be translated to easily accessible formats, yet. As a result, a limited set of established molecular markers have been utilized thus far whereas a vast majority of enriched genes at the select areas remain currently uncharacterized. Allen brain Atlas (ABA) offers huge expression data of mouse brain in public domains including ***in situ*** hybridization images. Here, we attempted to search noble candidate marker protein in a systematic way, from the ABA database and were able to successfully provide candidate genes for distinct neuronal subtypes in the mouse ventral tegmental area, which substantiates the usage of protocol and algorism for future studies.

Title: Noninvasive region- and cell-specific RNA acquisition from fixed and fresh frozen brain tissues using KuiqpicK

Authors: *S. L. KARSTEN, A. ZAVALA, Z. MA, L. C. KUDO;
NeuroInDx, Inc., Signal Hill, CA

Abstract: Current methods of region-specific RNA isolation involve either microdissection or fluorescence assisted cell sorting. Both methods are time-consuming, require expensive instrumentation, and result in the destruction/loss of the original and often rare tissue material that is under study. In addition, RNA isolation from the collected cells must be performed, thereby increasing the time and cost of such studies. We have developed a novel noninvasive approach for region-specific RNA acquisition from fresh frozen and fixed brain tissues that does not require microdissection or flow sorting procedures. RNA can be collected directly from the desired subanatomical regions, and used immediately for gene expression studies, including transcriptome analysis. Briefly, the tissue is evenly covered with a RNA capturing solution forming a gel like resin on the surface of a tissue section. Then taking advantage of a recently developed cell and tissue acquisition system, KuiqpicK (www.neuroindx.com/kuiqpick/), resin samples are collected from the corresponding region of a specific area, leaving the tissue intact. RNA contained in the collected resin is extracted using standard protocols and may be used directly for a range of downstream enzymatic reactions. Using this approach region specific RNA (e.g. dentate gyrus, CA1, 2, 3 areas of hippocampus) was collected from fresh frozen, sucrose treated and fixed brain tissues. Evaluation of isolated RNA for yield, degradation rates and suitability for cDNA synthesis and labeling protocols were performed. This protocol eliminates the necessity for tissue microdissection for acquisition of region-specific RNA and preserves potentially valuable tissue samples for further immuno-based studies. In addition to being rapid and simple, KuiqpicK provides near cellular resolution, which is critical for many downstream gene expression studies. Patent pending

Title: Characterization of post-synpatic density protein enrichment using targeted quantitative mass spectrometry methods

Authors: ***F. SAKAUE**[1], C. M. COLANGELO[2], L. M. CHUNG[3], T. B. ABBOTT[2], R. R. KITCHEN[1], A. C. NAIRN[1];

Abstract: The postsynaptic density (PSD) is a specialized protein complex at the synaptic junction of glutamatergic excitatory synapses. The protein components of the PSD, including neurotransmitter receptors, cytoskeletal proteins, and signaling molecules, can be altered by synaptic activity and drug exposure. Therefore, methodologies to quantify the changes in the abundance of PSD proteins should help our understanding of the molecular basis of synaptic plasticity. In this study, 112 proteins in PSD fractions prepared from rat brain were initially selected for analysis using multiple reaction monitoring (MRM) mass spectrometry based on the number of peptides detected, peak distribution and signal/noise ratio. However considerable variation in the levels of a sub-set of proteins was observed that was dependent on sample preparation. To produce more consistent data, we applied fraction-enrichment analysis and

analyzed the levels of a larger number of proteins than initially targeted by the MRM approach. Crude synaptoneurosome fraction (P2) and PSD fractions were prepared systematically and analyzed by SWATH LC-MS/MS, a novel data-independent acquisition technique. We examined the levels of ~1,700 proteins by SWATH that were differentially enriched in PSD compared to the P2 fraction. Bioinformatic analysis revealed classes of proteins that were enriched or excluded from the PSD fraction compared to the P2 fraction, and identified factors that contributed to higher levels of technical and biological variance for identified PSD proteins. The results from these studies will be helpful in defining proteins that exhibit robust association with the PSD, and that can be reproducibly analyzed by targeted mass spectrometric methods.

Title: Genomics and brain pathophysiology: Omega-3 fatty acid reprograms gene networks in the brain underlying the behavioral consequences of metabolic syndrome

Authors: *F. GOMEZ-PINILLA[1,2], Q. MENG[1], R. AGRAWAL[1], Z. YING[1], X. YANG[1]; [1]Integrative Biol. and Physiol., UCLA, LOS ANGELES, CA; [2]Dept of Neurosurgery,, UCLA, Los Angeles, CA

Abstract: Diet-induced metabolic syndrome (MetS) is becoming a major threat for neurological and psychiatric disorders. We previously found that rats treated with high fructose (15% in drinking water) developed peripheral signs of MetS and disturbances in learning and memory abilities (Agrawal et al., J Physiolo 2012). We profiled the transcriptome of the hypothalamus and hippocampus - brain regions with known functions in cell metabolism and cognition - of these rats by RNA sequencing. We discovered large-scale perturbations in gene expression in the hypothalamus and hippocampus with 581 and 146 genes showing differential expression and 99 and 53 genes with alternative splicing, respectively. We found that the dietary supplementation of docosahexaenoic acid (DHA), which ameliorates the unfavorable effects of fructose on the

brain, altered the expression of 654 and 462 genes, and exon splicing of 156 and 81 genes in the hypothalamus and hippocampus, respectively. Strikingly, among the hundreds of genes with expression changes in response to both fructose and DHA, 100% hippocampal genes and 98% hypothalamic genes demonstrated complete reversal of the directionality in gene expression. By integrating brain gene regulatory networks constructed from multiple rodent populations, we derived hippocampus and hypothalamus gene networks that entail the interactions among the genes affected by high fructose and DHA. We also identified shared key network regulators including Bgn, and Fmod which demonstrated opposite expression patterns under the two treatment conditions, suggesting dietary DHA normalizes the gene networks affected by fructose-induced MetS by affecting these key regulators. In summary, our study provides the much needed information on how MetS affects the interaction among multiple genes in brain regions involved in cognitive processing. Our results evoke a powerful strategy to target key aspects of the gene network organization with dietary agents such as, DHA to promote broad changes in the multifactorial spectrum of complex neurological disorders.

Title: Antigen and peptide microarrays reveal autoantibody targets in vaccine-induced narcolepsy

Authors: ***A. HÄGGMARK**[1], A. ZANDIAN[1], B. FORSSTRÖM[1], T. OLSSON[2], M. PARTINEN[3], M. UHLÉN[1], J. M. SCHWENK[1], P. NILSSON[1];
[1]SciLifeLab, KTH - Royal Inst. of Technol., Stockholm, Sweden; [2]Dept. of clinical neurosciences, Ctr. for molecular medicine, Karolinska Hosp., Solna, Sweden; [3]Dept. of Vaccines and Immune Protection, Natl. Inst. for Hlth. and Welfare, Helsinki, Finland

Abstract: Narcolepsy is regarded as a rare sleeping disorder with yet unknown cause, however, the specific loss of hypocretin producing neurons together with a strong HLA association have lead to the hypothesis that autoimmune components are involved. In several countries, the incidence of narcolepsy was dramatically increased after vaccination campaigns against the

pandemic H1N1 influenza in 2009. Children and adolescents were affected and symptoms were characterized by a higher prevalence of cataplexy as compared to narcolepsy patients with disease onset unrelated to vaccination. We have performed a broad scaled screening for novel autoimmunity targets by investigating the specificities of antibodies present in blood through antigen and peptide microarrays. In an initial screening stage, a Finnish cohort with 58 serum samples was analyzed for reactivity against 11500 antigens using planar microarrays with human protein fragments produced within the Human Protein Atlas project. Additionally, autoantibodies in narcolepsy samples were analyzed on ultra high density peptide microarrays containing 175 000 12-mer peptides with an overlap of 11 amino acids. Based on observations in the screening, 244 antigens and 40 peptides were selected and reactivity towards these were further investigated in an independent Swedish cohort including 179 narcolepsy patients and controls. This was performed in a suspension bead array setup where also previously published suggestions of autoimmune targets were included for profiling. The results from the massive screening and second stage validation revealed several potential autoantibody targets. The majority of them represented either of the following protein categories; enzymes, secreted proteins and membrane proteins. The identification of this set of autoimmunity targets, where the myelin protein zero-like 1 (MPZL1), plexin A3 (PLXNA3) and anoctamin 8 (ANO8) are among the most interesting, will after further exploration, have the potential to enable increased understanding and could finally shed some light on the disease mechanism behind vaccine-induced narcolepsy.

Title: RNA-sequencing implicates HMGN1 and HMGN2 in the modulation of transcriptional profiles of prefrontal cortex and hippocampus in mice

Authors: *P. LISOWSKI[1], S. ZHANG[2], T. DENG[2], T. FURUSAWA[2], M. BUSTIN[2];
[1]Dept. Mol. Biol., Inst. Genet. & Animal Breeding, Polish. Acad. Sci., Jastrzebiec N/Warsaw, Poland; [2]Lab. of Metabolism, Natl. Cancer Inst., Bethesda, MD

Abstract: High mobility group N (HMGN) family members are nucleosome-binding proteins that affect chromatin structure and modulate the fidelity of the cellular transcription profile. HMGN variants are expressed in most brain regions; however, their effect on the cellular transcription profile and on neurological functions is not known. Here, we study the role of this protein family in in the hippocampus (HP) and the prefrontal cortex (PFC)regions,by transcription profiling of genetically altered mice that either lack, or overexpress functional HMGN variants. Transcription profiles of 3 months-old wild-type (WT), HMGN1/2 double knockout (HMGN1/2 DKO), and HMGN1 overexpressing (HMGN1 OE) mice were analyzed by paired-end, deep RNA-sequencing, in triplicates, using IlluminaGAIIx. The sequence reads that passed quality filters were analyzed at the transcript isoform level with ANOVA and TopHat followed by Cufflinks. Approximately 100 of the transcripts showed differential expression in the WT vs. HMGN1/2 DKO and WT vs. HMGN1 OE, both in the hippocampus (HP) and the prefrontal cortex (PFC), with a fold change ≥ 2 and p-value <0.05. Functional annotation analysis revealed that loss or overexpression of HMGNs result in deregulation of genes involved in neurological system processes such as perception and cognition in the PFC while in the HP transcription of genes associated with neuronal signaling, RNA metabolic processes, transcription regulator activity, apoptosis, cell death, and cell homeostasis was affected. Thus, epigenetic factors such as HMGNs could affect the proper functioning of CNS by modulating the transcriptional profiles in adult brain. This preliminary study posits a potential role of HMGNs in neuropsychiatric disorders, and suggests targets for hypothesis generation on the role of HMGNs in adult brain.

Title: Molecular analysis of retinal neuronal mitochondria: Genome copy number and heteroplasmy

Authors: *D. R. MASSER[1], D. STANFORD[2], B. WRONOWSKI[2], W. M. FREEMAN[2]; [1]Physiol., The Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK; [2]Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK

Abstract: Diabetic retinopathy (DR), a secondary complication of metabolic dysregulation, remains the leading cause of blindness among working age adults. Although the pathophysiology of DR is not known, early deficits in retinal neuronal structure, function and gene expression occur in diabetic patients and these deficits have been recapitulated in experimental rat models. Mitochondria, the cellular organelle responsible for ATP generation through oxidative phosphorylation as well as calcium regulation, are implicated in neural deficiencies with DR in the retina. Mitochondria contain multiple circular 16.5 kb genomes (mtDNA), which encode necessary subunits of the respiratory chain. Maintenance of the mtDNA is important for mitochondrial health and function. We hypothesize that mtDNA copy number and maintenance are decreased with DR in retinal neuronal cells. In order to test this hypothesis, we have developed assays to quantify mtDNA copy numbers and assess mtDNA mutations and deletions, or degree of heteroplasmy, in retinal tissue from rat animal models. Absolute mtDNA copy number quantitation was achieved by using digital PCR (dPCR) with multiplexed custom TaqMan probe sets specific for mtDNA and nuclear DNA. Heteroplasmy was measured through mtDNA enrichment, rapid transposome-mediated library generation and next-generation sequencing. Sequencing reads were aligned to a mtDNA reference genome, and probabilistic variant detection and sliding window read depth analysis were carried out to identify mutations and deletions, respectively. We have applied these assays to retinal mtDNA isolated from the neural retina of non-diabetic Sprague-Dawley (SD) rats streptozotocin-induced diabetic SD rats, to test the effect of diabetes on mtDNA maintenance in the retina. Additionally, diabetic rats with systemic insulin treatment groups of differing durations were assessed to determine the effects of insulin replacement of mtDNA maintenance. These methods provide a powerful assessment of mtDNA maintenance in neuronal cell populations, which can be applied to any tissue or cell type, with metabolic dysregulation seen in diabetes.

Title: Three-dimensional (3-D) behavior analysis for mice using the commercial depth sensor

Authors: *A. TOYODA, T. GOTO, T. OKAYAMA;
Ibaraki Univ., Inashiki Ibaraki, Japan

Abstract: Behavioral tests of animals have been widely used for various studies of life sciences. Animal behaviors are often observed and evaluated by human eyes. Because the observations and assessments by humans are practically subjective and time consuming, many automated analysis systems for animal behaviors, especially for mouse behaviors have been developed and used for researches. Automated systems mainly use two-dimensional (2-D) images, while evaluating 2-D information has some difficulties in 3-D behaviors in mice. Therefore, we have been developing the analysis system for mouse behaviors using the commercial 3-D depth sensor, and will report the results of behavioral analysis for nest building and social interaction in mice at this annual meeting. Seven-week-old male C57BL/6J (B6) and retired ICR were used in this study. Mice were housed at room temperature (22 ± 1 °C) with exposure to light from 7:00 to 19:00 and ad libitum access to food and water. A cage was made with acrylic transparent boards which transmit near infrared light. A 3-D depth sensor (Xtion LIVE PRO, ASUS) was placed above the cage, and mouse behaviors were measured by the sensor following the data analyzes. Nest building and resident intruder tests were performed as the previous reports (Nature Protocols, 2006, Nature Neuroscience, 2006). All the experimental procedures followed the guidelines of the Animal Care and Use Committee of Ibaraki University. In the nest building test, we could observe the building processes of the nest using the 3-D depth sensor and finally evaluate the volume and shape of the nest. In the resident intruder test, B6 were repeatedly attacked by ICR and finally showed submissive postures as described previously. Using the depth sensor, we could evaluate and analyze the counts of biting and jumping behaviors in the tests. In the future, we try to apply this analysis system to other behaviors in mice and those in larger animals including farm animals.

Title: The calcium-activated chloride channel ANO2 as an autoimmunity target in multiple sclerosis

Authors: *P. NILSSON[1], B. AYOGLU[2], A. HÄGGMARK[2], J. M. SCHWENK[2], M. UHLÉN[2], N. MITSIOS[3], J. MULDER[3], L. ALFREDSSON[4], I. SKELTON KOCKUM[4], M. KHADEMI[4], T. OLSSON[4];
[2]SciLifeLab, [1]KTH - Royal Inst. of Technol., Solna, Sweden; [3]SciLifeLab, [4]Dept. of Clin. Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: Affinity proteomic strategies for broad and unbiased exploration of the autoimmunity repertoire hold a great promise towards identification and confirmation of novel antigenic targets in multiple sclerosis (MS). We have previously profiled IgG reactivity in a MS-related plasma sample cohort on protein microarrays with 11,520 protein fragments (representing 7,500 unique human proteins), which were generated within the Human Protein Atlas. Out of these, 51 were recognized differentially across the MS subtypes and non-diseased controls (Ayoglu B. et al., Mol Cell Proteomics, 2013). Here, we aimed to verify the significance of reactivities against these 51 targets, as well as other targets suggested from literature (e.g. KIR4.1), using plasma samples from a larger and independent cohort. Following the use of planar protein microarrays for the initial discovery stage, we here utilized suspension bead arrays for a multiplex profiling of IgG reactivity in 2,210 plasma samples against a set of 384 antigens while consuming less than a microliter of neat sample per analysis. Comparison of IgG reactivity in plasma from 1,106 MS patients and 1,104 non-diseased controls revealed anoctamin 2 (ANO2), a calcium-activated chloride channel also known as transmembrane protein 16B (TMEM16B), as a strong autoimmune target, which originated from our unbiased discovery approach. A statistically significant difference in positive reactivity between MS cases and non-diseased controls was found in particular for the intracellular N-terminal region of ANO2 (FDR-adjusted Fisher´s exact p-value=2x10-21). Further studies with available ANO2 antibodies in human post-mortem MS brain tissue revealed moderate staining in neuronal cell bodies and more prominent staining in reactive astrocyte-like structures from various parts of the tissue. A proteomic-based screening approach facilitated the discovery of anoctamin 2 (ANO2) as a novel autoimmune target candidate in multiple sclerosis, which was here verified in an independent set of 2,210 plasma samples. Subsequent efforts will reveal the contribution of the identified target to disease pathogenesis.

Title: Screening gene variants for disruption of microRNA binding activity and application to optic nerve degeneration in glaucoma

Authors: *A. N. DUBINSKY[1], A. R. LA SPADA[2,3], T. GAASTERLAND[4,5,6];
[1]Pediatrics, UC San Diego, La Jolla, CA; [2]Dept. of Pediatrics, Sch. of Med., [3]Dept. of Cell. and Mol. Med., [4]Inst. for Genomic Med., [5]Scripps Inst. of Oceanography, [6]Bioinformatics and Systems Biol. Program, UCSD, La Jolla, CA

Abstract: We aim to identify microRNA activity in glaucomatous optic nerves that may confer risk or progression in glaucoma, the second leading cause of irreversible blindness affecting over 60 million people worldwide. Primary open angle glaucoma (POAG) is the most common subtype of glaucoma and has complex genetics. Visual field loss is due to loss of axons in the optic nerve through apoptosis of retinal ganglion cells. Several genes were connected to glaucoma through genome-wide association, linkage and family studies. Our exome sequencing of 295 POAG patients identified potential causal variants in 90 genes, including 12 with variant sites in 3' untranslated regions (UTR). Such variants may significantly alter binding sites for microRNAs. Technologies are needed for accurate and efficient screening of microRNA binding site disruption by genome variants, and for tissue-specific microRNA regulation of genes implicated in disease through exome sequencing. Available algorithms to computationally predict binding sites have limitations that hinder their application to assess binding site differences due to genome variation. Existing binding site predictions require substantial computation and, in some methods, simulation of binding to generate predictive scores. For example, many databases that serve computed sites neglect the second arm of microRNA hairpins, which have been observed to be loaded preferentially into the microRNA RISC complex under tissue- or time-specific conditions. To address this shortcoming and analyze microRNA effects in glaucoma, we developed a novel, efficient process called ZoomMiR which allows detection of seed sites and ranks microRNAs for experimental screens. To validate

ZoomMiR output, we developed a novel method to assay disrupted seed sites in a reporter gene system. This dual luciferase reporter system permits the quantitation of binding of, and hence regulation by, a computationally ranked miRNA. We applied this method to variations found in POAG patients. Importantly, we identified a 3'UTR glaucoma risk SNP in CDKN2B and demonstrated it disrupted binding of a specific miRNA. Further, next-gen sequencing of microRNA from optic nerve and retina identified optic nerve-specific microRNA which ZoomMiR predicts bind several of the 90 genes associated with POAG through our exome sequencing. Together, ZoomMiR and our novel experimental approach provide critical screening functionality to identify genome variants that disrupt microRNA binding sites. We used the system to establish a molecular mechanism for a glaucoma risk SNP found through GWAS.

Title: Transcriptional profiling of *Drosophila* optic lobe neurons

Authors: *K. KAPURALIN[1], M. WERNET[1], C. DESPLAN[1,2], A. DEL VALLE RODRIGUEZ[1];
[1]New York Univ. Abu Dhabi, Abu Dhabi, United Arab Emirates; [2]Dept. of Biol., New York Univ., New York, NY

Abstract: The optic lobe development and function depends on the precise regulation of gene expression. However, our understanding of the complexity and dynamics of the transcriptome of neurons in the *Drosophila* brain is very limited. The main aim of our project is to generate a transcriptional profile for *Drosophila*'s optic lobe neurons and to correlate this transcriptome with their different defining anatomical and functional characteristics. Next generation RNA sequencing technology will allow us systematic characterization of the complete gene-expression profile of individual neuron types. Applying this technique to specific cell types requires a method for the isolation of specific subpopulations of cells, a laser based flow cytometry fluorescence-activated cell sorting. We have been screening unique database of *Drosophila* mutants in which transcriptional activator GAL4 is placed under the control of endogenous regulatory elements. Each GAL4 line is crossed to a UAS-GFP reporter line placing the

expression of GFP under the positive control of GAL4 in the progenies. Analysis of whole mount brain preparations is used for identifying and characterizing the morphology of neuronal populations. Flip-out technique followed by neuroimaging technique of confocal microscopy is used to confirm the single-cell specificity of GFP expression in the cell types of choice. GAL4 driver lines restricted to one neuron type in a specific neuropil of the optic lobe are selected for further studies. Adult optic lobes from those animals are dissected, tissue is dissociated into single cell suspension and individual neuronal types are separated according to their differences in GFP intensity and cell size by FACS sorting. Cell populations that are over 98% pure are further used for gene expression analysis. Transcriptional profiling of isolated single-cell types has the power to identify network of genes, neurotransmitters, receptors, peptides and transcription factors expressed by the individual neurons and to characterize neuronal diversity respectively. By combining molecular biology screening techniques with computational methods, we expect to uncover genetic programs responsible for controlling a neuron location, shape, synaptic connections and neurotransmitter synthesis. Understanding the dynamics of transcriptome is essential for studying the complexity of transcriptional regulation and its impact on phenotype and regulatory mechanisms that control differentiation.

Title: Label-free 3D imaging of live neurons

Authors: ***G. POPESCU**[1], T. KIM[2], C. LIU[2], M. U. GILLETTE[2];
[1]Univ. of Illinois At Urbana-Champaign, Urbana, IL; [2]Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Many of traditional investigations on neuronal culture are based on imaging methods, such as phase contrast of fluorescence microscopy, which are limited to 2D plane measurements. However, in reality, neurons from a 3D network, which eventually run throughout the entire living organism. Therefore, it is very important to investigate neurons using 3D imaging modalities. With the advances in biochemical markers and laser technology, fluorescence confocal microscopy has become one of the main methods to investigate live cells or a system of cells, such as embryonic body, in 3D with a high resolution. However, fluorescence confocal microscopy requires fluorescence markers that ultimately modify the live samples. Furthermore, the high-power laser illumination of the imaging system causes photo-toxicity which adversely affects live cells. Therefore, this 3D imaging technique is not optimal for live cell imaging in 3D. White-light diffraction tomography (WDT) is a recently developed tomographic imaging technique based on quantitative phase imaging (QPI) (Kim et al., Nat Photon, 8, 2014). This technique is based on a commercial phase contrast microscope upgraded with a QPI module, therefore, uses low-irradiance white-light illumination and also the environmental control to keep the specimen unaffected by the external stress. Based on a QPI method, this technique provides a 3D map of the refractive index distribution of the sample, which relates to the 3D distribution of the non-aqueous content within the cell. The sub-micron resolution of this technique is suitable for single cell imaging and the sub-cellular structures can be resolved in all three dimensions. Using this technique, both hippocampal neurons and dorsal root ganglion (DRG) neurons have been imaged in 3D. Throughout all of the imaging process, the neuronal samples are kept unmodified and live. Structures, such as nucleoli and nuclear membrane, within the cell body have been resolved in 3D. Furthermore, the 3D structure of neuronal processes has also been imaged. Dendritic connections made between two neurons have also been imaged. These results reveal that these connections are in fact made in 3D, connecting neurons at different heights from the bottom of the culture dish. Further optimization of this technique can reveal new and unique insights into the dynamics of the formation of neuronal circuits.

Title: Imaging Applications to Study Cells *in vivo* and *in vitro*

Authors: T. HUHTALA[1], V. JANKOVIC[2], *T. LAITINEN[1], K. LEHTIMÄKI[1], U. HERZBERG[2], A. NURMI[1];
[1]Charles River Discovery Res. Services Finland, Kuopio, Finland; [2]Celgene Cell. Therapeut., Warren, NJ

Abstract: Different cell types are currently under evaluation to be used as a novel methodology to treat various diseases and acute injuries. Before proceeding to clinical studies with cell administrations to patients, several properties need to be studied *in vivo* and *in vitro*. Imaging modalities like SPECT/CT and MRI offer effective tools to study e.g. ADME properties or local concentration of cells *in vivo*. Due to physical properties of these imaging technologies, SPECT/CT is suitable for ADME studies since whole-body imaging can be easily performed in rodents using small animal scanners. Also, high sensitivity of radiolabeled cells makes it optimal methodology to compare cell distribution from various areas and excretion from several time points within an individual. Also, possible effects of administration route can be easily compared. However, the anatomical resolution in SPECT is not optimal and differs from MRI's resolution, which especially in soft tissue is excellent. This makes MRI an effective tool for more detailed study e.g. cell concentration in specific tissue or organ. However, to track cells with MRI, cells need to be labeled for visualization. In our studies we have used Indium-oxine (^{111}In-ox) for SPECT/CT and ultrasmall superparamagnetic iron oxide (USPIO) in MRI to track and quantify cells *in vivo* and *in vitro*. Labeling efficiency with In-ox is high (ca. 80 %) with no effect on cell viability. After labeling, distribution of cells has been studied from various time points using SPECT/CT. More precise quantification of ^{111}In-ox labeled cells can be done using gamma counter analysis *post mortem*. Since the number of administered cells and total injected dose are known at the time of injection, results can be converted to cell number in organs at the time of termination. To measure sensitivity of MRI and the lowest number of detected cells, a titration curve of cells internalized with USPIO was generated using absolute T2 weighted MRI. Briefly, a titration curve consisting of 0 - 1e^6 cells in Matrigel was generated to determine the smallest measurable number of cells *in vitro*. In summary, current imaging modalities such as SPECT/CT and MRI offer extensive tools to study various properties of cells *in vivo* and *in vitro*.

Title: Exposures to cholinesterase inhibitors leads to persistent impairments of axonal transport *in vitro*

Authors: *J. GAO[1], J. MAGRANE[2], C. HERNANDEZ[1], A. TERRY[1];
[1]Pharmacol. and Toxicology, Georgia Regents Univ., Augusta, GA; [2]Dept. of Neurol. and Neurosci., Weill Med. Col. of Cornell Univ., New York, NY

Abstract: Axonal transport is a critical process in neurons that is responsible for the movement of mitochondria, lipids, synaptic vesicles, receptors and other key macromolecules to and from the neuron's cell body. It plays an essential role in neuronal function, neuronal maintenance and integrity, as well as synaptic transmission. Impairment of axonal transport has recently emerged as a common feature in several neurodegenerative disorders such as Alzheimer's disease, Parkinson's disease and Huntington's disease, and there is now substantial evidence that exposures to environmental toxicants may be a contributing factor. Previous studies in our laboratory indicate that organophosphate (OP)-based cholinesterase inhibitors can lead to protracted deficits in cognition in rodent models and that impairments in axonal transport (as indicated by deficits of vesicle movements in peripheral nerves *ex vivo*, mitochondrial movements in primary neuronal cultures *in vitro*, etc.), may represent a potential underlying mechanism of the cognitive dysfunction. In order to evaluate the effects of OP exposure on fast axonal transport of membrane bound organelles (MBOs), we transfected the amyloid precursor protein that has been tagged with a fluorescent protein Dendra (APPdendra) into primary cortical neurons and then treated them with the (OP)-based cholinesterase inhibitor, diisopropyl fluorophosphate (DFP). The percentage of stationary and mobile (anterograde and retrograde) MBOs and their velocities (μm/sec) was determined by a time-lapse imaging technique. Compared to vehicle-treated control axons (where the majority of APP movement was in the anterograde direction) DFP exposure resulted in more retrograde movements, a decrease in velocity, and a significant increase in the number of stationary MBOs. These preliminary results indicate that DFP can alter the fast axonal transport of MBOs that contain APP and provide further evidence that OPs can impair the neuronal trafficking of important macromolecules.

Abstract: Axonal transport is a fundamental process in neurons that is responsible for the movement of important macromolecules to and from a neuron's cell body through the cytoplasm of its axon. There is increasing evidence that impairments in axonal transport may contribute to the pathology of some neurological illnesses (e.g., Alzheimer's disease) especially those where cognitive function is impaired, and further, that exposures to environmental toxicants may be a contributing factor. The results of our animal experiments to date with the insecticide, chlorpyrifos and the nerve agent, diisopropylfluorophosphate, have established that subthreshold exposures (operationally defined as doses not associated with acute toxicity) to organophosphate (OP)-based cholinesterase inhibitors can lead to protracted deficits in cognition and that impairments in axonal transport may represent a potential underlying mechanism, as determined in primary neuronal cultures (*in vitro*), peripheral nerve preparations (*ex vivo*) and brain. The objective of the work described here is continue this line of research to evaluate the effects of subthreshold OP exposures on axonal transport *in vivo* (i.e., in the living mammalian brain). We took advantage of manganese (Mn)-enhanced magnetic resonance imaging (MEMRI) to image and tract-trace Mn-enhancement/s along a neural pathway connecting the retina to the superior colliculus and lateral geniculate nucleus. We hypothesized that exposing animals to the same OP-treatment regimens previously associated with cognitive dysfunction would also result in impaired Mn transport in brain. Adult male Wistar rats were administered a single, unilateral Mn chloride injection (intravitreal, 40 micromole/rat) then MEMRI was conducted 6 and 24 hr later in order to compare the Mn-enhancement between eye and optic nerve projections. OPs were administered subcutaneously (sc) and subjects were divided into two groups based on exposure period. In the acute exposure group, animals were co-administered OP (sc) and Mn (intravitreal). In the chronic exposure group, animals were administered OP (sc) for 14 consecutive days. To

detect persistent axonal transport disruptions in the chronic exposure groups, MEMRIs were acquired for each animal at baseline (pre-OP exposure) and compared to a short (24-hr) and extended (30-day) washout period timed from the last injection. To date, using the same dosing paradigm previously associated with cognitive dysfunction, our data indicate that axonal transport is impaired by OPs in the living rodent brain in a dose-dependent manner and that these impairments can persist up to 30 days after washout.

Title: A multicompartment microfluidic culture system for extended long-term fluidic isolation and study of axonal neurobiology

Authors: *T. SARMA, H. H. CAICEDO, G. PIGINO, S. BRADY;
Univ. Illinois Chicago, CHICAGO, IL

Abstract: Current *in vitro* compartmentalized culture methods for studying central nervous system axonal biology preclude relevant biological experimentation. We have developed and optimized an open-top multicompartmentalized microfluidic neuronal culture chamber that not only allows isolation of different neuronal subcellular compartments (i.e., either somatodendritic or axonal domains) into separate and precisely defined biochemical microenvironments but also allows extended long-term fluidic isolation between different compartments, efficient on-chip immunocytochemistry, in-situ cell transfection and optimum live cell imaging studies primary neurons and axons. Additionally, to allow targeting of proximal axons without affecting cell bodies, we engineered a central channel to facilitate fluid flow without the need of external pumps and tubing. We used our culture platform to study trafficking of p38-mCherry expressing-synaptic vesicles by fast axonal transport in isolated axons, using genetic and pharmacological manipulations. The results presented here document an optimized compartmentalized culture system that facilitates relevant biological experimentation for studying CNS neurons and subcellular compartments.

Title: Riesz transform-assisted differential interference contrast imaging: Application to three-dimensional kinematic analysis of the growth cone motility

Authors: *A. TAMADA[1,2,3], M. IGARASHI[1,2];
[1]Niigata Univ. Grad. Sch. of Med. and Dent. Sci., Niigata, Japan; [2]Ctr. for Transdisciplinary Research, Niigata Univ., Niigata, Japan; [3]PRESTO, Japan Sci. and Technol. Agency, Kawaguchi, Japan

Abstract: Differential interference contrast (DIC) microscopy has been frequently used for the high-contrast live-cell imaging without phototoxic fluorescent labeling. However, the shadow-cast appearance of DIC images along the shear axis has hampered three-dimensional (3D) visualization by the reconstruction of z-scanned images and an application of quantitative intensity-based image processing. To overcome these defects, we devised a novel technique that converts the non-linear shadow-cast DIC images into the linearized self-luminous images using the Riesz transform, known as a multidimensional extension of the one-dimensional Hilbert transform. The transform is a combination of the first-order Riesz transform along the shear axis that shifts the phase by 90 degrees, and the second-order transform along the orthogonal axis that reverses the phase. This transform succeeded in efficiently removing the shadow of DIC images and converting them to the images whose intensity reflected the optical depth of objects. We applied this novel Riesz transform-assisted DIC (RT-DIC) imaging technique to the visualization and quantitative analysis of the 3D growth cone motility in 3D collagen gel cultures. Reconstruction of the time-lapsed 3D RT-DIC images revealed a complex 3D motility of filopodia. These filopodia exhibit overall retraction, tip extension and right-screw rotation

(Tamada et al., J Cell Biol 188, 429 [‘10]), which were driven by the retrograde actin flow, actin polymerization and left helical actomyosin interaction, respectively. We further developed the automated, mathematical methods for analyzing the growth cone motility and structure. The structural feature was estimated by “the structure tensor”, which is defined as the second-moment matrix of image gradients. The filopodia were visualized as fiber-like structures estimated by the fractional anisotropy, calculated from the eigenvalues of the structure tensor. The direction of filopodia was estimated by the minor eigenvector. Motion parameters including acceleration, jerk and angular velocity were calculated from the velocity by the Frenet-Serret formulas. We concluded that we succeeded in full kinematic description of growth cone motility using these 3D RT-DIC images, suggesting that the methods described here will provide a precise kinematic analysis with a conventional label-free DIC microscopy.

Title: Gfp+ human stem cell derived neurons amenable to high content neurite outgrowth assays

Authors: J. LE[1], *S. L. STICE[2];
[1]ArunA Biomed. Inc., ATHENS, GA; [2]Dept Animal & Dairy Sci., Univ. Georgia, ATHENS, GA

Abstract: Adverse outcome pathways (AOP) are conceptual frameworks that portray existing knowledge concerning the linkage between a molecular initiating event and an adverse outcome. High throughput screening (HTS) and high content screen (HCS) approaches seek to gain a greater perspective of the AOP, leading to more efficient and reliable identification of adverse outcomes of compounds and chemicals. However, HCS assays often utilize primary or stem cell sources which are not amenable to large scale screening and can require extensive cell culture, fixation and permeation, and immunocyotochemistry prior to imaging. Thus, major costs are associated with 96-well and 384-well based high content neurotoxin screening. In addition, preserving or fixative steps can alter cell architecture and a new plate of cells is required for each time point, thus introducing variability to data. These GFP+ human stem cell derived neurons

were developed to provide a scalable solution to the previously labor intensive, single-end-point, and hence limited nature of neurotox assays, while preserving the breadth and quality of data. These neurons are differentiated from embryonic stem cell derived human neural progenitors that have been genetically modified with a non-viral vector encoding a Green Fluorescent Protein (GFP) reporter gene driven by a ubiquitous promoter. A method was developed to demonstrate their ability to form clonal colonies capable of proliferation and neural differentiation. Our previous hN2™ human neuronal cells faithfully reproduced early brain development, providing a cell model that is > 90% positive for β-III tubulin and >60% positive for MAP2. A new differentiation method has been developed which increases MAP2 expression to >90%, resulting in more mature neurons that exhibit significantly longer neurite length post-thaw. These GFP+ neurons maintain an adherent monolayer that is amenable to both high content imaging as well as high throughput screening. They have successfully been used in a neurite outgrowth assay to measure the effects of the neurotoxin bisindolylmaleimide 1 on neurite length. Our previous hN2™ cells demonstrated higher sensitivity to neural toxins than mouse cortical neurons, and our new GFP+ neurons are equally sensitive. By eliminating the need for fixing and staining cells, these GFP+ human neurons provide a scalable means to analyze neurite outgrowth in live cells spanning the course of hours to days following exposure to test compounds.

Title: Live imaging of the axon initial segment

Authors: *A. S. DUMITRESCU, M. P. MEYER, M. S. GRUBB;
Kings Col. London, London, United Kingdom

Abstract: The axon initial segment (AIS) is a specialised neuronal compartment involved in the maintenance of axo-dendritic polarity and in the generation of action potentials. Recent work has uncovered a great deal concerning the molecular composition of the AIS and its development. The AIS has also been shown to be a novel site for neuronal plasticity, as changes in ongoing activity levels *in vitro* and *in vivo* result in significant alterations in the structure's position or size. However, all findings described so far have been based on experiments carried out on fixed samples offering only a snapshot view. We are now pursuing live imaging experiments in order to follow the AIS as it undergoes plastic changes in real time, making use of two systems: (1) *in vitro* rat hippocampal dissociated cultures and (2) *in vivo* zebrafish. For the *in vitro* part of the project we have successfully live-labelled AISs with two separate plasmid constructs: a fusion protein of 270kD ankyrinG and GFP (AnkG-GFP), and a YFP-tagged AIS targeting sequence used by voltage-gated sodium channels (NavII-III-YFP). We have used them to follow rapid structural changes at the AIS in cultured dentate granule cells (DGCs), which undergo activity-dependent AIS shortening when chronically depolarised for only a few hours. The larval zebrafish is our model of choice for AIS *in vivo* imaging; however at the current time there is almost nothing known regarding the AIS in this animal model. We have started to address this significant gap in knowledge by developing tools to visualise the AIS in both fixed samples and live larvae. In an initial set of experiments on 5-7dpf zebrafish wholemount fixed tissue, we labelled individual AIS-like structures in retinal ganglion cells (RGCs), tectal and cerebellar neurons using antibodies against voltage gated sodium channels (Pan-Nav), the cell adhesion molecule neurofascin, and a custom-made zebrafish-specific antibody against AnkG. In parallel we have started to create zebrafish-specific fluorescently-tagged AIS live imaging probes. We are now testing the expression pattern of two constructs for this purpose: GFP-tagged fusion proteins of a beta sodium channel subunit (Navβ4-GFP) and neurofascin (NF-GFP). Once able to image AISs in both fixed and live zebrafish, we will exploit the power of this model organism to watch the structure develop and adapt, live and *in vivo*, during controlled manipulations of sensory experience.

Title: Thermal noise driven bio-nanomachine distinguishes between apoptotic and necrotic cell engulfment by macrophages

Authors: *V. V. DIDENKO, C. L. MINCHEW;
Neurosurg., Baylor Col. of Med., HOUSTON, TX

Abstract: We describe a new type of bio-nanomachine which runs on thermal noise. The machine is solely powered by the random motion of water molecules in its environment. The construct can rapidly detect DNA damage produced during phagocytic engulfment of dying cells in cell suspensions. Such suspensions, ranging from cultured cells to clinical biopsy specimens and blood test samples, are widely used in cell biology and biomedical research. The construct distinguishes the macrophages engulfing apoptotic cells from the macrophages digesting necrotic cells. The reaction takes 3 minutes. The positive detection is signaled by fluorescence at 525 nm. By being both a nanodevice and a biological probe, the new construct bridges the fields of bio-nanotechnology and cell biology. It can be useful in cell death studies as a real-time sensor. Analysis of its operation principles can be instrumental for the development of future molecular-scale appliances for biomedicine.

Title: Neuronal phagocytosis in SH-SY5Y cell culture and in rat brain

Authors: *V. WALLACE, L. FORTUNO, J. HINKLE, B. WARREN, R. MADANGOPAL, M. HENDERSON, B. HARVEY, B. HOPE;
NIH/NIDA, Baltimore, MD

Abstract: Endocytosis plays a central role in regulating intracellular homeostasis and extracellular interactions in the brain and includes the uptake of material into cells via pinocytosis (particles smaller than 0.5um) and phagocytosis (particles larger than 0.5um). While microglia are generally considered the resident phagocytes of the central nervous system, neurons can also participate in phagocytosis. Yet little is known about the phagocytic capacity of neurons and the role of neuronal phagocytosis in both normal neuron function and pathological states. Our objective is to assess the phagocytic capacity of neurons in cell culture and in brains of behaving rats. *In vitro* experimentation will elucidate the effect of particle concentration on passive endocytosis, cell viability, and intracellular particle localization. We are currently investigating the capacity of undifferentiated SH-SY5Y neuroblastoma cells to endocytose large particles (0.5-1.5um fluorescent microspheres) with different surface charges (positive, negative, and neutral). Fluorescence and confocal microscopy are used to assess particle uptake and cell viability. Subcellular distribution of particles in SH-SY5Y cells will be examined by immunolabeling cellular organelles. We are also undertaking *in vivo* studies to assess the extent of neuronal phagocytosis in different brain regions. Rats will be injected with different concentrations of positive, negative and neutral fluorescent microspheres, and brains will be examined at different time points following injections. We will use histochemistry of formaldehyde-fixed tissue to assess uptake into different cell types, including neurons, microglia, astrocytes, and oligodendrocytes. Fluorescently labeled cells will be further analyzed by flow cytometry to quantitate particle uptake into the various cell types. We hypothesize that different neuronal cell types in the highly heterogeneous brain will exhibit different capacities for phagocytosis.

Title: Minimally disruptive quantification of endogenous calcium binding using fluorescent lifetime imaging (FLIM)

Authors: *E. A. MATTHEWS, D. DIETRICH;
Dept. of Neurosurg., Univ. Clin. Bonn, Bonn, Germany

Abstract: While whole-cell patch clamp recordings have provided a wealth of information about the activity and function of neurons, one draw-back of the method is the dialysis of cellular components during the recording period. When using a patch pipette to infuse calcium dyes into the cell, endogenous calcium binding proteins - such as Calbindin - are at least partially removed, thus perturbing the natural calcium binding environment by adding an exogenous binding species while simultaneously removing or diluting the endogenous species. This problem can be mitigated by single cell electroporation of calcium dyes; however, with electroporation the exact concentration of added dye is not exactly known, which may limit the precise quantitative analysis of the resulting calcium transients. We have developed a 2-P laser scanning based approach to derive highly precise quantitative information about the resting calcium, activity induced increases in free calcium, and dye concentration using time correlated single-photon counting fluorescent lifetime imaging (FLIM) and single cell electroporation in dentate granule (DG) cells. Two calibrations are required for this approach: 1) calibration of the fast and slow fluorescent lifetime decay constants with free calcium concentration, and 2) calibration of the dye concentration in the cell based on a bead ratio. For the first calibration, we performed an *in vitro* determination of the effective K_d (151.8 nM), and the fast and slow fluorescent lifetime decay time constants of OGB-1 ($\tau_{fast} = 3.08 \times 10^{-10}$s; $\tau_{slow} = 2.83 \times 10^{-9}$s). For the second calibration, we lowered a pipette containing a standardized fluorescent bead next to neurons whole-cell patch clamped with known dye concentrations. After adjusting the somatic fluorescence for free calcium concentration, the ratio of the bead brightness to the cell soma at different dye concentrations yielded a calibration curve. These standardized beads are used in all subsequent experiments to control for electroporation efficiency. DG cells from P22-P30 mice were electroporated with OGB-1. In control experiments, patching the cells after electroporation revealed that cells were healthy and capable of firing action potentials. A stimulating pipette in the hilus provided antidromic stimulation to induce dendritic calcium transients from back

propagating action potentials. 2-P FLIM line scans (4-10 ms) from the dendrites were acquired during antidromic stimulation, and resting calcium concentration and free calcium concentration during stimulation were analyzed by biexponential reconvolution fitting. Dye concentration in each cell was determined by the bead ratio at the soma.

Title: Improving signal dynamics of fluorescent protein voltage sensors by optimizing FRET interactions

Authors: ***U. SUNG**[1], M. ALLAHVERDIZADEH[1], L. JIN[2], T. HUGHES[3], L. B. COHEN[1,2], B. J. BAKER[1];

Abstract: FRET (Fluorescence resonance energy transfer)-based voltage sensors can be especially useful for monitoring neuronal activity *in vivo* because the ratio of signals between the donor and acceptor pair removes common source noise. We aimed at improving the performance of protein voltage sensors by optimizing FRET interactions between donor and acceptor fluorescent proteins located in the voltage sensitive domain of the *Ciona intestinalis* voltage sensitive phosphatase. We designed a series of constructs with insertions of the two fluorescent proteins at different locations in the voltage sensitive domain. We engineered a total of 39 different combinatorial constructs to evaluate 6 different locations in the N-terminus of the voltage sensitive domain for one fluorescent protein and 8 different locations at the C terminus of the domain for the other fluorescent protein. Evaluation of voltage sensitive optical responses identified amino acid residues or combinatorial positions in the voltage sensitive domain linked to voltage responses with large signals, fast kinetics, and low membrane potential at half

maximum signal change. We found voltage sensors, named “Nabi”, with improved signal size (up to 16% ΔF/F) and faster time constant (~2 msec) compared to previously reported FRET based voltage probes. Nabi2 probes expressed well in cultured neurons and had easily detectable responses to individual action potentials. The Nabi2 responses were substantially faster than those of the fluorescent voltage sensor, ArcLight.

Title: The discovery of a novel conopeptide that is active in the mammalian nervous system from the worm-hunting Conus virgo

Authors: *S. S. ESPINO[1], J. IMPERIAL[2], M. AGUILAR[4], J. GAJEWIAK[2], M. WATKINS[3], R. TEICHERT[2], B. OLIVERA[2];

Abstract: The cone snails have proven to be a vast resource of biologically active natural products. These compounds known as conotoxins/conopeptides are especially interesting because they exhibit a very high degree of selectivity and potency towards their molecular targets. This research aims to discover novel conopeptides that are active in the mammalian nervous system from Conus virgo, a member of a clade of worm-hunting cone snail. This clade has not been previously explored for conopeptides that target the mammalian nervous system. Bioactivity guided purification using calcium imaging of dissociated mouse dorsal root ganglion (DRG) neurons led to the discovery of a conopeptide that inhibits the increase in intracellular calcium concentration upon depolarization with 20 mM potassium and 20 μM veratridine. Veratridine is a compound that delays the inactivation of voltage-gated sodium channels (VGSCs). This peptide is 32 amino acids long, cross linked by three disulfide bridges and is

provisionally named VrVIA. Analysis of the VrVIA precursor showed a very high degree of sequence similarity with the precursor sequence of omega-conotoxin GVIA (ω-GVIA) and omega-conotoxin MVIIA (ω-MVIIA). ω-GVIA and ω-MVIIA are potent antagonists of the N-type calcium channel (Cav2.2). Intracerebroventricular (ICV) injection of 1.0 nmol VrVIA into mice elicited a distinct behavioral phenotype characterized by hyperactivity and excessive grooming. This is different from the shaking phenotype elicited by ICV injection of ω-GVIA and ω-MVIIA. The differences in behavioral phenotype suggest that VrVIA may not target the N-type calcium channel. The inhibition of the increase in intracellular calcium concentration by VrVIA under the previously described depolarizing condition was observed in small, medium and large diameter neurons. Three types of inhibitory effects were observed. The first type was a rapidly reversible inhibition seen in a majority of the affected neurons. A small population of affected neurons exhibited a slowly reversible inhibition while another small population was irreversibly inhibited. Depolarizing the cells using 40 mM potassium occluded the inhibitory effect of VrVIA. In contrast, a modest inhibition by VrVIA was observed when cells were depolarized by the application of 20 mM potassium. The inhibitory effect was strongest when the inactivation of VGSCs was delayed by veratridine, suggesting that VGSCs are the probable target of VrVIA. The identification of the molecular target of VrVIA is currently being pursued.

Title: Live-cell imaging of individual endocytosis of AMPA receptor around postsynaptic membrane

Authors: *S. FUJII, H. TANAKA, T. HIRANO;
Dept. Biophys.,Grad. Sch. Sci. Kyoto Univ., Kyoto, Japan

Abstract: In the central nervous system, AMPA receptor (AMPAR) plays a major role in excitatory synaptic transmission. The efficacy of transmission changes depending on the neuronal activity, which is called synaptic plasticity and regarded as a basal mechanism of learning and memory. During expression of synaptic plasticity, the number of AMPAR is

dynamically controlled. AMPARs show substantial mobility such as lateral diffusion, exocytosis and endocytosis, which seem to change during synaptic plasticity. In the last decade, researchers have attempted to reveal trafficking of AMPARs during synaptic plasticity, and advances of imaging techniques have made it possible to observe lateral diffusion of AMPAR using quantum dot, and discrete exocytosis event using Total Internal Reflection Fluorescence Microscopy (TIRF). However, it has been difficult to observe individual endocytosis event of AMPAR. Here, we report visualization of individual endocytosis event of AMPAR using the pH-sensitive GFP variant, super ecliptc pHluorin(SEP)-tagged AMPAR and TIRF, both of which have been commonly used for observation of exocytosis. In addition, we changed extracellular pH intermittently to visualize vesicles containing AMPAR, which have been internalized just before the pH change to 6. At pH6, the fluorescent signal from SEP fused to AMPAR on the cell surface became undetectable, and only signals from SEP in intracellular vesicles with neutral pH were detected. Further in this study, we formed postsynaptic-like membrane (PSLM) on a glass surface using neurexin-coated glass (Tanaka et al., 2014 Nature Protocols), and succeeded in detecting endocytosis around PSLMs. Using this experimental method, we observed stimulus-triggered endocytosis of AMPAR. Bath application of NMDA enhanced endocytosis of AMPAR around PSLM, which might be related to long-term depression. Thus, a new methods to record individual endocytosis event of postsynaptic AMPAR has been established, which will contribute to study regulation mechanisms of the number of postsynaptic receptors both in a basal condition and during synaptic plasticity.

Title: Simultaneous voltage-sensitive dye (VSD) imaging of both surfaces of leech ganglia

Authors: ***A. STOWASSER**, D. A. WAGENAAR;
Biol. Sci., Univ. of Cincinnati, Cincinnati, OH

Abstract: One major goal for studying how information is processed by a nervous system is the development of techniques that allow recording the activity of a large number of neurons at once. In this context, the voltage sensitive dye VF2.1.Cl has been proven promising because the dye is very fast, sensitive, and non-toxic. Already, this dye has allowed the simultaneous observation of the activity of most of the neurons on one side of a leech ganglion. To take full advantage of this technique, we now developed a method that allows the simultaneous observation of both surfaces of a ganglion. With our customized double microscope we imaged simultaneously neural activity of both (dorsal and ventral) surfaces of isolated leech ganglia. Optical crosstalk between the layers was substantial, but could be effectively suppressed algorithmically. Stereotyped electrical activity associated with local bending in response to P-cell stimulation could be successfully reconstructed from VSD image sequences from both surfaces simultaneously. The technique should extend readily to other situations in which the activity of two distinct layers of neurons needs to be monitored.

Title: Bongoori is a genetically-encoded fluorescent protein voltage sensor that resolves action potentials at 60 hz in neurons

Authors: H. PIAO[1], B. KANG[1], D. RAJAKUMAR[1], A. JUNG[1,2], *B. J. BAKER[1];
[1]Ctr. for Functional Connectomics, Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of;
[2]Col. of Life Sci. and Biotechnology, Korea Univ., Seoul, Korea, Republic of

Abstract: Genetically-encoded fluorescent sensors of membrane potential fuse a fluorescent protein to a voltage-sensing domain. Using cassette mutagenesis to alter conserved charged and polar residues in the voltage-sensing domain changed the speed of the optical response, the size of the optical response, and the voltage-sensitivity of the optical response. Comparison of the voltage-sensing phosphatase from Ciona to other species identified several conserved charged and polar amino acids residing in the transmembrane domains. Mutations in the S2 and S4

transmembrane domains had the largest effect on voltage-sensitivity and signal speed. One mutation in the S1 transmembrane domain yielded an omega current. A combination of three mutations in the voltage-sensing domain and the tweaking of the linker sequence between the voltage-sensing domain and the fluorescent protein, super ecliptic pHlorin A227D yielded a new probe, Bongwoori, capable of resolving action potentials in primary cultured hippocampal neurons at 60 hz.

Title: *In vivo* quantification of amygdala subnuclei using 4.7t fast spin echo imaging

Authors: ***A. AGHAMOHAMMADI SERESHKI**[1], F. OLSEN[2], N. V. MALYKHIN[3]; [1]Ctr. for neuroscience, Univ. of Alberta, Edmonton, AB, Canada; [2]Biomed. Engin., [3]Ctr. for Neuroscience, Biomed. Engin., Univ. of Alebrta, Edmonton, AB, Canada

Abstract: Introduction: The amygdala an almond-shaped structure in the medial temporal lobe which is involved in the processing of emotions and memory. Changes in the amygdala have often been implicated to the pathophysiology of many neurological disorders. The amygdala consists of an evolutionarily primitive subdivision associated with the olfactory system (the cortico-medial region) and an evolutionarily recent subdivision associated with the neocortex (the basolateral region). The cortico-medial region includes the cortical, medial, and central nuclei, while the basolateral region consists of the lateral, basal and accessory basal nuclei. Over the past decade, interest in the human amygdala has grown considerably, spurred on by the progress in animal studies and the development of neuroimaging methods. However, the current information about function in the human amygdala has mainly been at the level of whole amygdala structure. The goal of the present study was to develop a comprehensive volumetric Magnetic Resonance Imaging (MRI) protocol which enables quantification of the amygdala subnuclei *in vivo*, to best correspond with its anatomical subnuclei. Method: Sixteen healthy

volunteers (8 males and 8 females, aged 18-47 years) with no prior history of neurological disorders were recruited. Images were acquired on a 4.7 T Varian Inova scanner with T2-weighted 2D FSE and whole brain T1-weighted 3D MPRAGE sequences. Our detailed volumetric protocol for the amygdala has been previously reported. In addition, we manually segmented the amygdala into five subnuclei (lateral, basal, accessory basal, cortical, and centromedial group) using DISPLAY Software (MNI, Montreal, QC), defined by the internal anatomy of the amygdala and neighbouring structures. Results: Intra-rater ICCs (intraclass correlations coefficient) for amygdala and its subregions were as follows: 0.93 for the amygdala, 0.97 for the lateral nucleus, 0.98 for basal nucleus, 0.98 for accessory basal nucleus, 0.92 for cortical nucleus and 0.88 for the centromedial subregion. Amygdala subnuclei volumes were consistent between hemispheres and showed distributions within the amygdala that were consistent with histological data. Conclusion: We developed a reliable MRI volumetric protocol for segmentation of the amygdala subnuclei *in vivo* for the first time. Future applications of this technique to psychiatric and neurological disorders may reveal new information about vulnerability of amygdala subnuclei to specific pathology.

Title: Lensed fiber optic stimulator for single neuron

Authors: *J. LEE[1], J. JANG[2], H. KIM[1], N. JEON[2], W. JUNG[1];
[1]biomedical engineering, Ulsan Inst. of Sci. and Technol., Ulsan, Korea, Republic of; [2]Seoul Natl. Univ., seoul, Korea, Republic of

Abstract: Optical stimulation has advantages of being noninvasive, high spatial resolution in two or three dimensions, and large-scale patterned stimulation over the existing electrode methods. To apply intrinsic characteristics of optical stimulation to *in vitro* and *in vivo* experiments, many fiber optic probes have been developed such as fiber optic light guides with uncaged neurotransmitters and two-photon optogenetic stimulation (TPOS). However, it has

known that the conventional probes has a restriction on focusing the light due to the property of light diffraction, so that it has difficulty of simulating the single neuron. In this study, we develop a optical stimulator based on lensed fiber for single neuron stimulation. We tried different fibers such as single mode fiber, photonic crystal fiber (PCF), band-gap fiber varying wavelength, pulsed width, and fiber length to explore characteristic of light delivery. Ball lensed fiber made it possible to focus light with the advantage of high coupling efficiency, strong focus power, and simplicity of fabrication. We also investigated the numerical analysis of fiber optic stimulator to derive optimal design. Numerical results reported optical performance of probe in terms of working distance (>2mm) and beam diameter (<10μm). In addition, photolysis technique of uncaged neurotransmitters was used with guided light. We explored the degree of uncaging dependent on duration, intensity and wavelength (350 ~800 nm) of light. To demonstrate the feasibility of fiber optic stimulation, cortical neurons in rat brain slice were optically activated. Evoked regular action potentials were recorded by extracellular electrodes and then numerous spikes in single cell were sorted out from the intricated electrical signals. This new type of optical stimulator is expected to become a new experimental method for investigating neural network in brain slice non-invasively.

Title: All-optical manipulation and recording of neural circuit activity *in vivo*

Authors: *A. M. PACKER, H. W. DALGLEISH, M. HAUSSER;
Wolfson Inst. for Biomed. Res., Univ. Col. London, London, United Kingdom

Abstract: Probing neural circuits at the spatial and temporal resolution at which they function is crucial to understanding how populations of neurons work together to drive behavior. Optical approaches provide a means to directly address these questions in a minimally invasive manner. We have developed an all-optical strategy for activating and recording the same neurons with cellular resolution in mice *in vivo* using a dual two-photon optogenetic and calcium imaging approach. The strategy relies on viral coexpression of a genetically encoded activity sensor (GCaMP6s) in conjunction with a red-shifted opsin (C1V1). A spatial light modulator enables targeting tens of user-selected neurons for temporally and spatially precise, simultaneous optogenetic activation using 1064 nm excitation. In parallel, simultaneous fast calcium imaging with single action potential resolution provides readout of the manipulation as well as its effect on hundreds of other neurons. We calibrated the reliability and temporal precision of both activation and readout of activity using cell-attached targeted patch clamp recordings from identified neurons. The combination of indicator sensitivity and lack of spectral overlap between the optogenetic excitation and GCaMP6s emission wavelengths minimizes the stimulation artifact. Thus, even for a single spike, the observed GCaMP fluorescence transient is larger than the optical artifact. The optical nature of the approach combined with a chronic window preparation provides the flexibility to select individual neurons for stimulation while the animal is awake and behaving under the microscope over weeks to months, and the ability to target activation of neurons which are normally active during a behavioral task. We demonstrate proof-of-principle experiments by activating groups of layer 2/3 pyramidal neurons in mouse barrel cortex in defined spatiotemporal patterns during behavior. Our method enables high-throughput, flexible, and long-term optical interrogation of neural circuits in the mammalian brain *in vivo*.

Title: *In vivo* optical and electrophysiological simultaneous recordings of auditory responses in mouse's inferior colliculus using a micro-endoscope

Authors: *H. YASHIRO[1], I. NAKAHARA[4,5], K. I. KOBAYASI[2,3], K. FUNABIKI[4,5,1], H. RIQUIMAROUX[1,2,3];
[1]Grad. Sch. of Life and Med. Sci., [2]Dept. of Biomed. Information, Fac. of Life and Med. Sci., [3]Neurosensing and Bionavigation Res. Ctr., Doshisha Univ., Kyoto, Japan; [4]Grad. school of Biostudies, Kyoto Univ., Kyoto, Japan; [5]Dept. of Systems Biol., Osaka Biosci. Inst., Osaka, Japan

Abstract: The *in vivo* imaging is a powerful method to reveal neural circuits of interest. Many studies have been conducted with confocal microscopes and fluorescence microscopes. Those microscopes could get images which had very high spatial resolution. On the other hand, it has been difficult to observe circuits located deep in the brain below cortex. Recently, penetrable endoscopes using an optical fiber bundle or GRIN lens were reported to solve those problems. However, those methods utilizing microscopes used to have very low temporal resolution compared to electrophysiological recording methods. We, therefore, developed a micro-endoscope system which enables us to record optical fluorescence and electrical neural activities simultaneously. The micro-endoscope was fabricated from a fiber bundle in which six-thousands of single mode fibers were bundled. The probe tip was gold-coated and further coated with enamel for insulation to be used as an electrode. The tip of fiber was beveled as pencil-tip-like shape for minimum invasion. Usually the impedance of electrodes was around 200 kΩ. Using our micro-endoscopic system, we could successfully in record fluorescence intensity change of calcium ion indicator dye (Oregon green 488 BAPTA-1 AM, Invitrogen), local field potentials (LFPs), and unit activities through endoscope tip at the same time from an identical recording site in the mouse's inferior colliculus (IC). In optical recording, calcium responses (ΔF/F) with sound stimuli (50 ms white noise burst or tone burst) were in the range of 3 ~ 6 %. By systematically changing the sound frequencies (5 ~ 60 kHz) and sound pressure levels (15 ~ 95 dB SPL, re: 20 μPa), we could measure frequency tuning of the recording sites which are above the observable range of conventional confocal microscope (for example, from at the depth of 380, 500, and 1500 μm from brain surface). Furthermore, there were several different activated areas activated by different sound stimuli in the same view field. In electrophysiological recording, neural activities were recorded in the range of 1 Hz ~ 10 kHz with 20 kHz sampling. In PC, we separated this electrical signal into LFPs (4 - 50 Hz) and unit activities (300 - 5000 Hz) by using a digital filter in Matlab (MathWorks). Thus, our micro-endoscopic system allows us to record calcium responses and electrical neural activities in the same area. This new system will be useful in analyzing several neural circuits, including the auditory system.

Title: Simultaneous Imaging of EB3 and ATP reveals the mechanism of cell shape control in HeLa cells

Authors: *R. SUZUKI, K. HOTTA, K. OKA;
Keio Univ., Kouhoku-Ku, Yokohama, Japan

Abstract: Although adenosine triphosphate (ATP) is a major energy source of cells, only a little is known about cytosolic ATP dynamics because of its analytical difficulty. Recent research showed that sponge's choanocyte, which engages in flagella's movement, has high level of ATP (Bilela et al., 2011). We, therefore, guessed that cytosolic ATP concentration changes during cytoskeletal movement or cell morphological change, especially at the peripheral region of the cell because of their high motility and limited volume. We used two fluorescent proteins: ATeam (ATP indicator based on Epsilon subunit for analytical measurements, Imamura et al., 2009) and EB3-mCherry (End binding protein 3 fused to mCherry). We can estimate ATP level by calculating the FRET ratio of ATeam. EB3 binds to the plus ends of microtubules, and fluorescent labeled EB3 is used for an indicator of microtubule dynamics. Moreover, EB3 probe also diffuses within cells, so we can detect the form of lamella, which consists of microtubule, and is an approximate form of the cell. We first observed HeLa cell expressing these two proteins under the physiological condition. Then, the fluorescent images were processed using hand-made computer software. Next, we choose some regions in the cell edge, and estimated relative ATP concentration, EB3 density, and the area of newly-generated cell edges. By calculating cross correlation among time-course of these parameters, we showed that EB3 accumulation induces lamella form's change, and this change involves rise of ATP concentration in these specific regions. Cell edge also has structure named lamellipodia or filopodia. These structures consist of actin filaments, and can be visualized by using FM4-64 which is a fluorescent dye visualized for cell membrane. Simultaneous observation of EB3-Venus and FM4-64 showed that there is a correlation between morphological change of lamella and that of filopofdia or lamellipodia. We also observed spatiotemporal ATP behavior before and after application of microtubule polymerization inhibitor, Taxol. Before the inhibition, cytosolic ATP is especially high at the peripheral area. After the inhibition, high ATP concentration area is

expands to all over the cytosol. These results indicate a possible : 1) ATP concentration of peripheral area is always maintained high. 2) EB3 accumulation at the edge of the cell induces lamella form's change and local ATP concentration increase. 3) lamella form's change causes lamellipodia or filopodia form's change, and the ATP is consumed during morphological changes of filopodia or lamellipoidia.

Title: Functional consequences of Na,K-ATPase topology in dendritic spines revealed by superresolution microscopy and 3D finite element modelling

Authors: ***H. B. BRISMAR**[1,2,3], T. LIEBMANN[2,3], O. MANNEBERG[1,3], A. APERIA[2,3], H. BLOM[1,3];
[1]KTH, Royal Inst. of Technol., Stockholm, Sweden; [2]Women's and Children's Hlth., Karolinska Institutet, Stockholm, Sweden; [3]Sci. for Life Lab., Stockholm, Sweden

Abstract: The Na,K-ATPase (NKA) plays an essential role for ion homeostasis in all mammalian cells, including neurons. It is one of the most abundant proteins in the brain and also the protein that consumes the largest fraction of energy in the brain. NKA exists as a heterotrimeric α/β/γ protein complex, where α is the catalytic subunit. Neurons express two α isoforms: the ubiquitous α1 (ATP1a1) and the neuron-specific α3 (ATP1a3). ATP1a3 has a lower sodium affinity and it is suggested that it is important for the efficient restoration of intracellular sodium following excitatory synaptic activity. Despite the enormous importance of NKA there is as yet little known about the isoform specific dynamic distribution and regulation in neurons. We have used super-resolution microscopy to dissect the spatial distribution of the neuron specific α3 and the ubiquitous α1 isoforms. The microscopic findings of dendrite and

spine localization of the protein have been used to create 3D finite element models for analysis of intracellular sodium maintenance in different models of synaptic activity. Super-resolution STED microscopy of antibody labelled NKA revealed a discrete distribution of proteins in both dendrites and spines. The findings were supported by PALM super-resolution microscopy based on PAGFP and mEos modified NKA isoforms. For quantification of protein density, the STED measurements were used as a lower estimate and the PALM measurements as an upper estimate. Mathematical modelling of an isolated dendritic spine with a discrete distribution of NKA based on the nanoscopic findings suggest that a discrete localization of NKA in spines lead to an efficient isolation of intra-spine Na+. Topologically discrete concentration of NKA in the spine neck contributes to an energy efficient restoration of intra-spine Na+. Based on findings from super resolved imaging and 3D finite element modelling we suggest that a compartmentalized distribution may have implications for the generation and regulation of intra-cellular sodium gradients.

[1]George Mason Univ., Fairfax, VA; [2]Univ. of Chicago, Upton, IL

Abstract: Copper (Cu), iron (Fe), and zinc (Zn) are found in small quantities in the brain, where they play a vital role in human health. Typically these trace metals are bound to proteins forming metalloproteins in neurons and glia, although some are found loosely bound or free in synaptic

vesicles. In the hippocampus, vesicular zinc has been shown to modulate synaptic transmission and plasticity by affecting the activity of both GABA and NMDA receptors thereby influencing inhibitory and excitatory transmission in the brain. While zinc is important for neuromodulation, excess zinc can be deleterious to health and has been found to reduce copper absorption. Like zinc, copper too plays a role in synaptic transmission and it's intracellular/extracellular levels are regulated by the ATP7A copper pump, which is found in large quantities in hippocampal pyramidal cells and interneurons. The role of iron in the hippocampus is less clear, though hippocampal pyramidal cells express a specific extracellular iron binding receptor, and studies have shown that knockout rodent models that fail to express this receptor have deficits in learning and memory. Because these metals are so vital to the brain's physiological state, insufficient intake or excess intake of Cu, Fe, and Zn can adversely affect human health. In fact, dyshomeostasis of these metals in the brain have been implicated in many neurodegenerative diseases such as Alzheimer's, Parkinson's, and Huntington's, by increasing production of reactive oxygen species and increasing the rate of cell death. It is important to gain greater insight into how these metals are distributed in the brain to gain greater understanding of both their physiological role, as well as their role in the diseased brain. With the use of beamline X-26A National Synchrotron Light Source at Brookhaven National Laboratory, we were able to visualize the spatial distribution of copper, iron, and zinc in rat hippocampus at concentrations below 20 ppm. In contrast to other methods, X-26A allows for the simultaneous visualization of metals at a spatial resolution of 5μm within a given region of the brain, and allows for visualization of both bound and free metal ions without tissue destruction. Thionin staining was performed in addition to synchrotron fluorescence to confirm the distinct separation of metal ion distribution in different cellular layers of the hippocampus. The results reveal that zinc is mostly distributed in dentate gyrus and CA3, with a similar pattern of distribution for iron, though iron appears to extend into CA1. Copper on the other hand appears to be restricted to areas of entorhinal cortex rather than dentate gyrus and CA regions.

Title: Identifying the intracellular zinc stores

Authors: Q. LU[1], H. HARAGOPAL[2], *Y. V. LI[3];
[1]Mol. and Cell. Biol. program, [2]Biol. Sci., [3]Biomed. Sci., Ohio Univ., Athens, OH

Abstract: Zinc is known to play an important role in regulating various physiological processes. In protein- bound form, it is involved in DNA and protein synthesis, hormone packaging, mitosis, apoptosis, and many other cellular functions. Unbound/free zinc is currently proposed to be a key modulator of intra- and intercellular neuronal signaling similar to calcium. Interestingly, the level of free zinc in neurons is tightly regulated. Indeed, like calcium, copper (II) and iron (III), disruptions in neuronal zinc homeostasis have been directly correlated with various neuropathological disorders like epilepsy, Alzheimer's disease, and Parkinson's disease. Outside of nervous system, cellular free zinc regulates insulin secretion, bone mineral density, and inflammation. Therefore, knowledge on intracellular zinc distribution is critical to understanding cellular zinc homeostasis. However, there is still a lack of comprehensive imaging data for it. Here, we used a membrane permeable zinc fluorescent indicator, Zinpyr1 along with organelle-specific fluorescent dyes to visualize the subcellular free zinc in 3 cell lines: Cath.a (neuronal), HIT-T15 (pancreatic beta cell-like), and HeLa (cervical cancer) cells. In the study, we treated the cells with 10uM of Zinpyr1 that was paired with 10uM of ER Tracker Red (stains endoplasmic reticulum/ER), 0.5uM MitoFluor Red 589 (stains mitochondria) or 10uM of BODIPY TR-ceramide (stains Golgi apparatus). We report from our colocalization data that free zinc is present within the ER, the Golgi apparatus and mitochondria but not the nucleus. Our studies in both neuronal and non-neuronal cell lines suggest that ER, mitochondria and Golgi apparatus are the general intracellular storage depots for free zinc.

Title: Synthesis and initial *in vivo* evaluation of [125I]iodoASEM, a radioligand for the α7 nicotinic acetylcholine receptor

Authors: R. MEASE[1], Y. GAO[1], T. TRAN[2], K. KELLAR[2], D. WONG[1], R. DANNALS[1,2], *M. POMPER[1], A. HORTI[1];
[1]Radiology, Johns Hopkins Univ., Baltimore, MD; [2]Georgetown Univ., Washington, DC

Abstract: The α7 nicotinic cholinergic receptor (α7-nAChR) is a cationic, ligand-gated calcium channel with five identical ligand-binding subunits. The α7-nAChR system has been implicated in a wide variety of pathologies of the central nervous system, including Alzheimer's disease, schizophrenia and neuroinflammation. Non-invasive study of the α7-nAChR may uncover new aspects of the physiology of this receptor system, enable characterization of disease states with which it is associated and may hasten drug development. We recently reported a series of 3-(1,4-diazabicyclo[3.2.2]nonan-4-yl)dibenzo[b,d]-thiophene-5,5-dioxide derivatives, many of which possess sub-nanomolar affinity towards α7-nAChR. Within that series is [18F]ASEM, the first target-selective radiopharmaceutical for imaging α7-nAChR in primate brain with positron emission tomography (PET). Also within that series is 3-(1,4-diazabicyclo[3.2.2]nonan-4-yl)-6-iodobenzo[b,d]thiophene-5,5-dioxide (iodoSEM, Kd < 300 pM), the radioiodinated form of which we describe here. Precursor 3-1,4-diazabicyclo[3.2.2-nonan-4-yl)-6-(3,3-dibutyltriazeno)dibenzo[b,d]thiophene dioxide (A-55) was synthesized either from diazotination of 6-amino-3-(1,4-diazabicyclo[3.2.2]nonan-4-yL)-dibenzo[b,d]-thiophene-5,5-dioxide followed by reaction with dibutylamine, or by Pd coupling of 3-bromo-6-(3,3-dibutyltriazeno)dibenzo[b,d]thiophene-5,5-dioxide with 1,4-diazabicyclo[3.2.2]nonane. Radioiodination was performed from A-55 in acetonitrile followed by addition of a solution of [125I]NaI then trifluoroacetic acid, with heating at 80oC for 20 min. The reaction mixture was purified by reverse phase radio-HPLC to produce [125I]iodoASEM. Radiochemical yields approximated 27% with specific radioactivities on the order of 55.5 GBq/μmole. Intravenous administration of [125I]iodoASEM to CD-1 mice generated brain uptake values over 5% ID/g in cortex and superior colliculus, known α7-nAChR target regions, at 1 h post-injection. Receptor blockade using the known α7-nAChR ligand, SSR180711 (s.c., 2 mg/kg), decreased uptake in superior colliculus to < 1% (P = 0.007), indicating binding selectivity. No blockade was evident in cerebellum. [125I]iodoASEM demonstrates high, regionally specific binding to α7-nAChR in rodent brain and can be used for quantification of α7-nAChR *in vitro* or *in vivo* with single photon emission computed tomography (SPECT) in pre-clinical experimental models. Notably, isotopic substitution with 123I or 124I could enable clinical translation for SPECT and PET, respectively.

Title: Characterization of [3H]LS-3-134, a novel arylamide phenylpiperazine D3 dopamine receptor selective radioligand

Authors: *R. R. LUEDTKE, Ph.D.[1], C. RANGEL-BARAJAS[1], M. MALIK[1], M. TAYLOR[1], K. A. NEVE[2], R. H. MACH[3];
[1]Dept Pharmacol & Neurosci, Univ. North Texas Hlth. Sci. Cter, FORT WORTH, TX; [2]DVA, Oregon Hlth. & Sci. Univ., Portland, OR; [3]Radiology, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: LS-3-134 is a substituted N-phenylpiperazine derivative that has been reported to exhibit a) high affinity binding (Ki value 0.2 nM) at human D3 dopamine receptors, b) >100-fold D3 vs. D2 dopamine receptor subtype binding selectivity and c) low affinity binding (Ki values >5,000 nM) at sigma 1 and sigma 2 receptors. Based upon a forskolin-dependent activation of adenylyl cyclase inhibition assay, LS-3-134 is a weak partial agonist at both D2 and D3 dopamine receptor subtypes (29% and 35% of full agonist activity, respectively). [^{3}H]-labeled LS-3-134 was prepared and evaluated to further characterize its use as a D3 dopamine receptor selective radioligand. Kinetic and equilibrium radioligand binding studies were performed. This radioligand rapidly reaches equilibrium (10-15 min at 37°C) and binds with high affinity to both human (Kd = 0.06 ± 0.01 nM) and rat (Kd = 0.2 ± 0.02 nM) D3 receptors expressed in HEK-293 cells. Direct and competitive radioligand binding studies using rat caudate and nucleus accumbens tissue indicate that [^{3}H]LS-3-134 selectively binds a homogeneous population of binding sites with a dopamine D3 receptor pharmacological profile. Based upon these studies we

propose that [^{3}H]LS-3-134 represents a novel D3 dopamine receptor selective radioligand that can be used for studying the expression and regulation of the D3 dopamine receptor subtype.

Title: Segmented analysis of astrocytic restructuring induced by chronic hypoxia in the adult mouse cortex

Authors: H. MAEDA[1], M. NITTA[1], T. SUGASHI[1], H. KAWAGUCHI[2], H. TAKUWA[2], H. ITO[2], I. KANNO[2], *K. MASAMOTO[1,2];

Abstract: The astrocytes play a major role in the maintenance of neural and vascular homeostasis in the brain. In response to hypoxia, the astrocytic processes change their shapes and increase contacts with the neighborhood vessels. These morphological changes are considered as an important mechanism in adaptation to brain hypoxia. In the present study, to characterize the compartmentalized differences in the structural plasticity of the astrocytes, we quantify the spatiotemporal dynamic changes in the astrocytic soma and process morphologies during adaptation to hypoxia in *in vivo* mouse cortex. Animal use and experimental protocols were approved by the Institutional Animal Care and Use Committee. The 3D structures of the astrocytes were repeatedly imaged with multi-photon microscopy (TCS SP5MP, Leica Microsystems) at 900-nm excitation, while the animals were exposed to limited oxygen environment (8-9% oxygen conditions) for 3 weeks. On each imaging date, the astrocytes were labeled with sulforhodamine 101 (5-10 mM in saline, 8 μL/g body weight i.p.), and the cortical image (1,024 pixel × 1,024 pixel, 0.3 μm/pixel) was taken through cranial window with a step size of 2.5 μm or 4 μm over 0 to 400 μm depths from the cortical surface. The obtained images were analyzed with a custom-written software in MATLAB (MATLAB2012b). First, a square region of interest (ROI; approximately 50 μm × 50 μm) was manually placed around the target

astrocytes at a center slice of the depth stack astrocytic images, and a total of 10 sequential slices were three-dimensionally extracted within ROI for each single astrocyte image. Then, the extracted images were three-dimensionally reconstructed. Finally, the number and area of the astrocytic processes, and somatic area were measured for each astrocyte. A total of 202 astrocytes were randomly extracted over depths of 0-300 μm in the mouse somatomotor cortex (N = 3 animals). We observed the maximum areas of the both astrocytic soma and processes at a depth of 150 μm in the cortex; 84 μm^2 and 136 μm^2, respectively, under pre-hypoxia treatment control conditions, while the number of the processes monotonically decreased with increasing depths in the measured cortex. After adaptation to 3-week hypoxia, the astrocytic soma was enlarged 1.5 to 2.0 fold relative to the pre-hypoxia control. In addition, a number of the processes also increased 1.5 to 2.0 fold. These data showed that the increase of the astrocytic cell volume was caused by the both increase of somatic volume and a number of the processes. In conclusion, the present analytical method allows for quantification of the compartmentalized differences of the astrocytic structure plasticity.

Title: Combining molecular genetics with constellation pharmacology to identify neuronal cell types

Authors: ***R. W. TEICHERT**[1], Y. ZHENG[2], D. D. GINTY[3], B. M. OLIVERA[1];
[1]Dept. of Biol., Univ. of Utah, Salt Lake City, UT; [2]Dept. of Neurobio., Harvard Med. Sch., Cambridge, MA; [3]Dept. of Neurobio., Harvard Med. Sch. and Howard Hughes Med. Inst., Cambridge, MA

Abstract: Recently we have published several papers that outline a pharmacological approach to identify and classify neuronal cell types in the mammalian nervous system. We call this approach “constellation pharmacology” because we use pharmacology to elucidate the cell-

specific combinations or “constellations” of receptors and ion channels that define each neuronal cell type. Notably, each neuronal cell type is distinguished by its unique expression pattern of plasma-membrane receptors and ion-channel subtypes that are functionally integrated to produce cell-type-specific physiological properties. We have developed and validated pharmacological assays that can interrogate a broad spectrum of G-protein coupled receptors (GPCRs), ligand-gated ion channels and voltage-gated ion channels in ~200 individual cells simultaneously, using changes in cytosolic calcium concentration as a read-out. In essence, constellation pharmacology incorporates functional calcium imaging with a large toolkit of highly selective pharmacological agents, including target-selective peptides, toxins, drugs, other small molecules and natural products. The cellular responses to each pharmacological agent can be used to parse heterogeneous neuronal/glial cell populations into subpopulations or subclasses. Such phenotypic responses also elucidate the specific receptor and ion-channel subtypes that are expressed in each cell type. The available toolkit of selective pharmacological agents is vast and continuously growing, but there are still conspicuous gaps in the toolkit that do not allow us to identify the entire constellation of receptors and ion channels in each neuronal cell type. However, we can overcome this problem by combining constellation pharmacology with other methods that also identify neuronal cell types and that can be used to further elucidate their cell-specific constellations. We are currently combining constellation pharmacology with mouse molecular genetics to create a more integrated and comprehensive definition of cell types in the nervous system. We illustrate the coupling of constellation pharmacology with several examples of genetically labeled (fluorescent) somatosensory neuronal subclasses. Among many results, we highlight a functional difference in KV1.2 potassium channels between proprioceptors and low-threshold mechanoreceptor neurons. We also demonstrate key differences in the functional expression of GPCRs between various somatosensory neuronal subclasses, using a combination of molecular genetics and constellation pharmacology.

Abstract: Genetically encoded fluorescent reporters are a common and invaluable tool for neuroscience. Many of the well-known and frequently used reporters such as green fluorescent protein (GFP), yellow fluorescent protein (YFP), mCherry, etc. have certain limitations for imaging neuronal populations. For example, they have low signal to background ratios, photobleach easily, and experience high tissue absorption when attempting deep tissue imaging (>500 μm). Infrared fluorescent protein (iRFP) is a genetically encoded fluorescent probe engineered from a bacterial phytochrome photoreceptor that has excitation/emission spectra (690 nm/ 713 nm) inside the near-infrared window, thus allowing for deeper tissue penetration and lower tissue auto-fluorescence because of its minimal absorption by hemoglobin, melanin, and water. iRFP's unique structure gives it high photostability as compared to the other known fluorescent reporter proteins. These properties of iRFP make it potentially useful for studies of neuronal function in the intact or slice-prepared brain. We have previously reported several adeno-associated viral (AAV) vectors containing the iRFP gene, including a membrane-restricted expression (mem-iRFP), and two translationally fused with the optogenetic proteins channelrhodopsin (ChR2) and halorhodopsin (eNpHR3.0) which demonstrated the successful transduction and expression of iRFP in neurons both *in vitro* and *in vivo*. We have now created several transgenic rat lines, on both the Sprague-Dawley and Long Evans backgrounds, that express iRFP in a Cre-dependent manner. We have crossed our line of dopaminergic transporter (DAT) promoter driven Cre expressing rats with our Cre-dependent iRFP (DIO-iRFP) rats. These double transgenic rats may facilitate neuroscience research, particularly in models of dopaminergic neuron dysfunction that occurs in drug addiction and Parkinson's disease. Overall, we have demonstrated that iRFP is a useful reporter protein for studying and manipulating rat neurons.

Title: *In vivo* imaging of CREB phosphorylation using a novel transgenic mouse line expressing bioluminescence probes

Authors: *T. ISHIMOTO, H. MANO, H. MORI;
Univ. of Toyama, Toyama 930-0194, Japan

Abstract: Cyclic adenosine monophosphate response element binding protein (CREB) is a transcription factor that is considered important for memory consolidation and recovery process of depression. Once serine 133 of CREB is phosphorylated, kinase inducible domain (KID) of CREB binds to KIX domain of CREB binding protein, and the downstream gene expression is induced. However, the spatiotemporal pattern of the phosphorylation of CREB *in vivo* has not been fully analyzed because of technical difficulty. We employed the split luciferase technique to monitor the phosphorylation of CREB in live cells and animals. In this technique, firefly luciferase was cleaved into N-terminal and C-terminal segments. The KID and KIX domains were fused with N-terminal and C-terminal segments of luciferase respectively. By the interaction between these two fusion proteins mediated by serine 133 phosphorylation of KID, split segments complement each other to be a functional luciferase that can emit light. The light emission was increased in response to forskolin treatment that up-regulated cAMP in HEK293T cells expressing probe proteins. The increase was cancelled by replacement of the serine 133 to alanine in the probe protein suggests the process is phosphorylation-dependent. To generate transgenic mouse line that expresses probe proteins, the bacterial artificial chromosome clone containing beta actin promoter and protein-coding region was used to insert the probe protein genes flanking IRES sequence by homologous recombination at the start codon was used. We found increased light emission from cerebral cortex of live transgenic mouse after the acute treatment of imipramine, a tricyclic antidepressant. Increase in CREB phosphorylation in cerebral cortex by the same treatment was confirmed using western blotting. These results demonstrate this transgenic mouse strain can be used for the imaging of CREB phosphorylation in live mouse brain. Furthermore, we also show the changes in pattern of CREB phosphorylation after reserpine treatment that is known to induce depression-like symptoms in mouse.

Title: Resin-free electron microscopy of nervous tissue: Preserved cytokeleton and immunogold labeling in a 3D ultrastructural landscape

Authors: V. VENKATARAMANI, H. HORSTMANN, *T. KUNER;
Functional Neuroanatomy, Heidelberg Univ., Heidelberg, Germany

Abstract: Conventional electron microscopy of cytoskeletal elements embedded in resin suffers from at least two fundamental drawbacks: fine filamentous structures are poorly visible and immunogold labeling is incompatible with detailed ultrastrucure. Here we introduce a novel approach applicable for scanning electron microscopy revealing intact cellular cytoskeleton and immunogold labeling in a highly detailed ultrastructural landscape of cells in their natural context. We sought to overcome charging effects in the scanning electron microscope which distort the image and hence lower the resolution. With a resin-free preparation we were able to enhance the electrical conductivity significantly thus achieving higher resolution scanning electron microscopy images of tissue blocks (~150 um thick) and Tokuyasu cryosections (300 nm thick). The resin-free method combines the modified rOTO-lead aspartate block stain with subsequent critical point drying. The surface of tissue blocks or sections was imaged with a SEM equipped with a field emission gun. To characterize the ultrastructure of nervous tissue on a molecular level we established pre-embedding immunogold labelling for tissue blocks and sections. We applied this approach to study the ultrastructure of the presynaptic calyx of Held and its postsynaptic principal neuron. The images reveal a complex filamentous cytomatrix with embedded synaptic vesicles, clathrin-coated vesicles, mitochondria and endosomal structures. The plasma membranes can be readily identified and active zone matrix as well as postsynaptic densities are clearly visible. Synaptic vesicles appear interconnected by filamentous structures and some are tethered to the active zone by short filaments. Postsynaptically, mitochondria, Golgi apparatus and endoplasmatic reticulum are suspended in a dense cytoskeletal network. Synapsin antibodies and immunogold labeling show the specific synaptic vesicle-associated distribution of 10 nm gold particles thoughout the vesicle clusters of the terminal with fully intact ultrastructure. Thus, our preparation method allows, for the first time, the molecular characterization of tissue on the ultrastructural level with preserved structural details.

Title: 3D isotropic reconstruction of biological samples through cycles of physical and virtual sectioning in electron microscopy

Authors: *B. H. LICH[1,2], F. BOUGHORBEL[1], P. POTOCEK[1], R. VAN DEN BOOGAARD[1], L. HEKKING[1,3], E. KORKMAZ[1], P. CERNOHORSKY[2], M. HOVORKA[2], M. LANGHORST[3]; [1]AAE III, FEI Electron Optics BV, Eindhoven, Netherlands; [2]FEI Brno, Brno, Czech Republic; [3]FEI Munich, Munich, Germany

Abstract: In recent years there has been a considerable advancement in SEM-based methods for 3D reconstruction of large tissue volumes. Serial Block-Face SEM (SBF-SEM) involves combination of imaging and in-situ sectioning of plastic embedded tissue blocks within the SEM vacuum chamber1, allowing for automated imaging and subsequent reconstruction of volumes of tissue. The use of low electron energies for imaging limits sample charging which can be further mitigated with imaging in low vacuum mode and by further increasing the conductivity of the sample through sufficient amount of heavy metal staining and in-situ metal coating of the block face. Here we introduce a novel solution for high spatial resolution and throughput SEM volume imaging overcoming the resolution limits set by mechanical slicing by combining it with virtual sectioning. Virtual slicing is realized by Multi-Energy Deconvolution SEM (MED-SEM), a non-destructive technique that allows high resolution reconstruction of the top layers of the sample.2 After cutting a thin layer of the blockface using a diamond knife, freshly exposed tissue is imaged several times using various accelerating voltages. These images are subsequently used for deconvolving the information into several virtual subsurface layers. This cycle of physical and virtual sectioning offers isotropic datasets with excellent z-resolution and can be fully integrated and automated

Title: Compatibility of long-range fluorescent tracers with locally dense 3D electron microscopy reconstruction

Authors: *A. EMENARI, C. HICKS, K. L. BRIGGMAN;
Natl. Inst. of Neurolog. Disorders and Stroke, NIH, Bethesda, MD

Abstract: Dense reconstruction of neural circuits is currently limited in scope by the size of realistic 3D electron microscopy (EM) volumes. However, neural circuits in most brain regions span volumes significantly larger than current EM volumes. This limits the information content within an EM volume for the case in which an axon exits the volume and is therefore not able to be traced to its source or target. We aim to combine long-range fluorescent axon tracing throughout the brain with local dense 3D EM reconstruction. One option is to inject widely available adeno-associated virus (AAV) constructs encoding fluorescent proteins into brain regions that we think project through the EM volume. This approach is however biased by the selection of these regions and limited to the number of discriminable fluorescent protein colors. We sought a less biased approach by injecting lipophilic tracers into the center of the EM target volume, under the assumption that lipophilic tracers will indiscriminately label membranes within the injection volume and diffuse along axons passing through the volume. For testing purposes, we have initially targeted the mouse dorsal lateral geniculate nucleus (dLGN) of the thalamus. The goal is to label both afferent and efferent axons passing through the volume that we will ultimately reconstruct by EM. In this study, we tested different injection methods that would both widely label the injection volume but also preserve ultrastructure. We tested both iontophoretic and pressure injections and a variety of solvents for the lipophilic dyes. Following injection and after a pre-determined diffusion duration we perfused animals and sectioned the brain into 300 um vibratome sections. The section containing the injection volume was stained for EM and assayed for ultrastructural preservation. We demonstrated that lipophilic dyes are able to diffuse to brain regions known to connect to the dLGN within 1-2 weeks *in vivo*. This

approach provides a method to incorporate long-range connectivity information with local dense 3D EM reconstruction.

Title: Automated segmentation of nervous tissue from densely stained serial blockface electron microscopy data

Authors: *M. BERNING, M. HELMSTAEDTER;
Neocortical Circuits Group, Max Planck Inst. of Neurobio., Munich, Germany

Abstract: So far, dense semi-automated circuit reconstruction from serial blockface EM (SBEM) data relied on a tissue staining which enhanced plasma membranes, but made the direct detection of synapses impossible. Here we present automated classifiers based on semi-automated screening of convolutional neuronal network architectures that enable the reconstruction of fully stained 3-dimensional EM neuropil data. Using these classifiers, we pre-segmented a volume of 55 x 66 x 140 µm3 SBEM data from mouse retina and volume-reconstructed bipolar cell axons, ganglion cell and amacrine cell dendrites from their respective skeletons and detected all chemical synapses between these neurons. We then investigated how our classifiers transfer to novel SBEM datasets and developed a CNN screening algorithm that works successfully on novel large-scale SBEM datasets from mouse neocortex. Our results resolve the tradeoff between synapse detection and semi-automated reconstruction performance in high-resolution connectomics and provide the tools for efficient circuit reconstruction in fully-stained SBEM datasets.

Title: Project Brainflight: Scaling connectomic reconstruction via lay-audience targeted image analysis

Authors: *E. DOW[1,2], Y. BUCKLEY[2], M. BERNING[2], T. BOCKLISCH[3], D. BRÄUNLEIN[3], T. HEROLD[3], N. RZEPKA[3], T. WERKMEISTER[3], M. HELMSTAEDTER[2];

Abstract: A key bottleneck for large-scale electron-microscopy (EM)-based connectomics is data analysis throughput. In the past, dense circuit reconstructions have been made possible by the efficient combination of automated and human annotation. But the scale of possible reconstructions was limited by the expense and organization of human employees: so far up to 20,000 work hours of paid annotation has been achieved. One possible approach for scaling connectomic reconstruction is the recruitment of voluntary public annotators via online interfaces. Here we present Project Brainflight (http://brainflight.org), a set of online browser and mobile games created for different lay target audiences to annotate serial blockface EM datasets. Key innovations were the development of a simple human computation task, which reduced training times from tens of hours to minutes; focused annotation of regions that could not be reliably segmented by algorithms, selected in an active-learning classifier setting; image manipulation and software optimization to allow the distribution of high-resolution data to standard mobile devices; true game elements that support continuous attention and enhanced motivation in lay audiences; and creation of thematic game elements for selected target audiences. Together, these developments allow us to crowd-source connectomic data analysis in the mouse cerebral cortex and other large EM data sets.

Title: Large volume en bloc EM staining for high resolution connectomics

Authors: *Y. HUA, M. HELMSTAEDTER;
Structure of Neocortical Circuits Group, Max-planck-Institute of Neurobio., Munich, Germany

Abstract: Large-scale connectomics requires dense staining of neuronal tissue blocks for automated volume EM imaging. Available protocols, however, only allow either small volume staining or selective staining of myelinated neurites. Here we report a large-volume dense en-bloc EM staining protocol that overcomes this limitation, making it possible to obtain tissue blocks sized more than a millimeter in their smallest dimension with homogeneous and high-contrast dense neuropil staining. Our protocol can be applied to multiple species and brain structures, as exemplified for samples from mouse neocortex, thalamus, and turtle cortex. The

protocol also reduces the previously substantial staining failure rate in en-bloc protocols, facilitating correlated large-volume functional and structural imaging in the neocortex.

Title: Automated synapse detection in large-scale serial block-face electron microcopy data

Authors: *B. STAFFLER[1], P. VAN DER SMAGT[2], M. HELMSTAEDTER[1];
[1]MPI of Neurobio., Martinsried, Germany; [2]TUM, Munich, Germany

Abstract: Serial block-face electron microscopy (SBEM) provides image volumes of the size and resolution sufficient for reconstructing all axons and dendrites densely in modules of a cortical column in mouse neocortex. For connectomic analysis, chemical synapses have to be identified in addition to neurite reconstruction. Blocks of, e.g., 500 µm x 500 µm x 500 µm volume in mouse barrel cortex contain several tens of millions of synapses. Human annotation would consume hundreds of thousands of work hours. Therefore, automated synapse detectors are required. While automated synapse detectors have been developed for data obtained by high-resolution FIB-SEM or high in-plane resolution ssTEM imaging, automated synapse detection in fully stained SBEM data is missing. Here we developed such classifiers. We first pre-segment the imaged volume into neurite segments of ~5µm average length (Berning & MH, unpublished). We then classify contact interfaces between neighboring neurites as synaptic or non-synaptic. We first manually labeled 30000 neurite-to-neurite contact interfaces. We then trained a boosted ensemble classifier for identifying synapses and their directionality. The so far best classifier yielded precision and recall rates of 59% and 85%, respectively. This performance already provides a reduction in manual annotation effort of factor 34 with a neuron-to-neuron connection recovery rate of about 97%. We are currently improving the classifiers to allow synapse detection at tolerable annotation cost, fully automated synapse detection at an error rate tolerable for connectomic analysis, and an extension to the detection of synapse types.

Title: Towards whole-mouse-brain serial block-face electron microscopy

Authors: *S. MIKULA, W. DENK;
Max-Planck Inst. For Med. Res., Heidelberg, Germany

Abstract: Volume electron microscopy techniques have proven successful for imaging volumes of a few hundred microns in size. However, almost all neural circuits are considerably larger than this, curtailing useful functional inference. To image the adult whole mouse brain, which measures 450 mm^3, at a resolution such that the entire circuit can be reconstructed, new methods are required. Current efforts to scale serial block-face electron microscopy (SBEM) to the whole mouse brain face three fundamental technical challenges: 1) preparing the whole mouse brain such that every neurite is traceable and every synapse is identifiable, 2) imaging with high-throughput scanning electron microscopy, and 3) reliably sectioning the sample at 20 - 30 nm thickness using an automated in-chamber microtome. We present results that the first challenge, sample preparation, has been addressed through our development of the BRAX (Brain-wide Reduced osmium staining with Amplification and eXtracellular space preservation) protocol, which produces samples that are suitable for mapping of the whole mouse brain. The second challenge, high-throughput imaging, seems to have been addressed with the recent introduction of the multibeam SEM, which we have used to acquire images from BRAX brains at >1 GHz pixel acquisition rate. The final challenge is reliable in-chamber thin cutting. While progress has been made on this front, reliably cutting whole-brain samples at 20 - 30 nm thickness is an as yet unsolved problem.

Abstract: Connectomic analysis of neuronal circuits promises to provide insights into songbird questions such as HVC's mechanism of ultra-sparse code generation or the mechanism of song learning in Area X. Serial block-face electron microscopy (SBEM) can be used to acquire 3D EM datasets, at synaptic resolution, that span hundreds of micrometers in all dimensions and therefore contain entire microcircuits. We acquired several teravoxel-sized SBEM datasets of Area X and HVC (different parts of the zebra finch song control system) and are in the process of testing anatomical predictions made by various functional models. Circuit reconstruction is performed using a combination of human annotations and machine learning.

Title: A correlative light and electron microscopy approach for reconstructing syringeal motor neuron circuits in a songbird

Authors: *T. TEMPLIER[1,2], R. H. R. HAHNLOSER[1,2];
[1]Inst. of Neuroinformatics, Univ. of Zurich and ETH Zurich, Zurich, Switzerland; [2]Neurosci. Ctr. Zurich, University of Zurich and ETH Zurich, Switzerland

Abstract: What are the identities of postsynaptic partners of a given neuron? Correlative array tomography (CAT) is a candidate technique to address this question; it consists of imaging hundreds of consecutive ultrathin sections of brain tissue using both light (LM) and electron (EM) microscopy, combining the strengths of the two imaging modalities, namely fast acquisition and multicolor imaging for LM and nanometer resolution for EM. We show that five conventional neuroanatomical tracers (fluorescent dextrans and biotinylated dextran amine) previously injected *in vivo* into a nervous system can be simultaneously visualized with LM after a single step of postembedding immunohistochemistry against fluorophores and biotin. The LM imaging is performed in an unattended manner after mapping of the coordinates of hundreds of consecutive sections present on a single conductive silicon wafer. Sections are further poststained and the wafer is placed into the imaging chamber of a scanning electron microscope, where unattended EM imaging is done at 5 MHz, providing images with excellent ultrastructure for reliable neuron tracing and identification of synaptic contacts. Finally, LM and EM images are automatically registered, yielding a 3-dimensional correlative LM-EM stack. In a songbird we aim to characterize how cortical and brainstem neurons project to different motoneuron pools that control the muscles of the vocal organ. Contextual information about projection neuron type is provided by LM visualization of neuroanatomical tracers injected *in vivo* into the different muscles of the vocal organ, into the brainstem, and into the motor cortex. By contrast, neuron tracing and unambiguous identification of synaptic contacts is achieved using EM.

Title: Combined whole-brain optical and electron microscopic imaging in the larval zebrafish

Authors: *D. G. C. HILDEBRAND[1,2], G. S. PLUMMER[1], R. PORTUGUES[1], I. H. BIANCO[1], T. M. QUAN[2], W.-K. JEONG[2], J. W. LICHTMAN[1], F. ENGERT[1];
[1]Harvard Univ., Cambridge, MA; [2]Ulsan Natl. Inst. of Sci. and Technol., Ulsan, Korea, Republic of

Abstract: A central goal of neuroscience is to determine how neuronal connectivity enables the information processing that underlies perception and action. Modern light- and electron-based imaging technologies enable detailed examination of the functional and structural features of neurons. When combined and scaled, these methods permit interrogation of structure-function relationships in neuronal circuits. For most model organisms, however, it remains difficult to perform such studies at the whole-brain level. The larval zebrafish is a vertebrate model organism that offers convenient optical access to its entire nervous system. Additionally, its small size makes it an excellent system for whole-brain examination with serial-section electron microscopy. We describe new methods that take advantage of the larval zebrafish model to enable structure-function studies in a complete vertebrate brain, present data that is being used to generate a proof-of-concept high-resolution larval zebrafish brain atlas, and show correspondence of neuron identity across imaging modalities.

Title: Microtubules imaged in three dimensions by electron microscopy without averaging

Authors: *A. FERA[1,3], T. S. REESE[3], M. VALE DE SOUSA[1], B. M. RIBEIRO[2], D. L. SACKETT[4];

Abstract: We report here the application to microtubules of a straightforward method to perform high-resolution EM tomography, including measurements. Under conditions where absorption contrast makes the largest contribution to an electron image, the analysis of the data can be done in real space without squaring individual contributions as is generally done. Eliminating the dependence on the imaginary part of the scattering wave function allows a much more direct combination of the images. Therefore, with a negative stain able to sustain a high electron dose, tomograms can be collected that allow a resolution directly at the pixel size smaller than 1 nm. It proved necessary to collect images above 160 keV in order for the negative stain not to rearrange after irradiation, as shown by Fera et al., 2012. Given that our observation likely depends on the negative stain making a closed shell of metallo-organic salt, the improvement could be realized with other staining methods. Here, we apply this method to a well-known cytoskeleton element, previously characterized by averaging methods. Microtubules reconstituted *in vitro* from rat-brain tubulin were deposited on carbon-only coated 200 mesh copper grids, negative stained with methyl-amine tungstate and imaged with a 200 keV Tecnai TEM equipped with a high-sensitivity 4096 pixel CCD camera. The round individual tubulin polymers appear much less uniform and more fragile than with averaging methods, and show a variable number of protofilaments and hence diameter, as also shown by AFM. As expected, microtubules typically appeared circular and hollow but with a height-to-width ratio of ~0.6 in accordance with recent finding on single microtubules. We suggest that these data open the way for studying more directly how enzymes cytoskeletonal components bind to microtubules.

Abstract: Here the *in situ* proximity ligation assay (PLA) was used to characterize a number of G protein-coupled receptor heteromeric complexes across different basal ganglia nuclei in macaques, comprising control animals as well as animals rendered parkinsonian (with and without levodopa-induced dyskinesia). The PLA technique enabled us to demonstrate the presence of a number of GPCR receptor heteromers in both the input and the output basal ganglia nuclei. At the level of the caudate-putamen (input nuclei), different types of GPCR

heteromers were found, those comprising dopaminergic D1-D3 and cannabinoid CB1-GPR55 receptor heteromers. When considering the internal division of the globus pallidus (GPi, output nucleus), we focused on cannabinoid CB1-CB2 heteromers as well as on receptor heteromers made of adenosine 2A (A2A) and cannabinoid receptor types 1 and 2 (CB1 and CB2). The putative changes in the number of all these different types of GPCR heteromers in the different diseased states was qualitatively assessed with the confocal microscope. Most importantly, ultrastructural confirmation of the pre- and/or post-synaptic localization of cannabinoid receptor heteromers was provided. To the very best of our knowledge, this represents the first time in which the PLA technique was taken to the electron microscope. Throughout these studies, we took advantage of different technical recipes for the PLA assay, including: (i) fluorescent detection by labeling secondary antibodies with PLA probes, (ii) fluorescent detection following direct labeling of primary antibodies and (iii) ultrastructural detection of PLA-labeled primary antibodies using peroxidase-labeled oligonucleotides, the latter incubated with colloidal gold-tagged goat anti-peroxidase antibody and finally visualized with a silver enhancement solution.

Title: A new laser mediated traumatic optic neuropathy model

Authors: *G. C. MUNGUBA[1], R. K. LEE[2];
[2]Bascom Palmer Eye Inst., [1]Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: Purpose: Current models of traumatic ocular neuropathy rely on blunt force trauma delivered by mechanical mechanisms. These models generate gross generalized damage that can

often very severe and lack good correlation to injuries observed with humans. We have developed a novel retinal injury animal model using a Nd:YAG laser generating a photodisruptive force above the retina to focus injury of a determined magnitude reliably into the rodent eye which is reproducible, can be followed longitudinally *in vivo*, is limited to the eye and does not result in mortality. This novel method more closely mimics the types of retinal injury and structural damage observed with human traumatic optic neuropathy. Methods: A Nd: YAG l laser was used to generate a photodisruptive blast injury with 0.4 mJ of energy above the level of the retina and behind the lens in the peripapillary region in Thy1-ChR2/EYFP murine eyes (n=45). Eyes were imaged using spectral domain optical coherence tomography (SD-OCT) and a confocal scanning laser ophthalmoscope (CSLO) before laser treatment and up to 20 weeks after treatment along with IOP measurements. Mice were sacrificed at various time points and perfused transcardially with paraformaldehyde. Histology of whole mount retina and retinal sections was determined with hematoxylin/eosin (HE) and immunostaining with RGCs markers, such as brn3b and thy-1. Results: After one week, the retina ganglion cells (RGCS) were observed to be significantly diminished in number in a wedge shape origination from the circumpapillary region of laser treatment as measured by CSLO (HRT). By 20 weeks, a similar pattern of ganglion cell layer loss was measured using SD-OCT. IOP was not statistically different at all measured time points. Histologically, HE staining demonstrated a significant loss of RGCs and nerve fiber layer, consistent with the imaging results from SD-OCT and CSLO only in laser associated regions. Similarly, immunohistological staining for RGC markers confirmed RGC loss in the regions of laser treatment compared to adjacent non-lasered regions of the retina. Conclusions: We developed a new model using a photodisruptive force generated by a Nd:YAG laser to reliably deliver blunt trauma to the retina and cause loss of RGCs and nerve fibers similar to that observed in traumatic optic neuropathy that is amenable to study of neuroprotective strategies *in vivo*.

Title: Exact firing rate equations for all-to-all connected networks of quadratic integrate-and-fire neurons

Authors: *A. C. ROXIN[1], D. PAZÓ[2], E. MONTBRIÓ[3];
[1]Ctr. De Recerca Matemàtica, Bellaterra, Spain; [2]Inst. de física de cantabria (CSIC-UC), Santander, Spain; [3]Univ. Pompeu Fabra, Barcelona, Spain

Abstract: Spiking network models are an important theoretical tool for understanding the collective dynamics of large numbers of recurrently coupled neurons. Most studies of network dynamics have been numerical, while in a few cases it has been possible to calculate stationary network states as well as their stability, e.g. [1,2]. Unfortunately a general analysis of non-stationary dynamical states in spiking network models has not been possible. Such an analysis would be valuable given that non-stationarity in brain activity is likely the norm and not the exception. Here we show that the dynamics of networks of all-to-all connected quadratic integrate-and-fire neurons is described exactly by a low-dimensional set of equations, in the limit of large system size. Specifically, if heterogeneity in the system is purely quenched (i.e. no external noise injection), then the dynamics for each network in the model evolves along a two-dimensional manifold which is globally attracting. The two dimensions are the mean firing rate and mean subthreshold potential, the dynamics of which obey coupled, nonlinear differential equations. These equations capture the response of the network to arbitrary external inputs, as well as intrinsically generated dynamical states. [1] Amit and Brunel, Network 1997. Title: Emergence of spatially localized slow activity in structured leaky-integrate- and-fire networks

Authors: *Y. N. BILLEH[1], M. T. SCHAUB[2], C. A. ANASTASSIOU[3], M. BARAHONA[2], C. KOCH[3];
[1]Computation & Neural Systems, Caltech, Pasadena, CA; [2]Imperial Col. London, London, United Kingdom; [3]Allen Inst. for Brain Sci., Seattle, WA

Abstract: Unraveling the interplay between neuronal connectivity and the spatio-temporal dynamics exhibited by neuronal networks is a key direction to advance our current understanding of neuronal information processing. Here we investigate how certain topological features of leaky-integrate-and-fire (LIF) networks underpin the propensity of the network to generate *spatially localized slow* (SLS) activity, defined as the simultaneous increase in the firing frequency and in the coherence of action potentials over particular sub-groups of neurons [1]. Using full-scale dynamical simulations, we show that the ability of LIF networks to support SLS dynamics is pre-determined by spectral properties of the asymmetric synaptic weight matrix. In particular, when it exhibits an eigenvalue gap and the leading eigenvalues are almost real, the observed SLS activity is approximately proportional to the gap. Furthermore, the separation of the leading eigenvalues is linked to a localization of the associated Schur vectors on groups of neurons, leading to spatially coherent dynamical activity on those groups. To understand the origin of the eigenvalue gap, we consider stylized analytical rate models and use the insights gained to develop new network topologies with alternative connectivity paradigms that display SLS activity. Specifically, such dynamics can be achieved by modifying merely the connectivity patterns *between* excitatory and inhibitory neurons leading to SLS dynamics involving both excitatory and inhibitory neurons. We also show that SLS activity can be exhibited on multiple hierarchical timescales. Our work provides a step towards understanding the influence of network structure (increasingly uncovered through advancements in neuroanatomy and connectomics) on spatio-temporal neural activity and the dynamical roles of such neuronal circuits. **References** [1] A. Title: Feedback connections stabilize propagation of synchronous spiking in cortical neural networks

Authors: *S. MOLDAKARIMOV[1], M. BAZHENOV[2], T. J. SEJNOWSKI[3];
[1]UCSD, La Jolla, CA; [2]Univ. of California, Riverside, Riverside, CA; [3]Salk Inst., La Jolla, CA

Abstract: Precisely timed action potentials have been related to stimuli and behavior in monkeys, indicating that the neural coding may be based on precise spike timing of cortical neurons, synfire chains. An assumption that sensory information may be encoded by precise spike timing has been challenged by the critical question of whether synfire chains can successfully propagate through hierarchies of cortical areas. It is possible that noise would destroy millisecond precision during transmission of synfire chains through many layers of cortical networks. Previous studies demonstrated that synfire chains can propagate through the layers of a feedforward network. In the feedforward models, a spike precision sharpens as it propagates through the network. A separatrix divides the state space into two areas: stable and unstable. In the stable area, all trajectories converge into an attractor state representing successful propagation of synfire chains, and neural activity starting anywhere inside this area reaches a stable state with millisecond precision. Synfire chains starting outside the stable area decay after a few steps of transmission. These observations suggest that only strong enough stimuli, which evoke high number of spikes would successfully propagate through the cortical layers without degradation of temporal precision, while neural activities that are too weak will die out. Here we show that inclusion of feedback connections into a feedforward model enhanced propagation of synfire chains through the network layers, while preserving temporal precision. The enhancement of synfire chains propagation was due to feedback inputs increasing the number of spikes in the synfire chains. This moved the initial state of the stimulus into the basin of attractor representing successful synfire chains propagation. In addition, the feedback inputs changed the position of the separatrix, moving it downward and, therefore, increasing the basin of the attractor of the propagation regime.

Title: Breaking asynchrony in balanced networks with spatially dependent recurrent connections

Authors: *R. ROSENBAUM[1,2], J. E. RUBIN[1], B. DOIRON[1];
[1]Mathematics, Univ. of Pittsburgh, Pittsburgh, PA; [2]Applied and Compuational Mathematics and Statistics, Univ. of Notre Dame, Notre Dame, IN

Abstract: The spiking dynamics of networks of cortical neurons exhibit strong spatiotemporal variability. Balanced network models -- characterized by a dynamically stable balance between strong excitatory and inhibitory synaptic currents -- offer an appealing theoretical framework for studying this neural variability. Balanced networks produce intrinsically noisy spiking dynamics with statistical features similar to those observed in cortical recordings, including an asynchronous state in which pairwise correlations between neuronal spike trains are extremely small on average [1]. While this asynchronous state is consistent with some experimental recordings [2], it is inconsistent with many other recordings that show moderate correlations between the spike trains of cortical cells [3]. This raises the question of whether recurrent networks can exhibit moderate correlations while maintaining a stable balance between excitation and inhibition. We show that balanced networks can, in fact, exhibit moderate pairwise correlations if the spatial heterogeneity of recurrent connections and correlated inputs is taken into account. We first derive concise conditions on the spatial profile of recurrent connections that is required for the asynchronous state to be realized in balanced networks. We then show that breaking these conditions can give rise to moderate spike train correlations, similar to those observed in many cortical recordings [3], while maintaining balance between excitation and inhibition. Our results indicate that the same balanced network can exhibit moderate or extremely weak correlations, depending on the statistical structure of the external input to the network. These findings could potentially resolve the ongoing debate over the magnitude of correlations in cortical networks [2,3]. 1. Renart, A., de la Rocha, J. et al. Title: Gene-Matched Network: A micro-circuit model constructed by combinatorial matching of neuronal diverse attributes

Authors: ***T. KITSUKAWA**, T. YAGI;
Frontier Biosci., Osaka Univ., Suita, Japan

Abstract: Micro-circuits in the brain are foundation of neuronal information processing. Recent physiological and anatomical researches have clarified that the micro-circuits are not random and not uniform in the connection among neurons. Rather, they are rich in bidirectional connections and clusters, and show small world property. These facts indicate that the brain micro-circuits consist of overlapping groups of neurons which are densely connected in each group. In order to model such micro-circuits, we constructed an artificial micro-circuit network model named "Gene-Matched Network (GMN)" by the matching of neuronal attributes. First, multiple attributes were randomly assigned to each neuron (e.g. attributes numbered as 5, 19, 32 and 46 out of numbers 1~50). These numbers are called ‘genes’ since this matching rule was inspired by the fact that neurons expressing the same recognition genes form connections. Second, therefore, connections were formed among neurons that expressed the same ‘gene’ (e.g. connecting all neurons with the number, '5'). The GMN contained high density of clusters and the small world property, similar to the brain micro-circuits. Further, the layered GMN could retain information even when the information was passed through 10 layers, while random networks with the same numbers of connections lost the information. This fact suggests that the GMN can be a basis of the information transfer in parallel information processing. In addition, we demonstrate that the information in the network can be represented as a vector using the gene numbers which were

used for making connection. This fact indicates that the matching rule is a novel method to represent information contained in networks. Further, we show how the GMNs could transform the information by concatenating GMN layers with various thresholds.

Title: A computational study on irregular, self-sustained activity states in cortical network models

Authors: ***A. C. ROQUE**[1], P. TOMOV[2], R. F. O. PENA[1], M. ZAKS[2];
[1]Physics, Univ. de Sao Paulo, Ribeirao Preto, Brazil; [2]Mathematics, Humboldt Univ. of Berlin, Berlin, Germany

Abstract: A question that arises when studying the self-sustained activity (SSA) of the cortex in the brain's resting state is what are the mechanisms responsible for SSA in the absence of external input. Most previous theoretical studies have tackled this question by considering random networks of integrate-and-fire neurons. They showed that SSA can exist under a balanced state in which excitatory and inhibitory inputs to a neuron mutually cancel each other. Here, we study this problem using a cortical network model with more realistic architecture and more realistic neuron models. Our model has hierarchical and modular architecture and is made of excitatory and inhibitory neurons that belong to 5 electrophysiological cortical cell classes: regular spiking (RS), intrinsically bursting (IB), chattering (CH), fast spiking (FS) and neurons that produce low threshold spikes (LTS). The first 3 neuron types are excitatory and the other 2 are inhibitory. Neurons were modeled by the Izhikevich model and synapses were modeled in a conductance-based way so that when a presynaptic neuron fires a fixed synaptic conductance increment (gex/gin) is added to the corresponding synaptic conductance and, after that, the synaptic conductance decays exponentially. We considered different versions of our model with

different number of modules and neuronal compositions. The population of excitatory neurons (80% of total) was composed of a mixture of up to two cell types, RS cells (always present at a variable proportion) and either CH or IB cells (at the remaining proportion), and the population of inhibitory neurons (20% of total) was composed of only one cell type, either FS or LTS. The models received external current injection of variable amplitude applied to a variable fraction of the neurons for a variable short time interval (initial conditions) and were left to evolve freely after the end of this current. For each network realization and different initial conditions we determined the region of the gex-gin parameter space for which the system exhibited SSA with firing properties similar to the ones observed experimentally. For all studied networks this region was highly fragmented but concentrated in an area of the parameter space in which the ratio gin/gex is between about 4 and 12. This suggests that the balance mechanism is also operating in our models. However, we observed additional mechanisms that favor SSA. The SSA lifetime increased with the number of modules and when the network was made of RS and CH excitatory neurons and LTS inhibitory neurons. These new mechanisms point to a synergy between network topology and neuronal composition of the network in the generation of SSA cortical states.

Title: How STDP shapes the microcircuit structure of neuronal networks

Authors: *G. K. OCKER[1], A. LITWIN-KUMAR[2], B. DOIRON[2];
[1]Neurosci., [2]Mathematics, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: In neocortex, specific microcircuits of connected pairs and triplets of neurons are over-represented compared to unstructured, random networks[1, 2]. These connectivity patterns are related to stimulus preference and activity levels[3]. Furthermore, theoretical studies show that they play an important role in shaping spiking activity[4, 5]. Understanding how microcircuit structure arises is an important open question with implications for how neuronal networks

develop, learn and process information. We have developed a mathematical framework for how spike timing-dependent plasticity (STDP) shapes the microcircuit structure of neuronal networks. We have combined a linear response theory for spiking statistics in networks of integrate-and-fire neurons[6] and an adiabatic theory for STDP[7]. Our theory self-consistently relates the evolution of spiking activity to the plasticity of the network structure. We then use this theory to derive a low-dimensional, closed dynamical system for the strengths of divergent, convergent and chain microcircuit motifs in the network. The form of this system naturally divides STDP rules into three classes, based on the relative shapes of the potentiation and depression windows and how the total amount of STDP relates to the synaptic weights. We show how the class of the STDP rule strongly determines the formation of microcircuit structure in the network. In particular, for additive STDP with balanced potentiation and depression, the underlying structural anatomy of the network is a crucial factor in determining the coordinated evolution of convergent, divergent and chain motifs across the network. Title: Non-random network structure of recurrent networks with STDP and potentiation decay

Authors: *A. J. MILLER[1], D. Z. JIN[2];
[1]Bridgewater Col., Bridgewater, VA; [2]Physics, Penn State Univ., State College, PA

Abstract: Spike-timing dependent plasticity (STDP) applied to synapses in recurrent networks of spontaneously active neurons leads to unstable synaptic growth. The instability is caused by feedback-driven growth along randomly strengthened synapses. Therefore, an additional homeostatic mechanism must be added to the dynamics of the synapses in order for recurrent networks to remain in an asynchronously spiking state. One possible homeostatic mechanism that can counteract the feedback-driven synaptic growth is a gradual, activity-independent potentiation decay. This combination of synaptic rules produces networks characterized by unimodal, statistically stationary distributions of synaptic strengths. While the distribution of strengths remains stationary, an individual synaptic connection fluctuates through a range of values. It has been previously shown that this combination of learning rules contributes to emergent synfire chain synaptic topology upon repeated external stimulation of recurrent networks initially in the stationary state. However, little else is known about network structure of these networks. Here we explore the network structure of statistically stationary recurrent networks, applying network measures such as strength and degree distributions, and clustering coefficients. We compare these measurements to the corresponding measures of random networks with identical distributions of synaptic strengths. Sample stationary networks for the analyses are produced by simulations of pulse-coupled leaky integrate-and-fire (LIF) neurons subjected to noisy external inputs and feedback inhibition. An additive-LTP, multiplicative-LTD STDP rule is applied to synapses along with a slow potentiation decay. For a range of potentiation decay rates and LTP strengths, various network measures are applied to samples of N=50 statistically stationary synaptic connectivities. Network measures averaged over each sample set suggest that the networks are not randomly structured, but rather contain a modular structure that depends on the potentiation decay rate.

Title: Modeling spike timing dependent plasticity in large cortical networks of biologically realistic neurons with GENESIS 2.4

Authors: *D. BEEMAN[1], H. CORNELIS[2];
[1]Univ. Colorado Boulder, BOULDER, CO; [2]Neurospaces Develop. GCV, Martelarenlaan 9 / 9, Belgium

Abstract: The Song, Miller, and Abbott (SMA) model of spike timing dependent plasticity (STDP) is a popular simple model of synaptic plasticity. It is typically implemented on networks of point integrate and fire neurons that behave differently than structurally realistic multicompartmental models. Until now neither of the two most popular simulators for modeling multicompartmental neurons (GENESIS and NEURON) provided a command or class of objects to model this type of plasticity. The object oriented paradigm for scripting simulations in GENESIS 2 allows modelers easily to modify/share/reuse pieces of simulation scripts or to extend the simulator itself. To implement this paradigm efficiently, GENESIS makes use of an 'hsolve' object that can increase the speed of network simulations by a factor of 10 to 20. However, this efficiency limits the ability to easily add new synaptic models. Inflexibilities of the architectures of 1990s era simulators were the reason that GENESIS development shifted to GENESIS 3 (G-3) after the release of GENESIS 2.3. G-3 is still in a development stage, and it was necessary to give GENESIS 2 a mechanism for hsolvable models of synaptic plasticity. This was achieved with changes to the core simulator code with an 'stdp_update' object that implements modifiable SMA mechanisms to act on GENESIS 'synchan' objects. It allows for axonal conduction delays and can easily be extended by users to add other types of plasticity. Although GENESIS 2.3 was intended as a final release of the GENESIS 2 series, it has continued to be widely used for large network models of multicompartmental neurons and for projects in modeling courses such as LASCON. Thus, there will be a 2.4 release in November 2014. It contains recent improvements, user contributions, tutorials, and new capabilities for modeling large networks, including hsolvable synaptic plasticity. GENESIS may be downloaded from http://genesis-sim.org/GENESIS. Figure 1 shows the development of 32 synaptic weights in a GENESIS modified SMA model.

Title: Using stimulation to reveal structure-function relationships in dynamic brain networks

Authors: *S. E. FELDT MULDOON[1,2], J. M. VETTEL[2], D. S. BASSETT[1];
[1]Dept. of Bioengineering, Univ. of Pennsylvania, Philadelphia, PA; [2]US Army Res. Lab., Aberdeen Proving Ground, MD

Abstract: Understanding the brain as a complex network of interacting components can provide insight into cognitive function. From this perspective, one can study two types of networks: the anatomical network composed of physical connections between neurons or brain regions, and the functional networks constructed from coherent neurophysiological activity. The relationship between these two types of networks is far from understood, and many questions therefore remain. Do underlying anatomical networks drive functional networks and if so how? What constraints do anatomical connections play in potential patterns of functional activations? In a novel approach to addressing this relationship, we examine the effects of stimulation on functional network structure in settings with a known underlying connectivity using a joint approach combining meso-scale computational modeling with comparisons to experimental stimulation data. We first derive a spatially embedded network model of brain dynamics using biologically motivated Wilson-Cowan oscillators, connected using a realistic inter-regional connectivity map obtained from diffusion spectrum imaging (DSI) of white matter tracts. In silico, we then systematically stimulate different nodes (brain regions) of our network to determine how structural node properties (such as the degree, betweenness, clustering, etc.) influence the ability of the node to modify functional network structure. These results are compared to experimental ECoG data obtained from epilepsy patients undergoing cortical stimulation mapping prior to resective surgery. We examine the relationships among structural connections, functional connections, and physical proximity to understand how these different networks interact as a function of stimulus amplitude and location.

Title: Spike rate dynamics of coupled adaptive model neurons

Authors: *J. LADENBAUER[1,2], M. AUGUSTIN[1,2], K. OBERMAYER[1,2];
[1]Technische Univ. Berlin, Berlin, Germany; [2]Bernstein Ctr. for Computat. Neurosci., Berlin, Germany

Abstract: How the properties of single neurons and their coupling give rise to different types of functionally relevant collective dynamics can be effectively studied using population activity models derived from recurrently coupled spiking model neurons and mathematical analysis techniques (see, for example, [1-3]). Here we first derive a low-dimensional model for instantaneous population spike rates from a network of adaptive spiking model neurons and then use this reduction method to examine how changes in neuronal excitability can (de)stabilize different network states. Specifically, we consider adaptive integrate-and-fire neurons [4], that can well reproduce the activity of cortical neurons, and in-vivo like fluctuating inputs. This neuron model includes a description of slowly decaying potassium currents (so-called adaptation currents), which have been shown to strongly affect neuronal spiking activity [5,6]. We extend different reduction techniques based on the Fokker-Planck equation [2,7] to take into account adaptation currents and we evaluate the reduced population activity models in terms of spike rate reproduction accuracy for a range of biologically plausible input statistics, computational demand and implementation complexity. This approach allows for the application of powerful methods to analyze the stability of network states, where, for example, stability bounds can be calculated for general coupling topologies [8,3]. Additionally, a direct link between macroscopic quantities (network activity) and microscopic properties (neuron biophysics) is retained. Using this framework we demonstrate how changes in neuronal excitability via adaptation currents lead to the (de)stabilization of asynchronous states as well as fast and slow oscillatory activity generated by different mechanisms. In this way we identify network regimes where switching between different dynamical states can be mediated by (top-down) neuromodulatory signals that target adaptation currents [9]. [1] X.-J. Title: Learning linear dynamical systems in spiking networks

Authors: *R. BOURDOUKAN, S. DENÈVE;
Ecole Normale Supérieure, Paris, France

Abstract: We live in a perpetually changing world where timescales of perceptual decisions or motor actions vary from a few milliseconds to several minutes. These tasks require constant temporal predictions of the future sensory inputs and motor trajectories. Many have been formalized as dynamical systems. It is however unclear how spiking networks can learn to implement such dynamics. Using a purely top down approach, we derive local current-based Hebbian plasticity rules allowing spiking neural networks to learn to implement a wide range of linear dynamical systems. The trained network exhibits many observations seen in the cortex such as irregular spiking and balance between excitation and inhibition. Learning in recurrent spiking networks is a notoriously difficult problem. Local changes in connectivity may have an unpredictable effect on the global dynamics. In addition, reproducing the Poisson-like statistics

of neural responses require the use of networks with balanced excitation and inhibition. These networks are chaotic and highly sensitive to initial conditions or perturbations. Here we overcome these limitations by combining a spike-based predictive coding approach with supervised learning. We use a recurrent network of LIF neurons that displays two types of connectivity: fast and slow. Fast connections are trained to balance excitation and inhibition. This produces Poisson-like spike train statistics, but also enforces a maximally efficient spike-based code. On top of that, a "sensory feedback" loop provides a very strong error signal to the untrained network, serving as a teaching current for slow connections. Under the effect of this strong feedback loop, the output of the neurons becomes effectively independent of the recurrent connectivity. This allows us to derive a simple Hebbian plasticity rule for slow connections from a gradient descent over a loss function. Over the course of learning, the prediction error, and thus the teaching signal gradually attenuate and disappear, as the network becomes autonomous. We found that these networks could learn extremely efficient (i.e. accurate and with a very small number of spikes) implementation of a wide variety of linear dynamical systems such as oscillators or integrators. The resulting network can be considered as "minimal" (in terms of connectivity and activity) in order to implement a given function. This contrasts with approaches based on liquid computing, where very large and dynamically complex networks have to be used.

Title: Feedforward supervised learning for deep neural networks with sparse dynamics

Authors: *T. SHINOZAKI, Y. NARUSE;
BIT laboratory, NICT, Kobe City, Hyogo, Japan

Abstract: A multilayered deep neural network is one of the most powerful methods for human-like recognition tasks, image (Le et al., 2012), and speech recognition (Dahl et al., 2012). Some previous studies demonstrated great performances with supervised learning in signal classification tasks (LeCun et al., 1989; Krizhevsky et al., 2012). Supervised learning for multilayered neural network generally uses gradient-based learning rules, in particular, back-

propagation learning (Rumelhart et al., 1986). However, the amount of supervisory information in the last layer is insufficient to supervise the whole deep neural network because the information is selected and reduced from layer to layer. This tendency is more serious in signal classification tasks which have limited discrete output. Thus, layer-wised learning is generally used for both mutually connected (Bengio et al., 2007) and feedforward networks, resulting in difficulties in incremental learning and online updating. This study proposes a novel supervised learning method for multilayered neural networks that uses feedforward supervisory signal. The learning method requires sparse dynamics, and uses additional advance input as a supervisory signal to learn the target input. Before the target input, advance input, which produces the required classification label, is propagated through the whole network, and then the target input is processed with the after-effect of the advance input. We validated the efficiency of the proposed method by the visual recognition task of MNIST handwritten image dataset (LeCun & Cortes) with a five-layer feedforward network. The proposed method improved the error rate from 15.6±0.7 % just after the pre-training, to 4.2±0.2 % after 20 iterations of the training set (n=10). One of the interesting point the proposed learning method is that it could seamlessly incorporate both reinforcement learning and competitive learning. Reinforcement learning emerges if there is no advance input, and the usual competitive learning emerges if there is no correct/incorrect signal. Therefore, the learning mode could be selected by the sequence of input and correct/incorrect signals.

Title: Learning higher-order structure of correlated input by excitatory and inhibitory spike-timing-dependent plasticity

Authors: N. HIRATANI[1,2], *T. FUKAI[3,1,4];
[1]Dept. Complexity Sci. and Engin., Univ. of Tokyo, Kashiwa, Japan; [2]JSPS, Tokyo, Japan;
[3]RIKEN BSI, Wako, Japan; [4]CREST, JST, Kawaguchi, Japan

Abstract: Spike-timing-dependent plasticity (STDP) is ubiquitously observed at synapses of the mammalian brain, and is considered to be critical for both developmental and adulthood neural plasticity. Previous studies suggest that STDP enables neurons to capture the principal component of input stimulus patterns and to learn the major feature of stimuli. However, it is still unclear how neurons capture higher-order components, especially when these features are encoded by synchronization of neural activity, not by firing rate. For example, the brain may extract faint sounds from a mixture of non-independent auditory sources, but the underlying mechanism remains unknown. Furthermore, it is unknown how the structure of spike correlation and various types of noise influence the learning process. In addition, recent experimental studies suggest that inhibitory synapses also show spike-timing-dependent synaptic plasticity, although its functional role is still uncertain. Here, we constructed a computational circuit model with linear Poisson neuron model to analytically investigate how and when STDP can detect higher-order structures. We show that lateral inhibition and inhibitory STDP are crucial for improving the performance of learning process.

Title: Autaptic connections shift network excitability and bursting

Authors: *L. K. WILES, D. S. BASSETT, D. F. MEANEY;
Bioengineering, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Although neurons receive thousands of inputs from other neurons in the brain, in some cases, a neuron synapses onto itself to form an autapse. Autapses are found in multiple brain areas, including pyramidal neurons in the cortex, but appear more commonly on inhibitory

neurons such as fast-spiking interneurons. Despite the evidence that they appear throughout the brain circuitry, the function of autapses on network dynamics is largely unexplored. We use a simple spiking model of neuronal activity in which neurons are connected in a distance dependent fashion and systematically adjust the fraction of autaptic connections to evaluate if these connections shift the network activity pattern. Moreover, we test if placing autaptic connections on highly connected neurons, which are thought to be influential on network dynamics, further shift network behavior. Based on studies in dissociated cortical neuronal networks, simulations consisted of networks of 800 excitatory and 200 inhibitory neurons, varying synaptic strengths, and averages of 75 excitatory and 18.75 inhibitory inputs onto a neuron. Spiking activity was analyzed for numbers of events per neuron and for coordinated firing across large numbers of neurons within a brief time period (network-wide bursting) defined in comparison to interspike-interval-shuffled surrogate data. We added a varying number of autapses either uniformly at random to neurons or preferentially to highly connected neurons, with appropriate statistical controls. In simulations without autapses, fast-spiking interneurons fired more frequently than excitatory neurons. Spontaneous bursting was significantly less common in networks where the excitatory synaptic strength was weaker than the inhibitory synaptic strength. In comparison, adding autaptic connections to excitatory neurons led to an increased number of spiking events in the network and to network-wide bursts in simulations where excitatory synapses were stronger than inhibitory synapses. Bursting behavior in the network occurred more readily with autaptic connections when autapses were selectively added to highly connected excitatory neurons rather than added to a random subset of neurons. Collectively, our results demonstrate that autapses on excitatory neurons increase network excitability and bursting. If selectively targeted to highly connected excitatory neurons in the network, the transition to bursting behavior will occur with fewer autaptic connections. Autapses provide an important network control mechanism that could play a key role in the excitability of healthy and diseased cortical networks.

Title: A new reduction method for setting synaptic weights of conductance-based neurons with slow and/or fast receptors to simulate behavior in a spiking neural network

Authors: P. M. DAYE[1], *L. M. OPTICAN[2];
[1]Movement disorders and basal ganglia laboratory, Inst. du Cerveau et de la Moelle épinière, Paris, France; [2]Natl. Eye Inst., BETHESDA, MD

Abstract: To simulate the function carried out by a neural area, using a large population of conductance-based neurons, one needs to compute a set of synaptic weights that will reproduce the behavior of that area. However, computing these weights is difficult, because of the non-linear dynamics of the mathematical model representing each neuron, and because the number of weights increases with the number of neurons. Therefore, approaches based on a reduced representation of the full conductance-based neuron model have been proposed (e.g., Ermentrout, 1994; Seung et al, 2001). These methods estimate an averaged representation of neuronal dynamics using the fact that slow receptors (e.g., NMDA, GABAB) dominate the overall dynamical behavior of the network. However, a model with neurons composed of either slow and/or fast receptors is required if we are to understand how drugs work in patients with brain diseases. Unfortunately, prior methods perform poorly with fast receptors (e.g., GLY, GABAA, AMPA). We developed an extension of the previous averaging techniques to compute the weights in networks composed of neurons with slow and/or fast synapses. Our new method reduces the conductance-based model of a neuron to a simpler dynamical model. The reduction technique is based on the total amount of neurotransmitter produced by the neuron over a period of time. The averaged model then estimates the amount of neurotransmitter produced by a neuron as a function of its synaptic inputs. The network weights are then computed by evaluating the change of synaptic conductance in a post-synaptic neuron generated by an afferent neuron. We demonstrate our new model reduction technique by computing the weights of a bilateral neural integrator. Then, we simulate the model of the integrator using either the full or the reduced representation of the neurons. To assess the quality of the reduced model, we first compare its dynamics to the dynamics of the full model (e.g., response to a step or a ramp input of neurotransmitter). Then we compare the integrator network built with either simplified or full representations of neurons (e.g., time constant of the persistent firing, sensitivity of persistent activity to eccentricity). Finally, using the integrator as benchmark, we compare our new technique to previous ones. We show that both approximate equally well the dynamics for slow receptors but our new technique better approximates the dynamics of fast receptors.

Title: Learning in recurrent networks with the Neural Marketplace algorithm

Authors: S. N. LEWIS[1], P. YGER[2], *K. D. HARRIS[1];
[1]Univ. Col. London, London, United Kingdom; [2]Inst. de la Vision, Paris, France

Abstract: The brain consists of billions of neurons, which self-organize into the world's most powerful information-processing machine. Outside of biology, the only system known in which comparable numbers of autonomous units organize into productive networks, is the global economy. In the economy, money can be interpreted as a signal passing in the opposite direction to goods, that informs firms that their products are useful to consumers. By competing for limited quantities of this retrograde signal, firms therefore increase the benefit they play to the economy as a whole. In the brain, the classical form of communication between neurons is anterograde, carried by action potentials. But signals also pass backward along axons, carried by slow chemical messengers such as neurotrophins. During development, competition for such retroaxonal factors determines whether cells live or die. But retroaxonal signals can play additional roles in developmental plasticity, including controlling the strength of input synapses to the presynaptic cell [Du & Poo, Nature 2004; Du et al, PNAS 2009, Sharma et al, Neuron 2010]. We have hypothesized that in adult learning, retroaxonal signals carried by messagers such as neurotrophins may play an analogous role by stabilizing recent changes to neuronal input synapses [Harris, TINS 2008]. Competition for these factors would therefore reward neurons that have found information useful to downstream targets, and cause their representations to become stable. We describe a mathematical model for such a form of self-organization, in which a small number of "consumer" neurons receive explicit fast error signals, while a larger number of "producer" neurons compete to supply them with information, guided by retroaxonal signals from the consumers and from each other. We show how slow retroaxonal signals can allow producers to estimate their value to the global network, and how these estimates allow the network to perform a form of parallel search over multiple producer cells. We validate our approximations and demonstrate the proposed learning rule using simulations of firing-rate and spiking neural networks performing a real-world speech recognition task.

Title: Dynamics of recurrent networks with multiple inhibitory subpopulations

Authors: *A. LITWIN-KUMAR[1,2], R. ROSENBAUM[2], B. DOIRON[2];
[1]Carnegie Mellon Univ., Pittsburgh, PA; [2]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Computational studies have typically treated inhibitory interneurons as a homogeneous population, but recent advances in the characterization of interneuron subclasses reveal heterogeneous functional and connectivity properties. In the mouse visual system, three major interneuron subtypes, parvalbumin-expressing (PV), somatostatin-expressing (SOM), and vasointestinal peptide-expressing (VIP) neurons comprise 80-90% of inhibitory neurons. Connectivity between these subtypes follows stereotyped rules: for example, SOM neurons are inhibited only by VIP neurons and VIP neurons only inhibit SOM neurons (Pfeffer et al. 2013). Further, these neurons perform distinct computational roles: VIP neurons disinhibit the pyramidal neuron population during locomotion via suppression of SOM neurons (Fu et al. 2014) while activation of PV or SOM neurons divides or subtracts pyramidal neuron responses to oriented bars, respectively (Wilson et al. 2012, Atallah et al. 2012). We study the dynamics of networks with inhibitory neuron connectivity that matches experimental recordings. Our self-consistent theory describes conditions under which the dynamics of such networks are stable and how perturbations of distinct neuronal subclasses recruit activity changes through recurrence. We apply these conclusions to study disinhibition, surround suppression, and subtraction or division of orientation tuning curves in a model network. Our calculations and simulations establish conditions under which activity consistent with experiment are possible. They also lead to predictions concerning connectivity and network dynamics that can be tested via optogenetic manipulations. Finally, they illustrate that the recurrent dynamics of these networks must be taken into account to fully understand many effects reported in the literature. Pfeffer, C.K. et al. Title: Irregular and uncorrelated activity can arise as a natural consequence of synaptic inhibition

Authors: *J. E. RUBIN[1], C. O. DIEKMAN[2], D. TERMAN[3];
[1]Mathematics, Univ. of Pittsburgh, Pittsburgh, PA; [2]Mathematical Sci., New Jersey Inst. of Technol., Newark, NJ; [3]Mathematics, The Ohio State Univ., Columbus, OH

Abstract: Normal brain states are often characterized by irregular spiking activity, with little correlation among neurons within particular brain regions. In particular, there are many examples of inhibitory networks involved in such irregular activity. For example, experiments have revealed that, within the globus pallidus of the basal ganglia, the spike times across pairs of neurons are rather completely uncorrelated under normal resting conditions. Indeed, a hallmark of the Parkinsonian state is the replacement of this uncorrelated activity by more correlated firing. Another example is cortical networks in the dorsolateral prefrontal cortex, which have been identified as playing a key role in working memory tasks. Experiments have demonstrated that during persistent activity, neurons in this area exhibit highly irregular firing patterns with a

Poisson-like spike time distribution. Although there have been numerous theoretical and experimental studies of each of these brain regions, the mechanisms underlying their irregular and/or uncorrelated activity remain poorly understood.// Here, we introduce a novel mechanism for irregular dynamics in Hodgkin-Huxley-like conductance-based models for neuronal activity. Unlike many previous studies, it does not rely on a balance of excitation and inhibition. Nor does it require large-scale networks. In fact, the irregular spiking can be generated in purely inhibitory networks consisting of just two cells, from which it scales up to larger purely inhibitory or excitatory-inhibitory networks. Mathematical analysis of the model demonstrates that the irregular dynamics arises naturally through interactions between standard ionic currents and synaptic inhibition. The analysis leads to rather precise conditions on parameters for when irregular dynamics emerge.// We also consider how changing parameters in the model may switch the network activity between phase-locked and uncorrelated spiking. Such a switch in network activity is often associated with the switch between a normal brain state and a pathological one. For example, these results may offer useful insights into how Parkinsonian conditions lead to abnormally high correlations in activity within the globus pallidus, which in turn could influence activity downstream from the globus pallidus and throughout the basal ganglia-thalamo-cortical network.

Title: An energy efficient neuron model with excitatory and inhibitory inputs

Authors: ***J. XING**[1,2], T. BERGER[1], T. J. SEJNOWSKI[2];
[1]Dept. of Electrical and Computer Engin., Univ. of Virginia, Charlottesville, VA; [2]Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: Neural information processing within neural microcircuitry is determined by the balance between excitation and inhibition (E/I balance). Toward understanding it better from an information-energy efficiency standpoint, we earlier calculated the maximum Shannon mutual

information transfer per unit of energy expenditure of an idealized integrate-and-fire (IIF) neuron all of whose synapses are excitatory but have differing weights. Since it is well known from neuroscientific experiments that the postsynaptic potential (PSP) accumulation in real neurons is not monotonically increasing but behaves like a diffusion process that possesses both local decrease and local increase, in this paper we extend the IIF model to a biophysically more realistic one in which synaptic weights not only are assumed unequal but also can be inhibitory. Such inhibitory signals are also widely considered essential for keeping signal processing in the brain from becoming unstable. Based on information theory and stationary processes, we have derived the formula for the long-term average mutual information rate. We also establish that the probability density function (pdf) of interspike interval (ISI) duration induced by the bits per joule (bpj) maximizing pdf of the combined excitatory and inhibitory postsynaptic potentials (EPSPs/IPSPs) remains a delayed gamma distribution as in the IIF model with only excitatory synapses. The bpj optimizing input density, in the case of inhibitory as well as excitatory unequal weights, still satisfies an inhomogeneous Cauchy-Euler equation with variable coefficients.

Title: System size resonance in a Fitzhugh-Nagumo artificial neural network

Authors: *J. A. TAPIA[1,2], E. MANJARREZ[1];
[1]Inst. de Fisiología, Benemérita Univ. Autónoma de Puebla, Puebla, Mexico; [2]Escuela de Biología - BUAP, Puebla, Mexico

Abstract: The stochastic resonance refers to an enhancement of the signal perception by a nonlinear system with the addition of an optimal noise. This phenomena has been observed in

artificial neurons by means of computational simulations (Goldbach et al, 2008) and within electronic devices (Calvo et al, 2006). Furthermore, there is a stochastic resonance phenomenon in the spinal monosynaptic reflex observed during the simultaneous arrival of a subtrheshold signal and a noisy input to sensory pathways (Manjarrez et al 2005). The aim of the following work was to develop an artificial neuronal network with an architecture similar to that of the monosynaptic spinal circuit which exhibited a stochastic resonance signal enhancement. We developed an electronic circuit based on the Fitzhugh - Nagumo equations. This artificial network consisted of a layer of interneurons (AIN) and a layer of motoneurons (AMN). The final output is the sum of all the artificial motoneurons. We applied a subthreshold signal simultaneously with a white Gaussian noise input to all the artificial interneurons, this noise was applied at ten different levels. The signal to noise ratio (SNR) was calculated in the bandwidth of the subtreshold signal. The number of interneuron-mononeuron pairs was increased from 1 to 10.We observed an increase in the SNR when applying an optimal intermediate noise (S=[36 - 60.9]mV). By increasing the number of AIN/AMN pairs the optimal noise was decreased. Furthermore, the amplitude of the calculated SNR was increased with the increase of the number of neurons. This electronic circuit provides insight of a possible system size resonance phenomenon in the biological systems. Also, this device could lead to a new type of signal processing unit, in which environmental noise cannot be reduced by traditional methods; or in which we could take advantage of the noise itself. Furthermore, we could fine tune the “sensorial circuit” to increase the SNR by having the amount of needed neurons according to the environmental noise.

Title: Dynamics of large networks of excitatory and inhibitory units with sparse, partially symmetric couplings

Authors: *D. MARTÍ[1,2], N. BRUNEL[3], S. OSTOJIC[1,4];
[1]Group For Neural Theory, DEC, Paris, France; [2]INSERM, Paris, France; [3]Dept. of Statistics and Neurobio., Univ. of Chicago, Chicago, IL; [4]CNRS, Paris, France

Abstract: Over the past ten years, several studies based on multielectrode recordings have revealed that cortical pyramidal neurons connect with each other according to patterns that display a non-trivial statistical structure. One prominent example of such structure is the fact that bidirectional connections between neurons appear more often than one would expect if connections were random. It is still unclear how this prevalence of bidirectional connections affects the dynamics of cortical circuits, and what possible functional role it plays. To elucidate this question we study the dynamics of large-scale networks of excitatory and inhibitory units with unclustered, random, sparse, and partially symmetric connections. We investigate networks of both rate units and spiking neurons and show that, in both cases, the nature of the network dynamics is strongly determined by the spectrum of eigenvalues of the connectivity matrix. For weak couplings, the real part of the eigenvalues is small and the network is in an equilibrium state with constant firing rates. For increasing connection strengths, the real part of the eigenvalues gets larger and the network eventually undergoes an instability that leads to a rate-chaotic regime, characterized by heterogeneous and fluctuating firing rates with a characteristic timescale that depends only mildly on the coupling strength. Using numerical simulations and mathematical analysis, we show that introducing partial symmetry in the couplings slows down the rate fluctuations in the chaotic regime, a result that can be qualitatively explained by the appearance of connection that contribute to activity reverberation. More quantitatively, this slowing down is brought about by the flattening of the eigenspectrum along the real axis and the subsequent concentration of low-frequency modes. For the non-chaotic regime, we compute how symmetry modulates the timescale of the noise filtered by the network operating at the transition point. In that case symmetry increases the characteristic asymptotic decay time of the autocorrelation function. Furthermore, for sufficiently symmetric connections the system operating in the chaotic regime exhibits aging effects, by which the timescale of the rate fluctuations slowly grows as time evolves, and which is a characteristic of systems out of equilibrium exhibiting a very large relaxation time.

Title: Temporal expectation in chaotic balanced networks

Authors: *A. P. PONZI, J. R. WICKENS;
OIST, Okinawa, Japan

Abstract: Neuronal activity becomes anticipatory in predictable sensory environments. In streaming perceptual discrimination tasks performance improves with predictability of both what stimuli will occur and when [1]. Temporally regular sensory streams entrain ongoing brain oscillations but how this happens and why it enhances discrimination is unknown. Here we show that temporal expectation emerges naturally from the dynamics of recurrent balanced neural networks. This is because the weakly chaotic oscillations they generate can be partially or fully stabilized by repetitive stimulus sequences in sensory driving streams. Periodicities in driving phase lock periodic orbits embedded in the underlying chaotic set, resulting in phase synchronized [2] stimulus stream specific network trajectories which though strongly varying have a stable phase evolution. This occurs even when stimulus streams realistically consist of brief 50 ms cue stimuli trial presentations separated by 800 ms long inter-trial-interval (ITI) periods of cue-independent static background input. Studies show that recurrent networks display temporally extended stimulus specific dynamical activity patterns as reactive responses to input stimuli and that these evolving trajectories provide a substrate for working memory and represent elapsed time [3]. We here extend this to demonstrate that in phase synchronized networks the temporally evolving response profiles of sequentially activated cells are specific to the stream context the stimuli are embedded in and thus anticipatory of the type and timing of upcoming stimuli. We show that such single cell activity patterns provide greater discriminatory information of the preceding cue during the subsequent ITI than purely reactive responses. This is because the more chaos is stabilized by the driving stream the more reproducible the ITI period cue response across multiple trials. We show that while phase synchronization and therefore ITI period stimulus discriminability increase continuously with both the temporal regularity of the stream and the predictability of the stimulus type these two kinds of anticipation interact in a non-linear way. The more temporally irregular the stream the less type predictability enhances discriminability. Our results are reliable with significant noise in the network dynamics, occur at natural streaming frequencies although networks possess only biological timescales and are consistent with multiple studies of streaming perceptual discrimination tasks.

Title: A modified kinetic Inverse Ising method for the inference of synaptic spatial structure and characteristic times

Authors: *P. DEL GIUDICE[1], C. CAPONE[2], C. FILOSA[3], G. GIGANTE[4], F. RICCI TERSENGHI[3];
[1]TESA, [2]Italian Natl. Inst. of Hlth., Rome, Italy; [3]Univ. of Rome Sapienza, Rome, Italy; [4]Italian Natl. Inst. of health and Mperience, Rome, Italy

Abstract: A long standing problem in neuroscience, both in modeling and in data analysis, is the one of inferring synaptic couplings from correlations of the sampled neural activities. The recent availability of techniques allowing simultaneous recording from several tens electrodes, in-vitro as well as in-vivo, gave new momentum to research in this direction. In particular, much effort has been devoted to develop and refine inference methods inspired by the statistical mechanics of spin systems (so called 'inverse Ising' methods). In the original proposal ([1]), simultaneously recorded data are binned in time, binarized and interpreted as successive configurations of a spin system with pairwise interactions at equilibrium. Inference proceeds then as the solution of a constrained optimization problem: determine the spin couplings providing the maximum entropy (Gibbs) distribution compatible with the observed mean activities and pair spatial correlations, used as constraints. 'Brute-force' solutions can be obtained by iterative procedures akin to learning algorithms in Boltzmann machines; the need to reduce the computational load for large networks motivated the use of various forms of mean-field estimates of the correlations from the measured mean activities. The interest in relaxing the assumption of equilibrium later led to the development of inference methods based on kinetic Ising models; for a review of the state of the art see [2]. In this work, using simulations of networks of integrate-and-fire neurons, we incorporate in kinetic inverse Ising inference methods the important notion that spikes are transmitted between neurons with delays, which are estimated from the profile of the cross-correlation function prior to the inference procedure, and inform the choice of the time bin used in the inference algorithm. A method is also developed to take into account a finite time of integration of the synaptic input. Finally, we analytically and numerically study the relationship between the inferred and the real synaptic efficacies, and how the choice of the time bin affects

it. Such relationships turns out to be quadratic both for excitatory and inhibitory synapses, but it depends critically on the time bin for the excitatory synapses only, whilst being essentially independent of the time bin for the inhibitory ones. Preliminary results on the application of the inference method to data from neural cultures will be reported. Title: Context-driven generation of virtual dendritic morphologies enables complete population-level construction and analysis

Authors: *C. SCHNEIDER[1], H. CUNTZ[2,3], I. SOLTESZ[1];
[1]Anat. and Neurobio., Univ. of California, Irvine, Irvine, CA; [2]Ernst Strüngmann Inst. (ESI) for Neurosci. in Cooperation with Max Planck Society, Frankfurt/Main, Germany; [3]Inst. of Clin. Neuroanatomy, Goethe Univ. Frankfurt, Frankfurt/Main, Germany

Abstract: Dendritic morphology has been shown to have a dramatic impact on neuronal function, and there is an inherent variability in this morphology that is often overlooked when studying computation in neural networks. While detailed models for morphology and electrophysiology exist for many types of single neurons, the role of detailed single cell morphology in the population has not been studied in detail anatomically or computationally. Current techniques for the construction of morphological models largely ignore the structural location and context that the morphologies originate from, focusing on independent branching statistics. The current study instead uses the structural context of the neural tissue in which dendritic trees grow to drive the morphological generation process. Utilizing parallel computing,

the complete population of the most numerous cell type in the hippocampus, the dentate gyrus granule cell, was generated within a realistic structural context, with a granule cell layer that contains all somata and a molecular layer that contains the dendritic trees. By growing dendrites within elliptical cones, which are characteristic of the dendritic field of dentate granule cells, in the realistic structural context of the volume of these neural layers, dendritic trees could be generated that were statistically and visually indistinguishable from experimental reconstructions. Branching statistics can now be linked to larger scale neuroanatomical features and the input organization of granule cells can be studied at the level of the population. This also provides a framework by which to populate network models with detailed single-cell morphological models and three-dimensional, intersection-based connectivity. This procedure can be repeated for other cell types within the dentate gyrus and for other brain regions, and represents a major advancement in the development of realistic large-scale neural network models. This work was funded by NASA NNX10AD59G and NIH grant NS35915 to I.S.

Title: Hubs, clusters and communities of hundreds cortical neurons

Authors: *M. SHIMONO, J. M. BEGGS;
Indiana Univ., Bloomington, IN

Abstract: Neuronal networks are essentially non-random. At same times, although neurons show multiple-scale behaviors on both of temporal and spatial scales, how non-randomness in several different topological sizes relate each other has not been demonstrated experimentally before. This study aimed to clarify important relations between non-randomness in groups of 3-6 neurons and non-randomness in groups of 50-100 neurons through five steps. First, we recorded spontaneous activity of up to 500 neurons from rodent somatosensory cortex using 512ch. multi-

electrode system over one hour. Second, we prepared an analysis scheme to reconstruct effective networks using transfer entropy. Third, after evaluating similarities of topologies of effective networks in 3-6 neuron scales (clusters including motifs [Figure1-B]) with topologies of synaptic connections measured using cutting edge patch-clamp experiments recording from up to 12 neurons simultaneously. Fourth, we constructed community or modular structures representing non-randomness of larger group of neurons [Figure1-C]. Fifth, we evaluated how much these two kinds of non-randomness are fragile when distributing connections connecting with several percentages of high-degree neurons (hubs) to many other low-degree neurons. From these procedures, we found three things. First, effective networks consisting of hundreds of cortical neurons have distinctive non-random structures of connectivity at two different scales. Second, the degree-distribution showed power-low distributions. This supported the existence of "hubs" in the cortex. Third, structure at these scales showed different dependencies on connections from hub neurons with the smaller groups being relatively more fragile than the larger groups because large-scale nonrandom structure can exist even after small-scale nonrandom structure is completely disrupted.

Title: Network structure generates priors for internal probabilistic model

Authors: *N. HIRATANI[1,2], T. FUKAI[1,2];
[1]RIKEN Brain Sci. Inst., Saitama, Japan; [2]Dept. of Complex Sci. and Engin., Univ. of Tokyo, Chiba, Japan

Abstract: Many experimental results suggest that connections in neural circuits often have characteristic structure that is arguably genetically determined. For example, in the olfactory bulb of *Drosophila*, some connections are highly stereotyped while others are random. In somatosensory cortex of rats, there is an intrinsically clustered connection structure. However, functional roles of these structures remain elusive. In particular, each synapse can show a wide range of plasticity depending on spike timing and firing rate, and theoretical results suggest that various structures can be learned by randomly connected networks. In addition, recent experiments revealed that EPSPs typically follow long-tailed distributions in cortex. In particular, strong synapses have significant effects on the post synaptic neuron. This means that the network structure defined by strong synapses can override the structure defined by connectivity, and possibly play a major role in information processing. Thus, we studied the functional role of network structure under the presence of synaptic plasticity and synaptic weight variability. By assuming that neuronal circuits provide internal models of probabilistic phenomena, we constructed network models with synaptic plasticity. Our results suggest that network structures provide priors for internal probabilistic models, and enables learning even from noisy or incomplete stimuli. As a result, the learned network can perform inference nearly optimally. We further discuss the functional roles of synaptic rewiring, especially when the external environment shows variability.

Abstract: Recent interest has grown around burst suppression (BS), a pattern of the electroencephalogram characterized by quasi-periodic alternation of high-voltage activity (burst) and isoelectric silence (suppression). Burst suppression is associated with significant reduction of neural activity, such as in deep general anesthesia and certain types of coma. A recent computational model (Ching et. al., 2012) has suggested a role for cerebral metabolism in the slow - up to tens of seconds - time-scale process that governs the termination and re-initiation of bursts. Specifically, in the model, reductions in cerebral metabolic rate, typical of the etiologies of BS, lead to the formation of a slow metabolic depletion-recovery cycle. That is, activity-dependent substrate depletion during bursts, followed by substrate recovery during suppressions. In this sense, the mechanism involves a slow, metabolic process that gates the neural activity. Missing from the model, however, is a role for homeostatic coupling between neural and metabolic processes, i.e., a supply-demand feedback effect wherein the neural activity itself gates metabolism. Here, we develop a general, low-dimensional neural mass model for burst suppression that contains homeostatic coupling between the neural and metabolic dynamical processes. Specifically, we add cerebral metabolic dynamics to a neural mass model of a cortical population. The metabolic dynamics involve a variable corresponding to substrate that gates the neural activity, the intensity of which then determines the metabolic consumption and recovery rates via a homeostatic coupling function. This creates a physiologically consistent, reciprocal interaction between the neural and metabolic processes that, in baseline conditions, supports continuous activity. Through detailed computational simulation and analysis, we subsequently show that burst-like activity can manifest in the neural dynamics through downregulation of either metabolism or neuronal activity, independently. The latter result, in particular, fills an important gap in explaining how burst suppression might arise through the actions of anesthetic drugs on neural dynamics, absent a direct effect on metabolism. For example, it characterizes why increasing inhibition leads to bistable, i.e., burst-like activity, rather than a gradual 'tapering off'. Our modeling results are fully consistent with empirical characterizations of burst suppression across etiologies. Moreover, the model highlights the importance of including the biophysical dynamics of homeostatically coupled processes, such as metabolism, in computational neural models.
